Preface

The multidisciplinary nature of pediatric critical care medicine creates a considerable challenge to those who seek to master the discipline. The knowledge that the critical care pediatrician must possess encompasses aspects of many different organ-based specialties. Our goal for this text is to help young critical care physicians review and master fundamental principles of our specialty for the purpose of achieving certification. In addition, we hope that the text will be a practical resource for the practice of pediatric critical care incorporating concepts of pathophysiology, therapeutic theory, and management principals.

We are indebted to our authors for their willingness to share their considerable expertise and contribute to this labor. We are grateful for their efforts and their patience as we navigated the pitfalls in getting the work completed.

We hope that the text will help the practitioner achieve success in the practice of pediatric critical care medicine. The care of children is both a privilege and a blessing. To care for children at their most vulnerable time cannot help but provide the practitioner with awe for the beauty of life and the resilience of the child's spirit, a respect for the power of a parent's love, and an appreciation of the blessing of our own children's health.

Steven E. Lucking, MD
Hershey, PA, USA

Acknowledgments

When we first began this endeavor years ago, we were told by many experienced colleagues that putting together a quality textbook is a labor of love, a greater truth has not been told. However, when we were told a second edition would be so much easier than the first, that turned out to be not so true.

The work has been difficult at times, but always rewarding and worthwhile. As editors, we are proud of the textbook, but clearly recognize that the project would never have come to fruition without key individuals who have supported us through this arduous process.

To our wives: Lynn, Tricia, Janet, and Peggy, who supported and guided us throughout the entire project. Without their love, wisdom, and tireless support, this book would have never reached completion.

To our children, who serve as the inspiration and guiding force for each of us.

To the authors of every chapter. Without their intellect, hard work, and drive to teach, the dissemination of this important knowledge to the next generation of pediatric intensivists would not be possible. We particularly want to thank our authors for their efforts during the late stages of the publication when many of them assumed increased clinical and administrate duties in response to the COVID-19 pandemic. On that note, the editors decided not to include a separate section on the SARS CoV-2 virus and the pandemic as the data was still in evolution and publication of an evidence based chapter would have been premature.

Two additional special acknowledgements:

We want to thank and acknowledge our Co-editor, Dr. Steven Lucking. After 35 years of service as a Pediatric Intensivist, Steve will be turning his attention to travel, baseball, and serving as a pediatrician on medical missions. Steve has been a foundational and transformative leader in the field of pediatric critical care. He has been the quintessential bedside intensivist—shepherding our sickest children through the rigors of critical illness. He has served as a mentor to many—always placing the academic achievements of his colleagues above his own. Always an advocate, critical thinker, and most importantly a selfless friend.

Lastly, my wife Lynn Maffei, who during the writing of the second edition, developed a health crisis. She has been the model of courage, perseverance, and faithfulness. Our love can and will overcome all.

» God watches over small children and fools…he has us all covered.

Genomics and Genetic Predisposition to Critical Illness in the Pediatric Intensive Care Unit

Mary K. Dahmer and Michael W. Quasney

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_1

1

Learning Objectives

- Understand the basics of human genetics, including terminology related to inheritance, predisposition to human disease, and gene expression.
- Review advances that have been made in the field of human genomics and genetic research into the development of critical illness.
- Discuss genetic variants in genes that predispose certain individuals to critical illness or protect individuals from the development of certain critical illnesses.

1.1 Introduction

Advances continue to be made in the understanding of the contribution of genetics to the development of human disease, including illnesses found specifically in the intensive care unit (ICU). With the mapping of the human genome and ongoing mapping of genetic polymorphisms and haplotypes in humans, the field of critical care medicine has now begun to study the impact of genetics on common illnesses, such as sepsis and acute respiratory distress syndrome (ARDS), that affect children who require critical care. In addition, how differences of the host defense response lead to variable outcomes in outwardly appearing similar disease states and how genetic differences in response to therapy will help practitioners tailor therapeutic interventions to an individual child's genetic composition can be examined. While we are still years away from true individualized medicine, we are now closer than ever to understanding why two children might respond to the same environmental insult in vastly different ways.

Before being able to appreciate the advances in research that have been accomplished in relation to the genetic impact on critical illness in children, it is important to understand the basics of human genetics and become familiar with the terminology that is utilized to discuss these remarkable advances. Once the genetic basics are clear, genetic variants that may impact critical illness in children will be discussed.

1.2 Human Genetics

1.2.1 Structure and Function of Genes

The order of nucleotide bases is termed the sequence and is read in the 5′ to 3′ direction.

The nucleus of all cells holds chromosomes that contain deoxyribonucleic acid (DNA), the genetic material that is inherited from parents. DNA is responsible for determining the structure of the cell, the function and activity of the cell in response to various stimuli, and the interaction the cell has with other cells and the extracellular environment. The DNA molecule consists of two chains of deoxyribonucleotides held together by complementary base pairs. The deoxyribonucleotides contain the four nucleotide bases, adenine (A), thymine (T), guanine (G), and cytosine (C) that are covalently bound together by phosphodiesterase bonds linking the 5′ carbon of one deoxyribose group to the 3′ carbon of the next group. The two chains of deoxyribonucleotides are linked by hydrogen bonds between the A's of one strand and the T's of the other. Likewise, the G's of one strand are linked by hydrogen bonds to the C's of the complementary strand. These two complementary strands form the DNA double helix (Fig. 1.1), with one strand running in the 5′ to 3′ direction while the other strand runs in the 3′ to 5′ direction. The order of nucleotide bases is termed the *sequence* and is read in the 5′ to 3′ direction. The genetic

information of an individual is encoded by the precise positioning and order of these base pairs.

The entire DNA content of an organism is their genome.

The entire DNA content of an organism is their *genome*. Every cell of an organism contains two copies of the DNA, with the exception of red blood cells, which lack a nucleus and DNA, and sperm and egg cells, which contain one copy of the DNA. Humans have 46 chromosomes, including 22 pairs of autosomal chromosomes and one pair of sex chromosomes. Each chromosome is made up of a centromere and two telomeres (ends) (Fig. 1.2). The two arms of the chromosome are the short arm (p) and long arm (q). The parts of the genome that contain nucleotide sequences that code for the basic physical and functional units of heredity are the *genes*. It is estimated that the human genome contains about 20,000–25,000 genes. Most genes code for proteins, although some genes code for ribonucleic acid (RNA) involved in assembling proteins (transfer RNA and ribosomal RNA) or RNAs, which regulate gene activity. The structure of genes is very complex and highly variable. Genes which code for proteins are made up of a variable number of *exons*, which contain the actual coding sequence for the proteins, and *introns*, which are noncoding regions which separate the exons (Fig. 1.3). While the function of the introns is unclear, some disease processes have been found to be associated with certain nucleotide variations located in these intron regions. Genes also have regulatory regions, including promoter sequences that generally reside at the 5′ end of the gene (referred to as upstream) and regions at the

Genes are made up of a variable number of exons, which contain the actual coding sequence for the proteins, and introns, which are noncoding regions which separate the exons.

1

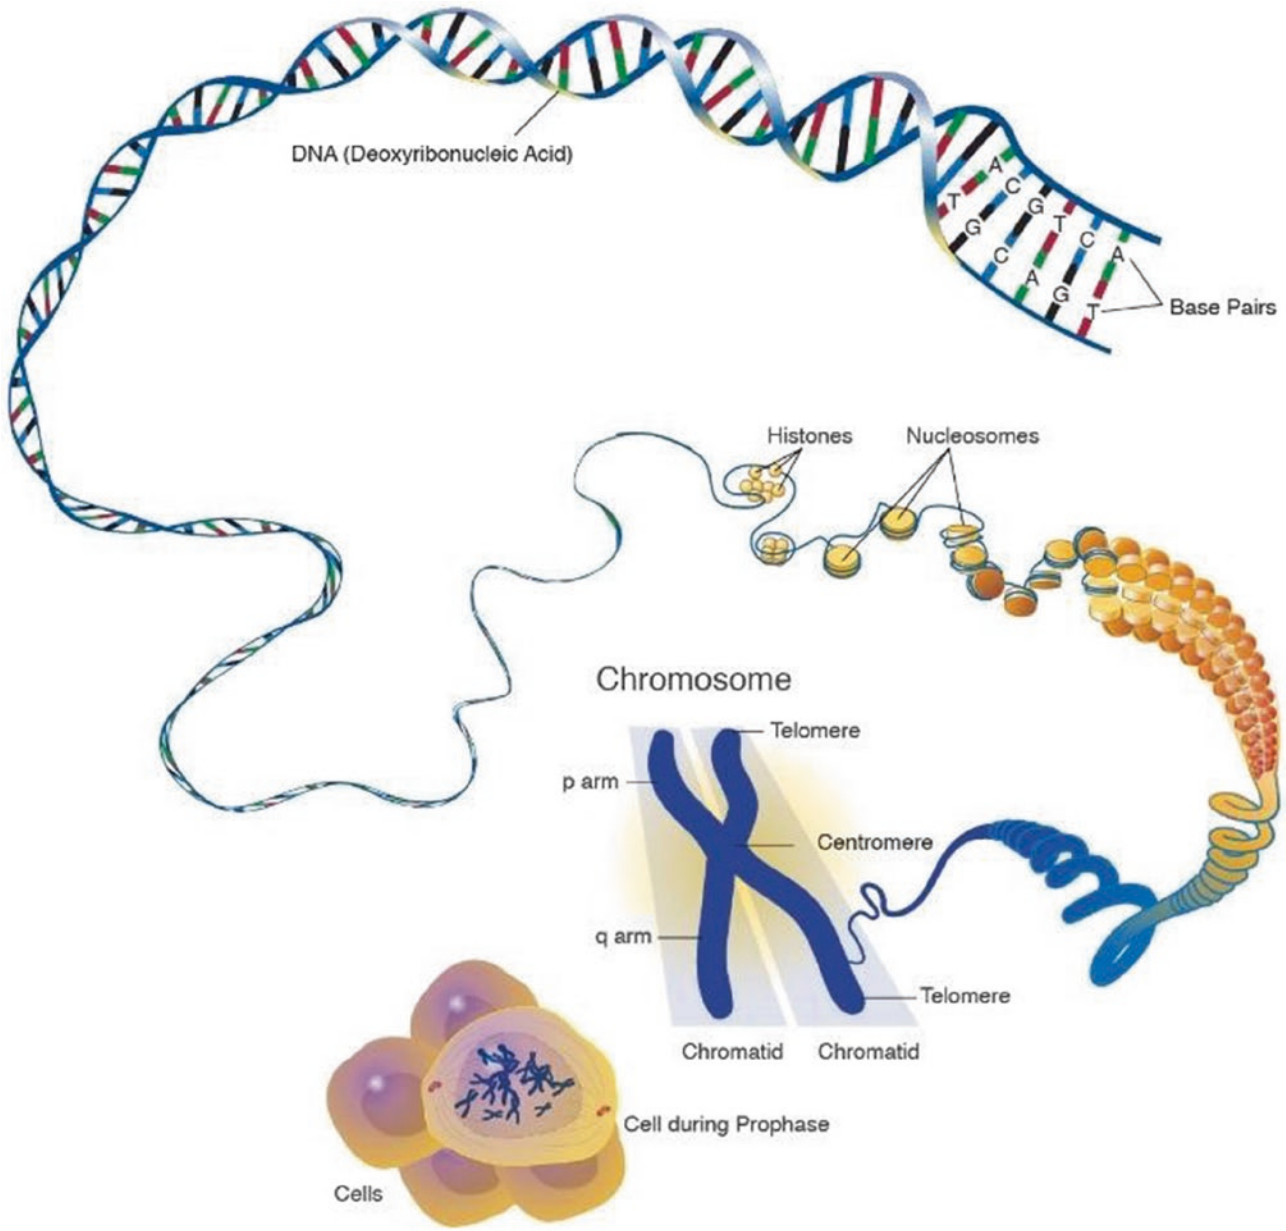

Fig. 1.2 The structure of a chromosome. (Courtesy: National Human Genome Research Institute ► http://www.genome.gov/glossary.cfm#s)

3′ end associated with the stability of the mRNA. In some cases, regions within introns act as regulatory regions.

Another important concept in genetics is the *locus*, which refers to a specific site or position on a chromosome and can refer to either a gene or a specific genetic variant (variation in the DNA sequence). The sequencing of the human genome revealed that the genome contains many sites, where the base pair present at a locus differs between individuals. It is important to remember that as individuals contain two copies of each chromosome (with the exception of chromosomes X and Y), a locus will have two copies of the gene or nucleotide of interest, one coming from each chromosome. Consequently, an individual may have two slightly different sequences for a specific gene because the nucleotides within that gene have sites that differ between the two copies. These

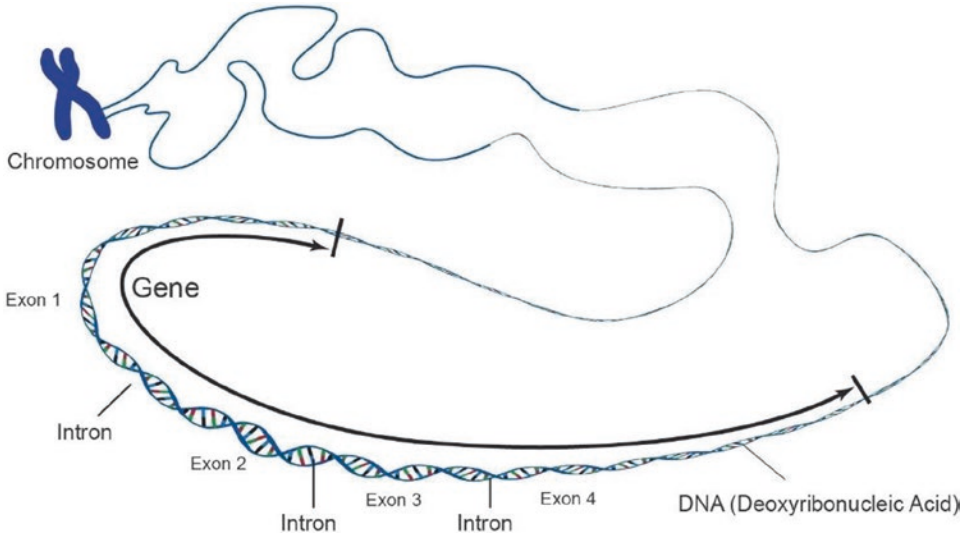

Fig. 1.3 The structure of a gene, including the exons (coding sequence) and introns (noncoding sequence). (Courtesy: National Human Genome Research Institute ► http://www.genome.gov/glossary.cfm#s)

alternative forms of a gene are termed *alleles*, or *variants*. The term allele or variant can refer to either a gene or a specific nucleotide position (locus), where there is a genetic variant within the gene. The alleles present in a specific individual at a genetic locus is that person's *genotype*. The genotype may refer to the whole gene, or more commonly to a specific nucleotide within a gene. An example is the surfactant protein B (SP-B) +1580 site. An individual's genotype at that site may either be TT, CT, or CC. Individuals are *heterozygous*, if they possess two different alleles at the locus of interest, and *homozygous*, if they possess two identical alleles at that locus.

1.2.2 Genetic Recombination and Mapping of Genes and Genetic Variants

There are many potential benefits of identifying genes/gene variants involved in disease. These include, but are not limited to, an improved understanding of the disease etiology, insight into the mechanisms of disease pathogenesis, an ability to develop an early disease risk assessment, the potential to discover novel therapeutic drug targets, the ability to estimate the therapeutic response to specific pharmacologic therapies, the possibility of targeted disease prevention strategies to be utilized in high-risk populations based on genetic predisposition, and the movement from the classic symptoms-based disease definition toward a true molecular definition of complex disease processes.

Before the sequencing of the human genome, *linkage analysis*, which is related to genetic recombination, was the predominant method of identifying and mapping disease causing genes in the genome. *Genetic recombination* is the reshuffling of genes from generation to generation and is the basis of genetic diversity in sexually reproducing organisms. Genetic recombination results in an exchange of genetic material between homologous chromosome pairs, which results in segments of DNA being exchanged with the other chromosome of the pair, thereby shuffling the genetic material. Linkage analysis relies on the genetic recombination frequency between two loci on a single chromosome to identify locations in the chromosome associated with disease. Recombination frequencies can be measured by genotyping individuals for the loci of interest in a family pedigree. The closer together two loci are on a chromosome, the lower the likelihood of recombination occurring between them.

If loci are very close, they are said to be linked. In linkage analysis, the reliability of genetic linkage between loci is determined using the *LOD score*, which is an estimate of whether two loci are likely to lie near each other on a chromosome and are therefore likely to be inherited together. A LOD score of 3 or more, which represents odds of 1000:1 or greater in favor of linkage, is used to indicate statistically significant linkage and, therefore, concludes that the two loci of interest are close. This approach has been used to identify and map genes responsible for disease to a particular location in the genome based on being inherited with respect to a locus of known map location, with the assumption of no genetic recombination.

Linkage disequilibrium (LD), often referred to as allelic association, is a measure of physical association between two alleles and occurs when closely linked alleles are inherited together during many generations.

With the completion of the Human Genome Project in 2003, which sequenced the human genome, there was no need to use linkage analysis to determine the location of a variant within the genome. However, it became clear that even after recombination over generations, many variants are inherited together, and these variants are said to be in *linkage disequilibrium* (LD). LD refers to the nonrandom association of alleles (or variants). LD is a measure of physical association between two alleles and occurs when closely linked alleles are inherited together during many generations. Therefore, if variants are in LD, the presence of one variant can be used to study the other.

A haplotype represents a combination of polymorphic alleles on a single chromosome delineating a pattern that is inherited together and transmitted from parent to offspring.

A *haplotype* represents a combination of two or more variants on a single chromosome delineating a pattern that is inherited together and transmitted from parent to offspring. Haplotype analysis is a useful tool for analysis of disease gene discovery, as investigators may capitalize on the fact that many of the variants of interest are not transmitted independently of each other, and the presence of one gene variant can tag the presence of another variant from the same chromosome. In some cases, haplotype assessment can provide a higher level of specificity, sensitivity, and accuracy in "true" associations with disease risk or severity. By focusing on haplotypes as well as single-nucleotide variants, researchers are now able to more accurately study genetic predisposition to various diseases of interest. With the recent report of the International HapMap Consortium and the identification and cataloging of haplotypes now available, the utility of this type of study is brought into focus as an important tool to guide genetic association studies on complex human diseases. However, the degree of LD between variants and the type and frequency of haplotypes differs significantly between races and ethnicities. Consequently, race and ethnicity need to be considered and accounted for in genetic association studies.

1.2.3 Genetic Mutations and Other Genetic Variants

Genetic mutations are rare changes that occur in the sequence of DNA that occur in less than 1% of the population.

Genetic mutations are changes that occur in the sequence of DNA. The term mutation generally refers to rare changes (present in less than 1% of the population) that are detrimental or that cause disease. Mutations can be classified as somatic mutations, which occur in somatic cells and are not commonly passed onto offspring, and germline mutations, which occur in the reproductive cells and are passed onto offspring. There are several different types of mutations. *Translocations* are large-scale mutations consisting of switching of chromosomal regions between one chromosome and another chromosome. Mutations can also consist of single changes in the nucleotide bases and include substitution, deletion, or insertion of nucleotides. Insertions and deletions can also involve hundreds of nucleotides. Mutations that occur in the coding regions can have several consequences: they can change the amino acid of the protein at a single site; they can cause a premature stop codon resulting

in early termination of translation, and, consequently, lead to a truncated protein; or they may have no effect at all if the mutation leads to a nucleotide substitution that does not alter the amino acid. Likewise, mutations in noncoding regulatory regions (such as promoters) may also affect the expression of the gene by altering the quantity of mRNA transcribed and, hence, the level of the protein. Mutations in the intron/exon boundary region may also lead to incorrectly spliced mRNAs and result in significantly different proteins or differences in levels of protein products.

The mutations discussed in the preceding paragraph are variations which are rare. However, it is estimated that the human genome contains over 10 million relatively common genetic variants that occur at a frequency greater than 1% in the population which are referred to as *polymorphisms*. If the polymorphism is a change in a single nucleotide, it is referred to as a *single-nucleotide polymorphisms (SNPs)*. It is now clear that most genes are polymorphic, that is, they contain multiple sites that vary between individuals. *Copy number variants (CNVs)* are stretches of DNA of greater than 1 kb that show differences in the expected number of copies of the DNA in greater than 1% of the human population. Very recently, it has become clear that CNVs are also common in human genomes and contribute significantly to human genetic variation. The differences in the nucleotide sequence described above are what give rise to our genetic variability; they account for inherited differences in our physical traits and the way we respond to environmental stimuli and medications. While the majority of these nucleotide variations do not cause a disease, some genetic variations may influence the development of certain diseases. These more common genetic variations, whether SNPs or small insertions or deletions of nucleotides, are the ones currently being examined in many studies for associations with susceptibility to and outcome from diseases seen in the intensive care unit setting.

Polymorphisms are variations that occur at a frequency greater than 1% in the population; if the polymorphism is a change in a single nucleotide, it is referred to as a single-nucleotide polymorphism (SNP).

Genetic polymorphisms, like the rarer mutations, may influence the functional activity of the protein product or may influence the quantity of the mRNA made if present in a regulatory region. There has been an explosion of studies attempting to determine if these genetic polymorphisms may account for some of the clinical variability we as clinicians observe at the bedside in the ICU. For example, can the difference in disease severity between two children with pneumonia be associated with variations in their genes coding for one of the surfactant proteins?

1.2.4 Gene Expression

Gene expression is the process by which the information contained within genes is used to make proteins (Fig. 1.4). This occurs by a combination of two distinct processes: transcription and translation. *Transcription* is the process by which the genetic information in DNA is transcribed into messenger RNA (mRNA). mRNA differs from DNA in that it is single-stranded, has a modified sugar backbone, and contains uracil (U) instead of T. The process of transcription involves the unwinding of the two complementary strands of DNA, the enzyme RNA polymerase binding to the promoter region of a gene on a single strand of DNA, and synthesizing the mRNA molecule by adding ribonucleotides in an order that is complementary to the DNA strand. The transcribed mRNA thus contains all the genetic information between the transcriptional start and stop sites on the DNA, including exons and introns. The noncoding intron sequences are removed by a process referred to as splicing, which connects all the exons together to form the final mRNA product. This mRNA represents the coding DNA sequences for a single gene. (It should be

Gene expression is the process by which the information contained within genes is used to make proteins.

Transcription is the process by which the genetic information in DNA is transcribed into messenger ribonucleic acid (mRNA).

Translation is the process by which the genetic information from mRNA is utilized to guide the synthesis of proteins.

noted that splicing variations have been identified that influence disease processes that impact the final protein product by altering the mRNA sequences that are spliced together.) The mRNA is then transported to the cytoplasm and *translation* occurs, in which the genetic information from mRNA is utilized to guide the synthesis of proteins. Proteins are composed of amino acids. There are 20 different amino acids in humans, and each is encoded by a set of 3 nucleotides in the mRNA. These three nucleotides are called triplets or *codons*. The corresponding *anticodon* on the transfer RNA (tRNA) links with a codon, presenting its unique amino acid in the process of translational protein synthesis.

Since all cells that contain a nucleus carry the full set of genetic information, it is necessary for gene expression to be selective and tightly controlled, in a way that guarantees specific proteins are expressed in specific cells under appropriate conditions. This differential expression of genes ensures that cells develop correctly, can differentiate and function as specialized cells, and can mount various responses to external stimuli. In certain disease states, expression of specific genes may change, thereby providing a clue as to which genes

may be important in that disease process. Recent advances in technology have provided a valuable tool to evaluate the expression of genes during various diseases, including sepsis. These technologies include gene expression microarrays and RNA sequencing. Genome-wide expression microarrays contain small strands of DNA (which act as probes), representing all the genes in the genome attached to a solid substrate, such as a glass slide or silicon chip. mRNA is isolated from, for example, blood from patients with sepsis and controls without sepsis. If mRNA from a specific gene is present, it will hybridize to its complementary sequence on the microarray, and its signal is related to the amount of mRNA present. The comparison of array results between those with and without sepsis will indicate which genes' expression is altered in sepsis. In this fashion, one can identify specific genes that are expressed in the development of sepsis. Several examples of the use of this technology in the critically ill patient have been published, which have aided our understanding of the pathophysiology of certain ICU-specific diseases.

1.2.5 Phenotype

The observable characteristics of an individual define that individual's phenotype.

Up to this point, we have discussed the structure of DNA and the process of getting from the code in the DNA to protein. It is the functional aspects of these proteins that give rise to the observed traits, whether it be the color of one's eyes, the rate of metabolism of a drug, or the efficiency with which a protein receptor on a cell surface recognizes a pathogen. The observable characteristics of an individual define that individual's *phenotype*. This may include common physical and biochemical characteristics but can also describe a person's disease status (such as in cystic fibrosis). Phenotypes caused by mutations in a single gene may show *Mendelian inheritance patterns*. These patterns can be autosomal dominant (where a single copy of the gene causes the phenotype), autosomal recessive (where both copies of the gene are necessary for the phenotype), or sex linked (where the mutation occurs on the X chromosome). It is crucial to note that Mendelian inheritance patterns are seen only for single-gene disorders. Critical care diseases and syndromes, such as sepsis and ARDS, are complex disorders, whose genetic predisposition to the development of the disease is much more complex and likely involves multiple genes and other factors, such as environmental exposures. The multifaceted gene-gene and gene-environment interactions make the study of these diseases extremely complex.

1.3 Genetics of Common Complex Disorders

Disease aggregation may be due to complex genetic factors, the interaction of multiple genes on the development of the disease of interest, a host of environmental factors which place the individual at risk for the disease, or, most commonly, a combination of all of the above factors.

There are many common complex disorders that display obvious familial aggregation of cases but have no clear Mendelian inheritance patterns. The most commonly studied in medicine are cancer, diabetes, hypertension, and obesity, among others. The disease aggregation may be due to complex genetic factors, the interaction of multiple genes on the development of the disease of interest, a host of environmental factors which place the individual at risk for the disease, or, most commonly, a combination of all of the above factors (◘ Fig. 1.5). In other words, a person's genetic background may make them prone to a specific disease; a person may have *susceptibility gene variants* or susceptibility genes. Due to their inherited genetic makeup, the individual is at a higher inborn risk for developing the disease of interest but only if they are exposed to the environmental stressor that is known to associate with the disease. The susceptibility gene variant will not lead directly to the disease but

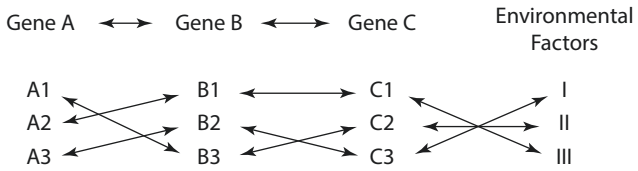

Fig. 1.5 The complex interactions that can occur between genes that may impact a disease process (gene-gene interaction) as well as between the genes of interest and environmental factors (gene-environment interaction)

will put that person at a higher risk if they are exposed to the environmental risk. For example, individuals may possess a susceptibility gene variant for the development of lung cancer, but this will lead to the development of cancer only if they are subject to a known environmental risk factor, such as smoking. Alternatively, a newborn may possess one or more susceptibility gene variants for the development of bronchopulmonary dysplasia, but if they are not born prematurely and do not require mechanical ventilation in the newborn period (and therefore are not subject to the environmental stressors known to impact the development of this lung disease), they will never develop this disease despite being genetically susceptible.

Gene variants can also decrease the susceptibility, or increase the resistance against a disease. These are *protective gene variants*. To give an example, there are individuals who smoke their entire adult lives and yet never develop chronic obstructive pulmonary disease. It is likely that these individuals possess protective gene variants against the development of this disease, even in the face of a strong environmental insult. A person may possess both susceptibility and protective genetic variants for the same disease, and the mix of these variants will together impact the overall genetic risk of that person to the disease of interest. This resultant genetic risk interacts also with the environmental risk of the individual, leading to the overall risk of that person developing the disease. In critical care, it is unlikely that one gene will cause the diseases that are treated in the ICU; it is more likely that multiple genes will interact with multiple environmental insults to predispose individuals to disease processes resulting in an overall risk for an individual patient to develop a certain disease of interest. Interestingly, certain populations seem to be immune to certain complex diseases. Examples include the Australian aborigines and Inuits from Greenland, in which both populations appear to be resistant to the development of type 1 diabetes. It is plausible that the disease resistance observed in these populations is due to absence of susceptibility gene variants or presence of protective gene variants in the group's gene pool.

Critical care diseases and syndromes, such as sepsis and ARDS, are complex disorders where genetic predisposition to the development of the disease is much more complex and likely involves multiple genes and other factors, such as environmental exposures. There are two hypotheses addressing the involvement of genetic variants in non-Mendelian inherited diseases or predispositions. One hypothesis is that the genetic component of these diseases or predispositions is due to the combination of many common (15–50) genetic variants acting together. Genome-wide association studies which genotype individuals at 1–2 million variant sites across the genome are used to identify common variants associated with disease. Thus far, many studies examining the impact of common genetic variants on disease have explained only a small component of the heritability of such disease. Consequently, a new hypothesis proposes that these multifactorial diseases and predispositions are due to the combination of a smaller number of more rare polymorphisms. Such rare variants will likely need to be identified by either exome sequencing (sequencing

only the DNA contained in exons coding for proteins) or whole genome sequencing. Exome and whole genome sequencing are expensive and consequently have not been widely used thus far, but costs are decreasing and the next 5–10 years will likely demonstrate whether rarer polymorphisms are also involved in non-Mendelian inherited diseases and predispositions.

When it is determined that a complex disease has familial aggregation, it is important to take into account that families may also share environmental or social factors that predispose to the disease of interest, and therefore the entire impact may not be genetic. One example would be radon gas present in a neighborhood leading to an increased incidence of lung cancer in families living in close proximity. While it may be assumed that the genetic impact is responsible for the development of the disease, environmental exposure is the likely source. Twin studies and adoption studies are utilized to attempt to determine the relative weight of genetics and environment in the development of a certain disease.

1.4 Genetic and Genomic Studies in Critical Care

Genomic medicine and the concept that an individual's genetic makeup may influence not only the severity of and outcome from their critical illness but also their response to the therapies have begun to make their way into the intensive care unit. This section will highlight studies involving analysis of gene expression and genetic association studies in patients with critical illness. While it may appear that advances have been made in the field, it is important to understand that we are not yet in the age of personalized medicine and much work needs to be done.

1.4.1 Genomics Studies in the ICU

With the advent of the DNA microarray technology, gene expression patterns in thousands of genes can lead to insight into disease pathogenesis, treatment, and outcome.

The expression of specific genes in many cases represents the body's specific and complex response to environmental stimuli, such as in the case of a severe infection, trauma, or cardiopulmonary bypass. Examining gene expression may provide a clue as to which genes are important in a specific critical illness. Many studies have examined gene expression in critically ill patients, but most examine the expression of only a few genes. With the advent of the gene expression microarray technology discussed above, investigators have begun to explore gene expression patterns across the genome in children with septic shock using mRNA isolated from whole blood representing the gene expression response in circulating white blood cells. These studies have compared gene expression from blood samples obtained within 1 day of admission to the ICU with that observed in blood of healthy controls, examined longitudinal changes in gene expression in children with septic shock (days 1 and 3), and compared expression in patients with septic shock to expression in children with sepsis or systemic inflammatory response syndrome (SIRS). Genes that were upregulated, downregulated, or unchanged between the groups were examined. The genes that were upregulated when the septic shock group was compared to healthy controls included genes related to immunity and inflammation as would be expected. Unexpectedly, the study demonstrated that many genes related to zinc biology and zinc homeostasis were downregulated. The significance of this finding was supported by the observation that children who did not survive septic shock had lower serum levels of zinc and the demonstration in a murine model that zinc depletion leads to increased mortality from sepsis. In addition, genes involved in T-cell receptor signaling and antigen

presentation appeared decreased suggesting that septic shock may be associated with depression of the adaptive immune system. Interestingly, expression studies of adults with sepsis and septic shock did not identify a downregulation of genes related to zinc biology, although upregulation of genes related to immunity and inflammation and downregulation of genes related to the adaptive immune system was observed.

Gene expression has also been used to identify subgroups of children with septic shock. When a heterogeneous group can be divided into subgroups that are distinguished by differences in the underlying pathophysiology, these subgroups are often called subphenotypes or endotypes. Using genome-wide gene expression profiling from whole blood (which measures the levels of all mRNA transcripts, also referred to as the transcriptome), pediatric septic shock has been demonstrated to encompass two distinct endotypes. These two septic shock endotypes differ in outcomes and reveal differences between endotypes in the underlying biology of septic shock. Endotype A has a higher rate of mortality, and lower expression of genes of the adaptive immune system and the glucocorticoid receptor signaling pathway, compared to endotype B. Interestingly, these septic shock endotypes can be distinguished by the expression of 100 genes, suggesting that a clinically feasible gene expression-based subclassification strategy for septic shock may not be far off.

It is important to note that the septic shock endotypes described above are not primarily intended to estimate the risk of mortality from sepsis. Rather, the primary intent of the endotyping strategies was to subgroup patients based on biological commonalities, which can potentially be targeted with existing or new therapies, such that patients with endotypes that are most likely to benefit are targeted for treatment. The fact that the reported endotypes have differences in outcome adds to the potential clinical relevance of the endotyping strategies.

Genome-wide gene expression microarrays have also been used to investigate the expression profile of adults with ARDS. Although the studies done thus far are relatively small (3–31 patients with ARDS), they have increased our understanding of ARDS and identified potential new biomarkers for ARDS. mRNA for pre-B-cell colony-enhancing factor (PBEF), a cytokine that is involved in the maturation of B-cell precursors, inhibition of neutrophil apoptosis, and perhaps regulation of endothelial cell calcium-dependent cytoskeletal arrangement, was noted to be significantly increased in cells from bronchoalveolar lavage from adults with ARDS, a finding that was also consistent in both a canine and mouse model of acute lung injury. In addition to the elevated mRNA levels, PBEF protein in bronchoalveolar lavage fluid was also elevated in adults with ARDS. Elafin, a potent neutrophil elastase inhibitor, was identified as the gene with the highest fold change in expression when comparing blood samples from patients during the acute and recovery phase of ARDS. Subsequent examination of plasma elafin levels in two different cohorts demonstrated that levels were significantly lower in the acute phase compared to the recovery phase, the same trend as had been observed in gene expression.

A number of studies have compared the gene expression profile from whole blood of patients with sepsis and ARDS to that of patients having sepsis without ARDS. Expression of genes related to neutrophil-related processes were elevated in the patients with ARDS, but were not explained by differences in circulating neutrophil counts, suggesting that the expression of the proteins encoded by these genes are increased in neutrophils of patients with ARDS. In addition, genes related to cell cycle processes were higher in those with ARDS. Since the patients with ARDS generally had a higher

severity of illness, it is still unclear whether these differences in gene expression specifically relate to ARDS. In another study, a comparison of expression of interferon-stimulated genes (ISG) could be grouped into low, middle, and high expression levels; individuals with either high or low expression had fewer ventilator-free days and higher mortality.

1.4.2 Genetic Predisposition in the ICU

As described above, a large amount of genetic variability exists throughout our genome. Whether these differences influence the susceptibility to or outcome from diseases in the critical care setting is an area receiving a great deal of interest. Perhaps the greatest amount of focus of genetic association studies on critical illnesses is in sepsis and ARDS. The general approach has been to do genetic associations studies comparing the frequencies of polymorphisms in a cohort of patients with sepsis (or ARDS) and an at-risk cohort without sepsis (or ARDS). A few genome-wide association studies (GWAS) have been done in patients with sepsis or ARDS. This section will review some of these studies.

1.4.3 Influence of Genetic Variation in Patients with Sepsis

Individual variability in the susceptibility to and outcome from critical care diseases has long been observed, and advances in genomic medicine now give an opportunity to understand these differences.

Individual variability in the susceptibility to and outcome from sepsis and lung injury has long been observed in critically ill patients. Why one child with pneumococcal pneumonia has little consequence of their infection and can be treated as an outpatient while another child develops refractory septic shock and respiratory failure has been attributed to a number of factors. These factors have included virulence of the pathogen, length of time between onset of symptoms and appropriate treatment, and comorbid conditions. While all these factors certainly contribute to the severity of disease, a growing body of evidence suggests that genetic variations in the individual patient may also contribute to the severity of, and outcome from, critical disease. These genetic polymorphisms may not be of any consequence during normal healthy periods, but their importance may become evident only during a severe stressor, such as an infection, trauma, cardiopulmonary bypass, or other scenarios seen in the intensive care unit. A strong genetic influence on the outcome from infections was indicated by a family-based study of adoptees. Adoptees with a biological parent who died due to infection before the age of 50 had a relative risk of death due to an infection of 5.81 (CI = 2.47–13.7); a higher relative risk than that seen when risk related to early death of a biologic parent due to cardiovascular and cerebrovascular disease (4.52; 1.32–15.4) or cancer (1.19; 0.16–8.99) was examined. Thus, an individual's genetic makeup may influence the severity of disease in infection and sepsis.

Genetic variations that lead to alterations in the amount or functional activity of any of the proteins involved in the recognition of or response to pathogen-associated products may influence the individual's response.

Given the tens of thousands of genes in the human genome and the millions of genetic polymorphisms, on which polymorphisms and in which genes should investigators focus? Either a candidate gene study or genome-wide association study (GWAS) can be performed. In a candidate gene study, the genes selected are those encoding protein products known to be involved in the pathogenesis of disease. In a GWAS, genetic variants across the genome are studied with no preconceived notion as to whether the gene of interest encodes for a protein involved in disease. The advantage of such an approach is that it has the capability to identify variants in genes not yet known to be involved in the disease of interest and thus can increase the understanding of the underlying pathogenesis. GWAS generally require

many hundreds to thousands of patients, while candidate gene association studies can be done with hundreds of patients. Consequently, most genetic association studies done in patients with sepsis or ARDS have used a candidate gene approach.

For sepsis, candidate genes used in genetic association studies include the genes for proteins involved with the pathways by which pathogens lead to the clinical symptoms of sepsis (Table 1.1). The body's response to infections involves recognition of pathogen-associated products followed by an inflammatory response that involves a large number of cellular proteins. Genetic variations that lead to alterations in the amount or functional activity of any of these proteins involved in the recognition of, or response to, pathogen-associated products may influence the individual's response. Variants in many candidate genes have been examined for association with sepsis. Many early studies were done before it was clear how many genetic variants are present in the genome and before the differences between races and ethnicities in LD and frequencies of variants were understood. This is likely part of the explanation as to why different genetic association studies have demonstrated conflicting results. Described below are several examples where there is strong evidence that genetic variants are associated with either susceptibility to sepsis or outcome from sepsis.

Genetic variation in mannose-binding lectin may be an important contributor to difference in the host response to infectious illness observed in children.

An example of the influence of genetic variations in proteins involved in the recognition of pathogens on the severity of infections includes polymorphisms in the genes coding for mannose-binding lectin (MBL), a heterotrimeric protein involved in binding bacterial surface carbohydrates and the opsonization of bacteria. A helical domain in the tertiary structure of the protein is crucial for the formation of the active heterotrimer. Three genetic polymorphisms in the gene coding for MBL result in amino acid changes in the helical tails of the protein and result in increased degradation and decreased serum levels of MBL. Genetic association studies have demonstrated associations between the 3 MBL genetic polymorphisms and increased susceptibility to infections, hospitalizations due to infections, number of acute respiratory infections and risk of meningococcal infections in children, and pneumonia and sepsis in neonates. In adults, these polymorphisms have been associated with recurrent respiratory infections, invasive pneumococcal infections, and viral coinfections with pneumococcal pneumonia.

The family of leukocyte Fcγ receptors is also involved in the recognition of bacteria, such as *Streptococcus pneumoniae*, *Haemophilus influenzae* type b, and *Neisseria meningitides*. Fcγ receptors bind the Fc portion of IgG bound to bacteria, thereby facilitating phagocytosis and inducing the inflammatory response. Several polymorphisms have been described in the genes coding for the various Fcγ receptors that alter their binding affinity to the various subclasses of IgG. Two such polymorphisms have been described in the genes coding for the FcγRIIIb receptor and the FcγRIIa receptor. In the case of the FcγRIIIb receptor, the genetic polymorphism results in a four-amino-acid substitution (allotypes FcγRIIIb-NA1 or -NA2) in the receptor that alters the opsonization efficiency. In the case of the FcγRIIa receptor, the genetic polymorphism results in replacing a histidine for an arginine in the extracellular domain of the receptor at amino acid position 131. The variant FcγRIIa receptor containing the histidine binds the Fc region of IgG2 with a lower affinity and results in reduced phagocytosis in vitro compared with the more common FcγRIIa receptor containing the arginine. In association studies, a higher frequency of individuals homozygous for the NA2 allotype of the FcγRIIIb receptor or an arginine at position 131 in the FcγRIIa receptor was found in patients with severe meningococcal disease or fulminant meningococcal sepsis.

Table 1.1 Genetic polymorphisms and risk of infection and sepsis

Gene	Polymorphism[a]	Consequence of polymorphism
MBL	Variant B, C, D	Variants associated with decreased levels and activity and increased risk of infection
FCγRIIa	H131R	R associated with decreased affinity to IgG_2 and opsonization and increased risk of infection and septic shock
CD-14	−159 C/T	T allele associated with increased levels and susceptibility to sepsis and sepsis-related mortality in adults
TNF-α	−308 G/A, −238 G/A, LT-α + 250 G/A	A alleles for each polymorphism are associated with increased TNF-α levels, increased mortality in sepsis and meningococcal disease, increased sepsis in adults with pneumonia, and increased mortality in bacteremia and sepsis
IL-6	−174 G/C	G associated with increased IL-6 levels in patients but C associated with increased levels in monocytes from neonates, sepsis in neonates but not adults, and severe sepsis and organ dysfunction in children
IL-1ra	Variable 86-bp repeat	A2 associated with increased levels of $IL\text{-}1_{RA}$ and variable results of association studies examining risk of sepsis and mortality
IL-10	−1082 G/A, −819 C/T, −592 C/A	GCC haplotype associated with increased levels and sepsis but not mortality
IRAK-1	+1595 T/C	C associated with increased NF-kB translocation and presence of shock and higher 60-day mortality in adults with sepsis
ACE	287 bp I/D	DD associated with increased serum and tissue levels and more severe meningococcal disease in children; no association with sepsis related mortality in neonates or adults
PAI-1	4G/5G	4G associated with increased levels and septic shock in meningococcal disease
Protein C	−1641 A/G and −1654 C/T	AC haplotype associated with increased mortality and organ dysfunction in adults with sepsis and with decreased protein C serum level; GC haplotype associated with more severe sepsis in children less than 1 year of age with meningococcemia

MBL mannose-binding lectin, Ig immunoglobulin, *TNF* tumor necrosis factor, *LT* lymphotoxin, *IL-1ra* interleukin-1 receptor antagonist, *IL-10* interleukin-10, *IRAK-1* interleukin receptor-associated kinase 1, *ACE* angiotensin-converting enzyme, *PAI* plasminogen activator inhibitor

[a]Terminology used for the various polymorphisms are the ones most commonly used in the literature and may refer to the nucleotide position, amino acid position, or name of the allele. This table is representative of polymorphisms examined in sepsis but does not include all such polymorphisms

Loss of homeostatic mechanisms regulating the coagulation/fibrinolytic system also plays an important role in sepsis. Plasminogen activator inhibitor 1 (PAI-1) inhibits fibrinolysis, thereby favoring the formation of microthrombi in the capillaries. The pathophysiology of multiple organ dysfunction syndrome in patients with sepsis is thought to involve, in part, intravascular fibrin deposition. Thus, elevated PAI-1 activity could contribute to organ failure in

sepsis, and elevated plasma concentrations have been observed in patients with sepsis. A genetic variation in the gene coding for PAI-1 consisting of either the presence of 4 guanines or 5 guanines at a specific location appears to influence the amount of PAI-1 produced. Individuals homozygous for the 4G genotype (4G/4G) produce more PAI-1 than individuals homozygous for the 5G genotype (5G/5G) or individuals that are heterozygous (4G/5G). Association studies have demonstrated that children with meningococcal disease who were 4G/4G at this site had an increased risk of death compared to children who were 4G/5G or 5G/5G. More recent studies in both children and adults have demonstrated higher mortality in individuals homozygous for the 4G allele in a number of infectious diseases.

Variants in other candidate genes involved with inflammation and with other aspects of the pathophysiology of sepsis have also been reported to be associated with sepsis. Table 1.1 lists additional selected variants that have been reported to be associated with sepsis using a candidate gene approach. To date, only two GWAS studies have been performed in patients in sepsis with both looking for association of SNPs with death in patients with sepsis. Both were relatively small for GWAS, but in each case, they identified proteins that had not yet been implicated in the pathophysiology of sepsis.

1.4.4 Influence of Genetic Variation on Lung Injury and Acute Respiratory Distress Syndrome

Severe lung injuries in both adults and children can be precipitated by a diverse array of causes and are classified as either direct injury, when the insult is from the alveolar side of the alveolar/capillary membrane, or indirect injury, when the insult is from the capillary side. Major causes of direct lung injury include pneumonia, aspiration, pulmonary contusion, and inhalation, while major causes of indirect injury include sepsis, trauma without pulmonary contusion, cardiopulmonary bypass, and multiple transfusions. Despite these various causes, the central pathogenesis of ARDS involves derangements in multiple biological processes. These include activation of inflammation, loss of coagulation and fibrinolytic homeostasis, disruption of vascular permeability, epithelial and endothelial cell apoptosis as well as proliferation, and derangements in surfactant. Some of these processes, notably inflammation and coagulation, play key roles in the pathophysiology of sepsis as well as ARDS. Thus, it is not surprising to find that the candidate genes examined in genetic association studies for ARDS are in many cases the same as those examined in sepsis (Table 1.2). This section will review some of the genetic variations with the most consistent association with either the development of or outcome from ARDS.

Interleukin-6 (IL-6) is a cytokine with pleiotropic effects that is released in response to infection or injury and impacts host defense in part through its effect on stimulating the synthesis of acute phase proteins and on specific subgroups of T cells. Increased levels of IL-6 are found in plasma and bronchoalveolar lavage fluid in patients with ARDS and are associated with outcome. Genetic variants and haplotypes in IL-6 promoter have been shown to be associated with plasma levels of IL-6 and with development of ARDS. One explanation for why these haplotypes are associated with ARDS would be if they are associated with differences in the levels of IL-6.

As discussed previously, expression microarrays have been invaluable in identifying other potential mediators involved in the pathophysiology of lung injury. The expression of pre-B-cell colony-enhancing factor (PBEF) was

Table 1.2 Genetic association in studies of acute lung injury or ARDS

Gene	Polymorphism[a]	Consequence of polymorphism
SP-B	−1580 T/C and intron 4 dinucleotide repeats	C allele and dinucleotide variants associated with ARDS and need for mechanical ventilation
MBL	Variant B, C, D	B variants associated with increased susceptibility to ARDS; greater organ dysfunction and higher mortality in patients with ARDS
PBEF	−1001 T/G, −1543 C/T	−1001 G/−1543 C haplotype associated with a higher risk of ARDS
TNF-α	−308 G/A	−308 A allele associated with increased mortality in adults with ARDS
IL-6	Haplotypes	Specific IL-6 haplotypes are associated with ARDS
NRF2	−617 C/A	A allele associated with lower transcription and increased risk of ARDS in adult trauma patients
NFκBIA	−881 A/G, −826 C/T, −297 C/T	−881 G/−826 T/−297 C haplotype associated with increased risk of ARDS
IL-10	−1082 G/A, −819 C/T, −592 C/A	−1082 GG associated with higher IL-10 levels, increased risk for development of ARDS, and lower mortality and organ failure in adults with ARDS
ACE	I/D	DD associated with increased susceptibility to and outcome from ARDS
MLCK	Multiple SNPs and haplotypes	Several SNPs and haplotypes associated with both sepsis and sepsis-induced or trauma-induced ARDS

SP-B surfactant protein B, *MBL* mannose-binding lectin, *PBEF* pre-B-cell colony-enhancing factor, *TNF* tumor necrosis factor, *IL-6* interleukin-6, *NRF2* NF-E2 related factor 2, *NF-κBIA* nuclear factor-kappa inhibitor A, IL-10 interleukin-10, *ACE* angiotensin-converting enzyme, *MLCK* myosin light chain kinase

[a]Terminologies used for the various polymorphisms are the ones most commonly used in the literature and may refer to the nucleotide position, amino acid position, or name of the allele. This table is representative of polymorphisms examined in sepsis but does not include all such polymorphisms

found to be significantly elevated in both animal and human studies of ARDS using this approach. PBEF is a lesser studied cytokine involved in the maturation of B-cells, inhibition of neutrophil apoptosis, and perhaps regulation of the endothelial cell calcium-dependent cytoskeletal arrangement. Two genetic polymorphisms have been identified in the promoter region, −1001 T/G and −1543 C/T which appear to influence the development of ARDS. Carriers of the G allele at position −1001 had a 2.75-fold increased risk of ARDS, and the G allele remained an independent risk factor after controlling for several other variables. The T allele at position −1543 was found at a lower frequency in adults with ARDS. Combining these two polymorphisms in a haplotype analysis demonstrated that adults with the −1001 G/ −1543 C haplotype had a higher risk of ARDS (7.7-fold). The consequence of these two polymorphisms remains to be elucidated, though the −1543 T allele may result in reduced expression.

1

Deficiency in, or impaired activity of surfactant protein B appears to play a role in a number of interstitial pulmonary diseases in humans including ARDS.

Pulmonary surfactant is synthesized by the type II alveolar epithelial cells and is required for normal lung function. One of surfactant's primary functions is to lower the surface tension at the alveolar air-liquid interface. Surfactant is composed of phospholipids and four proteins, surfactant protein (SP)-A, SP-B, SP-C, and SP-D. Knockout models in mice have demonstrated that of these four proteins, only SP-B is absolutely required for postnatal survival. Deficiency in or impaired activity of SP-B appears responsible for a number of interstitial pulmonary diseases in humans, including ARDS. Several genetic variations exist in the genes coding for the surfactant proteins, and two will be discussed here: the SP-B + 1580 T/C polymorphism and insertion/deletion polymorphism consisting of dinucleotide (CA) tandem repeats in intron 4. Several studies have demonstrated an association between these polymorphisms and the need for mechanical ventilation in children (SP-B + 1580 T/C) and mechanical ventilation and ARDS in adults (SP-B + 1580 T/C polymorphism and insertion/deletion of dinucleotide (CA) tandem repeats). The consequences of these variations are not fully known. The SP-B + 1580 T/C polymorphism results in an amino acid change in exon 4 in a region of the amino terminal propeptide, which is thought to play a role in targeting of SP-B to lamellar bodies. The resulting amino acid change alters glycosylation of SP-B and may affect the level of SP-B by altering its processing or stability. Aberrant proteolytic processing of the SP-B product encoded by the C allele is supported by a recent report, demonstrating that the C allele is associated with the absence of a specific pro-SP-B cleavage product in neonates. The intron 4 dinucleotide repeat length variation polymorphism is associated with incompletely spliced SP-B mRNA. Interestingly, in Caucasians this length variation polymorphism in intron 4 is in linkage disequilibrium with the SP-B + 1580 T/C polymorphism; the C allele is associated with the deletion variant at the intron 4 polymorphic site. Further, work is needed to not only define the consequence of these genetic variations on surfactant function but also to further evaluate whether these genetic variations influence the development of ARDS.

Angiotensin-converting enzyme (ACE) may also have a role in lung injury. ACE is present in pulmonary endothelium and is responsible for converting angiotensin I (ATI) to ATII. ACE levels are elevated in the bronchoalveolar lavage fluid of adults with ARDS, and higher levels are associated with mortality from ARDS. The key component is most likely ATII, which has apoptotic effects on alveolar epithelial and endothelial cells in vitro. ATII receptor antagonists block pneumocyte apoptosis in a model of meconium aspiration. Another important component of this system is ACE2, a homolog of ACE expressed in human lungs, which is a negative regulator of the renin-angiotensin system as well as the probable receptor for the SARS virus in humans. Lung injury models using knockout mice lacking the ACE2 gene have higher ATII levels and exaggerated lung injury compared to wild-type mice. However, the lung injury is reversed if the ACE gene is inactivated in the ACE2 knockout mice. This suggests that ACE induces lung injury through ATII and that ACE2 protects against lung injury. Indeed, ACE inhibitors and ATII antagonists appear to decrease the severity of lung injury in animal models and the risk of aspiration pneumonia in some adult populations, and reduce the 30-day mortality in adults with pneumonia. Several studies have demonstrated the ACE D/D genotype is associated with the susceptibility to and outcome from ARDS (Table 1.2).

More recently, GWAS and exome sequencing have been used to identify genetic variants that may be associated with ARDS. As discussed above, because GWAS require a large number of patients, those done using ARDS

patients have limited power to detect associations. Only two GWAS on ARDS have been done thus far. The first in trauma patients did not identify any variant that reached the significance threshold. The second, done very recently, used several new analytic tools to analyze the results and found several SNPs associated with ARDS. These were in genes encoding for proteins not known to be involved in the pathophysiology of ARDS. One of these variants was in the gene for the P-selectin ligand and changed one of the amino acids in the protein. Using animal models, P-selectin was implicated in ARDS pathophysiology. Further studies will be required to determine if the P-selectin ligand is involved in ARDS in patients. Lastly, an exome sequencing study, in which all the exons encoding for proteins were sequenced, has been done on ARDS patients and identified variants in two genes not previously implicated as playing a role in ARDS pathophysiology, the X-linked gene arylsulfatase, and the XK Kell blood group complex member 3 gene. Future studies will be needed to determine if these genes are involved in ARDS.

1.4.5 Other Potential Areas of Interest in Genetic Variation in the ICU

Genetic polymorphisms in genes coding for proteins involved in coagulation and fibrinolysis may be very important in the risk of bleeding and thrombosis in critically ill children.

Two other areas should be mentioned with regard to the influence of genetic variations in the ICU. The first is in the area of coagulation. Several examples of genetic polymorphisms in genes coding for proteins involved in coagulation and fibrinolysis were discussed above in relation to sepsis and ARDS. However, these and many other genetic variations that exist in other components of the coagulation cascade could also influence the development of thrombosis, including deep venous thrombosis in critically ill patients. Thrombosis of central venous catheters is a recurring problem in ICUs, and while certain environmental factors play a role (e.g., length of time catheter is in place, size of the patient and vessel), genetic polymorphisms in the patient favoring the formation of thrombi may also play a role.

The area of pharmacogenomics attempts to determine the influence of genetic variations in genes affecting the various aspects of drug action.

Finally, the action of every drug that is used in the ICU can potentially be influenced by genetic variation in the patient. Such medications include inhaled β_2-agonists, or the array of intravenous vasoactive agents, sedatives, muscle relaxants, antibiotics, steroids, etc. All bind to protein receptors and either activate or block specific signal transduction pathways, many bind protein carriers or transporters, and most are metabolized by various protein enzymes. Every gene coding for each of these proteins has multiple genetic variations with the potential to influence the levels or activities of these proteins. The area of pharmacogenomics attempts to determine the influence of genetic variations in genes affecting these various aspects of drug action. However, while the list of genetic polymorphisms in genes affecting drug action is growing rapidly, there are few clinical examples of the degree of influence that these genetic variations have on the response to drugs in the ICU. For example, warfarin is the most widely used oral anticoagulant for long-term prophylaxis and treatment of thromboembolic disorders and is used in many children and adults with mechanical valves. The metabolism of and response to warfarin involves several enzymes, two of which exhibit genetic variations that dramatically alter the levels of warfarin. For one of these genes, CYP2C9, the common allele is referred to as CYP2C9*1 and is consider the wild-type, while CYP2C9*2 contains a C to T nucleotide change at position 430 in exon 3 and CYP2C9*3 contains an A to C nucleotide change in exon 7. CYP2C9*2 has approximately 80% of the metabolic activity of the wild-type CYP2C9*1, while CYP2C9*3 contains only 20% of the wild-type activity. By also using genetic variation in

a second gene, vitamin K epoxide reductase complex subunit 1 or VKORC1, one can account for more than 50% of the observed dosing variability. Current practice in the use of warfarin usually involves starting at an age and weight specific dose and monitoring coagulation studies. However, because of the genetic variations in these two enzymes and perhaps others, different patients take different amounts of time to achieve the appropriate therapeutic dose. Knowing the specific genotypes of patients prior to initiating warfarin may allow for more appropriate dose selection, less time to achieve therapeutic levels, and less risk of adverse events. Recently, an algorithm using the patient's genotypes at these two sites has been developed that allows for more accurate dosing in some populations. Although these algorithms are being developed and tested, it should be kept in mind that they do not account for drug-drug interactions.

1.5 Conclusion

The era of the study of the genetic impact on critical illness in children is present. Clinicians must be prepared to deal with the growing body of literature related to genetic and genomic influence on critical disease development, treatment, and outcome and be able to critically review the literature in order to determine the impact on the patients they are caring for daily. For the results of these representative genetic association studies to make the leap into clinically impacting care, they must meet certain criteria. First and foremost, the phenotype must be well defined; that is, the enrolling patients with ARDS or sepsis must meet strict and well-accepted criteria. Second, they must be high-quality studies, utilizing highly sensitive and specific methods for genotyping. Third, the studies must use a large sample size or replication cohorts to assure that no type I or type II errors are made based simply upon the number of individuals studied. Finally, the impact of the genetic variant on the protein product must possess biologic plausibility as impacting the development or the outcome of the disease of study. It is likely that the results of genomic and genetic studies will initially be used to stratify critically ill patients into subgroups to determine if such subgroups respond differently to treatment. Only after studies demonstrate an impact of genomics or genetics on outcome is it likely that tailoring therapy based on subgrouping patients using genetics or genomics will be used to more precisely target treatment to the individual patient.

Review Questions

1. Which part of the gene encodes for the actual amino acid sequence of proteins?
   A. Alleles
   B. Codons
   C. Exons
   D. Introns
   E. Promoter regions

2. A new fast-acting anticonvulsant is produced that is superior to anything currently known. This new anticonvulsant's mechanism of action involves its conversion to an active metabolite by enzyme A in the bloodstream and the binding of this metabolite to a specific receptor in the brain coded for by gene B. After several doses, the child continues to have seizures. You hypothesize that your patient may have a genetic variation either within the gene coding

for enzyme A, which results in your patient being unable to convert the drug to the active metabolite, or in gene B coding for receptor, such that the active metabolite cannot bind. Which of the following describes the best approach to test your hypothesis? Your budget is limited and there is no way to measure the active metabolite.

A. Perform whole genome sequencing.
B. Isolate mRNA from whole blood and use polymerase chain reaction technology targeting genes A and B to identify and quantify amounts of mRNA transcribed.
C. Perform a transcriptional microarray to examine whether genes A and B are being transcribed.
D. Isolate DNA from your patient and sequence genes A and B.
E. Isolate DNA from a brain biopsy and sequence gene B coding for the receptor.

3. Which of the following statements regarding genetic mutations is most accurate?
   A. Germline mutations which occur in reproductive cells are the only mutations of clinical consequence.
   B. Mutations in the intron/exon boundary region are of no clinical significance because they are excised during the process of splicing.
   C. Mutations in the noncoding regulatory regions may alter the quantity of mRNA transcribed, but do not affect the expression of the gene.
   D. Mutations that occur in the coding regions of the gene may have several consequences, including no effect at all on the end product protein.
   E. Translocations are large-scale mutations that entail switching of chromosomal regions between different loci on the same chromosome.

4. You are caring for two brothers with acute respiratory distress syndrome secondary to smoke inhalation from an apartment fire. These two infants were apparently sleeping in the same crib when they were rescued simultaneously by fire fighters. The first infant was extubated within 48 h of intubation and is doing well with a minimal oxygen requirement. The second remains intubated on high-frequency oscillatory ventilation. In attempting to understand the difference in their clinical response to the seemingly identical insult, you suspect that it may be related to a polymorphism in one of the genes that codes for surfactant protein B. In considering this possibility, which of the following is true?
   A. Although plausible, it is unlikely to be associated with a polymorphism because polymorphisms are rare occurring in less than 1% of the population.
   B. It is not plausible because variances in the translation of such a complex protein require differences in an entire haplotype, and not simply a single-nucleotide polymorphism.
   C. It is plausible because genetic polymorphisms may influence the quantity of mRNA transcribed and/or the functional activity of the surfactant protein B.
   D. It is unlikely as there are no reports of associations between surfactant protein gene polymorphisms and outcomes from pulmonary disease.
   E. It is unlikely because dysfunctional surfactant protein B demonstrates an X-linked pattern of inheritance.

5. A patient of yours has severe ARDS with pneumococcal pneumonia. You do not observe any variant in the genes for surfactant A, B, C, or D, but you do identify a novel variant in gene Z, which codes for a protein involved in sur-

1

factant production. The variant lies in an intron but in a splice junction between an exon and an intron. Which of the following is most accurate?

A. The variant could account for the phenotype as it is in a highly conserved area of the gene, and the nucleotide change could result in a significant amino acid change.
B. The mutation could not account for the phenotype because it is in an intron and does not involve coding sequences.
C. The mutation could not account for the phenotype because it is not in a gene coding for surfactant A, B, C, or D.
D. The variant could not account for the phenotype because it would be spliced out of the final transcript.
E. The variant could account for the phenotype by altering the splicing of the primary transcript and creating a nonfunctional protein.

Learning Objectives

- Describe metabolic pathways (glycolysis, Krebs cycle, electron transport, oxidative phosphorylation) that are essential to cellular respiration.
- Define the factors that determine the arterial oxygen content.
- Detail how to calculate oxygen delivery.
- Demonstrate the interdependence of the lungs, heart, and blood on peripheral oxygen delivery.
- Describe the mechanisms for the measurement of oxygen consumption.
- Describe the variables that can influence oxygen consumption in critically ill children.
- Define the use of and limitations of the Fick equation in the evaluation of the adequacy of oxygen delivery.
- Define the oxygen extraction ratio; describe how it varies with regional demands and disease states.
- Describe the difference between aerobic and anaerobic metabolism.
- Describe what ATP and NADP really do.
- Describe the biochemical (laboratory) evaluation of the adequacy of circulatory function.

2.1 Introduction

Every cell in an aerobic multicellular organism needs a system to receive oxygen and dispose of waste. This process presents unique challenges to each organism. The fact that animals as big as blue whales and as small as hummingbirds, under widely diverse conditions, evolve mechanisms to ensure adequate oxygen delivery is one of the most fascinating topics in physiology. In addition, organisms must maintain oxygen delivery during pathologic stress states that can include infection, injury, intoxication, and metabolic abnormalities.

The maintenance of adequate oxygen delivery to meet the demands of the tissues is the essence of critical care medicine.

Maintaining an adequate oxygen delivery to meet the demands of organs and tissues is a fundamental task in critical care medicine. Inadequate oxygen delivery, which can occur on a global level as in cardiogenic shock or on a regional level such as traumatic brain injury, must be recognized and treated in order to achieve optimal outcomes. Therefore, an understanding of the determinants of oxygen delivery and oxygen consumption in the critically ill pediatric patient is essential for any pediatric critical care clinician.

Molecular oxygen moves down a concentration gradient from the atmosphere to the blood, and from there to the cell and into the mitochondria. Ultimately, oxygen will be used not only in cellular respiration as the final step in the energy production from carbohydrates, fats, and protein but also in several oxidative reactions unrelated to energy. This chapter reviews oxygen-related biochemical processes, their alterations in critical illness, and the various methods for measuring oxygen delivery and consumption.

2.2 Biochemical Basis

All tissues need energy to maintain their biological processes. This energy is provided by a series of biochemical oxidation/reduction reactions. Oxidation refers to the process in which a molecule, not necessarily involving oxygen, loses electrons. Reduction is the reverse process in which a molecule gains electrons.

In oxidation reactions, the electron moves down an energy gradient, releasing energy with every oxidation/reduction cycle. A portion of this energy is captured in reduction reactions by certain molecules, such as adenosine triphosphate (ATP), that become reservoirs of energy. ATP is the most important

energy storage/supply molecule because of two key properties. First, the two outer bonds between the three phosphate groups have a very high latent or intrinsic energy, many times more than that of most chemical bonds. This energy is liberated when the bond is broken. Second, these "high-energy" bonds are very unstable and can easily break down, making such energy readily available. ATP is constantly being used and regenerated; in fact, the rotatory machine at the core of the ATP-synthase can rotate hundreds of times per second, and the number of protons going through all the mitochondria in the cells of the human body every second is approximately equivalent to the number of stars in the known universe – for a fascinating discussion of the energy considerations of cellular metabolism, see "The Vital Question" by Nick Lane.

ATP is the main energy carrier in the cellular system. The high-energy molecules nicotinamide adenine dinucleotide (NADH) and nicotinamide adenine dinucleotide phosphate (NADPH) are also essential to the energy-generating processes of the cell because they donate electrons to an electron transport system that results in the production of ATP. The phosphorylation of ATP is a reduction reaction, with a net increase in stored energy. Dephosphorylation, such as the transformation of ATP into ADP, releases energy. Although part of this released energy is dissipated as heat, much of it is used to generate the work needed for normal cellular function (e.g., maintaining a sodium gradient across a biological membrane).

Cellular respiration occurs in three stages (◘ Fig. 2.1). The first step is *glycolysis*, during which one molecule of glucose is converted into two molecules of pyruvate with the net production of two ATP molecules and two NADH molecules. This first step is anaerobic; it does not require oxygen and occurs in the cytoplasm of the cells.

Pyruvate metabolism is a reaction that links glycolysis with the second step, the Krebs cycle. Under aerobic conditions, pyruvate metabolism consists of the conversion of pyruvate into acetyl-CoA while NAD + is reduced to NADH. Acetyl-CoA enters the Krebs cycle where the oxidation process continues. Amino acids from protein breakdown also enter the Krebs cycle by conversion to pyruvic acid or acetyl-CoA. Lipid metabolism generates glycerol and fatty acids that enter the Krebs cycle as metabolites of glycolysis or as acetyl-CoA.

The *Krebs cycle*, which occurs in the mitochondria, is illustrated in a simplified form in ◘ Fig. 2.2. For the two molecules of acetyl-CoA that enter the Krebs cycle (from one molecule of glucose), two ATP molecules, six NADH molecules, and two FADH molecules are produced, while four molecules of carbon dioxide are released. Although two ATP molecules are produced, the true energy gain from the Krebs cycle is generated from the NADH and FADH molecules.

NADH and FADH undergo redox reactions that cause the sequential transfer of electrons down the *electron transport chain*. The transfer of electrons causes a hydrogen gradient to develop across the inner mitochondrial membrane. These redox reactions are facilitated by a series of protein complexes (I, II, II, and IV), ubiquinone (Q), and cytochrome c. The transfer of electrons down the electron transport chain terminates with the activation of ATP synthase (ATPS). Activated ATP synthase leads to *oxidative phosphorylation* as oxygen serves as the final electron donor. Oxygen is reduced to water and an excess of 30 molecules of ATP are produced.

For the Krebs cycle, electron transport, and oxidative phosphorylation to occur with efficient production of energy, oxygen must be present. Under anaerobic conditions, the final electron acceptor can be a metabolite, such as pyruvate that will conserve some of the latent energy. The anaerobic pathway is far less efficient than the aerobic process in producing energy. Anaerobic metabolism cannot support the functioning of most tissues for extended peri-

Energy from nutrition is extracted and stored in ATP in three stages. The first step, glycolysis, is anaerobic. A linking reaction results in the conversion of pyruvate to acetyl-CoA that then enters the Krebs cycle (second step). In the third stage of the process, molecules of NADH and FADH from the Krebs cycle enter the electron transport chain and facilitate a cascade of electron transfers resulting in the activation of ATP synthase.

Activated ATP synthase catalyzes oxidative phosphorylation. Oxygen is reduced to water and an excess of 30 molecules of ATP are produced.

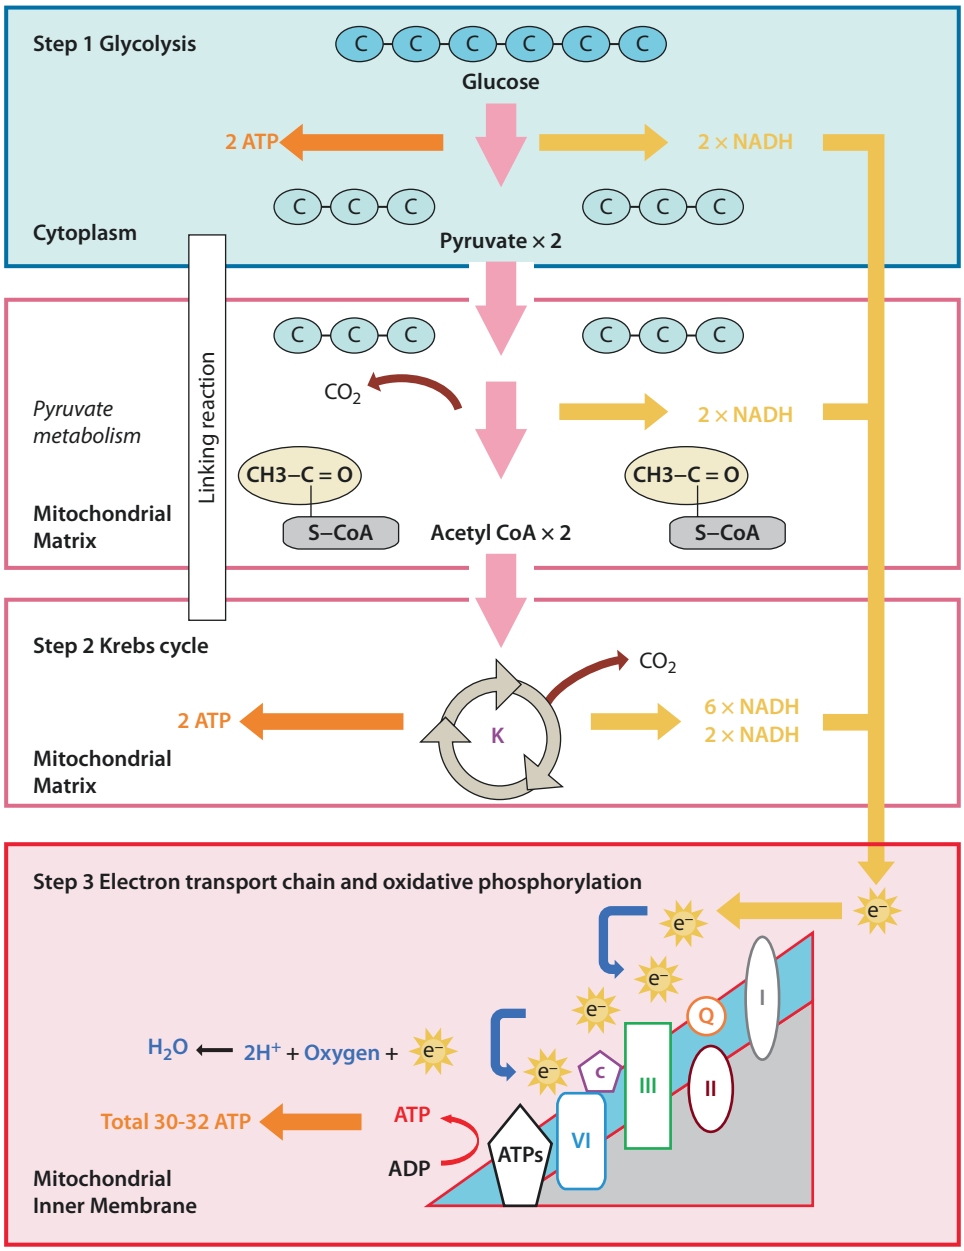

Fig. 2.1 Overview of cellular respiration. (Courtesy of F. Maffei)

In the absence of oxygen, elevation of lactate levels and accumulation of H^+ result in metabolic acidosis.

ods, particularly those with high-energy demands, such as the brain or the heart. If oxygen is not present, pyruvate cannot enter the Krebs cycle, and instead, it is converted into lactate resulting in elevations of blood lactate levels. Therefore, an elevated plasma lactate level can be used as an indicator of anaerobic metabolism and insufficient oxygen delivery. When oxygen becomes available, most of the lactate will rapidly be reconverted to pyruvate and subsequently enter the Krebs cycle. Most of this reconversion occurs in the liver.

Elevation of blood lactate may occur in the absence of tissue hypoxia. Inflammatory mediators, catecholamines, and other factors, which may stimulate Na/K adenosine triphosphatase activity, can produce elevated lactate. This is commonly referred to as type B lactic acidosis. In addition, a decrease in lactate clearance can produce elevated blood lactate levels. This has been found to occur in the presence of hepatic insufficiency and with severe sepsis.

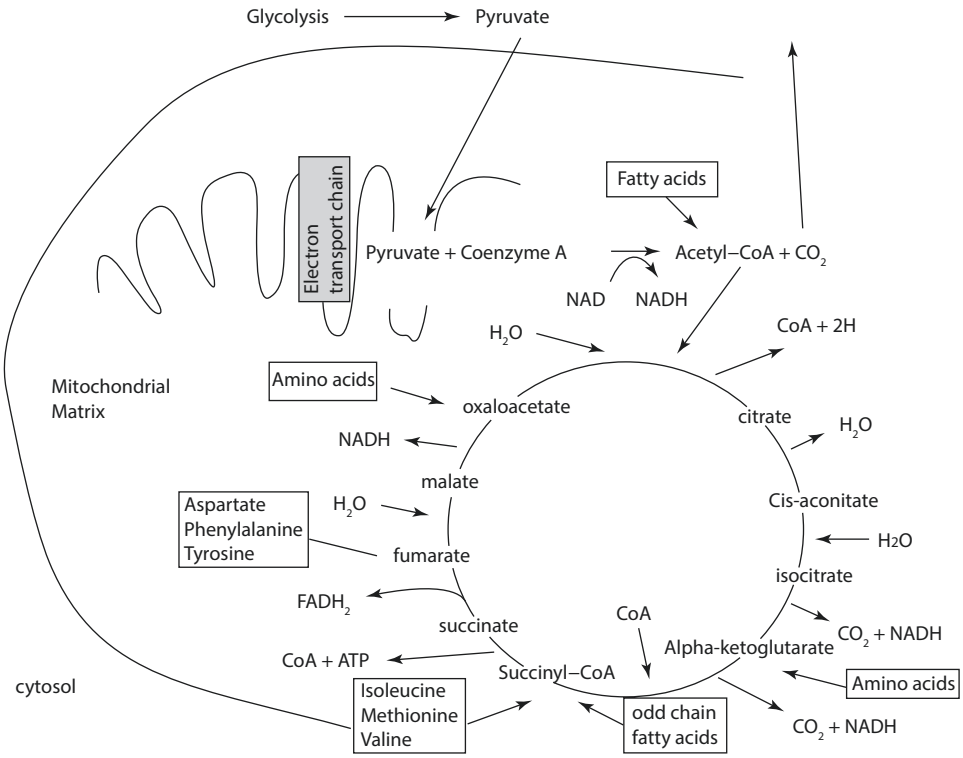

Fig. 2.2 The Krebs cycle

Lactate elevation is not the primary contributor to the metabolic acidosis seen during tissue hypoxia. A second biochemical process that occurs in the setting of hypoxia is the accumulation of hydrogen ions. These hydrogen ions diffuse out of the cell because oxygen is not available to be the final acceptor of hydrogen. The primary mechanism of hypoxic acidosis is not the accumulation of lactate, but rather the accumulation of unused hydrogen ions.

As noted, the acidosis that accompanies anaerobic metabolism is primarily intracellular. This concept is particularly important as it relates to therapy. The intravenous administration of sodium bicarbonate can correct the extracellular acidosis, but because bicarbonate is not readily diffusible, it will only slowly correct intracellular acidosis. The rapid infusion of bicarbonate may worsen intracellular acidosis. With rapid infusion of sodium bicarbonate, there will be a significant increase in blood levels of carbon dioxide, liberated from the dissociation of carbonic acid formed when bicarbonate ion buffers extracellular hydrogen ion. Carbon dioxide readily diffuses into cells, where it associates with water to reform carbonic acid, thereby worsening the intracellular acidosis. Therefore, the routine use of sodium bicarbonate to correct the hypoxic acidosis may be deleterious. As such, the ideal treatment for acidosis associated with anaerobic metabolism is to *improve oxygen delivery*.

The use of sodium bicarbonate to correct hypoxic acidosis may be deleterious. The ideal treatment for acidosis associated with anaerobic metabolism is to improve oxygen delivery.

There are certain clinical circumstances where the use of sodium bicarbonate may improve oxygen delivery. Profound extracellular acidosis may adversely affect myocardial function and the response to catecholamines; therefore, sodium bicarbonate may improve cardiac function, increase the cardiac output, and, thus, increase oxygen delivery. Sodium bicarbonate may also be useful when hypoxia is secondary to severe pulmonary hypertension. Acidosis increases pulmonary vascular resistance. The administration of sodium bicarbonate may ameliorate pulmonary vasoconstriction, thus improving oxygenation.

2

2.3 Oxygen Delivery

In order to appreciate the factors that influence the delivery and utilization of oxygen, it is necessary to have a clear understanding of the terms used to describe this process. These definitions include the following:

Oxygen delivery (DO_2) The rate of oxygen delivered per unit of time to a tissue, an organ, or the entire body.

Oxygen consumption (VO_2) The oxygen utilized per unit of time by a tissue, an organ, or the entire body.

Oxygen extraction (O_2ER) The fraction of the oxygen delivered in the blood that is utilized or consumed by a tissue, an organ, or the entire body of patient.

Oxygen demand A theoretical concept describing the amount of oxygen that a tissue, an organ, or the entire patient's body would need to consume to meet all its needs under a given set of circumstances.

Oxygen demand cannot be measured, but it is a useful concept when reflecting upon the factors which affect oxygen delivery and consumption.

When oxygen demands are being met, further increases in oxygen delivery will have no effect on oxygen consumption.

Oxygen debt The difference between oxygen delivery and the estimated oxygen demand. Theoretically, when there is a significant oxygen debt, increases in oxygen delivery will increase oxygen consumption. Alternatively, when oxygen demands are being met (no oxygen debt), further increases in oxygen delivery will have no effect on oxygen consumption.

The global delivery of oxygen throughout the body (DO_2) is defined as the product of the oxygen content of the arterial blood (CaO_2; in mL/dL) and the blood flow or cardiac output (CO; in L/min) as expressed in the following equation:

$$\text{Oxygen delivery} = \text{CO} \times \text{arterial}\,\text{O}_2\,\text{content}$$

$$\text{DO}_2 = \text{CO} \times \text{CaO}_2$$

$$\text{DO}_2\,(\text{mL/min}) = \text{CO}\,(\text{L/min}) \times \text{CaO}_2\,(\text{mL/dL})$$

This equation is multiplied by 10 to convert the units into mL/min:

$$\text{DO}_2 = 1000\,\text{mL/min or } 550-650\,\text{mL/min/m}^2 \text{ if CI used}$$

There are several determinants of the cardiac output and CaO_2. Each can become deranged in critically ill patients (Fig. 2.3). Identification of the primary derangement and the initiation of appropriate directed therapies are required to achieve physiologic stability. The determinants of oxygen delivery are arterial oxygen content and cardiac output. Each will be discussed in detail.

2.3.1 Arterial Oxygen Content

The arterial oxygen content is the sum of the oxygen bound to hemoglobin and the oxygen dissolved in the blood. Most of the oxygen in blood travels bound to hemoglobin; only a minimal amount is present as dissolved oxygen. Therefore, the oxygen content depends primarily on the oxyhemoglobin saturation and the hemoglobin concentration. The formula for the calculation of arterial oxygen content is:

$$\text{CaO}_2 = \text{Hgb} \times 1.34 \times \text{SaO}_2 + \text{PaO}_2 \times 0.003$$

The individual variables are as follows:

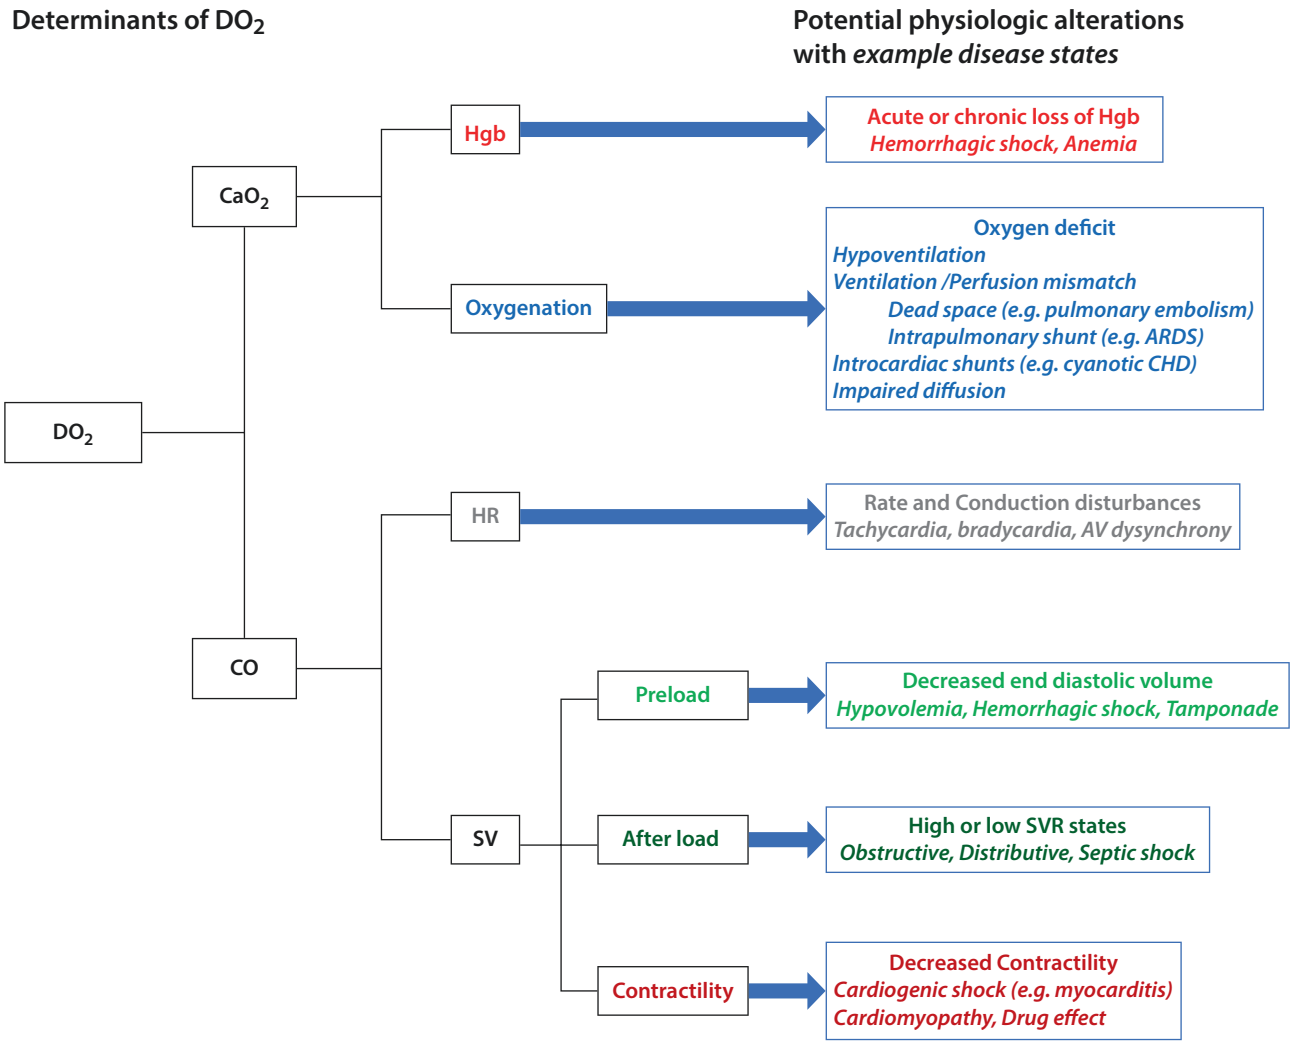

Fig. 2.3 Determinants of oxygen delivery, physiologic alterations, and corresponding disease states. (Courtesy F. Maffei). ARDS acute respiratory distress syndrome, CHD congenital heart disease, SVR systemic vascular resistance

Hgb is the hemoglobin concentration in g/dL; 1.34 is the constant that defines the maximum oxygen-binding capacity of hemoglobin in mL O_2/gm at 100% oxyhemoglobin saturation (in other words, it is the amount of oxygen a fully saturated gram of hemoglobin can carry); SaO_2 is the percent of hemoglobin saturated with oxygen; PaO_2 is the partial pressure of oxygen in the arterial blood in mm Hg; 0.003 is the constant that defines the solubility of oxygen in the blood in mL O_2/dL/mm Hg. The units for CaO_2 are mL/dL.

The formula demonstrates that a drop in oxygen saturation, as in acute respiratory failure, or a drop in the hemoglobin, as in acute hemorrhagic anemia, will significantly decrease the arterial oxygen content and, therefore, decreases oxygen delivery. The correction of the oxyhemoglobin desaturation and/or the transfusion of packed red blood cells will both increase oxygen delivery.

For example, a healthy child may have an arterial oxygen content of approximately 16.4 mL/dL (assuming a hemoglobin concentration of 12 gm/dL, 100% oxyhemoglobin saturation and a PaO_2 of 105 mm Hg).

Mathematically,

$$CaO_2 = \left[(12\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (1.00) + \begin{pmatrix} 105\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix} \right]$$
$$= 16.1\,\text{mL/dL} + 0.3\,\text{mL/dL} = 16.4\,\text{mL/dL}$$

In contrast, a child with hypoxia due to acute respiratory distress syndrome, (SaO_2 = 88%, PaO_2 = 60), and concomitant anemia (Hgb 9 g/dL), will have an arterial oxygen content of approximately 10.8 mL/dL.

Mathematically,

$$CaO_2 = \left[(9\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (0.88) + \begin{pmatrix} 60\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix} \right]$$
$$= 10.6\,\text{mL/dL} + 0.2\,\text{mL/dL} = 10.8\,\text{mL/dL}$$

Transfusing the child with packed red cells to a hemoglobin of 12 g/dL would increase his CaO_2 to 14.3 mL/dL and thereby increase his arterial oxygen content by approximately one-third.

$$(14.3 - 10.8)/10.8 = (3.5/10.8) = 0.32$$

In a child with mild anemia (hemoglobin of 9 g/dL) who has a 100% oxyhemoglobin saturation and a PaO_2 of 105 mm Hg, the arterial oxygen content would be 12.4 mL/dL.

Mathematically,

$$CaO_2 = \left[(9\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (1.0) + \begin{pmatrix} 105\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix} \right]$$
$$= 12.1\,\text{mL/dL} + 0.3\,\text{mL/dL} = 12.4\,\text{mL/dL}$$

An increase in the PaO_2 up to 500 mm Hg with supplemental oxygen would increase the arterial oxygen content to only 13.6 mL/dL. This would increase his CaO_2 by less than 10% [(13.6–12.4)/12.4 = (1.2/12.4) = 0.097]. Therefore, since hemoglobin cannot be more than 100% saturated, increasing the PaO_2 to high levels has minimal impact on CaO_2 except for patients suffering from severe anemia, where the dissolved oxygen represents a significant component of the total CaO_2.

This is illustrated in a child with severe anemia presenting with a hemoglobin of 5 g/dL, an oxygen-hemoglobin saturation of 100%, and a PaO_2 of 105 mm Hg. This child will have a CaO_2 of 7.0 mL/dL without supplemental oxygen.

Mathematically,

$$CaO_2 = \left[(5\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (1.00) + \begin{pmatrix} 105\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix} \right]$$
$$= 6.7\,\text{mL/dL} + 0.3\,\text{mL/dL} = 7.0\,\text{mL/dL}$$

Placing the child on a 100% non-rebreather mask and increasing his PaO_2 to 500 mm Hg would increase his CaO_2 to 8.2 mL/dL.

Mathematically,

$$CaO_2 = \left[(5\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (1.00) + \begin{pmatrix} 500\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix} \right]$$
$$= 6.7\,\text{mL/dL} + 1.5\,\text{mL/dL} = 8.2\,\text{mL/dL}$$

The increase would represent a 17% increase in his CaO_2 [(8.2 − 7.0)/7.0] = (1.2/7.0) = 0.17.

If, in addition, a transfusion was administered to increase the hemoglobin to only 8 g/dL, CaO_2 would rise significantly.

Mathematically,

$$CaO_2 = \left[(8\,\text{g/dL}) \times (1.34\,\text{mL/g}) \times (1.00) + \begin{pmatrix} 500\,\text{mm}\,Hg \times \\ 0.003\,\text{mL/dL/mm}\,Hg \end{pmatrix}\right]$$
$$= 10.7\,\text{mL/dL} + 1.5\,\text{mL/dL} = 12.2\,\text{mL/dL}$$

CaO_2 would increase an additional 50% [(12.2 − 8.2)/8.2] = (4.0/8.2) = 0.49.

Increasing dissolved oxygen content in patients with severe anemia can substantially improve oxygen delivery.

The decision regarding blood transfusions to improve oxygen delivery should not solely be based on hemoglobin concentration, except in the case of acute severe anemia. Although, mathematically, CaO_2 will increase with a PRBC transfusion, studies have revealed that a "liberal" policy of blood transfusions may be associated with increased mortality in certain critically ill patients. In a landmark study, stable, critically ill children randomized to a hemoglobin threshold of 7 gm/dL had outcomes similar to children randomized to a hemoglobin threshold level of 9.5 gm/dL. In post hoc analyses, similar results were found among the subsets of general postoperative and postoperative cardiac patients. In fact, among the subset of general postoperative patients, the restrictive transfusion strategy was associated with a shorter length of PICU stay. Several factors have been invoked to explain the lack of benefit to "liberal" transfusions, including the relative impairment of oxygen dissociation from stored blood, transfusion reactions, microcirculatory changes, volume overload, and activation of inflammatory mediators present in the transfused blood.

2.3.1.1 Arteriovenous Oxygen Content Difference

$$\text{avDO}_2 = CaO_2 - CvO_2$$

The arteriovenous difference ($CaO_2 - CvO_2$) can be used as a measure of the adequacy of O_2 delivery. With a normal O_2 consumption of approximately 250 mL/min and cardiac output of 5000 mL/min, the normal arteriovenous difference is approximately 4–6 mL O_2/dL of blood or 40–60 ml O_2/L of blood. A decrease in DO_2 leads to higher oxygen extraction, which increases the AV difference. A decrease in O_2 extraction (e.g., cyanide poisoning, sepsis) leads to a lower AV difference.

2.3.2 Cardiac Output

The second component of the oxygen delivery is systemic cardiac output (CO), the amount of blood that is being pumped to the systemic circulation in liters per minute. In the absence of intracardiac or large systemic to pulmonary shunts, the systemic cardiac output is the product of the heart rate (HR) in beats per minute and the left ventricular stroke volume (SV) in milliliters:

$$\text{CO} = \text{HR} \times \text{SV}$$

and is frequently indexed (CI) to body surface area (BSA) (m^2).

$$\text{CI} = \text{CO} / \text{BSA}$$

2

Newborns and children with noncompliant ventricles have relatively rigid ventricular walls limiting their distention. Consequently, they may have a less ability to increase stroke volume depending more on heart rate to increase cardiac output.

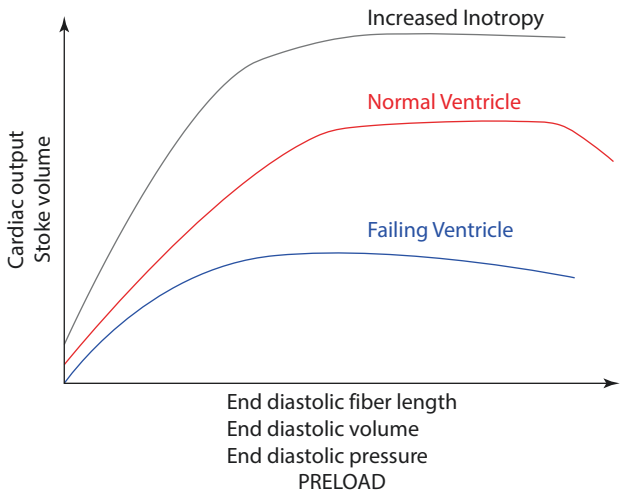
2.3.2.1 Heart Rate

The normal heart rate varies with age. Newborns and children with heart disease have relatively noncompliant ventricular walls that limit distensibility. Consequently, they have a less ability to increase stroke volume and, thus, may be more dependent on heart rate to increase cardiac output. Lack of chronotropic response limits the ability to increase stroke volume, but extreme tachycardia also limits stroke volume. Pathologically high heart rates (e.g., supraventricular tachycardia) may adversely affect cardiac output by limiting ventricular filling time during diastole, thus reducing preload and decreasing the stroke volume.

2.3.2.2 Stroke Volume

Stroke volume is the volume of blood pumped with each cardiac contraction and reflects three components: preload, contractility, and afterload. Preload is defined as the stretch of the cardiac myocytes just prior to contraction. Preload is related to the sarcomere length and is difficult to assess clinically. According to the classic Frank-Starling relationship, the strength of the muscular contraction depends on the initial length (stretch) of the muscle. As the stretch of the cardiac myocyte is increased, the strength of the muscular contraction increases up to a point. The cardiac myocyte can be stretched to a point beyond which maximal contraction occurs, and the strength of the contraction begins to decrease as further stretching of the myocyte occurs (◘ Fig. 2.4). Clinically determining preload can be difficult. The left ventricular end-diastolic volume, which is the volume of blood in the left ventricle just prior to contraction, is probably the best surrogate of systemic preload.

Thermodilution techniques are available that can determine global end-diastolic volume but are invasive and not well established in pediatric critical care. Echocardiography and magnetic resonance imaging may also be used to estimate left ventricular end-diastolic volume but are technician dependent and do not allow for moment-to-moment monitoring.



◘ **Fig. 2.4** Frank-Starling relationship between preload and ventricular function. The *middle curve* represents a normal myocardium. As preload increases, markers of contractility increase. *The lower curve* represents a myocardium that is dysfunctional. The curve is shifted downward and to the right, such that for the same preload, there is decreased ventricular function. Finally, *the upper curve* represents the normal myocardium receiving inotropic support. Note that the curve is shifted upward and to the left, such that for the same preload, there is increased ventricular function

Left ventricular end-diastolic volume may be estimated by left ventricular end-diastolic pressure. This estimation may be confounded by a change in the distensibility of the ventricular wall or pressure increases outside of the ventricle (increased intrathoracic pressure, pericardial tamponade, etc.).

Left atrial pressure has been used as an indirect measure of preload but requires the placement of a pulmonary artery catheter (PAC). Using the PAC, the pulmonary artery occlusion pressure can be obtained and will reflect left atrial pressure, which can be a clinically useful surrogate of systemic preload. The pulmonary artery occlusion pressure is determined by inflating the balloon of a pulmonary artery catheter such that it floats out and wedges into a distal pulmonary artery. The distal lumen of the pulmonary artery catheter is distal to the balloon and, therefore, measures the downstream pressure without interference from proximal pressures as the inflated balloon isolates the distal pressures. Placement of a PAC is invasive, and adult studies have suggested that the routine use of such monitoring may be associated with worse outcomes.

Central venous pressure, as measured in the right atrium or a major vein within the thoracic compartment, has been used to estimate preload. The ability of central venous pressure to reflect true preload may be impeded by multiple factors, including ventricular compliance and atrioventricular valvular disease. However, because of its clinical availability, it is commonly used to assist in the assessment of preload.

In addition to preload, stroke volume is determined by contractility. Cardiac contractility is defined as the extent of shortening that occurs in cardiac myocytes when stimulated independent of preload or afterload. It refers to the intrinsic strength of the myocardial muscle and is the measure of cardiac muscle performance. It depends on many factors, including the mass of muscle, the molecular aspects of muscular contraction, the degree of stimulation by catecholamines, and the concentration of electrolytes, such as calcium, potassium, and magnesium. Factors that increase cardiac contractility move the Frank-Starling curve upward and to the left (◘ Fig. 2.4). Thus, for the same preload, increased contractility usually results in increased stroke volume.

Like preload, clinically determining contractility is difficult. Techniques such as the thermodilution-derived cardiac function index and the echocardiographic stress index have been developed, but their application to pediatrics has been limited to date. Doppler tissue imaging represents a new echocardiographic technique that may assist in the determination of contractility by measuring the velocity of myocardial motion. Echocardiographic determination of the shortening fraction and the ejection fraction remain the most commonly utilized surrogates of contractility.

The shortening fraction (at times referred to fractional shortening) is the percent change in the diameter of the left ventricle, which occurs with contraction. It is determined by taking the difference in left ventricular diameter between diastole and systole and dividing that value by the left ventricular end-diastolic diameter. Normal values for shortening fraction in infants and children are between 28% and 46%. The shortening fraction assumes that the ventricle has a symmetric cylindrical shape and has a normal volume state. Diseases with abnormally shaped ventricles (e.g., hypoplastic left ventricle) and those causing asymmetric wall abnormalities reduce the ability of shortening fraction to reflect the overall systolic function.

Contractility depends on many factors, including the mass of muscle, the molecular aspects of muscular contraction, the degree of stimulation by catecholamines, and the concentration of electrolytes, such as calcium, potassium, and magnesium. Factors that increase cardiac contractility move the Frank-Starling curve upward and to the left.

The ejection fraction is another echocardiographic parameter that can be used to asses left ventricular function. It is determined in a manner like the shortening fraction, but it utilizes end-diastolic volumes rather than diameters. Normal values tend to range from 55% to 65%. Ejection fraction is categorized as normal (≥55%), slightly reduced (41–55%), moderately reduced (31–40%), and markedly reduced (≤30%).

Afterload may be defined as the force opposing contraction of the left ventricular myocytes during systole. It can be quantified as the left ventricular wall stress. The left ventricular wall stress may be estimated using the Law of Laplace, which relates wall stress to the pressure, radius, and thickness of a sphere or cylinder in the following formula:

$$\text{Wall stress} = (\text{Pressure})(\text{Radius}) / (\text{Wall thickness})$$

Because the left ventricle is not a sphere or cylinder, the application of the Law of Laplace is an oversimplification. In using this equation to assess left ventricular afterload, the pressure refers to the transmural left ventricular pressure, the radius refers to the left ventricular end-systolic dimension, and the wall thickness to the left ventricle wall. These measures should all be taken at the end of left ventricular systole. The left ventricular wall thickness and dimension may be determined echocardiographically. The transmural left ventricular pressure is the difference between the pressure inside the ventricle and the pressure outside the ventricle.

The determinants of the cardiac output (heart rate, preload, afterload, and contractility) and the arterial content of oxygen (hemoglobin and oxygenation) can each become deranged in critically ill patients. Careful monitoring and adjustment of these variables are required in order to achieve the best clinical outcome.

Extraventricular pressures have been determined using esophageal or pleural pressure monitoring, although clinically these values are not commonly measured. It is important to note that the use of positive-pressure ventilation will change the intrathoracic pressure from a negative to a positive. As such, positive-pressure ventilation will decrease left ventricular afterload because subtracting a positive from a positive (the intraventricular pressure) is a smaller number. In contrast, normal, negative-pressure ventilation results in increased left ventricular afterload because subtracting a negative (intrathoracic pressure) from a positive (intraventricular pressure) results in a higher number (i.e., increased afterload).

2.4 Interdependence of the Heart, Lungs, and Blood on Peripheral Oxygen Delivery

Oxygen delivery is dependent upon multiple variables, all of them intimately related. Any derangements of the determinants of **arterial oxygen content** (hemoglobin concentration, oxygenation) or **cardiac output** (preload, contractility, afterload, or heart rate) will affect oxygen delivery.

The lungs have the primary role of extracting oxygen from inspired gas. The blood has the primary role of carrying that oxygen to the tissues, and the heart has the primary responsibility of circulating that blood and oxygen to the tissues. These three systems work interdependently to assure adequate oxygen delivery to the tissues. This interdependence is best exemplified by reviewing the physiologic responses to alterations in any of these systems.

One of the most common causes of inadequate oxygen delivery in pediatrics is acute hypoxemia. Hypoxemia is detected in vivo by chemoreceptors located in the carotid and aortic bodies. When these chemoreceptors are triggered by hypoxemia (PaO_2 < 60 mm Hg, corresponding to SaO_2 < 93%), there is stimulation of the respiratory area of the medulla. This results in an increase in minute ventilation, a higher alveolar oxygen concentration (PAO_2), and ultimately, an increase in the arterial oxygen content as a result of the increase in the oxygen saturation and the PaO_2. Furthermore, signals are sent from the chemoreceptors to the vasomotor center of the brainstem, leading to increased sympathetic tone. This sympathetic stimulation increases the heart rate, improves the preload by venous constriction, and increases contractility, all of which improve cardiac output and, thereby, augment oxygen delivery.

Sympathetic-mediated compensatory responses have the potential to become maladaptive, resulting in increased afterload and increased oxygen consumption by the myocardium. When prolonged, this compensatory response may lead to myocardial dysfunction, especially in the setting of preexisting cardiac disease. These compensatory mechanisms are not well developed in newborns who often develop hypotension, bradycardia, and apnea in response to acute hypoxemia.

Hypoxemia is detected by special nerve chemical receptors located in the carotid and aortic bodies. When these chemoreceptors are triggered by hypoxemia (PaO_2 < 60 mm Hg, corresponding to SaO_2 < 93%), there is stimulation of the respiratory area of the medulla. This results in an increase in minute ventilation, a higher alveolar oxygen concentration (PAO_2), and, ultimately, an increase in the arterial oxygen content as a result of the increase in the oxygen saturation and the PaO_2.

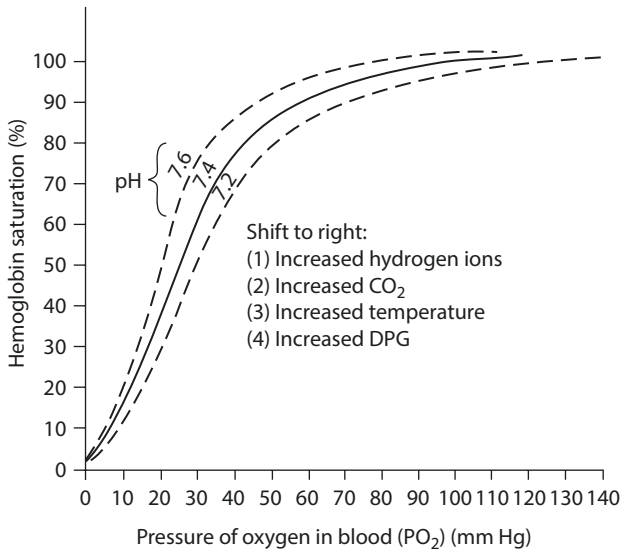
Hemoglobin is the molecule responsible for carrying oxygen in the blood. It can adapt to physiologic changes associated with hypoxia to improve oxygen delivery to the tissues. In the presence of acidosis, which often accompanies hypoxia, hemoglobin's affinity for oxygen decreases, facilitating the release of oxygen to the starved cells (■ Fig. 2.5). The affinity of hemoglobin for oxygen is also decreased in the presence of increased concentrations of 2,3 diphosphoglycerate (2,3 DPG), which occur in the presence of hypoxemia.

Of note, the concentration of 2,3 DPG declines over time in stored packed red blood cells. This loss of 2,3 DPG decreases the ability of PRBC transfusion to release oxygen at the tissue level. In addition, it is important to recognize that there are different forms of hemoglobin with different affinities for oxygen. For example, fetal hemoglobin constitutes a significant proportion of the total hemoglobin in newborns and small infants. This form of hemoglobin has an increased affinity for oxygen, which facilitates the transfer of oxygen from the maternal adult hemoglobin across the placenta. However, following birth, when the oxygen concentration at the pulmonary alveolar level is much higher, this increased affinity for oxygen is no longer needed. In fact, this elevated affinity for oxygen may impair the unloading of oxygen at the tissue level postnatally, which may be problematic in conditions associated with decreased oxygen delivery.

Certain factors may decrease oxyhemoglobin dissociation in the capillary circulation, thereby making less oxygen available. Factors that shift the oxygen-hemoglobin dissociation curve to the left include severe alkalosis, the depletion

Factors that shift the oxyhemoglobin dissociation curve to the **r**ight promote the **r**elease of oxygen from Hgb, whereas factors that shift the curve to the **l**eft promote **l**atching of oxygen onto Hgb.

In the presence of acidosis, the affinity of hemoglobin for oxygen decreases, facilitating the release of oxygen to the starved cells. The affinity of hemoglobin for oxygen also decreases with increases in the concentration of 2,3 diphosphoglycerate (2,3 DPG), which occur in the presence of hypoxemia.



■ **Fig. 2.5** The oxyhemoglobin dissociation curve. The curve is shifted to the right by factors that enhance oxyhemoglobin dissociation and allow oxygen to be more readily available to the tissues. These factors include 2,3-diphosphoglycerate (2,3 DPG), which may be increased by glycolysis, exercise, hypoxemia, fever, and/or acidosis. The curve is shifted to the left by severe alkalosis, the depletion of 2,3 DPG, the presence of fetal hemoglobin, and certain hemoglobinopathies

of 2,3-diphosphoglycerate (2,3 DPG), fetal hemoglobin, and certain hemoglobinopathies. Factors that shift the oxygen-hemoglobin dissociation curve to the right and promote the release of oxygen to the tissues and include increased 2,3 DPG, exercise, hypoxemia, fever, and/or acidosis.

Tissue hypoxia triggers the kidney to secrete the hormone erythropoietin, stimulating the bone marrow to increase the production of red blood cells.

Sustained hypoxia induces changes in cellular gene expression. A family of transcription factors, known as hypoxia-inducible factors (HIF), has been characterized, furthering the understanding of the molecular response to hypoxia. When oxygen saturation is chronically low, as in cyanotic heart disease, the bone marrow responds by increasing the red blood cell production, leading to an increased hemoglobin concentration and improved CaO_2. The molecular signal in this response is the hormone erythropoietin secreted by the kidney. Erythropoietin stimulates the bone marrow to increase the production of red blood cells. When hypoxemia is chronic and severe (e.g., uncorrected cyanotic heart disease), the resultant polycythemia increases blood viscosity and the resistance to blood flow in the microcirculation. This may result in compromised oxygen delivery to tissues despite a high hemoglobin concentration.

When hemorrhagic shock is the cause of inadequate oxygen delivery, baroreceptors located in the carotid sinus, aortic arch, and venoarterial junctions of both atria are triggered. Triggering of these baroreceptors stimulates the brainstem to increase the cardiac output primarily through an increase in the heart rate, to compensate for the low arterial oxygen content. When hypovolemia compromises cardiac output, peripheral vasoconstriction results, optimizing perfusion of vital organs and minimizing the risk of ongoing bleeding.

Multiple compensatory responses exist to preserve DO_2 during low cardiac output states. Low cardiac output may be secondary to hypovolemia, cardiogenic shock, or distributive shock. Reponses include increasing systemic vascular resistance, conserving salt and water, and increasing heart rate and contractility.

If physiological alterations occur gradually, adequate compensation is more likely to occur. This is especially true regarding the development of anemia. Chronic anemia, as occurs with iron deficiency, allows for maintenance of oxygen delivery by gradual increases in preload and heart rate and, therefore, cardiac output. Additional capillary beds open within vital organs minimizing the distance from the oxygen supply to the cells. These opened capillary beds result in a decreased systemic vascular resistance, which fosters an increased cardiac output and manifests itself as a widened pulse pressure with decreased diastolic pressures. Unlike acute anemia, intravascular volume is not only maintained but may be elevated. Even children with a hemoglobin concentration less than 4 g/dL can compensate remarkably well if the anemia has developed slowly. However, it is important to recognize that compensation results in a hypervolemic, high cardiac output state. Traditionally, very small aliquots of red blood cells transfused over 3–4 h were used in the correction of long-standing severe anemia. Transfusion volumes of 4–8 mL/kg may be tolerated because the overall improvement in oxygen delivery outweighs the potential for volume overload, particularly when diuretics are used concomitantly.

During low cardiac output states, baroreceptors throughout the body sense the inadequate flow and the compensatory mechanisms begin (▶ Box 2.1). Sympathetic activation results in catecholamine secretion and peripheral vasoconstriction. This leads to shunting of blood from the periphery to the core circulation to optimize oxygen delivery to the brain and heart. The heart rate increases in response to the release of catecholamines. The increase in chronotropy attempts to preserve cardiac output if stroke volume is decreased.

To increase preload, renin-angiotensin-aldosterone and antidiuretic hormone are secreted, resulting in salt and water retention. The respiratory rate increases, thereby lowering the CO_2, improving alveolar oxygen, and, ultimately, increasing the arterial oxygen content. With disease progression, these compensatory mechanisms may produce physiologic impairment and ultimately may become overwhelmed.

Box 2.1 Compensatory Responses to Poor Cardiac Output That Act to Preserve DO_2

Baroreceptors sensing a fall in CO initiate complex and interconnected cascade to maintain blood pressure and cerebral and coronary perfusion. Key elements of the response include:

- Sympathetic activation results in catecholamine secretion.
- Neuroendocrine chemo- and osmoreceptor response increase stress hormone secretion (e.g., catecholamines, cortisol, antidiuretic hormone).
- Reduced renal blood flow activates the renin-angiotensin system, resulting in angiotensin II-mediated vasoconstriction.
- Decreased capillary hydrostatic pressure promotes movement of interstitial fluid to the vascular space.

The result is preservation of systolic blood pressure at the expense of shunting blood from splanchnic organs, the kidney and skin. The examination findings that reflect these compensatory mechanisms include cool skin, delayed capillary refill, and narrowed pulse pressure (i.e., systolic pressure preserved, diastolic increased).

2.5 Oxygen Consumption

Oxygen consumption (VO_2) is the amount of oxygen consumed by the tissues per minute and is related to energy expenditure. Energy expenditure is the amount of energy consumed from substrates (carbohydrates, lipids, amino acids) during the process of energy generation. Energy expenditure can be measured and/or estimated from the oxygen consumption and carbon dioxide production.

Energy expenditure can be measured directly with calorimetric methods or can be estimated from oxygen consumption, using specific formulas to convert it to energy.

Critically ill children may have abnormally high or low oxygen consumption (Table 2.1). Oxygen consumption may be low because the metabolic activity of the tissues has decreased (e.g., barbiturate-induced coma, hypothermia) and the tissues have impaired oxygen uptake (e.g., cyanide toxicity) or because of inadequate supply.

When oxygen consumption is low because of inadequate supply, the cause may be the result of a derangement of one of the determinants of oxygen delivery. Cellular hypoxia may occur in the setting of mismatched oxygen consumption (high) and oxygen delivery (low). In some circumstances, the abso-

Table 2.1 Factors affecting VO_2

Factors that increase VO_2	Factors that decrease VO_2
Inflammation	Inadequate DO_2
Hyperpyrexia	Impaired cellular uptake
Shivering	Hypothermia
Pain	Mechanical ventilation
Agitation	Sedation/analgesia/NMB
Increased work of breathing	Coma, brain death

lute value of oxygen consumption may be high when compared to normal values, but the tissues may still be starving because oxygen demands are higher yet. Most tissues can increase their extraction of oxygen severalfold to satisfy their oxygen needs.

Under normal conditions, oxygen delivery is determined by the oxygen needs of the tissues. If the cells do not need additional oxygen, increasing oxygen delivery will only minimally impact oxygen consumption (supply independent). However, if the tissues are starving for oxygen despite increasing the amount of oxygen extracted from the blood, consumption will begin to fall linearly with decreasing oxygen delivery. The point at which this occurs is termed the critical point of oxygen delivery. Below that point, cells are resorting to anaerobic metabolic pathways to survive. This is termed the supply-dependent portion of the oxygen consumption curve (Fig. 2.6).

In critically ill patients with sepsis or acute respiratory distress syndrome (ARDS), this normal biphasic relationship may not occur. Oxygen consumption may continue to increase, even as DO_2 increases beyond values seen in healthy individuals. Oxygen consumption remains supply dependent to much higher levels of oxygen delivery. This leads to "pathologic supply dependency" (Fig. 2.7). The reason for this alteration in the normal relationship between oxygen supply and delivery has not been clearly elucidated and seems to apply primarily to sepsis and ARDS. It has been suggested that it occurs because the critical point of oxygen delivery has been reset to a much higher point. Alternatively, it may be the result of impaired ability of the tissues to increase oxygen extraction.

2.5.1 Measurement Techniques

The determination of oxygen consumption provides insight into the adequacy of oxygen delivery and utilization at the tissue level. However, accurately determining oxygen consumption at the tissue level is extremely difficult. Several methods for the determination of oxygen consumption have been developed for clinical use. One approach is to assess the composition of inhaled and exhaled respiratory gases and determine oxygen consumption using indirect calorimetry.

Indirect calorimetry is based on the basic law of thermodynamics that energy utilization entails the consumption of oxygen with the production of carbon dioxide, nitrogenous waste, and water in a stoichiometric fashion.

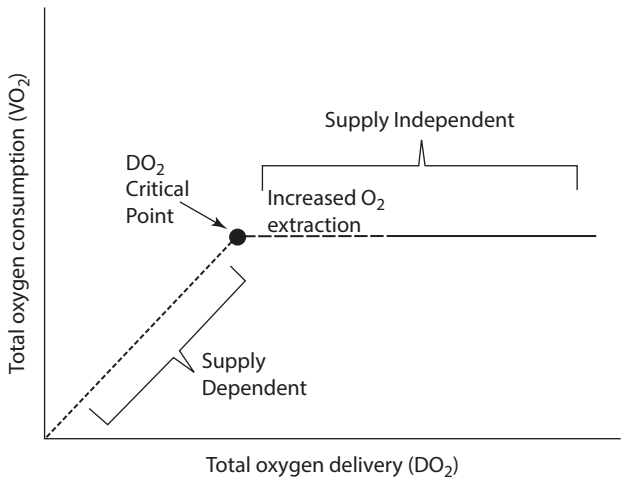


Fig. 2.6 Oxygen consumption/oxygen delivery relationship

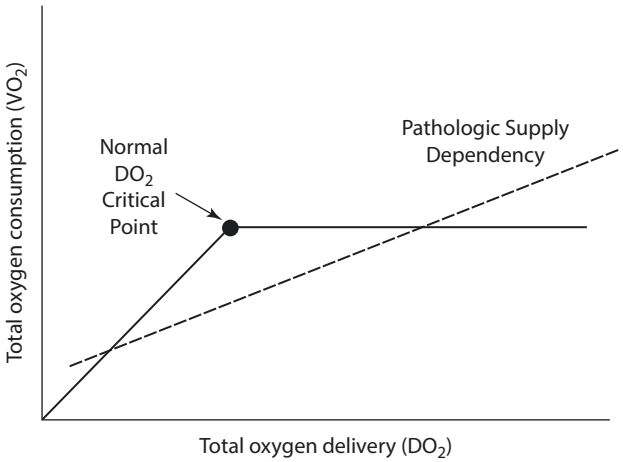

Fig. 2.7 The oxygen consumption/oxygen delivery relationship in pathologic states such ARDS and sepsis. In this figure, the *solid line* represents the normal biphasic relationship between oxygen consumption and delivery. The *dotted line* represents the pathologic relationship observed in critically ill patients with sepsis or ARDS. In this condition, supply dependency is observed at much higher levels of oxygen delivery. (Adapted from Crocetti and Krachman (2002))

Commercially available indirect calorimetry machines require that the patient breathes through a valved system that separates inspired and expired gases. The inspired gas has a known concentration of oxygen, nitrogen, and carbon dioxide. The volume of expired gas is measured, and the amount of expired oxygen and carbon dioxide is determined. With these values, oxygen consumption (VO_2) can be determined using the following equation:

$$\dot{V}O_2 = \dot{V}_I\left(F_IO_2\right) - \dot{V}_E\left(F_EO_2\right) \quad \left(\dot{V}CO_2\right) = \dot{V}_E\left(F_ECO_2\right) - \dot{V}_I\left(F_ICO_2\right)$$

where VO_2 is the oxygen consumption, V_I is the volume of inspired gas, F_IO_2 is the fraction of oxygen in the inspired gas, V_E is the volume of exhaled gas, F_EO_2 is the fraction of oxygen in the exhaled gas, VCO_2 is the production of carbon dioxide, F_ICO_2 is the fraction of carbon dioxide in the inspired gas, V_E is the volume of exhaled gas, and F_ECO_2 is the fraction of carbon dioxide in the exhaled gas. This approach can be fraught with error particularly if there are leaks in the respiratory circuit (including around the endotracheal tube) and if the F_IO_2 is greater than 0.40. Consequently, other methods to estimate oxygen consumption have been developed.

The reversed Fick equation uses the arteriovenous oxygen saturation difference to estimate oxygen consumption. It requires determination of the cardiac output, the arterial oxygen content, and the mixed venous oxygen content. The measurement of cardiac output and mixed venous oxygen content requires the placement of a pulmonary artery catheter.

The reversed Fick equation uses the arteriovenous oxygen content difference to estimate oxygen consumption. It requires determination of the cardiac output, the arterial oxygen content and the mixed venous oxygen content. Using this method, oxygen consumption will be equivalent to the difference between the arterial and mixed venous oxygen content, multiplied by the cardiac output.

$$\dot{V}O_2 = \left(CaO_2 - CmvO_2\right) \times CO$$

Oxygen consumption is measured in units of mLs of oxygen consumed per minute. As such, the above equation is multiplied by a factor of 10 to account for units.

$$\dot{V}O_2\left(mL/min\right) = \left(CaO_2\left(mL/dL\right) - CmvO_2\left(mL/dL\right)\right) \times CO\left(L/min\right) \times 10\left(dL/L\right)$$

Like the measurement of intracardiac pressures, the determination of cardiac output and mixed venous oxygen content requires the placement of a PAC. Placement of a PAC can be technically difficult in small infants. In addition, PAC-derived data has multiple limitations which has led to its decrease use in pediatric critical care.

2.5.1.1 Mixed Venous and Central Venous Oxygen Saturation

At rest, the body normally extracts only 25% of the total amount of oxygen delivered. Provided that cardiac output is adequate to meet tissue oxygen demand and the hemoglobin concentration is in the normal range, ~25% of the delivered oxygen is consumed. Therefore, in a healthy steady state, DO_2 is luxurious when compared to oxygen demand with approximately 75% of the oxygen delivered remaining unused. Of note, oxygen extraction varies across organ beds with some organs being high extractors (e.g., the brain and myocardium) and other organs being low extractors (e.g., skin and kidneys).

A true mixed venous saturation ($SmvO_2$) requires the placement of a PAC to sample pulmonary artery blood. Without a pulmonary artery catheter in place, the pulmonary artery $SmvO_2$ can be approximated by sampling venous blood from a central catheter with its tip located at the SVC-RA junction. Venous blood oxygen saturation from the SVC-RA junction is referred to as a central venous oxygen saturation ($ScvO_2$) or right atrial saturation. The $ScvO_2$ can be an estimate of the adequacy of global oxygen delivery. If the oxygen delivery is insufficient to meet cellular oxygen demands, oxygen extraction by the starved tissues will increase, and $ScvO_2$ will decrease.

The $ScvO_2$ can be an estimate of the adequacy of global DO_2. If DO_2 is insufficient to meet cellular oxygen demands, oxygen extraction will increase, and $ScvO_2$ will decrease.

Adequate oxygen delivery results in normal oxygen extraction and a normal $ScvO_2$ of greater than 70%. The use of $ScvO_2$ has grown as an endpoint of resuscitation in adult and pediatric critical care. The same principle can be applied to assess oxygen delivery and consumption in regional beds, such as the cerebral circulation, by measuring the venous oxygen saturation in the jugular vein.

Like indirect calorimetry, the reversed Fick procedure has several limitations that must be taken into consideration when interpreting its results. For example, it provides an estimation only of global oxygen consumption; important regional differences may not be detected by this method (Table 2.2). In addition, oxygen extraction may be blocked by metabolic toxic factors. In this setting, the oxygen extraction would be normal or decreased, resulting in a

Table 2.2 Organ-specific distribution of blood flow, percent cardiac output and $avDO_2$, oxygen extraction ratio

Organ	Resting blood flow (mL/100 g/min)	Maximal blood flow (mL/100 g/min)	Potential flow increase (fold)	Percentage of resting cardiac output	$avDO_2$ mL of O_2 per 100 mL blood (O_2ER)
Brain	54	140	2.6	14	6 (31%)
Heart	70	390	5.6	4.5	11 (57%)
Liver/splanchnic	98	250	2.6	25	5 (26%)
Kidney	310	390	1.25	20	1.5 (7.8%)
Muscle	4	18	4.5	21	5 (26%)
Skin	8	150	19	7.5	2 (10%)

high central or mixed venous saturation despite the presence of tissue oxygen starvation. Although cyanide poisoning is the classic example of impaired oxygen utilization, experimental studies suggest that endotoxin may block oxygen metabolism under certain circumstances (e.g., septic shock).

The presence of an intracardiac, left-to-right shunt will complicate interpretation of the Fick equation as the pulmonary artery saturations will be "contaminated" with the highly saturated blood returning from the lungs to the left side of the heart. Depending on the degree of the shunt, the oxygen saturations will be higher than that of the central venous system. Finally, a traditional critique of the Fick equation was that it provided an estimate of oxygen consumption at isolated points in time. Given that the physiology of the critically ill child may change rapidly, clinically significant changes may not be detected.

With the advent of oximetric catheter technology, the central venous oxygen saturation can be measured continuously. It is important to note that when continuous oximetric monitoring is performed in a central vein rather than the pulmonary artery, the position of the catheter may influence the venous saturation. For example, a central venous catheter placed in the inferior vena cava is likely to reveal a higher oxygen saturation because the kidneys, acting primarily as filters, typically consume relatively little oxygen. In contrast, a central venous catheter placed in proximity to the coronary sinus may reveal low venous saturations as the oxygen extraction of myocardial tissue by mass is higher than other tissues.

There is a wide variability in organ resting and maximal blood flow rates. The ability to extract oxygen also varies widely among individual organs. The heart and brain are very high extractors, whereas high flow filtering organs like the kidney and liver are relatively low oxygen extractors (Table 2.2).

Central venous oxygen saturations can be measured continuously, thus overcoming limitations of the classic Fick procedure which requires PAC placement.

2.6 Oxygen Consumption Variability

2.6.1 Factors That Affect Oxygen Consumption

A multitude of factors can affect oxygen consumption (Fig. 2.8). Oxygen consumption can be increased by several pathological conditions, including catabolic states (e.g., sepsis, burns, fever). During fever, oxygen metabolism must be increased to generate the excess of energy lost as heat. In addition,

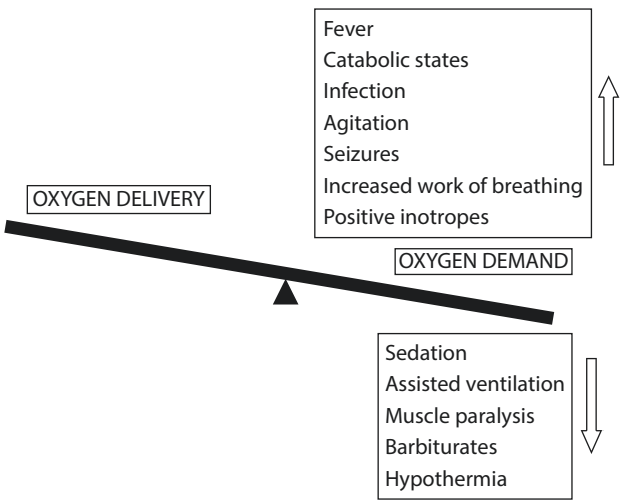

Fig. 2.8 Factors affecting oxygen utilization

oxygen consumption is increased during episodes of increased motor activity. Increased motor activity may occur with agitation, shivering, or seizures. Seizures can profoundly increase oxygen consumption.

Increased work of breathing may substantially increase the consumption of oxygen; as much as 40% of the cardiac output may be required to support excessive work of breathing. The initiation of mechanical ventilation in the setting of respiratory distress can be used to substantially decrease the consumption of oxygen. The need to decrease oxygen demand is an appropriate indication for the use mechanical ventilation in the treatment of shock.

Infusions of inotropic medications increase myocardial oxygen consumption. The increase is associated with the excess energy needed to increase the contractile force of the myocardial tissue, as well as the associated increase in heart rate caused by most catecholamines. Vasopressors may further increase myocardial oxygen consumption secondary to the additional energy needed to pump against the increased vascular resistance. Phosphodiesterase III inhibitors, such as milrinone increase the contractility without chronotropic or alpha-adrenergic effects. However, myocardial oxygen consumption will still increase in response to the additional myocardial work.

VO_2 is increased by catabolic states, fever, infection, increased motor activity, increased work of breathing, and the use of inotropic agents. VO_2 is decreased by sedation and paralysis, mechanical ventilation, barbiturate coma, hypothermia, and severe anoxic-ischemic brain injury.

In contrast, several clinical conditions and medical interventions may result in a decrease in oxygen consumption. For example, the use of sedation and neuromuscular blockade may result in decreased muscular activity, decreased agitation, and inhibition of catecholamine production, thereby decreasing the consumption of oxygen. Understanding that the brain is one of the most metabolically demanding organs, any condition that results in significantly diminished brain activity will be associated with dramatically decreased oxygen consumption. Barbiturate-induced coma to treat brain injury or status epilepticus represents one such example. Brain death is perhaps the most extreme example. Similarly, hypothermia globally decreases the metabolic demands of the body, including the brain, and, therefore, may be associated with decreased oxygen consumption. This effect of hypothermia is used clinically to reduce the oxygen needs of the body in certain settings, such as during cardiac surgery or following cardiac arrest.

2.7 Oxygen Extraction

The oxygen extraction ratio (O_2ER) is the fraction of the arterial oxygen content that is consumed as the blood traverses the organ or tissue. It is determined by dividing the difference of the arterial and venous oxygen content by the arterial oxygen content:

$$O_2ER = \left(CaO_2 - CvO_2\right) / CaO_2$$

$$O_2ER = avDO_2 / CaO_2$$

The normal oxygen extraction ratio is 0.2–0.3, indicating a significant excess capacity of oxygen being delivered under normal circumstances.

The normal global O_2ER is only 0.2–0.3, reflecting an excess of oxygen being delivered to the tissues. This excess provides an added margin should oxygen delivery becomes compromised, thereby minimizing the need for anaerobic metabolism. The oxygen extraction ratio varies widely with differences in the basal metabolic activities of different tissues (Table 2.1). Organs with higher metabolic demand will consume more oxygen. Consequently, the venous oxygen content in these tissues will be lower, and they will have higher oxygen extraction ratios.

The oxygen saturation, and hence the oxygen content, of the coronary venous blood is the lowest in the body. The myocardial oxygen extraction ratio

is very high (~0.6). During conditions of reduced supply, the myocardium has limited ability to increase the oxygen extraction. This places the myocardial tissue vulnerable to ischemia.

The brain is also characterized by high metabolic demands, thereby creating a high oxygen extraction ratio. The adequacy of oxygen delivery to the brain has been evaluated by measuring the venous saturation of the blood in the jugular bulb. Other organs such as the skin and the intestinal tract have relatively low oxygen demands. In conditions of compromised oxygen delivery, blood flow is shunted away from these tissues and reserved for the more integral organs. This process is usually well tolerated but may lead to tissue ischemia in certain circumstances. For example, the use of vasoactive infusions, such as epinephrine or norepinephrine during conditions of compromised oxygen delivery, may increase the vasoconstriction of the intestinal vessels and further decrease the oxygen delivery to these tissues. The relative ischemia of the intestinal tissue has been one of the precipitating factors for the systemic inflammatory response syndrome. According to this theory, ischemia compromises the integrity of the intestinal epithelium, allowing bacteria and bacterial products to gain access to the circulation and activate the inflammatory response. This is the rationale for the use of gastric tonometry as a surrogate for splanchnic oxygen delivery.

In addition to variations among individual organs, oxygen extraction varies with disease states. For example, in the setting of septic shock, the oxygen extraction ratio may be low, high, or normal, depending on the balance of oxygen demand, supply, and utilization. In conditions that block the utilization of oxygen, such as cyanide poisoning, the oxygen extraction ratio will appear low to normal despite the presence of cellular hypoxia.

2.8 Assessment of Oxygen Delivery/Oxygen Consumption

The clinical evaluation of the match between oxygen delivery and oxygen consumption is integral to the practice of pediatric critical care medicine.

Serial physical examinations performed by a trained clinician is the most useful tool in estimating the adequacy of oxygen delivery. This is the basic premise of the Pediatric Advanced Life Support (PALS) course established by the American Heart Association. The clinical evaluation of end-organ delivery of oxygen is initially performed by rapid physical examination, which includes the assessment of peripheral perfusion, heart rate, blood pressure, urine output, and mental status.

The clinical evaluation of the match between oxygen delivery and oxygen consumption is integral to the practice of pediatric critical care medicine. Clinical signs of poor cardiac output such as poor peripheral perfusion, tachycardia, or altered mental status must be quickly recognized to ensure prompt interventions.

Measurable components of CaO_2 (e.g., hemoglobin and the oxygen saturation) should be obtained when oxygen delivery is suspected to be inadequate. Additional laboratory studies may provide therapeutic targets. Electrolytes important in cardiac contractility and electrical propagation should be evaluated and include ionized calcium, potassium, and magnesium. Arterial blood pH should be measured as severe acidosis can negatively affect contractility. Anaerobic metabolism will lead to an elevation in the hydrogen proton concentration in the blood and will be manifested as metabolic acidosis and a rising base deficit. Elevation of blood lactate in the presence of acidosis should alert the clinician to the likelihood of tissue hypoxia.

Serial measures of acidosis *(pH, base deficit),* lactate, $SmvO_2$, or $ScvO_2$ can help the clinician identify states of declining DO_2 and high oxygen extraction. Rising lactate and falling $ScvO_2$ or $SmvO_2$ are consistent with anaerobic metabolism. Utilizing exam findings and biomarkers, pediatric critical care providers can conceptualize whether the critically ill child they are caring for is improving or deteriorating based on the DO_2-VO_2 relationship (◘ Fig. 2.9).

Serial measures of acidosis (pH, base deficit), lactate, $SmvO_2$, or $ScvO_2$ can help the clinician identify states of declining DO_2 and high oxygen extraction consistent with anaerobic metabolism.

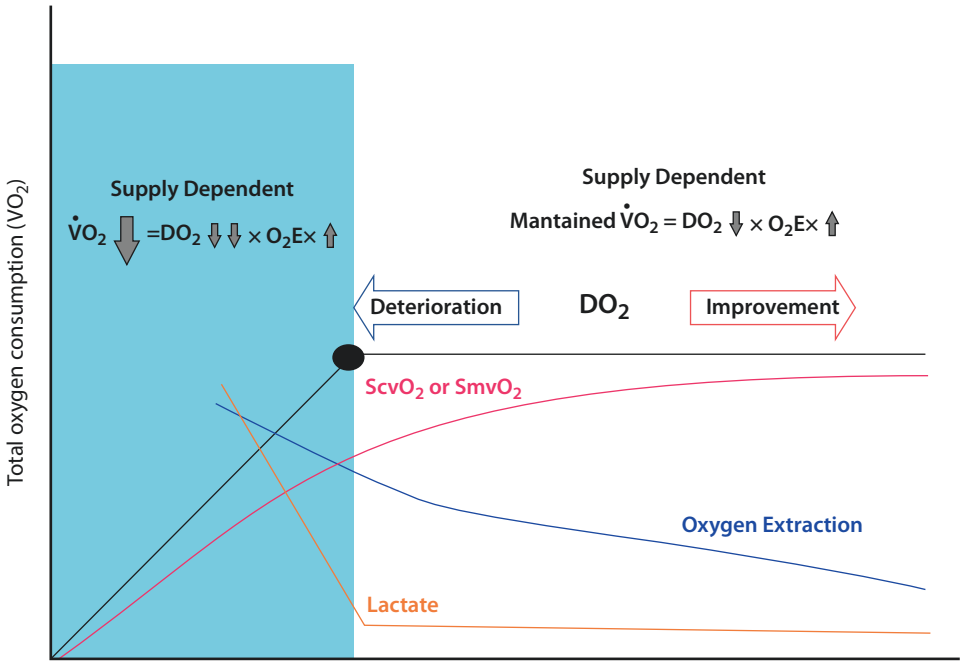

Fig. 2.9 The relationship between oxygen delivery (DO_2), oxygen consumption (VO_2), oxygen extraction (O_2Ex), and central or venous saturation ($ScvO_2$ or $SmvO_2$). As DO_2 decreases, VO_2 is initially maintained because oxygen extraction is increased. At this point, VO_2 remains independent of DO_2, and the relationship is described as supply independent. Lactate remains normal, although $ScvO_2$ may begin to decline. As DO_2 continues to decline, oxygen extraction can no longer keep up with cellular demands and VO_2 falls precipitously. The critical DO_2 point (black dot) is passed the DO_2-VO_2 relationship becomes *supply dependent* (blue area) and represents physiologic deterioration. Biochemically, $SmvO_2$ falls as lactate rises

2.9 Summary

The physiology of oxygen transport and its manipulation have a central role in the management of the critically ill child. The pediatric critical care provider must have a keen understanding of the definitions, equations, and tools used to assess the adequacy of oxygen delivery. Oxygen delivery is primarily dependent on the hemoglobin concentration, the arterial oxygenation, and the cardiac output. The cardiac output is determined by the combined effects of preload, afterload, contractility, and heart rate. Oxygen consumption is influenced by many factors and may be reduced or increased in critical illness. A clear understanding of cellular respiration, oxygen delivery, and oxygen consumption is essential to the practice of pediatric critical care medicine.

Review Questions

1. Which statement is correct regarding the biochemical consequences of tissue hypoxia?
   - A. Anaerobic metabolism is as equally efficient as aerobic metabolism in producing energy but produces acid by-products such as lactate.
   - B. Elevated lactate levels can be readily buffered by the addition of sodium bicarbonate.
   - C. Lactate is produced as a by-product of anaerobic glycolysis during tissue hypoxia but may also be produced in the absence of tissue hypoxia.
   - D. Restoring tissue perfusion and oxygenation results in lactate being reconverted into glucose in the liver.
   - E. The reduction in pH seen during states of tissue hypoxia is primarily due to the accumulation of lactate.

2. A 16-year-old 50 kg male is admitted after correction of severe scoliosis and rib deformity that required a thoracotomy and chest tube placement. Upon admission, he is mildly tachycardic to 108 bpm, normotensive, and well perfused. His oxygen saturation is 99%, PaO_2 is 198 mm Hg on 50% FiO_2, and his hemoglobin is 10.9 g/dL.

You are called due to a steady increase in bloody chest tube output. He is now tachycardic to 149 bpm, has a blood pressure of 86/58 mm Hg, and is cool distally. His oxygen saturation is 87%, and PaO_2 is 65 mm Hg on 30% FiO_2.
Current hemoglobin is 7.6 g/dL.
What percent decrease in arterial oxygen content has occurred?

A. 10%
B. 15%
C. 30%
D. 40%
E. 50%

3. Rather than transfusing PRBC, you increase his FiO_2 to 60%. His PaO_2 increases to 120 mm Hg and SaO_2 to 100%.
You decide to calculate what the increase in CaO_2 would have been by transfusing PRBC to increase the hemoglobin from 7.6 g/dl to 9 g/dl without increasing the FiO_2.
Assume that after the transfusion, your PaO_2 would have increased slightly to 82 mm Hg and SaO_2 to 94%.
Which would have had a greater impact on CaO_2 and what was the best clinical correct approach?

4. Which of the following is true regarding oxygen-hemoglobin dissociation curve?
   A. Fetal hemoglobin increases oxyhemoglobin dissociation in the capillary circulation, thereby making more oxygen available at the tissue level.
   B. Hypoxemia increases oxyhemoglobin dissociation in the capillary circulation, thereby making more oxygen available at the tissue level.
   C. Increased temperature decreases oxyhemoglobin dissociation in the capillary circulation, thereby making less oxygen available at the tissue level.
   D. Severe acidosis decreases oxyhemoglobin dissociation in the capillary circulation, thereby making less oxygen available at the tissue level.
   E. Severe alkalosis decreases oxyhemoglobin dissociation in the capillary circulation, thereby making more oxygen available at the tissue level.

5. Which of the following is a true statement regarding physiologic determinants of oxygen delivery?
   A. Arterial oxygen content can be maximized, yet a state of decreased oxygen delivery may persist.
   B. Oxygen delivery is primarily determined by the rate of oxygen extraction.
   C. The determinants of cardiac output and the determinants of arterial oxygen content are different and have limited interdependence.
   D. The fractional inspired oxygen content impacts arterial oxygen content, and, therefore, oxygen delivery, more than the hemoglobin concentration.
   E. Therapies aimed at improving oxygen delivery are primarily related to maintaining alveolar oxygenation.

6. Which of the following is most correctly matched?
   A. Epinephrine .05 mcg/kg/min – decreased myocardial oxygen consumption.
   B. Low oxygen delivery – increased oxygen extraction.
   C. Cyanide poisoning – increased oxygen extraction.
   D. Neuromuscular blockade – increased oxygen consumption.
   E. Shivering – decreased oxygen consumption.

7. Which statement best reflects the ability of the body to extract oxygen?
   A. Baseline oxygen extraction varies among individual organs but remains constant during changes in clinical conditions.
   B. High oxygen extraction is reflected in a lower venous oxygen content.
   C. The normal oxygen extraction ratio (O_2ER) is approximately 50% of the oxygen being delivered to the tissues. The excess in delivered oxygen allows for an increase during stress states, thereby minimizing the need for anaerobic metabolism.
   D. Organs with lower metabolic demand will consume less oxygen and, consequently, will have a lower venous oxygen content.
   E. The oxygen extraction ratio (O_2ER) is determined by dividing the difference of the arterial and venous oxygen content by the cardiac output.

8. A 3-year-old presents with pallor, a murmur, and a heart rate of 140 bpm. He is afebrile and his pulse oximetry is 97%. There is no history of acute blood loss, but he consumes up to a liter of cow's milk per day. Laboratory analysis reveals a white blood cell count of 12, 300 cells/μL, hemoglobin of 4.5 g/dL, and a platelet count of 210,000/μL. His smear reveals microcytic and hypochromatic RBCs. He has a bicarbonate of 18 mmol/l. His arterial blood gas reveals pH 7.32, $PaCO_2$ 33 mm Hg, PaO_2 65 mm Hg, base deficit −9, and an oxygen saturation of 97%. The most appropriate next course of action is which of the following?
   A. Transfuse 15 mL/kg of packed red blood cells over 2 h.
   B. Transfuse 5 mL/kg packed red blood cells over 4 h and administer a dose of sodium bicarbonate.
   C. Transfuse 5 mL/kg packed red blood cells over 4 h and begin erythropoietin.
   D. Transfuse 5 mL/kg of packed red blood cells over 4 h and begin supplemental oxygen.
   E. Transfuse 15 mL/kg of packed red blood cells over 4 h and monitor for signs of pulmonary edema utilizing furosemide if necessary.

9. A 14-year-old multiple trauma victim with adult respiratory distress syndrome is admitted to the PICU. To optimize his care, you have placed an intravenous oximetric catheter with its tip in the superior vena cava to monitor venous oxygen saturation continuously. The patient is intubated, mechanically ventilated, and heavily sedated. His superior vena cava saturation has consistently been in the low 80 range but has suddenly begun to decrease into the low 70s. His pulse oximeter is unchanged and continues to read 99%. His vital signs are stable except for a fever spike up to 39.8 °C and a 5–10 beat increase in his heart rate. He remains heavily sedated on a midazolam infusion. The most likely explanation for his sudden decrease in superior vena cava saturation is which of the following?
   A. Acute occult blood loss
   B. Decreased cardiac output
   C. Increased metabolic demand
   D. Migration of the catheter into the right atrium
   E. Subclinical seizure

10. Hypoxemia is detected by special nerve chemical receptors located in the carotid and aortic bodies. When these chemoreceptors are triggered by hypoxemia (PaO_2 < 60 mm Hg, corresponding to SaO_2 < 93%), which of the following physiologic responses ensue?
    A. Stimulation of the respiratory area of the medulla resulting in a decrease in minute ventilation, respiratory pauses, and potentially apnea.
    B. Stimulation of the respiratory area of the medulla resulting in an increase in minute ventilation, a higher alveolar oxygen concentration (PAO_2), and, ultimately, an increase in the arterial oxygen content.
    C. Stimulation of the vasomotor center of the brainstem leading to decreased sympathetic tone and bradycardia.
    D. Stimulation of the vasomotor center of the brainstem resulting in decreased sympathetic tone, decreased metabolic rate, and decreased oxygen consumption.
    E. Stimulation of the vasomotor center of the brainstem resulting in increased sympathetic tone, increased systemic vascular resistance, and decreased cardiac output.

11. Of the organs listed, which pair represents the organ with the highest resting blood flow (mL/100 g/min) and the organ with the highest oxygen extraction ratio?
    A. Skin/heart
    B. Kidney/heart
    C. Muscle/heart
    D. Kidney/brain
    E. Splanchnic bed/brain

12. Which of the following labels best describe the graph?

    A. A = supply independent, B = supply dependent, C = pathologic DO_2
    B. A = supply dependent, C = supply independent, D = pathologic supply dependency
    C. A = supply dependent, B = pathologic supply dependency, C = supply independent
    D. A = supply independent, B = critical DO_2, D = supply dependent
    E. A = supply dependent, C = increased O_2 extraction, D = normal DO_2

13. Which definition and formula are incorrectly matched?
    A. Oxygen delivery: DO_2 (ml/min) = CO (L/min) × CaO_2 (mL/dL)
    B. Arterial oxygen content: CaO_2 (mL O_2/dL) = $Hgb_{gm/dl}$ × 1.34 × SaO_2 + (PaO_2 × .003)
    C. Arteriovenous oxygen content difference: avDO2 (mL O_2/dL) = CaO_2 – CvO_2
    D. Oxygen extraction ratio: O_2ER = (CaO_2 – CvO_2)/VO_2
    E. Oxygen consumption: VO_2 (mL O_2/min) = CO × (CaO_2 – CvO_2)

14. A 12-year-old male with relapsed ALL presents with septic shock that requires volume resuscitation and the institution of a norepinephrine infusion. He undergoes placement of a right radial arterial catheter and central venous catheter via the internal jugular vein. The tip of the catheter is at the SVC-right atrial junction.
    The following data is obtained:
    Hemoglobin 7.8 gm/dL, PaO_2 85 mm Hg, SaO_2 92%. Lactate 5.5
    Blood drawn from the CVP reveals: PvO_2 30 mm Hg and SvO_2 56%
    What is the $avDO_2$?
    A. 3.9 mL O_2/dL
    B. 5.3 mL O2/dL
    C. 5.5 mL O_2/dL
    D. 6.3 mL O_2/dL
    E. 6.8 mL O_2/dL

15. Using the same data, calculate the oxygen extraction ratio.
    A. 20%
    B. 30%
    C. 40%
    D. 50%
    E. 55%

Answers

1. C
2. D Decreasing from 15 to 9, our patient lost 40% of CaO_2.
   CaO_2 = 10.9 gm/dL × 1.34 mL O_2/gm Hgb × .99 + (198 × .003) = 15.06
   CaO_2 = 7.6 gm/dL × 1.34 mL O_2/gm Hgb × .87 + (65 × .003) = 9.06
3. The patient had symptomatic anemia from acute blood loss. Increase the FiO_2 while awaiting transfusion.
   Increasing FiO_2 to 100% and no transfusion:
   CaO_2 = 7.6 gm/dL × 1.34 mL O_2/gm Hgb × 1+ (120 × .003) = 10.5
   Transfusion to 9 gm/dL and no FiO_2 increase:
   CaO_2 = 9 gm/dL × 1.34 mL O_2/gm Hgb × .94 + (82 × .003) = 11.5
4. B
5. A
6. B
7. B
8. D
9. C

10. B
11. B
12. B
13. D
14. A CaO_2 = 7.8 gm/dL × 1.34 mL O_2/gm Hgb × .92 + (85 × .003) = 9.85
    CvO_2 = 7.8 gm/dL × 1.34 mL O_2/gm Hgb × .56 + (30 × .003) = 5.94
    9.85–5.94 = 3.9
15. C 9.85–5.94/9.85 = 40%

Learning Objectives

- Describe the components of the soluble coagulation/fibrinolysis system.
- Describe how the endothelium and coagulation/fibrinolysis system promote blood flow without clotting.
- Describe how the endothelium and coagulation/fibrinolysis system stops bleeding and promotes healing after focal vascular injury.
- Describe endothelium and platelet/von Willebrand factor hemostatic system pathophysiology in thrombotic thrombocytopenic purpura.
- Describe endothelium and fibrin coagulation system pathophysiology in consumptive disseminated intravascular coagulation (DIC).
- Describe endothelium, complement system, platelet/von Willebrand factor hemostatic system, and fibrin coagulation system pathophysiology in hemolytic uremic syndrome (HUS).
- Describe endothelium, platelet, and fibrin coagulation system pathophysiology in nonconsumptive secondary thrombotic microangiopathy.
- Describe endothelium, platelet, and fibrin coagulation pathophysiology in bleeding disorders, including von Willebrand's disease, severe trauma, hemophilia, liver failure, and uncontrolled DIC.
- Describe diagnostic tools to assess the presence and cause of pathologic thrombosis and bleeding.
- Describe the pros and cons of using specific and nonspecific therapies to reverse thrombosis and/or bleeding disorders in critically ill children.

3.1 Introduction

Circulating blood is the lifeline of our existence, transporting oxygen, glucose, and other substrates for energy production. The circulatory system supplies complements, platelets, and white blood cells to combat infections and repair tissues, as well as platelets and soluble coagulation and anticoagulation proteins and proteases, to prevent uncontrolled bleeding and clotting. The coordination of these vital functions is orchestrated by a thin layer of cells named the endothelium. Endothelial cells direct blood flow by differentially expressing vasoconstrictors (e.g., endothelin, 20-HETE) and vasodilators (e.g., nitric oxide, prostacyclin). These cells direct white blood cell trafficking by differentially expressing the adhesion molecules endothelial selectin (E-selectin), intercellular adhesion molecule (ICAM), and vascular cell adhesion molecule (VCAM). Finally, the endothelium directs clotting by differentially releasing ultra-large von Willebrand factor (ULVWF) multimers (initiating platelet aggregation), decreasing thrombomodulin (preventing anticoagulation), and increasing plasminogen-activator inhibitor type-1 (PAI-1) expression preventing fibrinolysis. This chapter focuses on the physiology and pathophysiology of the endothelium and the cellular and soluble coagulation and complement systems. The objective of this chapter is to prepare the pediatric intensivist to choose specific and nonspecific therapies for critically ill children with thrombotic and/or bleeding disorders.

3.2 Endothelial Interactions and Coagulation

Coagulation is mediated by complex interactions between platelets, endothelium, and the soluble proteins and proteases.

Coagulation is mediated by complex interactions between platelets, endothelium, and the soluble proteins and proteases. This system has a dual function maintaining the balance between systemic pro-coagulation and anticoagulation, which prevents systemic bleeding and clotting, but also directing platelet and fibrin clotting to areas of focal endothelial injury when endothelial and vascular injury occurs. The many soluble components of the fibrin coagulation

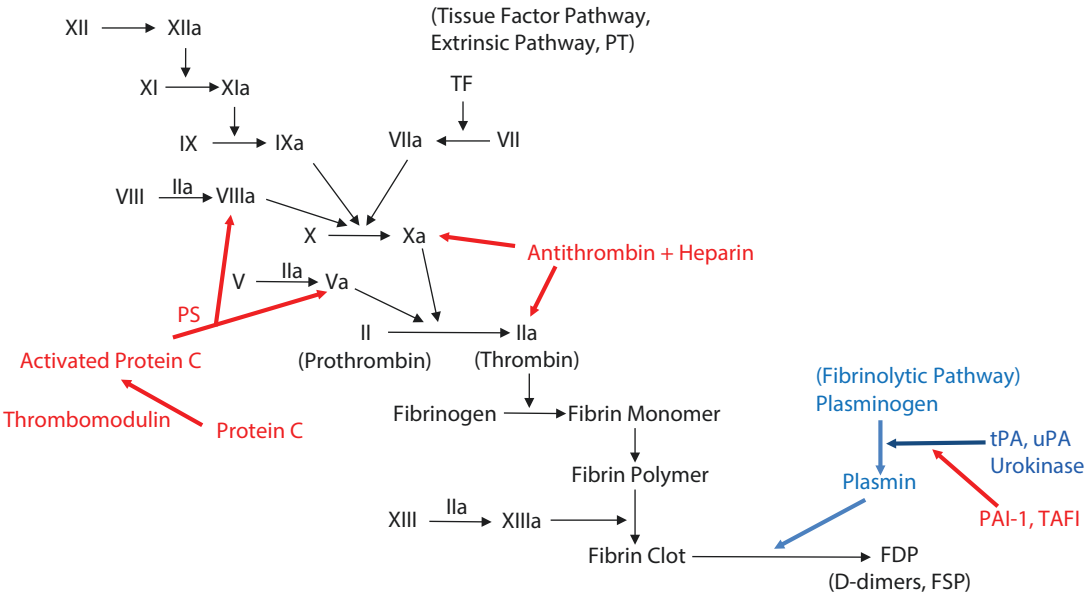

Fig. 3.1 The fibrin coagulation and fibrinolysis cascade coagulation

system are represented in Fig. 3.1. For the most part, the active enzymes in this system are serine proteases, which are produced in the liver. However, factor VIII, thrombomodulin, plasminogen activator inhibitor type-1, prostacyclin, and von Willebrand factors (VWF) are produced in the endothelium. Tissue factor is an important molecule because it is the initiator of the coagulation cascade. Thrombin (factor IIa) is the most important molecule and the final common pathway in the clotting cascade. The conversion of circulating prothrombin (factor II) into thrombin catalyzes the transformation of fibrinogen into a fibrin clot. It also activates the thrombin activatable fibrinolysis inhibitor (TAFI), which reduces the production of plasmin, inhibits fibrinolysis, and preserves the fibrin clot. Plasmin is the most important molecule in the fibrinolytic pathway. Conversion of circulating plasminogen into plasmin, the mediator of fibrinolysis, is controlled by endogenous plasminogen activator activity, including tissue plasminogen activator (tPA) in the plasma and uroplasminogen activator (uPA) in the ureters and bladder. The plasminogen activators are directly inhibited by plasminogen activator inhibitor type-1 (PAI-1). Protein C (in concert with thrombomodulin), protein S, tissue factor pathway inhibitor, antithrombin III, and heparin are the major anticoagulant proteins.

Under conditions of homeostasis, blood flows unimpeded by clotting because the endothelium, platelets, and soluble coagulation system are in the anticoagulant state (Fig. 3.2). The endothelium expresses prostacyclin and nitric oxide, which prevent platelet aggregation; tPA, which activates plasminogen to plasmin which lyses fibrin clots; and thrombomodulin, which converts protein C to activated protein C, which prevents thrombin generation and inhibits plasminogen activator inhibitor type-1, promoting fibrinolysis at the endothelium surface. Circulating endogenous heparin complexes with antithrombin III, further preventing systemic fibrin generation. Tissue factor pathway inhibitor, which also circulates through the vascular system, complexes with released tissue factor and inhibits factor VII-mediated coagulation. During homeostasis, the anticoagulant state is balanced with adequate levels of prothrombotic coagulation factors so that bleeding does not occur.

Thrombin (factor II a) is the most important molecule and the final common pathway in the clotting cascade.

Protein C (in concert with thrombomodulin), protein S, tissue factor pathway inhibitor, antithrombin II, and heparin are the major anticoagulant proteins.

When focal vascular injury occurs by way of trauma, the coagulation system directs a platelet and fibrin clot to the site while maintaining the systemic anticoagulant state.

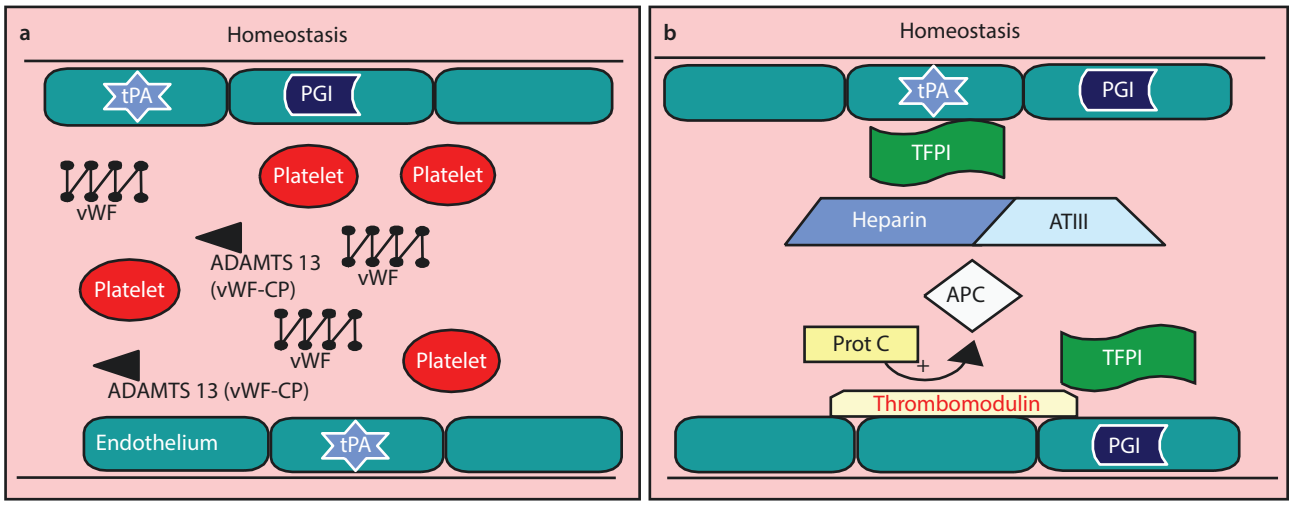

Fig. 3.2 Homeostasis is maintained by a platelet **a** and fibrin **b** anticoagulant state. *PGI* prostacyclin, *tPA* tissue plasminogen activator, *ADAMTS-13* (VWF-cleaving protease), *VWF* von Willebrand factor multimers, *TFPI* tissue factor pathway inhibitor, *APC* activated protein C, *ATIII* antithrombin III

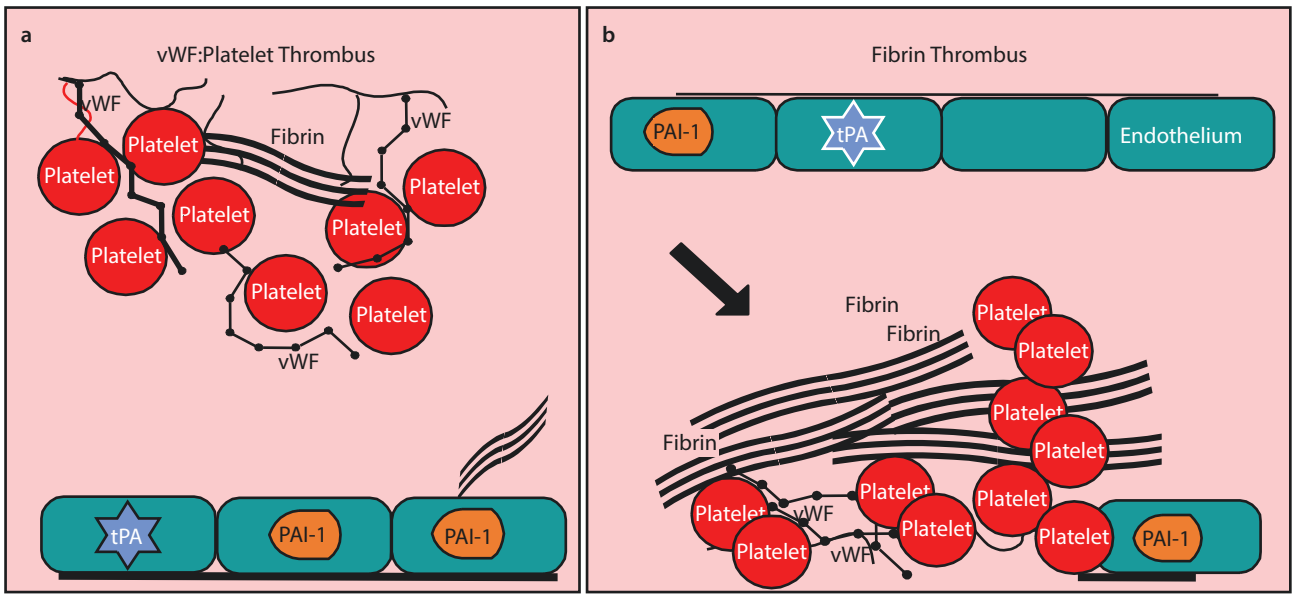

Fig. 3.3 Focal injury is repaired by a directed platelet and fibrin thrombus, which develops locally, while the anticoagulant state is maintained systemically. PAI-1 plasminogen activator inhibitor

During infection, fibrin thrombosis occurs because IL-1 and TNF-a decrease endothelial thrombomodulin expression, preventing activation of the anticoagulant protein C.

When focal vascular injury occurs by way of trauma, the coagulation system directs a platelet and fibrin clot to the site while maintaining the systemic anticoagulant state (Fig. 3.3). This occurs in three steps: vasoconstriction, platelet aggregation, and fibrin deposition. The endothelial disruption results in the release of the vasoconstrictor endothelin and the absence of the vasodilators nitric oxide and prostacyclin. The net effect of this loss of balance in vasomotor control is vasoconstriction and stasis. The injured endothelium releases ultra-large VWF multimers. These hyper-adhesive ultra-large VWF multimers initiate platelet aggregation and form the platelet plug at the site of the endothelial disruption. The loss of endothelium at this site exposes tissue factor in the absence of thrombomodulin. The fibrin clot is formed through the activation of factor VII by tissue factor in the absence of activated protein

C. Thrombin activates TAFI at the site, and the surrounding endothelium increases plasminogen activator inhibitor type-1, preventing fibrinolysis of the mature clot. Although the site of injury is in a procoagulant and antifibrinolytic state, the systemic endothelium and circulating system remain in an anticoagulant state. The focal clot is formed without systemic clotting. When the vascular injury is repaired and the endothelium is regenerated, the local anticoagulant state is restored and the focal clot is lysed.

Critically ill patients develop a systemic endothelial microangiopathic process, leading to thrombotic microangiopathy after many types of systemic insults.

When focal vascular injury occurs by way of infection, the coagulation system also directs a platelet and fibrin clot to the site while maintaining the systemic anticoagulant state (■ Fig. 3.3). This occurs in three steps: vasodilation (not vasoconstriction), platelet aggregation, and fibrin deposition. This process is mediated by cytokine production from immune cells, endothelium, vascular smooth muscle cells, and surrounding tissues. Nitric oxide is increased leading to local vasodilation with increased blood flow. The cytokines, IL-1, TNF-α, and IL-6 mediate focal thrombosis. The cytokines induce adhesion molecule expression in the endothelium (E-selectin, ICAM, and VCAM), which direct white blood cells and platelets to the site of injury. Platelet aggregation occurs because TNF-α, IL-6, and IL-8 stimulate the release of the hyper-adhesive ultra-large VWF multimers and inhibit the activity of the ADAMTS-13 (VWF-cleaving protease). Fibrin thrombosis occurs because TNF-α induces monocytes to release tissue factor, which activates coagulation, while IL-1 and TNF-α decrease endothelial thrombomodulin expression, preventing activation of the anticoagulant protein C. These cytokines also increase endothelial expression of plasminogen activator inhibitor type-1 (PAI-1), which prevents lysis of the clot. When the infection resolves, cytokine production stops and ADAMTS-13 activity is restored, tissue factor is not released, thrombomodulin expression is increased, and PAI-1 expression is decreased. The clot dissolves as increased ADAMTS-13 and thrombomodulin activity prevent further thrombosis and absent PAI-1 activity allows endogenous tPA fibrinolysis to proceed. As in the case of focal traumatic vascular injury, the systemic circulation remains in the anticoagulant/pro-fibrinolytic state during the entire process. The link between killing infection and promoting thrombosis is evident. Platelets both induce coagulation and release endogenous antimicrobial peptides, which destroy bacteria and fungi, and monocytes/macrophages both kill infection and release tissue factor, which induces fibrin clotting. During homeostasis, the coagulation system allows blood to flow unimpeded without clotting. During focal vascular injury caused by trauma or inflammation/infection, the endothelium changes phenotype to a procoagulant/hypo-fibrinolytic phenotype, which directs clotting at the site of injury, while maintaining an anticoagulant/pro-fibrinolytic phenotype outside of the locus of injury.

Prothrombotic and antifibrinolytic responses, which are helpful during focal injury, become injurious in the setting of systemic endothelial injury and are manifested by thrombocytopenia, systemic thrombosis, and multiple organ failure. Critically ill patients develop a systemic endothelial microangiopathic process, leading to thrombotic microangiopathy following many types of systemic insults (▶ Box 3.1). The pathophysiology of these thrombotic microangiopathic diseases induced by systemic endothelial injury can be characterized as part of a spectrum of four phenotypes: thrombotic thrombocytopenic purpura (TTP) (■ Fig. 3.4), consumptive disseminated intravascular coagulation (DIC) (■ Fig. 3.5), hemolytic uremic syndrome (HUS), and nonconsumptive secondary thrombotic microangiopathy (2° TMA) (■ Fig. 3.6).

3

Conditions associate with thrombotic microangiopathy

- Cancer
- Transplantation
- Cardiovascular surgery/cardiopulmonary bypass
- Autoimmune disease
- Systemic infection
- Vasculitis
- Toxins
- Cyclosporine A
- Tacrolimus
- Chemotherapy
- Radiation
- Ticlopidine

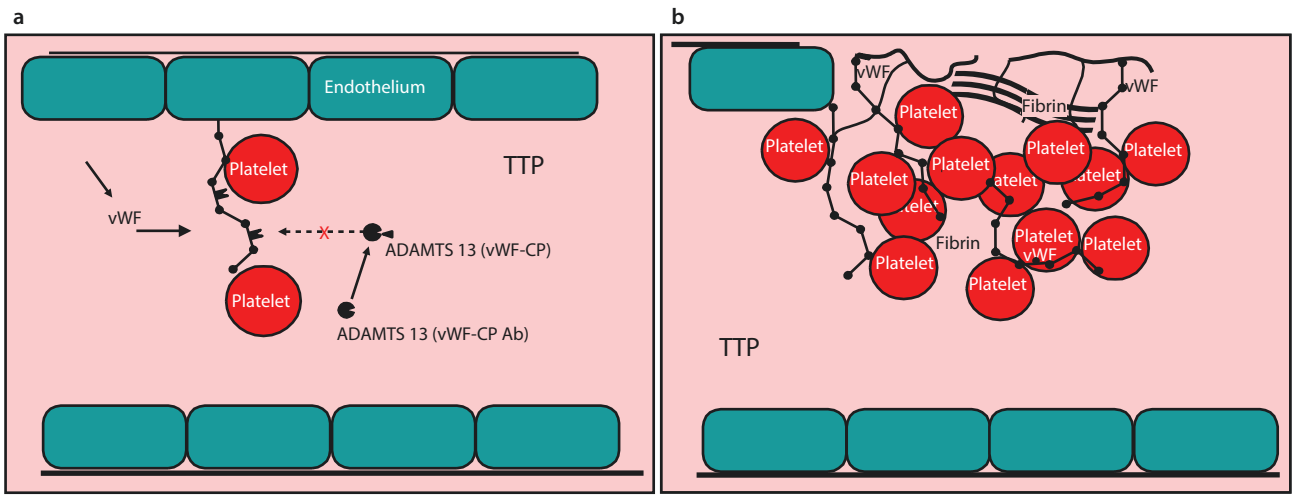

Fig. 3.4 Systemic inflammation results in systemic coagulation. Thrombotic thrombocytopenic purpura is a phenotype caused by ADAM TS-13 deficiency

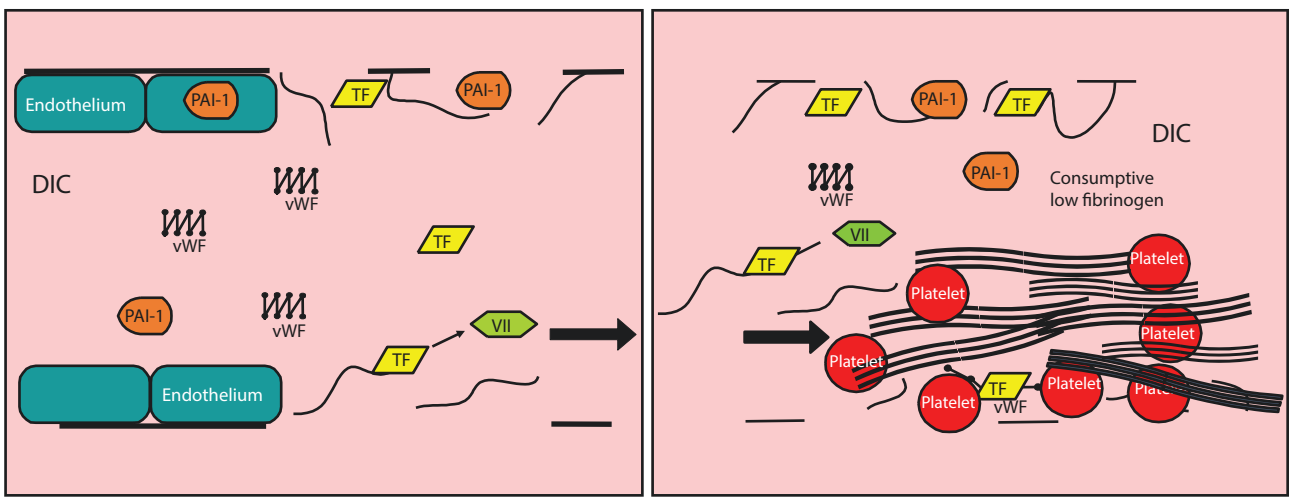

Fig. 3.5 Disseminated intravascular coagulation is a phenotype caused by increased tissue factor and PAI-1, unopposed by the anticoagulant proteins TFPI, protein C, AT III, and prostacyclin

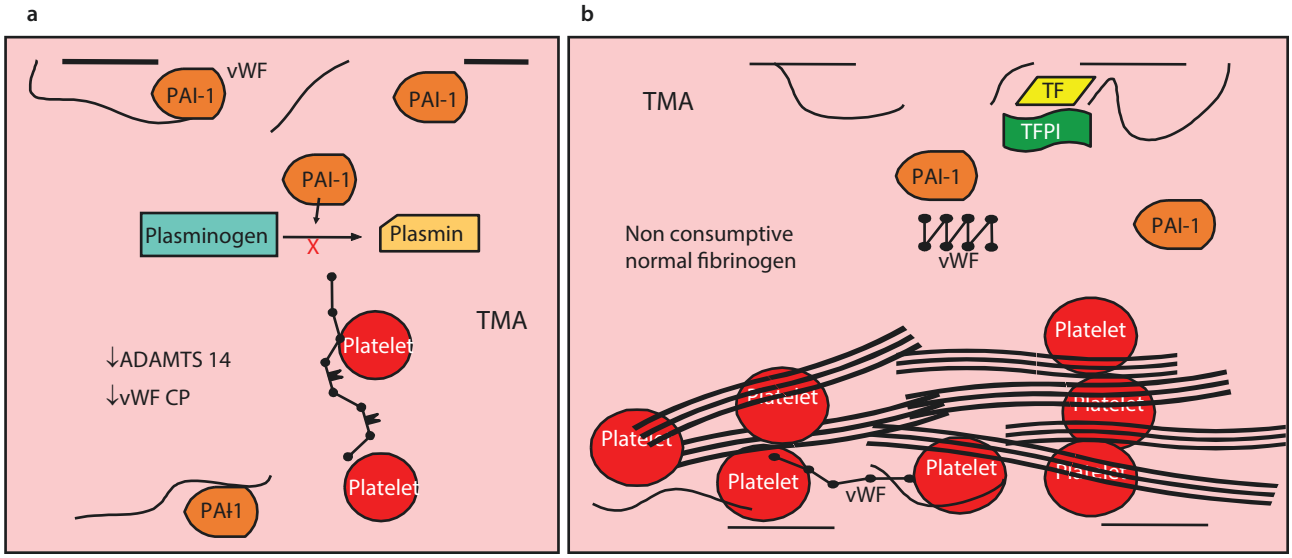

Fig. 3.6 Secondary thrombotic microangiopathy, caused by systemic endothelial injury, shares the TTP phenotype with deficient ADAMTS-13 and increased PAI-1 levels

The complement system needs to be mentioned, because it is functionally involved with endothelial interactions and coagulation. The complement system is essential for our immune response, as it acts as an effector of humoral defense against invading pathogens. However, when the complement system becomes dysregulated and overactive, it can lead to uncontrolled systemic inflammation and disseminated microvascular thrombosis due to the pathologic interactions, among the complement proteins, endothelium, platelet/VWF, and fibrin pathways. The complement system is tightly regulated to be activated on pathogen surfaces with limited deposition of complement proteins on normal host cells. This system comprises more than 30 components, which include serum protein and cell-surface molecules. There are three activation pathways: (1) the classical pathway, (2) the lectin pathway, and (3) the alternative pathway, which involves the direct activation of C3 through surface binding. Activations of complement will lead to generation of C3b by C3 convertases with the formation of the membrane attack complex (MAC, C5b-9). This MAC forms transmembrane channels, which disrupt cell membrane of target cells, leading to cell lysis and death.

Disseminated intravascular coagulation is a consumptive syndrome, consuming procoagulant factors such as fibrinogen.

Thrombotic thrombocytopenic purpura (TTP) has been described in two forms, acute and chronic relapsing. The classic "pentad" of TTP is composed of the constellation of fever, thrombocytopenia, abnormal mental status (with or without seizures), renal dysfunction, and microangiopathic hemolysis, indicated by an elevated lactose dehydrogenase (LDH) level and/or the presence of schistocytes. The acute form, which accounts for the majority of cases, occurs when ADAMTS-13 inhibitors and proteolytic inactivators develop, leading to acquired ADAMTS-13 deficiency. There is a growing list of ADAMTS-13 inhibitors, all of which are elevated during systemic inflammation and activated coagulation, including interleukin-6, granulocyte elastase, human neutrophil peptides, plasmin, thrombin, plasma free hemoglobin, Shiga toxin, and IgG autoantibodies (Fig. 3.4). This decrease in VWF cleaving proteinase activity results in an inability to cleave ultra-large and large VWF multimers to their smaller, less thrombogenic VWF multimers. VWF multimers have binding sites

to collagen and platelets. Because these antibodies are produced in the presence of disease states associated with increased shear stress, the circulating ultra-large VWF multimers unfold and spontaneously aggregate platelets, leading to disseminated VWF/platelet-rich microthrombi. The less common but chronic relapsing form of TTP occurs in patients with congenital deficiency of ADAMTS-13. These patients become ill during periods of systemic illness associated with increased microvascular shear stress. Fibrin thrombosis is involved as well. There is a reduction in tissue factor pathway inhibitor (TFPI) levels without an increase in tissue factor levels (TF) and an increase in PAI-1 levels.

In the setting of the thrombotic form of a DIC, a prolonged PT/aPTT may occur in the setting of a procoagulant rather than an anticoagulant state.

Disseminated intravascular coagulation (DIC) is a consumptive syndrome (consuming procoagulant factors such as fibrinogen) which is represented in its most severe form by purpura fulminans and in its least severe form by abnormalities in the platelet count, prothrombin time (PT), and activated partial thromboplastin time (aPTT). Disseminated intravascular coagulation is described as the constellation of thrombocytopenia, decreased factors V and VIII, decreased fibrinogen, and increased D-dimers. The depletion of factors and fibrinogen explains the common association with prolongation of the PT and aPTT. Two phenotypes of DIC have been recognized; one is associated with a predominant bleeding diathesis, and the other with disseminated systemic thrombosis. The most common causes of the thrombotic/hemorrhagic phenotypes include virus-induced hemorrhagic fevers, severe brain tissue disruption, and promyelocytic leukemia. The most common causes of the thrombotic phenotype are bacterial and fungal infections.

The tissue factor: factor VII pathway, not the factor XII pathway, is responsible for the prothrombotic form of DIC caused by systemic bacterial infection.

There has been a significant improvement in the understanding of the thrombotic form of DIC syndrome in recent years. In diagnosing the thrombotic process, it is important to understand the manner in which increased coagulation occurs despite prolongation of the PT/aPTT. Traditionally, prolongation of the PT/aPTT and reduced platelet counts are indicative of a greater tendency to bleeding. However, in the setting of the thrombotic form of a DIC, a prolonged PT/aPTT may occur in the setting of a procoagulant rather than an anticoagulant state. It appears counterintuitive for clinicians to recommend heparin therapy for patients with DIC when the patient has thrombocytopenia and a prolonged PT/aPTT.

Protein C, protein S, and antithrombin II are significantly reduced in patients with DIC.

Prothrombin time and aPTT are dependent on coagulation factors and fibrinogen. Prothrombin time and aPTT increase when these proteins are reduced and decrease when these proteins are increased. The tissue factor: factor VII pathway, not the factor XII pathway, is responsible for the prothrombotic form of DIC caused by systemic bacterial infection. When released into the circulation by monocytes or exposed by injured endothelium, tissue factor complexes with factor VII and initiates thrombosis (Fig. 3.5). If tissue factor promotes consumption of clotting factors to the point that factors V, factor VIII, and fibrinogen are depleted, the patient develops a prolonged PT/aPTT.

The endogenous anticoagulant system is also reduced and contributes to the thrombotic form of DIC. Protein C, protein S, thrombomodulin, and antithrombin III are significantly reduced in patients with DIC. Newborns with a congenital absence of protein C, protein S, or antithrombin III can develop spontaneous purpura fulminans, which is fatal if not treated with replacement of the anticoagulant proteins with fresh frozen plasma infusion (Table 3.1). The response of the antithrombotic system in systemic hemorrhagic fevers (dengue, Ebola, Korean, etc.), which are the leading cause of DIC in children in the Africa and Asian continents, is similar to that observed in meningococcemia in the Western world.

Table 3.1 Effect of nonspecific therapy on coagulation and fibrinolysis

Plasma infusion	Plasma exchange
Restores procoagulant factors	Restores procoagulant factors homeostasis
Restores anticoagulant factors (protein C, ATIII, TFPI)	Restores anticoagulant factor homeostasis (protein C, AT III, TFPI)
Restores prostacyclin	Restores prostacyclin homeostasis
Restores tPA	Restores tPA homeostasis
Restores ADAM TS-13	Restores ADAM TS-13 homeostasis
	Removes ADAMTS-13 inhibitors
	Removes ultra-large VWF multimers
	Removes tissue factor
	Removes excess PAI-1

The majority of patients with thrombotic microangiopathy have thrombocytopenia-associated multiple organ failure with a normal or mildly elevated PT/aPTT.

The antifibrinolytic system is predominant in patients with the thrombotic form of DIC. Tissue plasminogen activator levels initially increase. However, within 12–24 h, patients develop increased PAI-1 antigen levels and decreased plasmin α_2-antiplasmin production indicative of a hypo-fibrinolytic state. Children with meningococcal disease-associated purpura fulminans have increased PAI-1 antigen levels. The PAI-1 4G/5G promoter genetic polymorphism is associated with increased PAI-1 antigen levels and worse outcomes in children with meningococcal disease.

Hemolytic uremic syndrome (HUS) is a clinical "triad" of thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure. The underlying pathology of HUS is uncontrolled complement activation. HUS is divided into two major types, (1) infection-induced HUS, which includes Shiga toxin-producing *Escherichia coli* (STEC) and accounts for 90% of all HUS cases, and (2) atypical HUS, which includes genetic and acquired disorders of complement regulation and accounts for 10% of all HUS cases. The kidneys are the most common organ affected, but the brain and other organs can also be involved in severe cases. HUS patients suffer from overactive complement activation, deposition of complement proteins on various organs, disseminated microvascular thrombosis, and multiple organ failure.

Shiga toxin can bind to glycosphingolipid surface receptor globotriaosylceramide expressed on renal and brain endothelium. Shiga toxin can activate the complement system by (1) directly activating the alternative pathway, (2) releasing red blood cell microvesicles coated with MAC, (3) forming soluble MAC in blood, and (4) inhibiting factor H, which is an inhibitor of the alternative pathway. For atypical HUS, complement genetic pathway mutations account for 50–60%, and thrombomodulin mutations accounts for 5% of cases.

The linkage between the complement pathway, the endothelium, and coagulation is as follows. During systemic inflammation, the endothelium releases both the alternative complement proteins and ULVWF. ULVWF then anchors on the surface of the endothelium, where complement proteins are assembled, activated, and form MAC. MAC then causes local destruction of the endothelium. Shiga toxin can inhibit ADAMTS-13 and activate the endothelium to release both alternative complement proteins and ULVWF. Again, this leads to MAC formation and local endothelial injury. Shiga toxin also causes shedding of thrombomodulin from the endothelial surface, leading to less protein C activation and a prothrombotic state.

The clinical tests presently used to diagnose thrombosis or bleeding are not very effective.

Nonconsumptive secondary thrombotic microangiopathy occurs in critically ill patients with secondary TTP/HUS syndrome (Fig. 3.6). It is identified clinically by the constellation of criteria present with the primary form of thrombotic microangiopathy, TTP, with the exception that there is no evidence of hemolysis on the peripheral smear. The majority of patients with thrombotic microangiopathy have thrombocytopenia-associated multiple organ failure with a normal or mildly elevated PT/aPTT. These patients have increased or normal factor V, VIII, and X and fibrinogen levels but also have increased D-dimers. These children have thrombogenic ultra-large VWF multimers, ADAMTS 13 deficiency, circulating ADAMTS-13 inhibitors and increased PAI-1 but normal TFPI activity and TF activity (Fig. 3.6). The systemic endothelium is in a platelet procoagulant and fibrin antifibrinolytic state, but in contrast to DIC, it is not in a fibrin procoagulant state. Hence, consumption of procoagulant factors is not observed to the degree noted during DIC. This pathophysiologic process has been observed and described in patients with severe meningococcal sepsis, severe sepsis, severe malaria, thrombocytopenia-associated multiple organ failure, and hepatic veno-occlusive disease after stem cell transplantation.

Critically ill patients commonly have reduced anticoagulant proteins as well as procoagulant proteins.

Systemic bleeding can occur in critically ill patients with systemic endotheliopathy. In patients with TTP, DIC, or 2° TMA, bleeding occurs when too few platelets or procoagulant factors are left in the circulation to maintain hemostasis. Similarly, in patients with liver disease, coagulation disorders, such as von Willebrand disease or hemophilia, or exsanguinating trauma, there are too few functional platelets or procoagulant factors available to provide hemostasis. Moreover, excessive fibrinolysis can also result in bleeding. For example, certain microorganisms secrete fibrinolytic factors, varieties of snakes secrete venoms with prothrombotic and fibrinolytic factors, and some chemotherapeutic agents induce thrombosis and fibrinolysis, which result in bleeding. Therefore, the pediatric intensive care physician must be cognizant of both systemic thrombosis and bleeding in critical illness.

The clinical tests presently used to diagnose thrombosis or bleeding are not very effective (Tables 3.2 and 3.3). Thrombocytopenia may be a sign of proclivity to bleeding but may also be a sign of systemic thrombosis. Idiopathic thrombocytopenic purpura (ITP) presents with purpura and a bleeding risk, when platelet counts are <20,000/μL. When ITP is associated with platelet counts <10,000/μL, patients are at an increased risk of intracranial hemorrhage. However, new-onset thrombocytopenia and multiple organ failure are the hallmark of disseminated microvascular thrombosis in patients with TTP, DIC, HUS, or 2° TMA. The PT/aPTT and the international normalized ratio (INR) are also used as indicators of bleeding risk, particularly in patients with hemophilia who are deficient in specific procoagulant proteases. However, critically ill patients commonly have reduced anticoagulant proteins as well as procoagulant proteins. In these patients, prolonged PT/aPTT can be a sign of systemic thrombosis. The child with fulminant hepatic failure requiring transplantation illustrates this paradox. Before transplantation, the prolonged PT/aPTT is often associated with a proclivity to bleeding (greater reduction in procoagulant then anticoagulant factors). However, following transplantation, the prolonged PT/aPTT is associated with a greater proclivity to thrombosis (greater reduction in anticoagulant than procoagulant proteins).

There are two uncommonly used clinical tests that can be used to determine systemic clotting and fibrinolysis. With every thrombin molecule produced, the prothrombin activation fragment 1.2 (F1.2) is generated. Increased levels F1.2 levels are indicative of systemic thrombosis. When each fibrin monomer is lysed by plasmin, there is consumption of a plasmin α2-antiplasmin molecule. Increased plasmin α2-antiplasmin levels are associated with hypofibrinolysis and systemic clotting, and decreased levels are associated with increased fibrinolysis and systemic bleeding.

Table 3.2 Diagnostic criteria and treatment recommendations for thrombotic disorders

Diagnostic criteria	Treatment
TTP	*TTP*
Fever	(a) Steroids × 24 h
Thrombocytopenia	(b) Within 30 h perform 1.5 volume plasma exchange then 1 volume daily until resolution of thrombocytopenia (median 18 days)
Increased LDH	(a) If recalcitrant use cryopreserved supernatant
Schistocytes >5%	(b) If refractory, consider rituximab or vincristine
Neurologic and renal dysfunction	
DIC	*DIC*
Thrombocytopenia	(a) Reverse shock and underlying disease (increase flow with fluids and consider vasodilators – nitroglycerin, milrinone, pentoxifylline)
Decreased factors V, VIII, and X and fibrinogen	(b) Replace clotting factors with FFP, cryoprecipitate, and platelets via plasma infusion or plasma exchange
Decreased antithrombin III and protein C	(c) Anticoagulate with heparin, protein C, or antithrombin III, prostacyclin
Increased D-dimers	(d) Use fibrinolytics for life- or limb-threatening thrombosis. Remember to keep PT/aPTT and platelets normal when giving fibrinolytics
Prolonged PT/aPTT	(e) Give antifibrinolytics if life-threatening bleeding (rarely needed when PT/aPTT and platelet counts are maintained)
HUS	*HUS*
Thrombocytopenia Hemolytic anemia Acute kidney injury Complement activation	(a) Anti-C5 antibody (eculizumab) for atypical HUS (unclear role for STEC HUS) (b) Plasma exchange for autoantibody mediated HUS (factor H autoantibody) (c) Consider plasma exchange for non-autoantibody-mediated HUS
2° Thrombotic microangiopathy	*2° Thrombotic microangiopathy*
Thrombocytopenia	(a) Remove source of 2°TMA
Increased LDH	(b) Plasma exchange for adult severe sepsis (median 3 days) and for children with thrombocytopenia-associated multiple organ failure
Normal or elevated fibrinogen	(c) TTP-based plasma exchange protocol for children (see above) until resolution of thrombocytopenic multiple organ failure (median 12 days)
<5% schistocytes	
Multiple organ failure	

In terms of therapy, there is an array of nonspecific and specific therapies available to the intensivist for management of the critically ill child with disseminated microvascular thrombosis and bleeding (Fig. 3.7). Thrombotic thrombocytopenic purpura mortality was almost uniform before the use of corticosteroids and plasma exchange therapy, which significantly reduced TTP

There is an array of nonspecific and specific therapies available to the intensivist for management of the critically ill child with systemic thrombosis and bleeding.

Table 3.3 Diagnostic criteria and treatment recommendations for bleeding disorders

Diagnostic criteria	Recommended therapy
Trauma	*Trauma*
Bleeding from sites of trauma	(a) Surgical hemostasis
Prolonged PT/PTT	(b) Platelet and procoagulant factor replacement
Thrombocytopenia	(c) Activated factor VII can be effective when this fails
	(d) Aminocaproic acid reduces bleeding during ECMO
Liver failure	*Liver failure*
Decreased factor II, VII, IX	(a) Vitamin K
	(b) Platelet and procoagulant factor replacement
	(c) Activated factor VII can be effective when this fails
Congenital coagulant deficiency	*Congenital coagulation deficiency*
Deficient factor VII, factor VIII, factor IX, von Willebrand factor	(a) In the absence of consumption (DIC), 30 mL/kg of FFP (FVII, VIII, IX, VWF) or cryoprecipitate (FVIII, IX, VWF) corrects these deficiencies
	(b) Specific concentrates are available and effective
	(c) Activated concentrates should be used when bleeding is life-threatening (caution: can cause thrombosis)

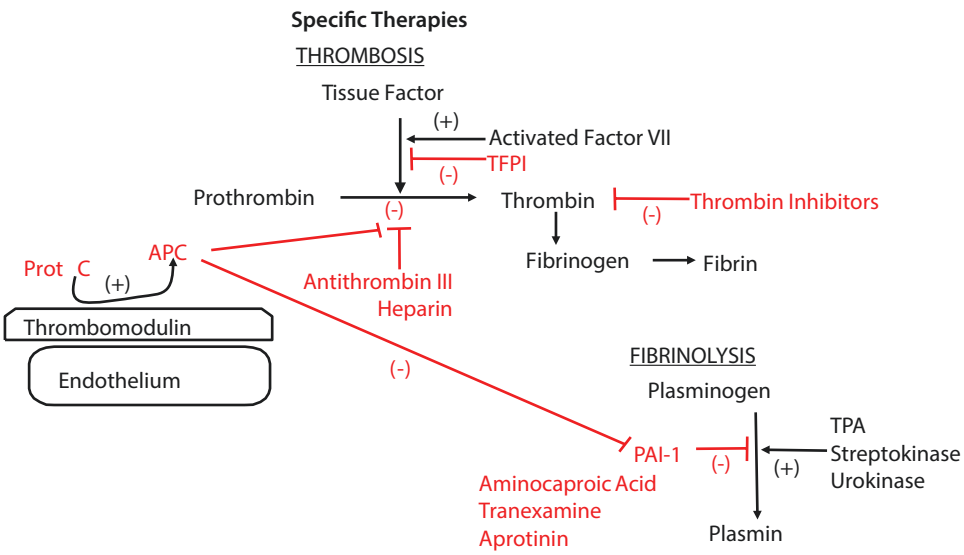

Fig. 3.7 Specific therapies used to **a** reverse thrombosis (*Pro C* = protein C concentrate, *APC* = activated protein C, *TFPI* = tissue factor pathway inhibitor, antithrombin III, heparin, thrombin inhibitors (such as argatroban and hirudin), **b** promote thrombosis (*activated factor VII*) and **b** promote fibrinolysis (*TPA* = tissue plasminogen activator, streptokinase, urokinase, defibrinopeptide), or **c** stop fibrinolysis (aminocaproic acid, tranexamine, aprotinin)

mortality. Interestingly, many of these patients treated in this way had evidence of DIC. Histology in these patients also demonstrated fibrin-rich microthrombi and inflammatory cell lesions compared to the pathognomonic platelet/VWF-rich microthrombi in TTP. These patients were defined as having TTP by a

process of elimination when no other causes (e.g., infection, toxin, autoimmune disease) could be found to explain the underlying microangiopathy. The presence of an underlying process excluded the diagnosis of TTP. In contrast, plasma exchange (median of 18 days) appears superior to plasma infusion in improving survival in patients with TTP with a normal PT/aPTT.

Plasma exchange appears superior to plasma infusion in improving survival in patients with TTP with a normal PT/aPTT.

Acute TTP can be treated successfully. As the process can be mediated by antibodies or other inhibitors to ADAMTS-13, a trial of steroid therapy is reasonable as a first step. Daily plasma exchange should be considered if resolution is not attained within 24 h of steroid therapy. Plasma exchange is more effective than plasma infusion, because antibodies or inhibitors can be removed from the recipient and ADAMTS-13 can be replaced in the donor plasma. In patients who are recalcitrant to fresh frozen plasma, the use of cryopreserved supernatant (fresh frozen plasma minus cryoprecipitate) or solvent-detergent-treated (SD) plasma may be attempted, as these plasma products are poor in large VWF multimers. Plasma exchange therapy is most effective when implemented within the first 24 h of disease and may be required for over 2 weeks. The endpoint of therapy is resolution of thrombocytopenia (attainment of a platelet counts greater than 100,000/mm^3) and no further deterioration of neurologic status. Vincristine and/or rituximab is recommended to stop antibody production in patients who are recalcitrant to plasma exchange therapy. Chronic relapsing TTP, though much less common, requires chronic plasma infusion therapy after resolution of the acute episode. Plasma infusions may be required on a monthly basis. The benefits of these therapies are considerable. The short-term risks associated with plasma exchange therapy include the need for a large-bore intravenous catheter, hypocalcemia secondary to citrate-based anticoagulation which requires calcium replacement, and hypotension requiring inotropes or vasopressors in patients with shock and secondary catheter-related infections. The long-term risks include blood-borne virus exposure.

Disseminated intravascular coagulation is a primary determinant of outcome in critically ill children.

Disseminated intravascular coagulation is a primary determinant of outcome in critically ill children. When experimental and clinical results in neonates suggested that heparin therapy did not improve outcome in DIC, it became generally accepted that the most important determinant of outcome was aggressive fluid resuscitation, restoration of normal or hyperdynamic circulation, and removal of the nidus of infection and/or systemic coagulation. The early years of pediatric intensive care has been successfully focused on this approach, such that DIC is now the least common manifestation of organ failure in children with multiple organ failure. However, despite reversal of shock, there are still children who develop DIC.

Coagulopathy is a predictor of mortality if it persists in children with multiple organ failure.

Coagulopathy is a predictor of mortality if it persists in children with multiple organ failure. The present mainstay of therapy with the thrombotic phenotype of DIC is replacement of plasma until PT/aPTT is corrected. This approach could be theoretically counterproductive in some patients. Although PT/aPTT can be improved as antithrombin III, protein C, thrombomodulin, and protein S are being replaced, concerns are raised as to whether concomitant replacement of coagulation factors in fresh frozen plasma is "fueling the fire." For this reason, many investigators who use plasma infusion recommend concomitant heparin infusion to allow ongoing anticoagulation. In countries where antithrombin III or protein C concentrates are available, physicians may use these concentrates in place of, or in combination with, plasma infusion. Both approaches have been found to be effective in reversing DIC. Some investigators theorize that activated protein C may be more effective if the ability of the host to activate this protein is diminished. However, data suggest that children with meningococcemia and adults with infectious purpura can activate exogenously administered protein C. Tissue factor pathway inhibitor concentrate is also effective in reversing DIC, but this therapy requires further investi-

gation. Several other infusion therapies have been promoted. Many use heparin to prevent ongoing thrombosis; however, heparin is a cofactor for antithrombin III and therefore does not prevent clotting efficiently if antithrombin III levels are low. Moreover, combined use of heparin and antithrombin III concentrate can cause an increased tendency to bleeding. Prostacyclin infusion can improve microcirculatory flow and decrease platelet thromboses. Other infusion therapies with similar effects include nitroglycerin, nitroprusside, milrinone, and pentoxifylline. Case reports describe fibrinolytic therapy with tPA, urokinase, or streptokinase, resulting in remarkable restoration of limb perfusion and unexpected survival in children with purpura fulminans. Continued use of urokinase requires intermittent plasma infusion to replace depleted plasminogen. The untoward complication of continued use of fibrinolytic therapies can be bleeding, if exogenous plasminogen activator activity is far greater than endogenous plasminogen activator inhibitor activity. It is likely prudent to maintain higher platelet counts and procoagulant factor levels (e.g., platelet, fresh frozen plasma [FFP] and cryoprecipitate infusion), when using fibrinolytic therapies. If patients develop life-threatening bleeding from these therapies, then antifibrinolytic therapies, including aminocaproic acid, tranexamine, and aprotinin, may be considered.

Plasma exchange is a nonspecific therapy, which has been reported to be effective for the reversal of DIC.

Plasma exchange is a nonspecific therapy, which has been reported by several groups to be effective for the reversal of DIC. These centers use whole blood exchange when infants are too small to tolerate the volume of extracorporeal blood or the large-bore catheter needed for centrifugation-based plasma exchange. The theory behind this therapy is straightforward. Plasma exchange allows for the simultaneous correction of the abnormalities of DIC, including increased circulating tissue factor and plasminogen activator inhibitor activity and decreased antithrombin III, protein C, protein S, and prostacyclin activity without incurring extreme fluid overload. Plasma exchange is performed using a one and a half volume exchange, which replaces approximately 78% of the host plasma. One series demonstrated that plasma exchange was associated with improvement in coagulopathy and survival of 7 of 8 children, with meningococcal associated purpura fulminans, who had a predicted mortality of greater than 90% based on a prolonged aPTT. An aPTT >50 s is predictive of a poor outcome in children with meningococcemia. In that report, the aPTT corrected because factor II, V, VII, and VIII levels were restored. However, protein C and antithrombin III levels were only minimally increased by plasma exchange. The attainment of a protein C level of 0.25 IU/mL is associated with normalization of coagulation in neonates with congenital purpura fulminans. The supplementation of plasma exchange with protein C and antithrombin III has the potential to be efficacious in patients with consumptive microangiopathy.

The prototype of the procoagulant form of DIC has been found in children with dengue fever (primarily in Southeast Asia). Physicians from Thailand have been credited with effective management approaches that have been associated with a tenfold reduction in mortality. Similar to observations with other thrombotic forms of DIC, the rapid reversal of shock is the most effective therapy. Children are continuously fluid resuscitated using hemoglobin as an endpoint. If hemoglobin concentrations increase, then it is indicative of hemoconcentration and hypovolemia, and more isotonic fluids are then given. This therapy is continued until the virus runs its course. There are a minority of children who develop bleeding diathesis despite adequate resuscitation. These children will exsanguinate without aggressive therapy. Unlike the practice in the Western world, hospitals that serve endemic dengue populations store whole blood rather than component blood products. These practitioners simply replace patient blood loss with whole blood whenever hemoglobin falls, providing a type of whole blood exchange therapy without the exchange

machine. The therapy is continued until the viral course is complete. This clinical approach has been associated with successful outcomes.

Anti-C5 antibody (eculizumab) is currently recommended for patients diagnosed with atypical HUS. For STEC-HUS, the benefit of eculizumab is still unclear and ongoing clinical trials will help to clarify its role. Therapeutic plasma exchange is a therapeutic strategy that can be started during the initial acute episode for which a clear diagnosis is not yet established such as pending complement, ADAMTS-13 and VWF levels. For those diagnosed with autoantibodies to complement inhibitors, such as factor H, then immune suppression to decrease antibody production with steroids, cyclophosphamide, and/or rituximab may be tried.

Secondary thrombotic microangiopathy may be diagnosed in critically ill patients with new-onset thrombocytopenia, organ failure, and elevated LDH.

Secondary thrombotic microangiopathy may be diagnosed in critically ill patients with new-onset thrombocytopenia, organ failure especially acute kidney injury, and elevated LDH or with an underlying predisposing condition (■ Table 3.2). Poor outcomes from these disease processes are well-documented. Favorable responses of adults and children with secondary thrombotic microangiopathy have been found with the use of the TTP-based plasma exchange therapy protocol. The biologic plausibility for the beneficial effects of plasma exchange in patients with TTP or DIC has been discussed, and the biologic plausibility for the therapeutic effect in patients with 2° TMA is similar. Plasma exchange normalizes plasminogen activator inhibitor-1 activity, allowing endogenous tissue plasminogen activator to lyse fibrin in a controlled and progressive fashion without bleeding. Plasma exchange also has a beneficial effect on VWF pathophysiology. It removes ADAMTS-13 inhibitors and ultra-large VWF multimers, restores ADAMTS 13 activity, and improves organ function.

Currently, there are ongoing trials of specific therapies for sepsis-induced systemic thrombosis, including trials of thrombomodulin. Unfortunately, there have been many prior failed trials, including activated protein C, tissue factor pathway inhibitor, and heparin. Current recommendations from the International Society on Thrombosis and Haemostasis are to provide supportive care with blood product replacement while performing prospective controlled trials to evaluate the benefit of specific therapies. For nonspecific therapy, two nonrandomized multicenter registry studies in children with thrombocytopenia-associated multiple organ failure showed that therapeutic plasma exchange was associated with improved survival. These multicenter registry studies followed an initial pilot study in children with thrombocytopenia-associated multiple organ failure that showed plasma exchange therapy could correct the coagulopathy, VWF-mediated thrombogenicity, and reverse organ failure. In addition, a single center study in adults with severe sepsis using plasma exchange therapy showed a reduction in mortality by 20%, which, however, was not statistically significant after adjustment for effects of unbalanced baseline characteristics.

In general, 1 mL per kg of fresh frozen plasma provides the equivalent of 1.5–2 unit/kg of procoagulant and anticoagulant activity.

Bleeding disorders can also be managed with specific and nonspecific therapies. In patients with congenital deficiencies, specific factors, such as factor VIII and factor IX, concentrates may be given for hemophilia just as protein C concentrate and antithrombin III concentrates may be given for purpura fulminans. However, plasma may also be effectively given. In general, 1 mL per kg of FFP provides the equivalent of 1.5–2 unit/kg of procoagulant and anticoagulant activity, since plasma volume is roughly 50–60 mL/kg. For most factors, a percentage activity > 30% or 15–20 mL/kg of FFP prevents proclivity to clotting (anticoagulant factors) or bleeding (procoagulant factors). However, if factors are being consumed by DIC or trauma-associated bleeding, then greater volumes of plasma will be necessary, or the use of multiple concen-

Activated factor VII can be used to stop life-threatening bleeding under some circumstances.

trates will be needed. Activated factor VII can be used to stop life-threatening bleeding under these circumstances. Plasma exchange therapy can be used to give 50–80 mL/kg of plasma (one and a half to two volume exchange) without fluid overload. In patients with fibrinolysis, the antifibrinolytics may be lifesaving (Table 3.3).

3.3 Conclusion

A consensus is developing that disseminated microvascular thrombosis and bleeding is a therapeutic target in children with thrombocytopenia-associated multiple organ failure. As with all therapeutic targets, the underlying cause of the disease must be removed for the therapy to have a long-term effect. Microvascular thrombosis and bleeding is associated with systemic insults, including shock, infection, drugs, toxins, and radiation. In order for therapies directed at microangiopathy to be beneficial, shock must be reversed, infection eradicated and removed, and precipitating drugs, toxins, and radiation stopped. Antithrombotic/fibrinolytic therapies can be expected to have the greatest effect on outcome when these tasks have been accomplished.

New-onset thrombocytopenia may be useful as an indicator of thrombotic microangiopathy in children with multiple organ failure. Although bone marrow aspirates/biopsy may diagnose bone marrow infiltration or bone marrow suppression, it has been found that many patients with infiltrative disease also have microangiopathy. Accurate diagnosis will require development of a user-friendly assay of ADAMTS-13, VWF multimeric analysis, and complement activities. For now, resolution of thrombocytopenia is a useful indicator of resolving thrombotic microangiopathy and a reasonable endpoint for successful use of antithrombotic and fibrinolytic therapies.

Randomized controlled trials suggest that steroids and nonspecific plasma exchange therapy improves survival for adult patients with primary TTP and adult patients with severe sepsis. Two nonrandomized multicenter registry studies suggest that plasma exchange therapy could correct coagulopathy, VWF-mediated thrombogenicity, and reverse organ failure in children with thrombocytopenia-associated multiple organ failure. Currently, there is no specific therapy (i.e., no monotherapy) that has been shown to improve outcome for sepsis-induced coagulopathy. Plasma infusion or exchange should be considered until normalization of PT/aPTT. Concomitant anticoagulant therapy is also recommended with low-dose heparin, antithrombin III, or protein C concentrates. The use of fibrinolytics has been recommended by some for patients with life-threatening or limb-threatening thrombosis. Careful attention to normalization of the platelet count and the PT/aPTT is recommended before therapy is initiated. Antifibrinolytics or activated factor VII can be used, if life-threatening bleeding ensues. Fresh whole blood banking procedures may have efficacy in hospitals with populations in common need of treatment for the hemorrhagic phenotype of DIC. Anti-C5 antibody (eculizumab) can be used in atypical HUS. In patients with bleeding disorders, specific and nonspecific therapies are also recommended. Specific therapies include platelets; factors VII, VIII, and IX; and antifibrinolytics, and nonspecific therapies include plasma infusion and plasma exchange.

Review Questions

1. Thrombotic thrombocytopenic purpura may be distinguished from nonconsumptive secondary thrombotic microangiopathy by the presence of:
   A. Altered mental status
   B. Fever
   C. Microangiopathic hemolysis
   D. Renal dysfunction
   E. Thrombocytopenia

2. Which of the following is the most essential component of the fibrinolytic pathway and the mediator of fibrinolysis?
   A. Activated factor VII
   B. Plasmin
   C. Protein S
   D. Thrombin
   E. von Willebrand fragment

3. Which of the following accurately describes a step in the process of forming a fibrin clot at the site of a focal traumatic vascular injury?
   A. The endothelial disruption results in the release of prostacyclin, which produces local vasoconstriction.
   B. The liver produces ultra large von Willebrand fragment (vWF) multimers, which initiate platelet aggregation and form the platelet plug at the site of endothelial disruption.
   C. The loss of endothelium at this site exposes tissue factor, which inhibits activation of factor VII.
   D. Thrombin activatable fibrinolysis inhibitor (TAFI) increases plasminogen activator inhibitor type-1 (PAI-1) activity, thereby fostering fibrinolysis.
   E. Thrombin production activates thrombin activatable fibrinolysis inhibitor (TAFI) at the site of the injury.

4. Which of the following pathophysiological mechanisms accounts for the clinical syndrome of acute thrombotic thrombocytopenic purpura (TTP)?
   A. A change in the metabolic milieu (e.g., acidosis) results in decreased ADAMTS 13 activity, leading to the inability to cleave unusually large and large von Willebrand fragment multimers to their smaller, less thrombogenic multimers.
   B. Shear injury of the vascular endothelium exposes tissue factor, resulting in the exuberant activation of factor VII, ultimately resulting in a prothrombotic state with high concentrations of unusually large and large von Willebrand fragment multimers.
   C. The formation of antibodies against the vWF-cleaving proteinase (ADAMTS 13) destroys vWF cleaving proteinase activity, resulting in the inability to cleave unusually large and large von Willebrand fragment multimers to their smaller, less thrombogenic multimers.
   D. There is a congenital deficiency of ADAMTS 13, which is exacerbated during intercurrent episodes of shear stress, resulting in the inability to cleave unusually large and large von Willebrand fragment multimers to their smaller, less thrombogenic multimers.
   E. There is an inherited predisposition to decreased protein C activity that is exacerbated by intercurrent disease processes, resulting in a prothrombotic state and high concentrations of unusually large and large von Willebrand fragment multimers.

5. A 6-year-old child who presented with fever and generalized tonic-clonic seizure activity requires intubation for airway control. His heart rate is 145 beats per minute, his blood pressure is 128/85 mm Hg, and his oxygen saturation is 100% on 30% oxygen via the ventilator. He is oliguric making approximately 0.8 mL/kg/h of urine. Laboratory analysis reveals the following:
   - Sodium: 132 mEq/L
   - Potassium: 5.4 mEq/L
   - Chloride: 95 mEq/L
   - Bicarbonate: 16 mmol/L
   - Blood urea nitrogen: 68 mg/dL
   - Creatinine: 3.2 mg/dL
   - Glucose: 232 mg/dL
   - White blood cell count: 6200/μL
   - Hemoglobin: 6.5 g/dL
   - Platelet count: 37,000/μL
   - Lactate dehydrogenase: 3326 units/L
   - Which of the following therapies would be most indicated for this child?
     A. Continuous venovenous hemofiltration
     B. Intravenous immunoglobulin
     C. Packed red blood cell transfusion
     D. Plasma exchange
     E. Platelet transfusion

6. Which of the following is activated by thrombin to reduce the production of plasmin and inhibit fibrinolysis?
   A. Activated factor VII
   B. Protein S
   C. Thrombin activatable fibrinolysis inhibitor (TAFI)
   D. Tissue plasminogen activator
   E. von Willebrand fragment

7. Which of the following is expressed by the endothelium and activates protein C, thereby ultimately promoting fibrinolysis?
   A. Plasmin
   B. Thrombin activatable fibrinolysis inhibitor (TAFI)
   C. Thrombin
   D. Thrombomodulin
   E. Tissue factor pathway inhibitor

8. Which of the following circulates throughout the vascular system forming complexes with any released tissue factor to prevent factor VII-mediated coagulation?
   A. Plasmin
   B. Plasminogen activator inhibitor type-1 (PAI-1)
   C. Protein C
   D. Tissue factor pathway inhibitor
   E. Thrombomodulin

9. The following are true about hemolytic uremic syndrome (HUS) except:
   A. HUS is characterized by thrombocytopenia, microangiopathic hemolytic anemia, and acute renal failure.
   B. Involves thrombosis without endothelial injury.
   C. Commonly occurs in the United States secondary to infection with toxin-producing *E. coli.*

D. Can involve the brain, pancreas, and other organs.
E. Responds to plasma exchange for atypical forms.

10. A 12-year-old child presents with fever, rash, and weak distal pulses and cool extremities. His heart rate is 178 beats per minute, and his blood pressure is 72/35 mm Hg. Laboratory analysis reveals the following results:
- pH: 7.27
- $PaCO_2$: 27 mm Hg
- PaO_2: 94 mm Hg
- Base deficit: −15.3
- Hemoglobin: 7.5 g/dL
- White blood cell count: 1200/μL
- Platelet count: 38,000 /μL
- PT: 21 s
- aPTT: 75 s
- A blood culture is positive for gram-positive cocci in chains. In addition to the reversal of shock, the therapy most likely to improve his likelihood for a successful outcome is:

A. Appropriate antimicrobial therapy
B. Bicarbonate therapy
C. Intubation and mechanical ventilation
D. Packed red blood cell transfusion
E. Plasma exchange

11. Nonconsumptive secondary thrombotic microangiopathy may be distinguished from disseminated intravascular coagulation based on the presence of which of the following hematologic parameters?

A. Anemia
B. Increased D-dimer levels
C. Increased or normal fibrinogen levels
D. Leukocytosis
E. Thrombocytopenia

12. What is the final product of the complement pathway activation that causes destruction to the endothelium during HUS?

A. C3b
B. Terminal C5a
C. Thrombomodulin
D. Membrane attack complex
E. C5

Answers

1. C
2. B
3. E
4. C
5. D
6. C
7. D
8. D
9. B
10. A
11. C
12. D

The Inflammatory Response

Mark W. Hall

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_4

Learning Objectives

1. Describe the cellular components of the immune system that determine the inflammatory response.
2. Understand the roles of the innate and adaptive immune systems in initiating and regulating the inflammatory response.
3. Describe the role of cytokines and chemokines in regulating the inflammatory response.
4. Describe the role of the complement system in the inflammatory response.
5. Understand the roles of other mediators, including eicosanoids, kinins, nitric oxide, glucocorticoids, and heat-shock proteins in modulating the inflammatory response.
6. Discuss the triggering and intracellular signaling mechanisms involved in inflammation, including the toll-like receptor/NFκB, JAK/STAT, and MAP kinase pathways.
7. Describe the impact of immunomodulatory strategies aimed at the reduction of hyperinflammation.
8. Describe the phenomenon of immunoparalysis and its importance in critically ill patients.
9. Understand the role of immunostimulatory therapies in the reversal of immunoparalysis.
10. Identify HLH/MAS as an important inflammatory phenotype in critical illness.
11. Understand the impact of critical illness itself on the inflammatory response.
12. Identify the unintended immunomodulatory effects of commonly used medications in the ICU.

4.1 Introduction

The activation and migration of leukocytes during infection or injury and the associated physiologic changes that occur thereafter characterize the inflammatory response. This response represents the body's attempt to identify, contain, and eliminate pathogens and to initiate tissue repair mechanisms. If this response becomes systemic, it results in an important source of morbidity and mortality in the pediatric intensive care unit (PICU). Septic shock, for example, can be thought of as the body's deadly overreaction to microbial invasion. Mediators and mechanisms of the inflammatory response are increasingly well understood, but treatments targeting inflammation in the ICU have been historically ineffective at improving outcomes. Mounting evidence suggests that a balance between pro- and anti-inflammatory influences is crucial for recovery from critical illness. In this chapter, this balance will be explored on both intra- and extracellular levels. The discussion will then shift back to the bedside to review the history of immunomodulation in the ICU, describe the impact of intensive care on the inflammatory response, and highlight promising areas of research into the modulation of the inflammatory response.

4.2 SIRS and CARS

SIRS and CARS represent opposite extremes of the inflammatory response.

The systemic inflammatory response syndrome (SIRS) and the compensatory anti-inflammatory response syndrome (CARS) can be thought of as opposite extremes of the inflammatory response (Fig. 4.1). SIRS has been defined as a clinical state characterized by at least two of the following findings: abnormal temperature (>38 °C or <36 °C), tachycardia, tachypnea (or hyperventilation),

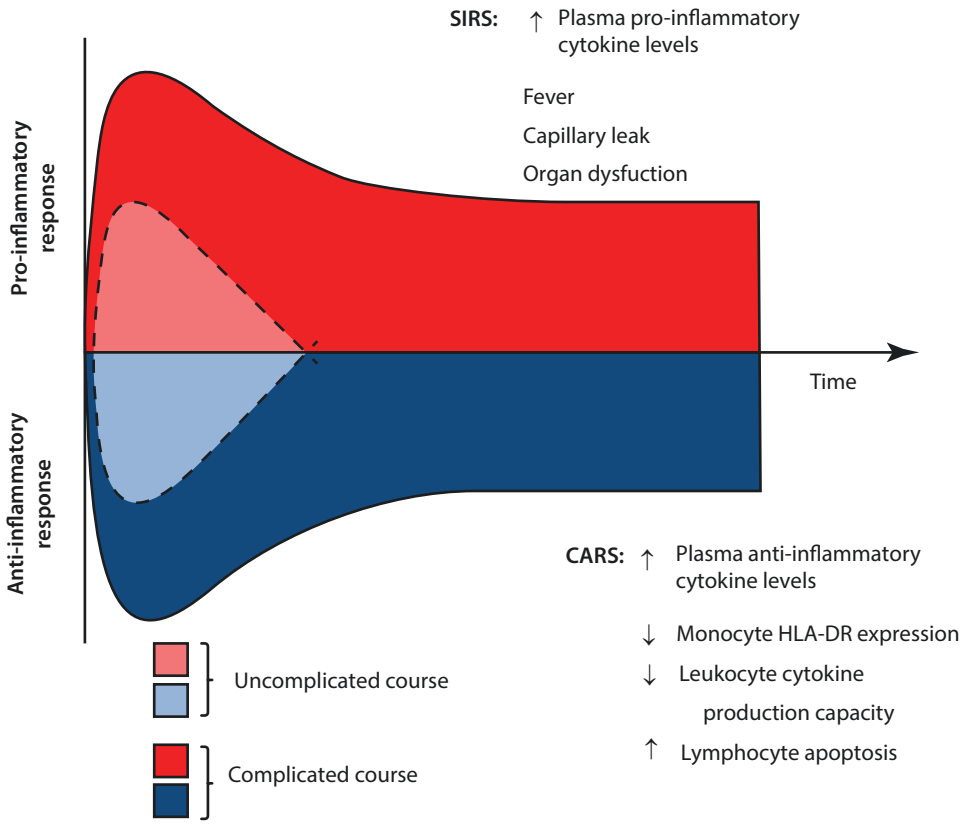

Fig. 4.1 The immunologic effects of the SIRS and CARS responses

and/or an abnormal white blood cell count (>12,000 cells/mm^3, <4000 cells/mm^3, or >10% bands. In the setting of documented or suspected infection, this syndrome has been historically known as sepsis. The inflammatory phenotype, however, is characteristic of many clinical states commonly seen in the PICU, including trauma and the post-operative state. CARS represents the body's attempt to restore homeostasis following an inflammatory insult through the near-simultaneous induction of counter-regulatory anti-inflammatory mechanisms. In contrast to SIRS, with its clinically obvious signs and symptoms, including fever, hemodynamic changes, and evidence of tissue malperfusion, CARS is typically asymptomatic. CARS, when severe and persistent, represents a form of acquired immunodeficiency and is itself associated with morbidity and mortality. The balance between pro- and anti-inflammatory influences is therefore key in determining the overall immune response.

4.3 Leukocytes and Inflammation

The cellular elements of the immune system can be divided into two main groups, those of the innate and adaptive immune systems. Both are required for a fully competent immune response, but they function in very different ways. The cells of the innate immune system (e.g., monocytes, macrophages, dendritic cells, natural killer (NK) cells, neutrophils) can recognize and respond to large subgroups of pathogens based on constitutively expressed pattern recognition receptors. For example, all monocytes respond to lipopolysaccharide (LPS) through its binding to the CD14/TLR4 complex. Innate immune cells do not require specific processing and presentation of antigens in order to become activated. They are themselves active in antigen processing and presentation to

cells of the adaptive immune system (discussed below). Under normal circumstances, innate immune cells display a similar immune response each time they encounter a given stimulus, rather than exhibiting an augmented or memory response with repeated exposures.

The innate immune system responds to the general classes of pathogens, while the adaptive immune system provides a highly antigen-specific immune response.

By contrast, the cells of the adaptive immune system (lymphocytes) become activated via the binding of highly specific receptors (surface immunoglobulin for B cells; the T cell receptor for T cells), whose specificity is the result of gene rearrangement within each individual cell. This allows for a high degree of lymphocyte diversity within a given individual. A repertoire of more than 1×10^{11} discreet antigens can be recognized by the adaptive immune system as a result of these rearrangements. Cells of the adaptive immune system usually require help, in the form of antigen presentation, from the innate immune cells to produce an effective immune response. This process starts with the ligation of the T cell receptor by an antigen-bearing class II major histocompatibility complex (MHC) molecule such as human leukocyte antigen (HLA)-DR on an innate immune cell. For activation to occur, a simultaneous co-stimulatory interaction must also occur between receptors on the T cell (e.g., CD28) and ligands on the antigen-presenting cell (APC) (e.g., CD80, CD86). Inhibition of the lymphocyte response can occur if co-inhibitory molecules are ligated instead (e.g., PD-1 [lymphocyte] and PD-L1 [APC]). Similarly, B cells often require co-stimulation by antigen-specific T cells to optimize antibody production. Lastly, the T and B cell populations, once activated, are both capable of producing memory cells that can respond more promptly and more robustly to repeated exposure to an antigen. The innate immune system, by virtue of its pattern recognition receptors, is typically the first cellular group to become activated by a given stimulus (over minutes to hours). The adaptive immune response usually requires more time for antigen processing, activation, proliferation, and differentiation (hours to days), leading to clonal expansion (several days). The following section will focus on how both arms of the immune system have highly specific roles but are ultimately complementary in maintaining and modulating the inflammatory response.

4.4 Innate Immunity

4.4.1 Pathogen Recognition

The effector cells of the innate immune system include neutrophils, monocytes, macrophages, dendritic cells, and NK cells.

Innate immune cells recognize pathogen-associated and damage-associated molecular patterns through receptors, including the toll-like receptors.

The major effector cells of the innate immune system include monocytes (which mature into macrophages upon activation and migration out of the bloodstream), neutrophils or polymorphonuclear cells (PMN), dendritic cells, and natural killer (NK) cells. Their properties are summarized in ◘ Table 4.1. As a group, these immune effector cells serve to ingest pathogens and effect intracellular killing, process and present antigens to adaptive immune cells, and produce chemicals that attract other lymphocytes to the area (chemokines) or directly induce inflammatory effects (cytokines). Most innate immune cells express cell-surface and intracellular receptors, which recognize and are activated by broad classes of molecules deemed PAMPs (pathogen-associated molecular patterns) and DAMPS (damage-associated molecular patterns) (see ◘ Table 4.2). Toll-like receptors (TLRs) are among the best characterized cell-surface receptors that interact with PAMPs. These receptors bind to families of ligands and initiate intracellular signaling cascades culminating in the activation of nuclear factor-κB (NFκB) and the transcription of pro-inflammatory gene products (see ▶ Sect. 4.7). In addition to TLRs, macrophages also express mannose receptors that result in phagocytosis of pathogens bound to their cell

Table 4.1 Cellular components of the innate immune system

Cell type	Site	Pathogen triggers	Receptor	Cytokine triggers	Primary actions	Mediators produced upon activation
PMN	Blood/ tissue	Bacterial peptides, opsonization	Chemotactic receptors, FcR	IL-8, FcR binding	Phagocytosis, intracellular killing, antigen presentation	TNFα, IL-1ra, ROS, BPI, lytic enzymes
Monocyte	Blood	TLR ligands, opsonization	Toll-like receptors, CD14, FcR	IFNγ, GM-CSF, TNFα, IL-1-β, IL-19, MIF	Antigen presentation, phagocytosis, cytokine/chemokine production	TNFα, IL-1β, IL-6, IL-8, IL-10, IL-19, IL-20, IL-27, TGFβ, IL-1ra
Macrophage	Tissue	TLR ligands, mannose, acetylated lipoproteins, opsonization	TLRs, CD14, mannose receptor, scavenger receptor. FcR	IFNγ, GM-CSF TNFα, IL-1-β, MIF	Antigen presentation, phagocytosis, intracellular killing, cytokine/ chemokine production	TNFα, IL-1β, IL-6, IL-8, IL-10, IL-12, IL-18, IL-27, IL1ra
Dendritic cell	Tissue/ lymph	TLR ligands, opsonization	TLRs, FcR	Flt3L, GM-CSF	Antigen presentation	IFNα, IL-12, IL-23, IL-27
NK cell	Blood/ tissue	Absence of MHC class I	Lectins	IL-12, IL-15, IL-18	Lysis of target cell	TNFα, IL-22, MIP-1α, perforin, granzymes

BPI bactericidal/permeability-increasing protein, *FcR* Fc receptor, *Flt3L* Flt3 ligand, *GM-CSF* granulocyte-macrophage colony-stimulating factor, *IFN* interferon, *IL* interleukin, *IL-1ra* interleukin-1 receptor antagonist, *MHC* major histocompatibility complex, *MIF* macrophage migration inhibitory factor, *MIP* macrophage inflammatory protein, *NK* natural killer, *PMN* polymorphonuclear cell, *ROS* reactive oxygen species, *TGF* transforming growth factor, *TLR* toll-like receptor, *TNF* tumor necrosis factor

Table 4.2 Pattern recognition receptors of innate immune cells

Receptor	Ligands	Ligand sources
TLR1	Triacyl lipopeptides	Bacteria and mycobacteria
TLR2	Peptidoglycans Lipoteichoic acid Lipoproteins Zymosan HMGB-1	Gram-positive bacteria Bacteria Fungi Damaged host cells
TLR3	Double-stranded RNA	Viruses
TLR4	Lipopolysaccharide HMGB-1	Gram-negative bacteria Damaged host cells
TLR5	Flagellin	Bacteria
TLR6	Lipoteichoic acid Zymosan	Gram-positive bacteria Fungi
TLR7	Single-stranded RNA	Viruses
TLR8	Single-stranded RNA	Viruses
TLR9	Unmethylated CpG DNA Host DNA HMGB-1	Bacteria and viruses Damaged host cells Damaged host cells
TLR 11	Profilin-like protein	*Toxoplasma gondii*
Mannose receptor	Mannose	Bacteria and viruses
Fc-receptor	Fc portion of immunoglobulin	Opsonized pathogen
NOD1[a]	Diaminopimelic acid	Gram-negative bacteria
NOD2[a]	Muramyl dipeptide	Gram-positive and gram-negative bacteria

TLR toll-like receptor, *NOD* nucleotide-binding oligomerization domain
[a]Intracellular inflammasome component

surface through recognition of bacterial, fungal, or viral surface carbohydrates. Receptors which bind the Fc portion of immunoglobulin are also present on most innate immune cells. These Fc receptors allow for the identification and phagocytosis of pathogens, which have been coated (opsonized) by antibody, thus marking them for destruction.

4.4.2 Migration

Cells of the innate immune system can be activated and recruited into the periphery through interaction with adhesion molecules as well as through response to cytokines and chemokines. As a result of local damage, immune cells and vascular endothelial cells upregulate expression of proteins on their surfaces that result in the adhesion of leukocytes to the vascular lining and ultimately their migration through it to become tissue effector cells. The groups of proteins most important in these interactions are the selectins and intercellular adhesion molecules (ICAM), expressed by endothelium, and the integrins and chemokine receptors, expressed by leukocytes. The classic example of this

process is the rolling of neutrophils across the vascular endothelial surface mediated by binding of endothelial E-selectin to the Sialyl-Lewis^x antigen on the PMN. This is followed by tight binding between endothelial ICAM-1 and the PMN integrin LFA-1. Migration into the tissues then occurs along a chemokine gradient (in this case IL-8).

Adhesion molecules expressed on both leukocytes and endothelial cells facilitate migration of immune cells into the tissues.

4.4.3 Antigen Presentation

Processed antigens are displayed by most innate immune cells on MHC class II molecules including HLA-DR.

The role of innate immune cells (chiefly macrophages and dendritic cells) in antigen presentation represents a critical convergence point between the innate and adaptive immune systems. After a phagocyte recognizes a pathogen through PAMP receptors or as the result of opsonization, the pathogen is engulfed and undergoes degradation in the phagolysosome. The resultant small peptides are then loaded onto MHC class II molecules including HLA-DR. These HLA-DR molecules carrying foreign peptides are then transported back to the cell surface, where they are displayed and ultimately presented to T cells, contributing to activation of the adaptive immune response. As an example of the importance of this process, reduction in HLA-DR expression on circulating monocytes has been associated with adverse outcomes in the setting of adult and pediatric critical illness (see ► Sect. 4.9).

4.4.4 NK Cells

NK cells are the only cells of lymphoid origin to be included in this review of the innate immune system (While B lymphocytes do express Fc receptors and can present antigen, the highly cell-specific nature of the surface immunoglobulin-ligand relationship places them in the adaptive immune system for the purposes of this discussion). NK cells express cell-surface lectin-like proteins that bind carbohydrates on host (self) cells. Ligation of these receptors induces the release of granules containing perforin and granzymes. These proteins result in cell membrane damage and apoptosis of the target cell. This process is inhibited by simultaneous ligation of host cell MHC class I molecules by the NK cell's killer cell immunoglobulin-like receptors (KIRs). Thus, only host cells whose MHC class I molecules have been destroyed or mutated by viral infection or malignancy are subject to destruction by NK cells. In addition to cytotoxicity toward virally infected host cells and those which have undergone malignant transformation, NK cells may play a significant role in airway inflammation. NK cells also play an important part in the compensatory anti-inflammatory response through their role in killing activated immune cells. Congenital or acquired reduction in NK cell activity is central to the pathogenesis of primary and secondary hemophagocytic lymphohistiocytosis (HLH).

4.5 Adaptive Immunity

While the innate immune system is crucial for the initiation and propagation of the inflammatory response, the adaptive immune system contributes to the persistence and modulation of that response. Antibodies produced by mature B cells (plasma cells) serve as activators of the innate immune cells via Fc receptors. Similarly, certain T cells produce cytokines that activate innate effector cells. Other T cells produce anti-inflammatory cytokines, which downregulate the inflammatory response.

T cell precursors undergo both positive and negative selection in the thymus in order to limit self-reactivity. During this process, T cells also differentiate into CD4 or CD8 positive cells. CD8+ T cells are cytotoxic cells that release lytic granules upon contact with a pathogen or pathogen-infected cell. Also, key to the inflammatory response are CD4+, or helper, T cells. A naïve CD4+ T cell, once activated, proliferates and differentiates into one of several subtypes, depending on the local cytokine milieu at the time of activation. While numerous subtypes of CD4+ T cells have been characterized, the T-helper 1 (T_H1) and T-helper 2 (T_H2) lymphocytes are of particular relevance to the immune response in critical illness. T_H1 cells activate phagocytes through the production of granulocyte-macrophage colony-stimulating factor (GM-CSF), interferon-γ (IFNγ), and other pro-inflammatory mediators. They also induce the production of opsonizing antibodies by B cells (IgG1, IgG3). T_H2 cells, on the other hand, produce cytokines such as interleukin-10 (IL-10), transforming growth factor-β (TGFβ), and other mediators, which promote an anti-inflammatory phenotype. T_H2 cells are also more potent activators of B cells, leading to enhanced production of neutralizing antibodies (IgM), and are active in hypersensitivity and autoimmune responses. The balance between the T_H1 and T_H2 phenotypes therefore serves as an important regulatory mechanism for the inflammatory response.

Other classes of CD4+ T cells have been shown to be important in modulating the immune response. Regulatory T cells (T_{reg}) are known to be potently immunosuppressive through cell contact-mediated inhibition as well as robust production of anti-inflammatory cytokines, such as IL-10 and TGFβ. Regulatory T cells can be identified by their cell-surface marker expression pattern (CD4+ CD25+ $CD127^{lo}$) and presence of the transcription factor Foxp3. On the other end of the inflammatory spectrum, high IL-17-producing T_H17 cells are potently pro-inflammatory and have been implicated in human allergic and inflammatory disease.

NK cells induce lysis of target cells that do not express compatible MHC class I molecules.

Newly activated T cells can differentiate into T_H1 cells, which mediate a pro-inflammatory response, or T_H2 cells, which can mediate an anti-inflammatory response.

4.6 Circulating Mediators of Inflammation

4.6.1 Cytokines

While leukocytes exert their effects in part by direct cellular action (phagocytosis, intracellular killing, cytotoxicity), the clinical syndrome of SIRS is largely the result of circulating proteins released by leukocytes, vascular endothelium, and other parenchymal cells upon activation by an inflammatory stimulus. These mediators are termed chemokines, if their primary action is to recruit other immune effector cells to the area, or cytokines, if their primary action is to modulate the function of a target cell in some way. Cytokines can exert pro-inflammatory or anti-inflammatory effects, depending upon which receptors and intracellular signaling pathways are activated. The production, action, and regulation of cytokines and chemokines are exceedingly complicated processes involving multiple cell types and feedback mechanisms. For the purposes of this chapter, an overview of a limited set of cytokines, their producers, targets, signaling mechanisms, and actions is provided in Table 4.3.

In brief, IL-1β, TNFα, IFNγ, IL-17, IL-18, IL-2, MIF, and GM-CSF are examples of mediators of the pro-inflammatory (T_H1-like) response. In contrast, IL-10, TGFβ, IL-13, IL-5, and IL-4 are mediators of the anti-inflammatory/autoimmune (T_H2-like) response. Interleukin-6 is produced by immune and endothelial cells in response to inflammatory stimuli and is the cytokine whose plasma elevations are most highly correlated with adverse clin-

Table 4.3 Overview of cytokines relevant to the inflammatory response

	Cytokine	Primary producer(s)	Primary target(s)	Primary signaling pathway(s)	Action(s)
Pro-inflammatory	IL-1β	Monocytes, macrophages	Vascular endothelium, monocyte, macrophages, T lymphocytes	NFκB	Fever, vasodilation, T cell, monocyte, macrophage activation
	TNFα	Monocytes, macrophages, T lymphocytes (T_H1), NK cells	Vascular endothelium, monocyte, macrophages, T lymphocytes	MAPK, NFκB, caspases	Fever, vasodilation, endothelial activation, apoptosis
	IL-18	Macrophages	NK cells, T lymphocytes	NFκB	T cell and monocyte activation, promotes T_H1 skewing
	IL-12	Macrophages, DCs	NK cells, T lymphocytes	JAK2/Tyk2/STAT4	Activates NK cells, promotes T_H1 skewing
	IFNγ	T lymphocytes (T_H1), NK cells	Monocytes, macrophages, T and B lymphocytes	JAK2/JAK1/STAT1	Activates monocytes and macrophages, promotes T_H1 skewing
	GM-CSF	T lymphocytes, macrophages	Monocytes, macrophages, PMN, DC	JAK2 /STAT5; NFκB	Promotes growth and activation of monocytes, macrophages, PMNs, DCs
	MIF	T lymphocytes (T_H1)	Macrophages	MAPK, PLA_2	Promotes macrophage activation, inhibits macrophage migration
	IL-6	Monocytes, macrophages, Vascular endothelium	Hepatocytes, T and B lymphocytes	JAK1/STAT1; JAK1/STAT3; MAPK	Promotes acute phase response, promotes T_H2 skewing, activates adrenal axis
Anti-inflammatory	IL-10	Monocytes, macrophages, T lymphocytes (T_H2)	Monocytes, macrophages	JAK1/Tyk2/STAT3	Inhibits monocyte, macrophage activation, promotes T_H2 skewing
	TGFβ	Monocytes, T lymphocytes (T_H2)	Monocytes, macrophages, B lymphocytes	Smad/Smad4	Inhibits monocyte, macrophage activation, promotes T_H2 skewing
	IL-13	T lymphocytes (T_H2)	T and B lymphocytes, monocytes, macrophages	JAK1/JAK3/STAT6	Inhibits monocyte, macrophage activation, promotes T_H2 skewing
	IL-4	T lymphocytes (T_H2)	T and B lymphocytes	JAK1/JAK3/STAT6	Induces lymphocyte T_H2 phenotype
	IL-1 ra	Hepatocytes, monocytes, macrophages, PMNs	IL-1 receptors	Receptor binding without activation	Prevents IL-1 action

JAK Janus-associated kinase, *MAPK* mitogen-activated protein kinase, *NFκB* nuclear factor-κB, *PLA* phospholipase A, *STAT* signal transducers and activators of transcription

ical outcomes in the setting of pro-inflammatory insults. Interleukin-6 has anti-inflammatory properties as well, including activation of the cortisol axis and promotion of a T_H2-like T cell response. For the purposes of this review, IL-6 is grouped with pro-inflammatory cytokines as elevation in its plasma concentration is usually associated with elevated levels of TNFα and IL-1β.

4.6.2 Chemokines

Chemokines can be produced by a wide variety of cell types, including immune cells. While some chemokines may serve to enhance cell activation, their main action is to induce recruitment of immune cells to target areas through migration along a concentration gradient. Chemokine proteins are traditionally grouped according to their amino acid sequences, specifically the arrangement of their cysteine (C) residues near the amino terminus. The major groups of chemokines include the CC, CXC, XC, and CX3C families (though most are of the CC or CXC varieties). The CXCL group, for example, is characterized by proteins containing an amino acid, which is flanked by two cysteines, with the letter L indicating that the protein is a ligand rather than a receptor. Conversely, the receptors for these proteins on target cells are referred to by the prefix of the chemokine followed by the letter R (e.g., CXCR1). Notable exceptions to this nomenclature include IL-8, which is the primary chemokine for neutrophils, and RANTES, an important chemokine for macrophage, PMN, NK cell, and eosinophil migration. Normal chemokine production is crucial for recruitment and activation of both innate and adaptive immune cells. Because these chemical signals are released in the context of inflammation, their plasma concentrations (particularly that of IL-8) have been linked to adverse outcomes in critical illness, including the acute respiratory distress syndrome, trauma, and sepsis.

Pro-inflammatory cytokines include IL-1β, TNFα, IFNγ, IL-2, and others. Anti-inflammatory cytokines include IL-10 and TGFβ.

Elevated systemic levels of IL-6 are associated with pro-inflammatory states, but it has both pro- and anti-inflammatory properties.

4.6.3 The Complement System

Not all innate immune effector molecules originate from leukocytes. A group of proteins manufactured in the liver and known collectively as the complement system is of great importance in the identification, clearance, and killing of pathogens. Most of these proteins are synthesized as precursor proteins, or zymogens, which require proteolytic cleavage for activation. The larger proteolytic byproducts are designated by the letter "b," while the smaller byproducts are designated by the letter "a." Through a series of self-amplifying cascades, the complement proteins ultimately serve three important functions: opsonization (marking pathogens or cells for ingestion by phagocytes), lysis of pathogens through the formation of lethal transmembrane pores, and the direct mediation of inflammation through chemokine/cytokine-like effects.

The complement system can be activated through either the *classical, alternative, or mannose-binding lectin (MBL) pathways* (see ◘ Fig. 4.2). The *classical pathway* is characterized by the binding of the C1 proteins to antigen-antibody complexes, certain bacterial cell membrane constituents, C-reactive protein, and a variety of other pathogen-associated ligands. This binding results in the recruitment and activation of C4 and C2 proteins, whose C4b and C2b byproducts combine to serve as a convertase for C3. C3 convertase activity is the convergence point for the three pathways of complement activation.

Chemokines induce migration of immune cells to target areas. Elevations in their plasma concentrations have been associated with adverse outcomes in critically ill patients.

The classical, alternative, and MBL pathways all result in the activation of C3.

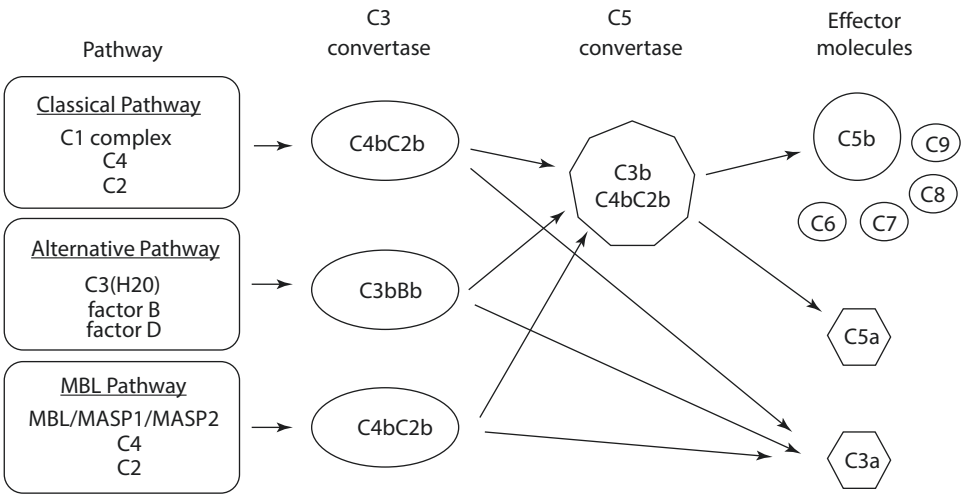

Fig. 4.2 Schematic of the complement system

The *alternative pathway* is different from the classical pathway in that it relies heavily on host (self) regulation to prevent damage to host tissues. This pathway begins with the spontaneous hydrolysis of plasma C3 (a process that is distinct from its cleavage into C3a and C3b). Hydrolyzed C3 and the plasma protein factor B form a circulating C3 convertase. The C3b produced by this $C3(H_2O)Bb$ complex can then bind to a cell surface (host or pathogen), where it can then be joined to another factor B molecule. This new membrane-bound C3bBb complex has potent C3 convertase activity. Host cells express cell-surface proteins, including complement receptor 1 (CR1), membrane cofactor protein (MCP), and decay accelerating factor (DAF), that destroy the C3bBb complex before damage can be done. Pathogens typically do not express these regulatory proteins, so C3 conversion can proceed unabated. Another plasma protein named properdin (or factor P), which binds poorly to mammalian cells but binds to many bacterial cell-surface constituents, serves to stabilize the C3bBb complex. The alternative pathway is therefore constitutively activated but is controlled by the host through negative regulation.

The last pathway of complement activation is the mannose-binding lectin pathway. MBL is a member of the family of plasma proteins known as collectins. These proteins, along with another group known as ficolins, bind to certain carbohydrate residues, including mannose, which are typically present on pathogen cell surfaces. In vertebrates, these residues have become obscured through the addition of sialic acid and other sugar groups, rendering them invisible to the MBL pathway. Once bound to an appropriate carbohydrate residue, this activated complex is now capable of activating C4 and C2 in the same manner as the C1 complex of the classical pathway. This, too, results in the formation of the C4bC2b convertase, which is capable of activating C3.

It is the cleavage of C3 into C3b and C3a which can be thought of as the first effector step in the complement system. C3a is a weakly inflammatory cytokine and chemokine. C3b, however, is the chief opsonizing molecule of the complement system. Most cells of the innate immune system express receptors for C3b that induce phagocytosis when ligated. Additionally, C3b can bind to its own C4bC2b convertase complex to form a new C5 convertase complex. C5a (known, along with C3a, as an anaphylatoxin) is a potent inflammatory cytokine, resulting in increased vascular permeability, increased endothelial adhesion molecule expression, and phagocyte recruitment. Both C3a and C5a are also thought to enhance T and B cell function through both direct and indirect mechanisms. C5b triggers the assembly of the membrane-attack com-

plex (MAC), characterized by the association of C5b, C6, C7, C8, and C9 on the pathogen cell surface. This complex forms a transmembrane pore which, if present in sufficient numbers, results in death of the pathogen.

This potentially lethal cascade of immune effector proteins has regulatory mechanisms in place to prevent inappropriate activation. The most obvious of these mechanisms is the fact that most of the proteins are present as inactive zymogens, requiring proteolytic cleavage for activation. The alternative pathway is also held in check by the presence of inhibitory host cell-surface proteins, including CR1, MCP, and DAF. In addition, the circulating plasma proteins, factor I, factor H, and C4-binding protein, disrupt the C3 convertase. These circulating regulators serve to limit the effects of the complement system to the surface of the cell which has been targeted for destruction. Another protective mechanism is the host cell-surface protein CD59 (protectin), which inhibits the formation of the membrane-attack complex on host cells.

Proteins of the complement system serve as important components of the innate immune system as well as activators of the adaptive immune response through the initiation of antigen phagocytosis for presentation and through their influence on the T and B cell responses. Complement production by the liver is constitutive but is upregulated by IL-6 in the setting of inflammation during the acute phase response. Congenital abnormalities in the complement proteins' structure or function result in clinically evident immunodeficiency with increased susceptibility to infection with *Neisseria* species.

4.6.4 The Acute Phase Response

The effector products of the complement system serve as opsonizers, cytokines, and direct mediators of pathogen killing.

The liver, when stimulated by certain cytokines, most notably IL-6, produces a number of proteins which are important for facilitating the inflammatory response, including fibrinogen, complement, C-reactive protein (CRP), serum amyloid protein (SAP), mannose-binding lectin and other collectins. CRP and SAP are multimeric molecules, which bind to bacterial and fungal cell wall constituents. There they serve as opsonizers as well as activators of the complement cascade through their interaction with the C1 complex. Serum CRP levels have historically been used as an indirect measure of inflammation, but it should be remembered that CRP is an important effector molecule of the innate immune system.

The hepatic acute phase proteins, including CRP, serve as indirect measures of inflammation as well as direct immune effector molecules.

4.6.5 Other Pro-inflammatory Mediators

In addition to the aforementioned cytokines, chemokines, and complement, there are several other classes of molecules that participate in the inflammatory response, including the eicosanoids, kinins, and nitric oxide. Eicosanoids are a group of lipid molecules, including the prostaglandins (PG), thromboxane (TX), and leukotrienes (LT), which are produced by a variety of cell types in response to stressors. Generation of these molecules requires the conversion of membrane lipid to arachidonic acid via the action of phospholipase A2. Arachidonic acid is then converted to PGH_2 by either cyclooxygenase (COX)-1 or COX-2, the targets of nonsteroidal anti-inflammatory drugs (NSAIDs). A series of constitutive and inducible synthases then generate a host of downstream effector molecules, including PGE_2 (an inhibitor of innate immune and T_H1 responses) and TXA_2 (a potent vasoconstrictor, promoter of platelet aggregation, and enhancer of innate immune and T_H1 responses). The net effect of COX-1/2 inhibition is anti-inflammatory, through reduction in TXA_2

production. Arachidonic acid can also be metabolized by the enzyme 5-lipoxygenase to produce LTA_4, which can be further modified to produce pro-inflammatory mediators, including LTB_4, LTD_4, and LTE_4. As a group, these molecules act as growth factors for innate immune cells and activators of phagocytosis and intracellular killing in phagocytes.

The kinin-kallikrein system is another family of peptides, produced by injured vascular endothelium, which serve to promote an inflammatory response. Through a cascade of zymogen activation, bradykinin and related kinins produce vasodilation, increased vascular permeability, and pain.

Arachidonic acid metabolites including TXA_2 and LTB_4 promote the inflammatory response.

Lastly, nitric oxide (NO) is produced by PMNs, monocytes, macrophages, and endothelial cells, as the result of upregulation of inducible nitric oxide synthase (iNOS) during activation by pro-inflammatory stimuli. Nitric oxide production is critical for intracellular killing by phagocytes through generation of reactive oxygen species (ROS), such as O_2^-, H_2O_2, and $ONOO^-$. Outside the phagocyte, NO results in local vasodilation and increased pro-inflammatory cytokine production and causes direct ROS-mediated oxidative tissue damage. Interestingly, NO has anti-inflammatory properties as well, including down-regulation of cellular adhesion molecules.

Nitric oxide production is critical for innate immune cells to effect intracellular killing.

4.6.6 Glucocorticoids

Glucocorticoids (GC), both endogenous and synthetic, have anti-inflammatory properties and have long been used in the treatment of inflammatory disorders. GC exert their effects through binding to the glucocorticoid receptor (GR), which is then internalized. The GC/GR complex is transported to the nucleus, where it inhibits the production of pro-inflammatory cytokines through the binding and inactivation of the pro-inflammatory transcription factor NFκB. In addition, the GC/GR complex binds to DNA and directly induces the transcription of inhibitors of inflammation including IκBα (see below). This anti-inflammatory effect seems to be highly dose dependent, however, as low doses of cortisol have been shown to enhance the hepatic acute phase response, increase expression of pro-inflammatory cytokine receptors, and increase production of macrophage migration inhibitor factor. In doses which are pharmacologically relevant to critically ill children, however, the net glucocorticoid effect is anti-inflammatory.

Glucocorticoids, in doses typically used in the ICU, result in an anti-inflammatory effect through inhibition of the NFκB pathway.

4.6.7 Heat-Shock Proteins

Heat-shock proteins (HSP) are produced by both prokaryotes and eukaryotes in response to cellular stress. Though initially discovered in the context of hyperthermic stress, these proteins are upregulated in response to a variety of stimuli, including ischemia-reperfusion and endotoxin exposure. The effect of HSP on the inflammatory response seems to be highly time dependent. If the heat-shock response is induced prior to exposure to a pro-inflammatory stimulus, cells demonstrate reduced production of pro-inflammatory cytokines. This is thought to be the result of inhibition of NFκB signaling through upregulation and enhanced function of the inhibitor IκBα (see below). If, on the other hand, the heat-shock response is induced *after* the onset of an inflammatory stimulus, it results in a pronounced apoptotic response.

Time-dependent effects of the heat-shock response include inhibition of the NKκB pathway and induction of apoptosis.

4.7 Intracellular Signaling

Mediators of inflammation, whether they are cytokines, chemokines, PAMPs, or DAMPs, can only produce their effects if the target cell is able to sense their presence, transmit that signal through the intracellular compartment, and induce the production of specific gene products. These processes are complicated, often with overlapping signaling pathways and feedback loops being activated following receptor binding by a given ligand.

4.7.1 Toll-Like Receptors and the NFκB Pathway

The TLR4/CD14 complex is the innate immune receptor for endotoxin and signals through the NFκB pathway.

NFκB must be liberated from its inhibitory molecule IκBα before it can be transported to the nucleus to serve as a transcription factor for pro-inflammatory cytokines.

As described in the innate immunity section, monocytes, macrophages, and dendritic cells possess cell-surface receptors that can recognize broad classes of pathogen-associated molecules. The TLR family is an example of these receptors, and TLR4, which is activated by bacterial endotoxin, represents a good case study of TLR signaling. LPS, bound to the plasma protein lipopolysaccharide-binding protein (LBP), binds to the cell-surface molecule CD14. LPS-bound CD14 then associates with TLR4 and its accessory proteins (see Fig. 4.3b). Successful formation of this complex leads to a series of intracellular events, including the phosphorylation of intermediary proteins. This cascade culminates in the liberation of the inhibitory protein IκBα from the transcription factor NFκB, which is then transported to the nucleus where it initiates transcription of genes encoding pro-inflammatory mediators. Multiple mechanisms of negative regulation of NFκB signaling exist. These include upregulation of IκBα mRNA production and stability, inhibition of NFκB DNA binding, and alterations in NFκB subunit arrangement such that the protein lacks a nuclear localization sequence.

4.7.2 JAK/STAT Signaling

Another important intracellular signaling pathway in the regulation of the inflammatory response is mediated by the families of proteins known as Janus-associated kinases (JAK) and signal transducers and activators of transcription (STAT). This pathway is used by a wide array of both pro- and anti-inflammatory cytokine receptors, including those for IFNγ and IL-6 (see Table 4.3). The resulting gene products depend on which STAT protein homodimer acts as the transcription factor for a given receptor. For example, when IFNγ binds to its receptor complex, it results in the phosphorylation of JAK2 and JAK1 (see Fig. 4.3a). Activated JAK1 then phosphorylates STAT1, which in turn forms a homodimer and is transported to the nucleus, where it serves as a transcription factor for pro-inflammatory genes. Multiple STAT proteins can be activated by the same JAK proteins. For example, ligation of the IL-6 receptor leads to the activation of JAK1, which can activate STAT1 (mostly pro-inflammatory gene products) and STAT3 (mostly anti-inflammatory gene products). The overall effect of ligand binding, therefore, depends on the balance between intracellular signaling pathways.

Negative regulation of the JAK/STAT pathway occurs primarily through the induction of suppressor of cytokine signaling (SOCS) proteins and phosphatases.

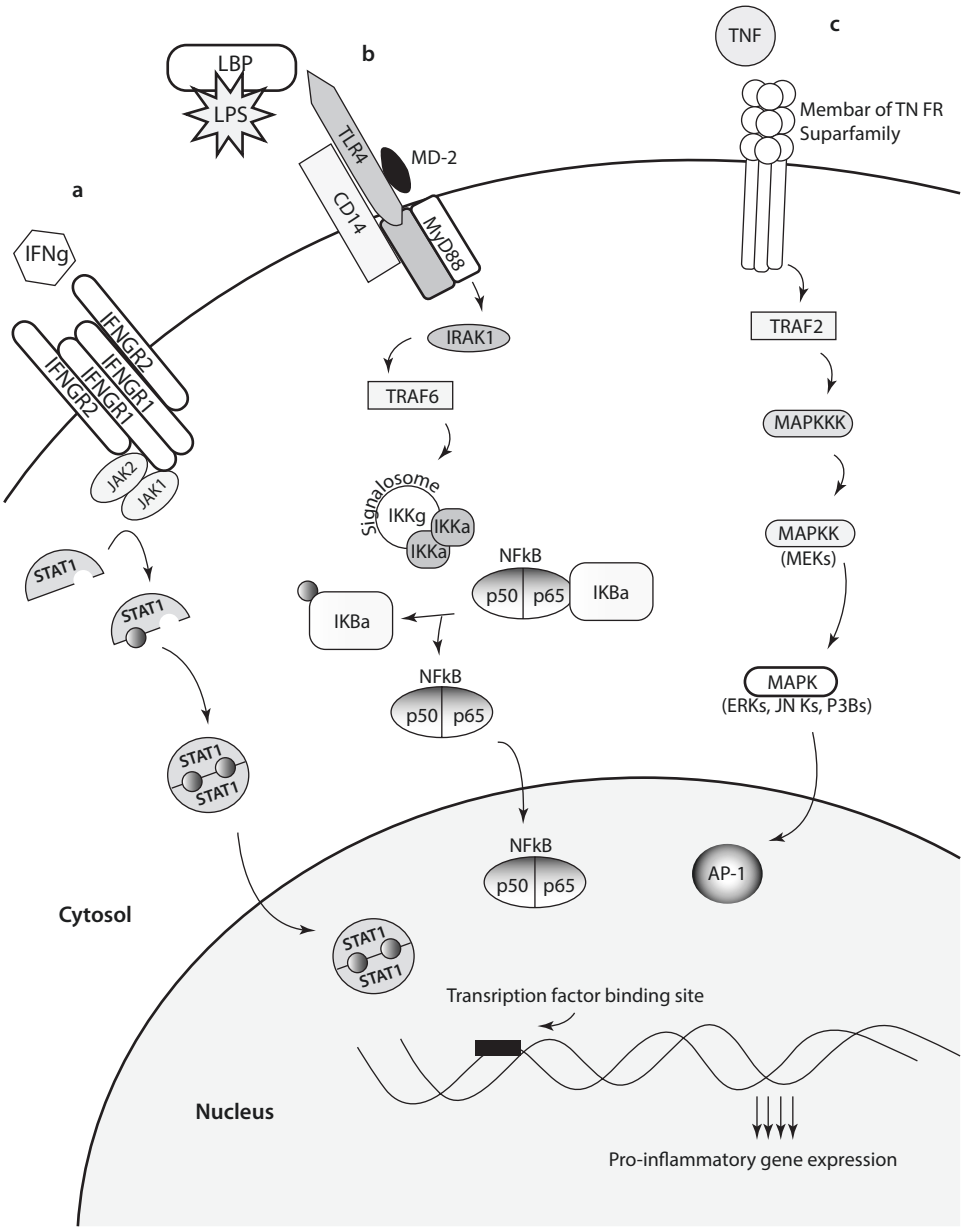

Fig. 4.3 Overview of signaling for the JAK/STAT **a**, TLR-NFκB **b**, and MAP kinase **c** pathways

The STAT family of transcription factors includes those that mediate both pro- and anti-inflammatory gene transcription.

The MAP kinases mediate pro-inflammatory gene transcription via activation of the transcription factor AP-1.

4.7.3 MAP Kinase Signaling

The mitogen-activated protein kinases (MAPK) participate in a variety of cellular processes, including growth, differentiation, and apoptosis, but they also function as signaling molecules for a number of cytokines and most chemokines. The MAP kinases extracellular signal-regulated kinase (ERK), c-Jun N-terminal kinase (JNK), and p38 have all been shown to mediate pro-inflammatory gene expression and/or immune cell activation. The MAP kinases require activation from a series of upstream kinases and, ultimately, activate one of the subunits of the AP-1 transcription factor (see Fig. 4.3c). The MAPK system is negatively regulated by the action of MAPK phosphatases (e.g., MKP1), which prevent transcription factor activation.

4.7.4 G-Protein-Mediated Signaling

Activation of receptor, which result in cell migration (e.g., chemokine receptors) or phagocytosis (e.g., Fc receptors), typically results in the activation of G-proteins, which signal through phospholipase C (PLC) or phosphatidylinositol 3-kinase-γ (PI3Kγ). These pathways, which often act in parallel with members of the MAPK family, result in the release of intracellular calcium from the endoplasmic reticulum. This promotes the assembly of the actin filaments necessary for cytoskeletal changes inherent in movement and phagocytosis. These pathways are similarly regulated by phosphatases.

NFκB, after liberation from the inhibitory molecule IκBα, is transported to the nucleus, where it serves as a transcription factor for pro-inflammatory.

4.7.5 The Inflammasome

The NLR (nucleotide-binding domain and leucine-rich repeat) receptor family has substantial homology to the TLR family and is known to be important in the recognition of *intracellular* PAMPs. These receptors include NOD1 (recognizes gram-negative cell wall components) and NOD2 (recognizes gram-positive and gram-negative cell wall components). They, along with other proteins, can assemble in the cytosol to form the inflammasome. Activation of the inflammasome results in the posttranscriptional processing and release of IL-1β and IL-18 and NFκB activation in innate immune cells.

The inflammasome complex is involved in intracellular PAMP recognition, activation of the NFκB pathway, and IL-1β processing and release.

4.7.6 Interrelationships

The complexity of signal transduction is compounded by the fact that mediators often signal through more than one pathway. IL-6, for example, signals predominately through the JAK/STAT pathway but is known to activate the MAPK pathway as well. Also, in the ICU patient, there are scores of cytokines, chemokines, and other mediators acting simultaneously.

The inflammatory response also affects multiple cellular processes besides the production of inflammatory mediators. Signaling through the TNF superfamily of cell-surface receptors, for example, is highly proapoptotic. This counter-regulatory mechanism helps turn off the inflammatory response once it has begun, by inducing apoptosis in the cells that produce pro-inflammatory cytokines. Similarly, it has been shown that phagocytosis of apoptotic bodies induces an anti-inflammatory phenotype and the production of T_H2-like cytokines by innate immune cells. It is in this setting of overlapping mediators and signaling pathways that clinical regulation of inflammation has proven so difficult.

Apoptosis serves as a negative regulator of inflammation via the death of inflammatory cells and deactivation of phagocytes, which have ingested apoptotic bodies.

4.8 Clinical Immunomodulation: Targeting Hyperinflammation

Given that the presenting signs and symptoms of sepsis are characteristic of a pro-inflammatory state, it is not surprising that the focus of research in immunomodulation has historically involved attempts at attenuation of the inflammatory response. The first target of immunomodulation was endotoxin. In 1982, Ziegler et al. demonstrated a reduction in both all cause and shock-related mortality in adults with sepsis who were treated with an antiserum harvested from healthy donors who had been vaccinated with killed *E. coli*. Later trials using IgG from similarly vaccinated donors and IgG from donors with a high titer to the LPS core antigen showed no benefit. Murine monoclonal antibodies to the lipid-A portion of the LPS molecule were similarly inef-

fective at improving sepsis survival in adults. The initial trial of a human monoclonal antibody did show a reduction in mortality, but a subsequent phase III trial was stopped after an interim analysis showed a trend toward *increased* mortality in some treatment groups.

In an attempt to reduce inflammation through the reduction of circulating IL-1β, recombinant IL-1ra has been administered to adults with septic shock with some initial success. Unfortunately, two large phase III trials in the mid-1990s were not able to demonstrate a survival benefit using rIL-1ra for this indication. Similarly, a large phase II trial of a bradykinin receptor antagonist failed to impact survival in adults with SIRS and gram-negative sepsis. A recombinant form of bactericidal/permeability-increasing protein (BPI), a protein made by activated PMNs which has both antimicrobial and endotoxin-deactivating properties, has undergone a phase III, randomized, controlled trial in children with meningococcemia, which demonstrated an improvement in functional outcome but not mortality.

TNFα has also been a target of immunomodulatory therapy in the ICU. Two studies in the 1990s attempted to use fusion proteins of soluble TNF receptor and IgG to bind circulating TNF and thereby reduce inflammation. Neither was successful at reducing mortality in adult sepsis. Four large anti-TNF monoclonal antibody studies in septic adults have been performed to date. The NORASEPT I and II and INTERSEPT trials all failed to demonstrate improvement in 28-day mortality. The MONARCS trial, conducted in over 2000 adults with severe sepsis, demonstrated a statistically significant reduction in 28-day mortality in the subgroup of patients who had plasma IL-6 levels over 1000 pg/ml, suggesting that patients with a particularly robust inflammatory response may benefit from anti-inflammatory immunomodulation.

Strategies designed to reduce levels of individual circulating pro-inflammatory mediators have largely been unsuccessful in improving mortality in sepsis.

Glucocorticoids represent another class of agents that has been used to reduce the inflammatory response in sepsis. Two meta-analyses published in 1995 evaluated the work of investigators, over the prior two decades, who had given methylprednisolone or dexamethasone to adult patients with sepsis. Both meta-analyses concluded that administration of these glucocorticoids resulted in *increased* mortality in adult sepsis. This can likely be explained by that fact that the anti-inflammatory effects of glucocorticoids also result in immunosuppression, particularly in the large doses used in the earlier trials. It is important to remember that different corticosteroids have different potencies with respect to their anti-inflammatory/immunosuppressive effects (see Table 4.4). Two later meta-analyses suggested a survival *benefit* with the use of low-dose (200–300 mg/day) hydrocortisone in adults with severe sepsis/septic shock. Subsequent clinical trials have yielded conflicting results, and the use of hydrocortisone as adjunctive therapy in sepsis remains controversial. If present, the benefits of hydrocortisone therapy are less likely to be the result of its anti-inflammatory properties than the hemodynamic effects of the drug (i.e., upregulation of catecholamine receptors; mineralocorticoid activity). A prospective pediatric study to address this important topic is ongoing.

Table 4.4 Relative potencies of commonly used corticosteroids

Corticosteroid	Anti-inflammatory effects (immunosuppressive)	Mineralocorticoid effects
Dexamethasone	30	0
Methylprednisolone	5	1
Hydrocortisone	1	5

Lastly, extracorporeal therapies, including hemofiltration, plasmapheresis and plasma exchange, have been used in the setting of sepsis in an effort to provide bulk removal of inflammatory mediators through diffusion, convection, or membrane adsorption. No method has been shown to impart consistent benefit in the setting of sepsis, though most have been evaluated in small studies and employed for short durations. An exception to this is an open-label, randomized, phase II trial of an extracorporeal endotoxin absorber, which was evaluated in 143 adult patients with severe sepsis/septic shock, presumably due to gram-negative infection. Patients who were randomized to the treatment group received the therapy daily for 4 days with no survival benefit seen. Pediatric data indicate that thrombocytopenia-associated multiple organ failure (TAMOF), a phenotype related to thrombotic thrombocytopenic purpura (TTP), may be a target for extracorporeal therapy. Patients with TAMOF have low levels of von Willebrand factor-cleaving protease activity, similar to TTP, contributing to the development of microvascular thrombosis. Both single- and multicenter studies of a prolonged, TTP-based plasma exchange regimen for children with TAMOF have suggested benefit. Of the extracorporeal therapies evaluated in controlled trials to date, plasmapheresis and plasma exchange have the greatest number of reports, indicating a survival benefit, though large randomized, controlled trials are still warranted.

Methylprednisolone and dexamethasone are not indicated for immunomodulation in sepsis. Hydrocortisone therapy may be considered.

Extracorporeal therapies, whose goal is bulk removal of cytokines, have not demonstrated consistent benefit in the setting of hyperinflammation; however, plasma exchange may be helpful in the setting of TAMOF.

4.9 Immunoparalysis

The historic focus on the pro-inflammatory features of critical illness has shifted to include the anti-inflammatory response. For example, while some deaths occur during the first 24–48 h after the onset sepsis, most occur beyond that time frame and often happen in the context of nosocomial infection or unresolving organ failure. An *underactive* rather than overactive innate immune response may be responsible for these adverse events. It has been known for some time that exposure to an inflammatory stimulus leads to a compensatory upregulation of anti-inflammatory cytokines. Numerous investigators have now shown that some patients do not return to normal immune function following an inflammatory insult, but instead develop a persistent, exaggerated anti-inflammatory response, which can be thought of as a type of secondary immunodeficiency.

This state has been termed immunoparalysis and is characterized by reduced expression of HLA-DR on the surface of circulating monocytes as well as an impaired ability of leukocytes to produce pro-inflammatory cytokines when stimulated ex vivo. Reduction of HLA-DR expression on circulating monocytes is associated with increased incidence of secondary infection and mortality in adult critical illness. Modest reductions in antigen presenting capacity can be well tolerated, but when the percentage of monocytes strongly expressing HLA-DR drops below 30%, risks for these adverse outcomes dramatically increase. Marked, persistent reduction in monocyte HLA-DR expression has been reported to be associated with adverse outcomes from trauma, sepsis, and pancreatitis in adults. Studies using a flow cytometric method, capable of quantifying HLA-DR molecules per cell, have suggested a cutoff of <8000 HLA-DR molecules per monocyte to define immunoparalysis in adults. Pediatric data are more limited, though a threshold of <30% monocyte HLA-DR positivity has been shown to be associated with nosocomial infection and death in children with MODS. A discrete threshold of HLA-DR molecules per monocyte has not been identified in children, however, with some investigators suggesting that a failure to increase monocyte HLA-DR expression over time may be more predictive of outcomes from pediatric sepsis than absolute expression thresholds.

Severe critical illness-induced immune suppression (immunoparalysis) is associated with adverse outcomes in the pediatric ICU.

Immunoparalysis is characterized by reduced HLA-DR expression on circulating monocytes and decreased production of TNFα by whole blood when stimulated with LPS ex vivo.

Reduced ability of whole blood to produce TNFα when stimulated ex vivo with LPS has also been shown to be associated with adverse outcomes in critically ill adults and children. A reduced TNFα response indicates hyporesponsiveness of leukocytes to a new challenge, as the response *should* be robust in an immunocompetent individual. Severe reduction in the TNFα response has been associated with increased risks of nosocomial infection, prolonged organ dysfunction, greater severity of illness, and/or death in children with multiple organ dysfunction syndrome, sepsis, trauma, cardiopulmonary bypass, and critical viral infections including influenza. Thresholds of the TNFα response that predict adverse outcomes will vary, depending on the stimulation methods used, and may vary by diagnosis. Standardization of the approach to measurement of the TNFα response will be key to its eventual incorporation into the clinical laboratory.

The adaptive arm of the immune system is also impacted by immunoparalysis. Lymphocyte apoptosis is a common feature of the immunoparalyzed phenotype. This can result in circulating lymphopenia as well as cellular depletion in lymphoid organs such as the spleen. Multiple studies have demonstrated significantly increased risk for the development of nosocomial infection in critically ill children, whose absolute lymphocyte counts are <1000 cells/mm^3, even if otherwise immunocompetent. In addition to a reduction in lymphocyte numbers, critically ill children can demonstrate reduced lymphocyte function as well. Wong et al. performed leukocyte mRNA profiling in a cohort of children with early septic shock and were able to classify subjects into endotypes based on up- or downregulation of genes important in glucocorticoid and lymphocyte signaling. Subjects with a predominately downregulated endotype demonstrated increased risks for prolonged organ dysfunction and death. Similarly, Muszynski et al. showed impairment in lymphocyte cytokine production capacity in septic children who went on to have adverse infectious outcomes.

High systemic levels of pro-inflammatory cytokines have consistently been associated with adverse outcomes from critical illness in adults and children. Wong et al. have been able to derive and validate a panel of serum cytokine biomarkers (the PERSEVERE model) that can risk-stratify children with early septic shock. Elevations in levels of these biomarkers, which include C-C chemokine ligand 3 (CCL3), IL-8, heat-shock protein 70 kDa 1B, granzyme B, and matrix metallopeptidase 8, have been reproducibly associated with mortality using the PERSEVERE model. Immunoparalysis has been associated with elevations in plasma levels of IL-10, and anti-inflammatory cytokine, suggesting skewing toward a T_H2-like state. Anti-IL-10 neutralizing antibodies have been demonstrated to reverse experimental immunoparalysis. Paradoxically, immunoparalysis is also frequently associated with elevated plasma levels of pro-inflammatory cytokines. The simultaneous presence of high systemic levels of inflammation and hyporesponsiveness of circulating leukocytes may be explained by the fact that pro-inflammatory cytokines are produced by injured, stressed, or infected parenchymal cells and vascular endothelium. The ongoing production of these mediators at the tissue level may contribute to the perpetuation of immunoparalysis, as systemic leukocyte function is downregulated in response.

Elevations in systemic levels of pro-inflammatory cytokines can occur simultaneously with immunoparalysis.

Early studies suggested that only a prolonged state of immunoparalysis (lasting >72 h after the initial insult) was associated with adverse outcomes. More recent data have shown that severe reductions in the immune response that occur as early as 24–48 h after the onset of critical illness confer increased risk for nosocomial infection, prolonged organ dysfunction, and/or death.

4.10 Immunoparalysis as a Target of Therapy

Immunoparalysis can be reversed through tapering of exogenous immunosuppression or administration of immunostimulatory drugs, such as recombinant IFNγ or GM-CSF.

Evidence exists that immunoparalysis is not simply an epiphenomenon associated with critical illness, rather it may represent a target for therapy. Rapid tapering of immunosuppression in adult solid organ transplant recipients with sepsis and immunoparalysis has been associated with improved monocyte function and survival of both patient and graft compared with patients whose immunosuppression was maintained. Reversal of immunoparalysis has also been studied in small populations of adults and children with immunoparalysis using drugs, including recombinant GM-CSF and IFNγ. Two small, uncontrolled case series, one using IFNγ and another using GM-CSF, demonstrated normalization of monocyte function in adult sepsis patients with immunoparalysis. Mortality in both cohorts was reduced compared to historical data from immunoparalyzed adults. Rosenbloom et al. demonstrated enhanced clearance of infection in GM-CSF-treated critically ill adults in a 40-subject randomized controlled trial, though a priori immune function testing was not employed. Two small studies, one adult and one pediatric, used prospective immune function testing to identify patients with immunoparalysis, who were then randomized to receive GM-CSF or control therapy. Both showed a greater improvement in monocyte HLA-DR expression and/or TNFα response in GM-CSF-treated subjects, and the pediatric study showed a marked reduction in nosocomial infection in the group that received GM-CSF. Two multicenter pediatric clinical trials of the GM-CSF for the reversal of immunoparalysis are currently underway, including one in pediatric critical trauma (NCT01495637) and one in pediatric sepsis-induced MODS (NCT03769844). The administration of drugs that target restoration of the ability of circulating leukocytes to mount an inflammatory response would seem to carry a risk for promoting inflammation. Reversal of immunoparalysis, however, has been shown to *reduce* systemic inflammation rather than increase it, presumably through restoration the body's ability to clear and repel infection and remodel injured tissues.

4.11 Secondary Hemophagocytic Lymphohistiocytosis and Macrophage Activation Syndrome

Secondary HLH/MAS represent inflammatory phenotypes that can complicate pediatric critical illness.

Congenital (primary) or acquired (secondary) impairment of NK cell and CD8+ lymphocyte function can result in runaway inflammation, due to an inability of these cytotoxic cells to eliminate activated macrophages and reticuloendothelial cells. The acquired form of this disorder is termed secondary hemophagocytic lymphohistiocytosis (HLH). When it occurs in the setting of rheumatologic disease, it is termed macrophage activation syndrome (MAS), though it is increasingly recognized that HLH and MAS likely represent the same disorder. HLH/MAS is clinically characterized by fever, cytopenias, hepatosplenomegaly, and elevations in laboratory measures that include serum ferritin and soluble CD25. These diagnostic elements also occur frequently in sepsis, making it difficult to distinguish between the two. Direct measurement of NK cell function and/or genotyping can help distinguish between sepsis and HLH/MAS, but the turnaround time is often too long for such testing to be clinically useful. Carcillo et al. have demonstrated, in single- and multicenter observational studies, that marked hyperferritinemia can identify children at high risk of mortality from sepsis. Their work also shows that the inflammatory phenotype of HLH/MAS can be coincident with TAMOF and/or immunoparalysis, suggesting that more than one phenotype-specific therapy may be

required for a given patient. While it is not clear that sepsis-induced hyperferritinemia and HLH/MAS should be treated similarly, it is noteworthy that HLH-style treatment regimens, including the drug anakinra, have been used with some success in this setting.

4.12 Critical Illness and the Inflammatory Response

4.12.1 The Impact of Critical Illness

End-organ dysfunction can affect the production and clearance of immune mediators as well as the production of immunologically active byproducts. Hepatic failure, for example, leads to impaired metabolism of pro-inflammatory cytokines, resulting in an inflamed state. Extracorporeal therapies such as dialysis, with prolonged contact of blood elements with plastic tubing and membranes, lead to the activation of complement. Transfusion of blood products, particularly packed red blood cells, has also been implicated as a source of both inflammation and immune suppression in the critically ill patient. Chronic renal failure leads to an upregulation of parathyroid hormone, which itself impairs B cell proliferation and antibody production as well as impairing neutrophil function. Plasma from uremic patients, typically high in pro-inflammatory cytokines, is also a potent promoter of apoptosis in lymphocytes and PMNs. Hyperglycemia is another common finding, which is associated with inflammation in the ICU. Ample experimental and clinical evidence indicates that glucose can serve as a potent activator of the inflammatory response through potentiation of the NFκB pathway in innate immune cells. Insulin administration results in anti-inflammatory effects indirectly through the reduction of serum glucose and through direct inhibition of the NFκB pathway.

Hepatic failure, hyperglycemia, and extracorporeal therapies can all potentiate the inflammatory response.

Lastly, the stress of critical illness itself can be immunosuppressive through the activation of the hypothalamic-pituitary-adrenal axis and the actions of catecholamines. As noted above, endogenous glucocorticoids contribute to the compensatory anti-inflammatory response syndrome through their inhibition of NFκB signaling. Stimulation of β-adrenergic receptors on innate immune cells results in the upregulation of anti-inflammatory mediators including IL-10. This process is particularly prominent in the setting of brain injury.

4.12.2 Effects of the ICU Pharmacopeia

Many drugs commonly used in the ICU impact the inflammatory response in ways that may not be obvious.

Some drugs, such as NSAIDs, glucocorticoids, calcineurin inhibitors, chemotherapeutic agents, and others, are used to intentionally induce immunosuppression or reduce inflammation. Conversely, hematopoietic stem cell factors, including GM-CSF, are used to promote a more vigorous immune response. A great many of the drugs that are used in the course of daily ICU care, however, have occult immunologic properties. While these drugs are being used for other purposes, it is likely that their cumulative effects modulate the host immune response in unintended ways. Representative drugs and their immunologic effects are listed in Table 4.5.

Table 4.5 Immunologic effects of commonly used ICU medications

Drug/class of drugs	Potential effect on the inflammatory response	Mechanism
Antibacterial agents	Potentiation	Release of bacterial components at the time of cell death
		Direct enhancement of intracellular killing (β-lactams)
	Attenuation	Bone marrow suppression (β-lactams)
		Decreased pro-inflammatory cytokine production (macrolides)
Benzodiazepines	Attenuation	Upregulation of the endogenous cortisol axis
Catecholamines[a]	Potentiation	Stimulation of α-adrenergic receptors
	Attenuation	Stimulation of β-adrenergic receptors
Furosemide	Attenuation	Reduced production of pro-inflammatory cytokines by mononuclear cells
Insulin	Attenuation	Indirect reduction in hyperglycemia-induced pro-inflammatory cytokine production
		Direct inhibition of the NFκB pathway
Opiates	Attenuation	Suppression of IFN production
		Induction of lymphocyte apoptosis
		Induction of macrophage apoptosis
		Induction of TGFβ

[a]In the event that both α and β receptors are stimulated (e.g., epinephrine), the immunologic β effects predominate

4.13 Summary and Future Directions

It is now clearly recognized that the balance between pro- and anti-inflammatory forces is crucial in critical illness and that imbalances in either direction increases the risk for adverse outcomes. Patients who suffer an inflammatory insult do not predictably benefit from therapies aimed at reducing inflammation. Rather, surveillance for, and reversal of, immunoparalysis represents a personalized medicine approach that has the potential to restore immunologic balance in critically ill children. The bulk of the work done in this area has focused on the restoration of innate immune function. The restoration of the adaptive immune response in immunoparalysis is beginning to be studied in septic adults. A dose-finding clinical trial of an antibody targeting programmed death ligand (PD-L)-1 was recently conducted, demonstrating that high-dose

anti-PD-L1 therapy could achieve receptor saturation and may improve immune function. Randomized controlled trials of drugs designed to preserve or enhance lymphocyte function (including targeting of the PD-1 pathway) are still needed in critically ill adults and children. Lastly, most of the tests that are performed to measure inflammatory mediators and to survey for immunoparalysis are limited to research use only. Following larger clinical trials, it will be necessary to move these tests to the clinical laboratory in order to bring therapies targeting restoration of immune function in critical illness to the bedside.

Review Questions

1. The innate immune system is notably different from the adaptive immune system in that innate immune cells:
   A. Do not express toll-like receptors on their surfaces
   B. Produce T_H2-like cytokines upon initial interaction with endotoxin
   C. Require thymic selection to prevent self-reactivity
   D. Respond more vigorously to antigen with repeated exposures
   E. Are typically the cells which initiate the immune response to pathogens

2. The pro-inflammatory mediator or signaling molecule which is *incorrectly* matched with its inhibitor is:
   A. C3a: C5a
   B. NFκB: IκBα
   C. STAT1: SOCS1
   D. MAP kinases: phosphatases
   E. IL-1β; IL-1ra

3. Inhibiting the action of the following mediators of inflammation in the plasma has resulted in consistently improved outcomes in the setting of sepsis:
   A. TNFα
   B. IL-1β
   C. Bradykinin
   D. LPS
   E. None of the above

4. The state of immunoparalysis is characterized by all of the following *except*:
   A. Association with the compensatory anti-inflammatory response syndrome
   B. Reduced monocyte HLA-DR expression
   C. Impaired production of TNFα upon ex vivo whole blood stimulation with LPS
   D. Irreversibility
   E. Association with mortality in the ICU

5. Which of the following drugs has been used for the purpose of immunomodulation in children with hyperferritinemic sepsis?
   A. IFNγ
   B. GM-CSF
   C. Anakinra
   D. Activated protein C
   E. Tacrolimus

Answers

1. E

   Innate immune cells, including PMNs, monocytes, macrophages, dendritic cells, and NK cells, are typically the immune effector cells which first recognize pathogens and initiate the inflammatory response. They do so by virtue of cell-surface receptors such as the toll-like receptors, which recognize pathogen-associated molecular patterns. The activation of the innate immune response is not associated with a memory response. Immunological memory is a feature of the adaptive immune system. The cytokines produced by innate immune cells upon initial exposure to endotoxin include TNFα and IL-1β. These cytokines are typical of T_H1 polarization. T lymphocytes undergo positive and negative selection in the thymus to minimize self-reactivity.

2. A

   Unregulated inflammation would quickly result in the death of the host. Accordingly, inhibitory pathways have evolved to provide negative feedback for most pro-inflammatory systems. IκBα, the SOCS family of proteins, and phosphatases serve as important negative regulators of the NFκB, JAK/STAT, and MAP kinase signaling pathways, respectively. IL-1ra is an example of a circulating inhibitor that competes with IL-1β for receptor binding. The complement system likewise is inhibited by an array of molecules, including the cell-surface proteins CR1, MCP, and DAF along with circulating inhibitors, such as factor I, factor H, and C4-binding protein. C3a and C5a are both anaphylatoxins, cytokines which result in increased vascular permeability, increased endothelial molecule expression, and phagocyte recruitment.

3. E

   Reduction in plasma concentrations of, or inhibition of receptor activation by, all of aforementioned mediators has been attempted in the setting of sepsis. Administration of anti-LPS IgG (pooled), murine monoclonal anti-LPS antibodies, recombinant IL-1 receptor antagonist, a bradykinin receptor antagonist, and anti-TNFα antibodies has not resulted in consistently reproducible improvement in mortality in the setting of sepsis. Evidence exists that a subset of patients with particularly pronounced inflammation may benefit from anti-TNFα antibodies, but their use is currently not the standard of care.

4. D

   Immunoparalysis represents an exaggerated compensatory anti-inflammatory response, which is characterized by reduced monocyte HLA-DR expression (with <30% of circulating monocytes being strongly HLA-DR positive) and reduced production of TNFα upon ex vivo stimulation of whole blood with LPS. A persistent state of immunoparalysis has been associated with increased mortality, persistent organ failure, and the development of secondary infection in adults and children. Immunoparalysis has been shown to be reversible through the tapering of exogenous immunosuppression or administration of T_H1-like cytokines, including IFNγ and GM-CSF. Evidence for the clinical benefit of the reversal of immunoparalysis is currently limited to small case series.

5. C

Anakinra, or recombinant IL-1 receptor antagonist, is part of some treatment regimens for HLH/MAS and has been used in children with hyperferritinemic sepsis. It targets IL-1β production by overactive macrophages and reticuloendothelial cells and may reduce symptoms of hyperinflammation in this setting. IFNγ and GM-CSF are both T_H1 cytokines that can be administered in recombinant form for the reversal of immunoparalysis. Neither activated protein C nor tacrolimus has a role in the management of sepsis or HLH/MAS.

Learning Objectives

- Understand the nutritional requirements of healthy children and how these are modified for critically ill children in the PICU.
- Be able to utilize available formulas and methods to determine caloric and protein needs of PICU patients.
- Be able to make appropriate choices for the provision of nutritional support to patients based on their disease state and clinical status.
- Be able to apply appropriate means for evaluating adequacy of nutritional support and make clinically relevant adjustments.
- Understand the principles of nutritional support for patients with specific disease states such as intestinal insufficiency, liver disease, renal insufficiency, as well as the principles of immunonutrition.

5.1 Nutrition in Healing

Malnutrition is common among PICU patients.

Provision of appropriate nutrition to ill children is fundamental to their recovery. Earlier studies have found that up to one quarter of children in the PICU are malnourished on admission or become nutritionally deprived during admission. Malnutrition in the PICU—whether premorbid or iatrogenic—is associated with longer hospital stays and poor outcome. Moreover, data suggest that malnutrition, either acute or chronic, is associated with physiological instability including impaired immune function and impaired ventilatory drive resulting in the need for increased quantity of care. Caloric intake to provide the body with sufficient energy to perform cellular activity, adequate protein intake for maintenance of cellular function and wound healing, and specific nutrients for biochemical functions are necessary in providing comprehensive care of the ill or injured child. In addition, the growth needs of children must be recognized and accounted for in providing protein, energy and nutrients. However, barriers to providing adequate nutrition exist in the critical care setting. These barriers include the need for fluid restriction, gastrointestinal intolerance (e.g., emesis, residuals, diarrhea), interruption of feeds for procedures, and hemodynamic, respiratory, or metabolic instability which may delay initiating nutritional support.

5.2 Determining Nutritional Needs

5.2.1 Energy

Metabolism downregulates in simple calorie malnutrition but increases in malnutrition associated with critical illness.

Calorie requirements are composed of the resting energy expenditure (REE), also known as basal energy expenditure (BEE), and the additional energy needed for activity, growth, and, in the ill child, healing from wounds or disease. A healthy child in the well-fed state favors anabolism and growth with high levels of insulin and growth hormone and low levels of glucagon and other counter-regulatory hormones. In individuals deprived of calories and nutrients, the metabolic machinery of the body downregulates, thereby effectively reducing energy expenditure to conserve fuel and ameliorate weight loss. Initially, glycogen stores (in the liver and skeletal muscle) are consumed to readily provide glucose. Later in the process of calorie malnutrition, ketones are synthesized from the oxidation of fat stores, producing ketone bodies which can be used for energy by most tissues. However, some body cells and tissues such as red and white blood cells and the myocardium require glucose for energy, necessitating consumption of amino acids from somatic (muscle) and visceral (organ) protein for gluconeogenesis. This process results in muscle wasting, visceral protein compromise, and excessive nitrogen loss.

Obesity is an increasingly prevalent issue for patients of all ages and can be a significant comorbidity in intensive care situations. Obesity in the pediatric critical care unit has been associated with higher risk of hospital-acquired infections, longer length of stay, and mortality although this assertion is disputed elsewhere in the literature. Assessing the calorie needs of obese children in the critical care unit is challenging and can result in over- or undernutrition when standard formulas are used.

In critically ill patients in the PICU with increased metabolic stress, high levels of counter-regulatory hormones (glucagon and cortisol) counteract the normal energy-conserving compensatory mechanisms resulting in accelerated loss of energy stores. Historically it had been assumed that ICU patients have increased calorie requirements. However, studies in both adults and children have not supported this concept. In fact, the adult critical care literature consensus as well as the most recent (2016) joint American Society for Parenteral and Enteral Nutrition (ASPEN) and Society of Critical Care Medicine (SCCM) guidelines caution against overfeeding calories to the critically ill adults. Indeed, two small pediatric ICU studies, utilizing indirect calorimetry (see below) for measurement of energy expenditure, demonstrate frequent overprescription of calories for critically ill children. However, practice in Pediatric Critical Care Medicine remains divided as to whether the critically ill patient in the PICU requires more or less energy than would be predicted by common measures applied to healthy children.

In practical terms, the determination of calorie requirements for individual PICU patients is challenging and fraught with inaccuracy. From the most technically demanding measures using indirect calorimetry to simple tables and equations based on anthropometric data, many methods exist for estimating calorie requirements, and all have limitations. However, an effort must be made early in the course of illness to determine the energy needs of each patient, to set nutrition goals, and to attempt to attain them.

There is no consensus regarding whether pediatric patients in the ICU have increased or decreased calorie needs over baseline. Factors that contribute to increased calorie need are head trauma and older age; factors that predict lower calorie need are younger age and the use of muscle relaxants.

5.2.2 Calorimetry

Indirect calorimetry involves the measurement of resting energy expenditure (REE) by measuring the difference in oxygen (O_2) and carbon dioxide (CO_2) contents between a known volume of inspired and expired air. This method, although considered the most accurate, is technically demanding and time-consuming, involves the use of expensive specialized equipment that is not universally available, and requires trained personnel. In order to obtain accurate information, the patient must be on a ventilator with stable ventilator settings during the period of measurement. The accuracy of the measurement is impaired when the patient requires a fraction of inspired oxygen (FiO_2) of 0.6 or greater and if there is endotracheal tube leak. In addition, the test assumes stable energy utilization throughout the analysis. The patient should be at rest without active nursing care or transports during the measurement. The device will measure oxygen utilization (VO_2) and carbon dioxide production (VCO_2) and calculate the REE using the modified Weir equation:

$$\text{REE} = \left[\text{VO}_2 \left(3.941\right) + \text{VCO}_2 \left(1.11\right) \right] \times 1440\,\text{min}$$

where REE is in Kcal/day and VO_2 and VCO_2 are measured in ml/min. Guidelines for the use of REE measurement in critically ill children include recommendation for indirect calorimetry in specific critically ill populations, including mechanical ventilation greater than 7 days, greater than 10% weight gain or loss during critical illness, and anticipated hypermetabolic or hypometabolic states.

The most accurate method for evaluating patient energy requirement is using indirect calorimetry, which measures oxygen utilization and carbon dioxide production to determine calories.

5.2.3 Respiratory Quotient

The results of the calorimetry measurement can also be used to determine the respiratory quotient (RQ). This is a measure of the ratio of expired CO_2 produced to inspired O_2 consumed. This ratio estimates the state of calorie usage in the patient. RQ represents a combination of various ratios of oxidative and reductive processes. It is specific and constant for the oxidation of fat, carbohydrate, and protein as well as lipogenesis. The metabolism of carbohydrates, for example, results in an RQ of 1.0 (for every carbon dioxide molecule produced, one oxygen molecule is utilized), whereas the RQ for the metabolism of lipid approaches 0.6, and the RQ for protein alone is 0.8. A typical mixed diet results in an RQ of approximately 0.8.

$$RQ = VCO_2 / VO_2$$

A nutrition regimen of higher fat content will result in a lower RQ, which may be advantageous for patients with CO_2 retention and difficulty weaning from the ventilator. A diet high in carbohydrates results in an RQ closer to 1.0 and, therefore, should be avoided in problematic hypercarbia.

5.2.4 Fick Equation

An alternative method for measuring caloric utilization is based on the Fick equation, which uses the cardiac output determined from a pulmonary artery (PA) catheter, the hemoglobin concentration, and the arterial and venous oxygen concentrations to calculate the REE:

$$REE = CO \times Hb \times \left(SaO_2 - SvO_2\right) \times 95.18$$

where REE is calculated in Kcal/day, CO is cardiac output in L/min, Hb is hemoglobin in g/dL, and SaO_2 and SvO_2 are the arterial and venous oxygen saturations, respectively.

Given the infrequency that PA catheters are utilized in pediatric critical care, this option remains a theoretically interesting but impractical alternative. With newer technologies, such as PiCCO, such measurements are more feasible, but this application has not been evaluated.

Measuring calorie needs by indirect calorimetry or by using PA catheter data, while perhaps more accurate, is cumbersome, and most PICUs do not have the machinery necessary. However, recently, a calculation to determine calorie needs based on VCO_2 alone has been developed and validated.

$$REE = 5.5 \times VCO_2 \times 1440$$

Here, REE is measured in Kcal/day and VCO_2 is measured in L/min. The advantage of this formula is that VCO_2 can be obtained from the most modern ventilators, and so this accurate estimation of energy needs can be done on any ventilated patient.

5.2.5 Formulas and Tables

Standard dietary guidelines are an appropriate starting point for determining micronutrient needs.

Recognizing that indirect calorimetry requires expensive machinery and technological capability, perhaps the most useful, inexpensive, and widely applicable method to determine the calorie needs of a child is to employ population-based tables (see Table 5.1). These tables are based on population studies of healthy persons and provide a rough guideline for initiating a

Table 5.1 Currently available methods to determine the estimated calorie needs of children and adults

Reference	Subject age (years)	Subject #	Site	Equations	Factors
World Health Organization	0–3	>11,000	Data taken from previously published work in developed and underdeveloped countries	Male: 60.9(W) – 54	Weight, age, gender

				Female: 0.034(W) + 0.006(H^*) + 3.530	
	>60			Male: 0.038(W) + 4.068(H^*) – 3.491	
				Female: 0.033(W) + 1.917(H^*) + 0.074	

Calorie estimation can be based on age, height, weight, and sex. The most commonly used formulas are provided. In practice, a factor is included to account for normal daily activity. The other formulas listed are for total calorie expenditure per day. *A* age in years, *W* weight in kg, *H* height in cm, H^* height in m

nutrition plan for the patient in the PICU. Reliable sources include the World Health Organization (WHO) data and the Schofield formula. However, recent recommendations discourage the use of "stress factors" with these tables as this often leads to over calculation of calorie requirements and overfeeding in patients who may be hypometabolic. Two small studies utilizing indirect calorimetry in critically ill children demonstrated overfeeding in 60% and 80% of

children with calorie prescription guided by standard equations. Indeed, no available formula or table is able to accurately take into consideration whether the patient is in a hyper- or hypometabolic state or account for medical interventions, such as mechanical ventilation, inotropes, neuromuscular blockade, and sedation. While the Harris Benedict equation and the United States Recommended Dietary Allowances are also readily available for establishing calorie needs in children, their use is not recommended in the critical care setting as they provide data for healthy children only. Despite these limitations, formulas and tables are simple to use and require no equipment more complicated than a measuring tape or scale. Moreover, the application of these simple methods provides health-care providers with a starting place and a goal for nutritional support.

5.3 Protein and Nitrogen Balance

Calculation of nitrogen balance can be used to determine protein requirements.

Because of the potential hypermetabolic state of critically ill children and the hormonal milieu favoring catabolism, it is anticipated that these patients will be consuming somatic and visceral protein to supply increased enzyme and energy needs. As with overall energy needs, determination of protein requirements is equally challenging and similarly controversial. As a rule, a minimum of 1.5 grams of protein per kilogram of lean body mass is recommended. The USRDA (1989) and WHO tables based on healthy children provide estimates but, unfortunately, less accurate estimations than can be obtained using more sophisticated techniques. For example, a more accurate method for determining protein requirements in the hospitalized child is to measure nitrogen balance. This method determines nitrogen loss by measuring 24-hour urinary nitrogen in combination with estimates of gastrointestinal nitrogen excretion. This result is used to extrapolate protein utilization and, thus, protein requirement. Patients with exposed dermis or weeping wounds and excessive gastrointestinal losses and patients on renal replacement therapy, dialysis, or plasmapheresis will have nitrogen losses that cannot be accounted for. As with overall caloric determination, the dynamic nature of the critically ill child mandates frequent reassessment to determine protein intake requirement regardless of the method used.

Calculation of protein requirement via urinary nitrogen is based on the concept that most nitrogen excreted from the body is a result of protein turnover. The bulk of this excretion occurs from the kidney in the form of urea, which is synthesized from nitrogenous waste in the liver. Protein is approximately 16% nitrogen by weight; therefore, every gram of nitrogen in the urine represents 6.25 g of protein broken down. In addition to urinary nitrogen loss, nitrogenous waste in the stool must be estimated. Protein loss from surgical, traumatic, and burn wounds cannot be directly measured and must be estimated empirically. Normally, nitrogen balance should approach zero. The discrepancy between intake and output should be addressed by adjusting protein content of the diet.

Of importance, as well, is the nonprotein calorie to nitrogen ratio (NPC:N_2). This simple calculation compares the calories from fat and carbohydrate with the total nitrogen content of the feeding (either parenteral or enteral). The equation is as follows, where the subtraction of 4 converts from total calories to nonprotein calories per gram of protein in the prescribed tube or intravenous preparation:

$$\text{NPC} : \text{N}_2 \text{ ratio} = \left(\text{total calories per gm protein} - 4\right) \times 6.25 \,\text{gm protein}$$

Outside of critical illness, the ratio, which is effectively a measure of the number of calories required to appropriately metabolize a gram of nitrogen, is 150:1–250:1 and should not fall below 100:1. At lower levels, the amino acids in the protein will be catabolized to provide calories, and the nitrogen will be discarded adding to the nitrogen stress of the patient. A recent randomized controlled trial of protein supplementation in critically ill children showed positive nitrogen balance only in the protein-supplemented group (3.1 gm/kg/day) compared with controls (1.5 gm/kg/day) with calories held constant. Of interest, the NPC:N_2 ratio was 129 in the protein-supplemented group compared with 256 in the standard formula group. This is consistent with the preponderance of evidence in adult critical care nutrition studies and current SCCM/ASPEN guidelines focusing on protein intake to achieve positive nitrogen balance in critical illness.

5.4 Micronutrients

The provision of additional vitamin C, zinc, and selenium promotes wound healing and increases antioxidant capacity.

Micronutrients include vitamins and minerals. These are essential as cellular intermediaries, enzyme cofactors, and antioxidants and are often deficient in critically ill children. Guidelines for the provision of micronutrients in critical illness in children are lacking. In general, micronutrient needs are best met using standard formulations, which usually approximate recommended dietary allowances. The assessment of nutrient deficiencies in critically ill patients is difficult given the variety of metabolic stresses, increased nutrient losses, decreased nutrient absorption, disordered nutrient distribution, and disordered homeostasis. For some minerals, such as calcium, phosphorus, and magnesium, plasma levels can and should be used to determine individual patient needs. Iron, copper, and zinc levels are measured much less frequently; however, supplementation of these and most other vitamins and trace elements is done on an empiric basis.

Micronutrients of particular interest in the PICU patient include those that have antioxidant properties and those that promote wound healing. Critically ill patients are known to have increased oxidative stress, exogenously, from exposure to high doses of oxygen via mechanical ventilation or supplemental oxygen, and endogenously, from the generation of free radicals in the face of injury and inflammation. In addition, wound healing, whether from trauma, surgical procedures, or decubitus ulcers, is dependent on specific nutrients. While the administration of a multivitamin to provide the recommended dietary allowance of all essential vitamins and minerals is a widely accepted practice in PICU care, extra supplementation of some nutrients may be advisable. *Vitamin C* has many biochemical functions including collagen formation, biosynthesis of bile and catecholamines, and antioxidant properties, all of which are beneficial for the recovering patient. Vitamin C levels have been shown to be low, and turnover increased in patients with critical illness; therefore, supplementation of vitamin C above the standard dose is advisable. *Vitamin E* functions as an antioxidant and is useful in maintaining cell membrane integrity as well as cellular immunity. The recommendation for the dose of vitamin E supplementation is controversial; however, supplying at least the RDA is considered prudent. The *selenium* requirement increases in critical illness as a result of increased cellular uptake and increased urinary loss. Supplementation of selenium (2 micrograms per kilogram per day) is recommended. *Zinc* is known to assist in wound healing in burn patients; zinc supplies in the critically ill patient are generally low as a result of increased urinary losses. In addition, patients with poor wound healing and burns have been found to have

low tissue zinc levels, and zinc supplementation has been associated with improved lymphocyte counts in critically ill children. Zinc supplementation, therefore, is prudent in critically injured patients, particularly those with wounds or bodily injury. In summary, a multivitamin with trace minerals (enteral or IV) should be standard protocol for all PICU patients with additional zinc, selenium, and vitamin C provided. *Vitamin D* deficiency has been studied recently as a cofactor in poor outcomes in the PICU due to its important role in macrophage, lymphocyte, and epithelial cell function. Vitamin D deficiency is common among critically ill children and correlates with increased severity of illness.

5.5 Immunonutrition

Immunonutrients such as nucleotides, lactoferrin, omega-3 fatty acids, arginine, and glutamine may enhance immune health but have not been found to improve outcomes in ICU patients.

One of the more interesting lines of research in this area is the idea of "immunonutrition," which posits that critically ill patients have immune dysregulation and that provision of particular nutrients may improve immune function, and infectious complications have been shown to be reduced in adult patients receiving formulas with immune-promoting components. These components include nucleotides, omega-3 fatty acids, glutamine (thought to be specifically protective of gastrointestinal mucosa), and arginine, a precursor of nitric oxide. In addition, probiotics and lactoferrin are considered beneficial in the immune health of infants and children. Although early research using these principles is promising, a meta-analysis of available literature does not support the claim of improved survival in patients given a formula rich in the so-called immunonutrients. The most recent critical care nutrition guidelines for adults from SCCM and ASPEN do encourage the use of certain micronutrients in selected circumstances (e.g., omega-3 fatty acids in traumatic brain injury).

5.6 Monitoring

Serum prealbumin and retinol-binding protein are more accurate measures of visceral protein stores than albumin and are not affected by fluid status.

The monitoring of the overall nutritional status of the outpatient is usually achieved with basic height and weight measurements over time and comparing these to national standards. While this is sufficient for the ambulatory patient, in the PICU, these measurements have limited value. Weight is highly variable from day to day in the critical care setting, and it is influenced by non-nutritional factors, such as fluid state and wound dressings, monitor leads, and other equipment. Although older children are not typically in the PICU long enough for stature to be a useful metric for acute nutritional status, in infants, length and head circumference should be measured and plotted on standard growth curves on a regular basis with the goal of maintaining a normal pace of growth. Other less commonly performed anthropometric measurements, such as arm circumference and triceps skinfold, are prone to inaccuracy in critically ill patients as these can be affected by edema.

In addition to determining nitrogen balance as previously described, the measurement of visceral proteins is a useful surrogate for protein status in the acutely ill patient. Typical visceral proteins measured are albumin, prealbumin and retinol-binding protein. The value of serum albumin measurements as a nutritional parameter is limited because of its long half-life and because these levels are influenced by the hydration status of the patient and whether exogenous albumin has been used as a volume enhancer. Other serum proteins such

as ferritin and transferrin will fluctuate widely in the face of acute inflammation and injury. Prealbumin and retinol-binding protein have been thought to be more accurate measures of visceral protein stores however they too can be influenced by physiologic factors. Prealbumin, which is named because of its proximity to albumin on an electrophoretic strip, functions in the transport of thyroxine and has a half-life of 24 to 48 hours and is more commonly used in nutrition evaluation. It is produced in the liver, and as such, its concentration may be decreased in liver disease. Prealbumin levels will be suppressed in response to systemic inflammation as a sign of acute catabolism. A consensus statement from the Academy of Nutrition and Dietetics (AND) and ASPEN noted that prealbumin is an indicator of inflammation and lacks the specificity to diagnose malnutrition. Indeed, studies have demonstrated a negative correlation between C-reactive protein (CRP) and prealbumin levels. Nevertheless, prealbumin level can be used as a surrogate for nitrogen balance, measuring visceral protein synthesis, during recovery as systemic inflammation subsides and nutritional repletion is established. One additional caveat to the use of prealbumin is its elevation in response to pharmacological doses of corticosteroids, disassociating its level (at times quite high) from overall nitrogen balance. The total lymphocyte count has been historically found to fluctuate with nutritional status and so can be used to assess nutritional status. However, in patients with immunodeficiency, either innate or acquired, a more and more common comorbidity in the PICU, low lymphocyte counts may not reflect nutritional status alone. In patients on parenteral nutrition, daily measurement of minerals, such as electrolytes, calcium, phosphorus, and magnesium, is essential in order to make appropriate adjustments to their formula. The measurement of other micronutrient levels and trace minerals should be performed based on the clinical features of the patient.

5.7 Glycemic Control

Hyperglycemia is seen in critically ill adults and children. Historically, this was accepted as a compensatory hormonal response to illness, and glucose levels in the 200 mg/dL range were accepted. Earlier studies demonstrated improved outcomes in adult ICU patients when glycemia was more tightly controlled with insulin. However, an international, multicenter trial (NICE-SUGAR Study) that randomized over 6000 critically ill adults to either tight glucose control (target glucose level 81–108 mg/dL (4.5–6.0 mMol/L)) or conventional therapy (target glucose level less than or equal to 180 mg/dL (10.0 mMol/L)) found that tighter glucose control resulted in increased mortality. More recent studies have had varying results with some indicating a benefit to tight glycemic control while a meta-analysis evaluating glycemic control indicated increased incidence of hypoglycemia in treated patients and no benefit with regard to mortality or acquired infections. Some post hoc analyses of the studies have pointed out the high use of TPN, contributing 87% of calories, in the studies purporting to demonstrate benefit, suggesting that TPN-related hyperglycemia may have increased mortality in the control groups. The prospective randomized controlled trial of tight glucose control in 35 pediatric intensive care units (HALF-PINT Study), performed in conjunction with the Pediatric Acute Lung Injury and Sepsis Investigators Network (PALISI), noted a higher rate of complications and no benefit of tight glucose control in children. Clinical equipoise is recommended when employing this strategy.

5.8 Nutrition Delivery

In general, the literature supports early initiation of enteral or parenteral nutrition for critically ill children in the PICU. The advantages of this practice include maintenance of gastrointestinal integrity, reduced incidence of multiorgan dysfunction, and reversal of a hypermetabolic state, and clinical studies typically show a correlation between early nutrition and improved outcomes. However, in the most acutely ill patients, there is evidence that nutrition may not be useful because the patient is highly catabolic and cellular metabolism is counter-regulatory with evidence of insulin resistance. In this scenario, nutrient supplies go unused and hyperglycemia may result. Nevertheless, given the preponderance of evidence in the literature supporting early feeding and recognizing that advancing to full calories may take several days, early feeding of patients in the PICU is encouraged whenever feasible.

5.9 Enteral Nutrition

Either parenteral or enteral nutrition can be used safely in the PICU; however, the preponderance of evidence suggests that enteral nutrition is superior.

Various studies have been conducted examining the risks and advantages of enteral nutrition with overwhelming support for use of the enteral route whenever possible. An earlier meta-analysis of the adult literature assessing the use of parenteral versus enteral nutrition found that nutritional outcomes between the groups were similar (nitrogen balance, weight gain); however, the enteral group had fewer overall complications. More and more, in pediatrics, early enteral nutrition is favored.

The advantages of enteral nutrition include the maintenance of gastrointestinal health, its ease, and its low expense. The provision of feedings directly to the gastrointestinal mucosa has been found to maintain brush border enzyme integrity and prevent gut atrophy. This results in the prevention of translocation of enteral bacteria, which may result in sepsis. Also, enteral feedings reduce cholestasis and promote normal hepatic and portal vein function. In addition, supplying nutrients directly to the alimentary tract allows the body to regulate nutrient intake using natural feedback mechanisms.

Nevertheless, there are contraindications to the use of enteral nutrition in the critically ill patient. The so-called absolute contraindications include mechanical failure of the gastrointestinal tract including ileus, bowel obstruction, gastrointestinal bleeding, and simple intolerance of feedings. Conditions of decreased gut profusion, such as infantile coarctation of the aorta, with compromised intestinal perfusion, also represent a contraindication to enteral feedings. In addition, most practitioners have a list of relative contraindications to feeding the gastrointestinal tract, which may include the use of vasopressor infusions, such as epinephrine, norepinephrine, or vasopressin, pancreatitis, recent hypoperfusion states such as hypotension and shock, lack of airway protection, or postoperative patients undergoing facial reconstruction for whom emesis could be dangerous or injurious to surgical wounds. Recent data suggest that the danger of enteral nutrition in patients on vasopressors is unfounded and that these patients tolerate enteral feeding with no difference in adverse outcomes. Patients on ECMO are successfully fed enterally, but their gastrointestinal health must be closely monitored as gut perfusion may be compromised on bypass.

Enteral feedings can be supplied via the stomach or the small bowel. Nasogastric tubes can be easily placed at the bedside and are typically well tolerated. When this is not possible, such as with gastric dysmotility, a transpyloric tube can be inserted nasally by bedside personnel or under fluoroscopy in interventional radiology.

5.10 Enteral Formulas: Standard

Enteral nutrition is supplied either orally in the healthier patients or through nasogastric, naso-duodenal (jejunal), or surgically placed enterostomal devices. The placement of a nasal feeding tube is inexpensive, relatively easy, and minimally traumatic to the patient. The wide variety of enteral formulations on the market worldwide facilitates tailoring the formula to the specific needs of the child. A dietitian on the PICU team can be of great value in determining the best formula for a particular patient.

Standard pediatric enteral nutrition formulas contain approximately 45–55% of calories as carbohydrate, 34–43% as fat, and 12% as protein.

Patients who lack specific digestive and absorptive deficiencies (i.e., normal digestion) should be started on standard age-appropriate formulas. There are a multitude of infant and child formulas available, which contain the appropriate proportions of calories to protein and micronutrients. In addition, expressed breast milk can also be provided for infants via an enteral tube. Most formulas are cow milk based and contain a greater proportion of protein from whey than from casein to mimic human breast milk. Most of these formulas also contain added taurine, which is a provisional essential amino acid for infants. Nutrition supplements for children are similarly formulated to meet the needs of the healthy ambulatory child. Thus, a typical standard tube feeding formula available for critically ill children is one formulated for healthy infants and children. It will be fortified with essential vitamins and minerals and contain approximately 45–55% of calories from carbohydrate, 34–43% from fat (including the essential fatty acids arachidonic, linoleic, and linolenic acids), and 12% from protein. The specific ingredients and age-appropriate nutrient variations differ among manufacturers. However, these standard pediatric formulas are relatively low in protein for the critically ill child. While there are a number of tube feeding formulas for critically ill adults, which can be used in the older child or adolescent, there are no tube feeding formulas developed for the critically ill infant and toddler. Most currently available pediatric tube feeding products have 12% calories from protein (i.e., 3 gm protein per 100 cal) and possess a NPC:N_2 ratio of 183, much higher than what is reported in the recent studies demonstrating benefit of protein repletion in critically ill children. Some centers add protein supplements to the tube feedings of all critically ill children who are receiving standard pediatric products.

Standard pediatric tube feeding formulas contain relatively low amounts of protein and are often supplemented with additional protein.

5.10.1 Enteral Formulas: Modified

Patients with macronutrient malabsorption, either anticipated or documented, may require a formula with contents altered to circumvent the deficiency. In patients with known pancreatic insufficiency (e.g., cystic fibrosis, pancreatitis), formulas that contain peptide and medium-chain triglycerides to bypass the pancreatic enzymes trypsin and lipase may be better tolerated in the acute setting. A continuum of levels of protein hydrolysis from large peptides to amino acids is available in the commercially available products and can be used in a variety of settings, such as protein intolerance (protein-losing enteropathy), protein allergy, and suspected gut atrophy. Patients with liver failure or cholestasis may require a greater concentration of medium-chain triglycerides, which bypass the biliary/micellar fat absorption system. Similarly, patients with chylothorax or chylous ascites require a formula with low fat content and/or a high percentage of fat as medium-chain triglycerides. However, in the setting of fat intolerance, care must be taken to supply a minimum of essential fatty acids to prevent deficiency.

5.10.2 Enteral Formulas: Specialized

Specialized formulas for specific disease states have been created and are commercially available. Specifically, nutritional supplements for patients with renal failure exist which are low in protein, high in caloric density, and with vitamin and mineral profiles, which complement the needs of the patient in renal failure whether or not they need dialysis. However, current SCCM/ASPEN guidelines for adults recommend not to restrict protein intake in the presence of acute kidney injury. For diabetics and critically ill patients who have problems with glycemic control, there are formulas, which are low in carbohydrate and higher in fat, with a formulation that optimizes the glycemic response. For patients with chronic pulmonary disease, cystic fibrosis, or acute respiratory distress syndrome, there are formulas which provide a high fat content and, therefore, provide a favorable RQ to decrease carbon dioxide retention. More rarely, patients with intestinal brush border enzyme deficiencies and inborn errors of metabolism will require highly specialized elimination formulas and should be referred to a dietitian and appropriate medical specialists.

5.10.3 Probiotics

The use of probiotics has gained a great deal of favor among pediatricians, who use these products to ameliorate the changes in gut microbiome in patients under treatment with antibiotics. The use of probiotics in the PICU has similarly gained favor. One study showed that in septic patients, the use of probiotics correlated with decreased pro-inflammatory cytokines and increased anti-inflammatory cytokines. While there have been other studies showing that the use of probiotics offers advantages to certain critically ill children by reducing nosocomial diarrhea and treating acute gastroenteritis, expert opinion suggests that it should not be employed broadly, and caution is indicated particularly for immunocompromised patients and those with central venous lines (related to specific components of some products).

5.10.4 Parenteral Nutrition

Frequent monitoring of serum electrolytes is necessary in patients receiving total parenteral nutrition.

For patients who cannot receive adequate enteral nutrition, parenteral nutrition is considered a safe and effective alternative. A great many variables must be assessed in preparing the parenteral nutrition formulation to assure that the correct amounts of electrolytes and calories are administered in the appropriate fluid volume. The process of ordering parenteral nutrition begins with determining the fluid needs of the child. Next, the number of calories to be supplied from lipid and dextrose is determined. Glucose delivery should not exceed 6 mg/kg/min in younger children or 4 mg/kg/min in older children and adults, although actual thresholds should be guided by frequent measurements of serum glucose levels. Care should be taken in prescribing pro-inflammatory soy-based intravenous fat emulsion (IVFE) in critically ill children with systemic inflammation. While there is no specific pediatric data, the evidence of harm from adult studies is compelling. When using IVFE during the later stages of critical illness, monitoring of serum triglyceride levels is essential because hypertriglyceridemia may occur and elevated serum triglyceride levels are a contraindication to the use of lipids in parenteral nutrition. Protein needs,

usually ranging from 1 gram per kilogram in highly protein-restricted patients to 3.0 grams per kilogram in neonates or older pediatric patients with severe nitrogen loss, can be satisfied with standard amino acid formulas. However, latest SCCM/ASPEN guidelines for critically ill adults recommend against routine protein restriction in the presence of hepatic or renal failure. Data from the PEPaNIC trial suggests that late (after 7 days) initiation of parenteral nutrition is advantageous over starting on day one of admission. However, the feeding protocol followed by this group provided early soy-based IVFE in quantities greater than the amount of protein intake, an approach well outside SCCM/ASPEN recommendations for adults. Indeed, this is the same group that has been criticized for their overfeeding with TPN in the adult tight glucose control studies. Current SCCM/ASPEN guidelines for adults recommend against soy-based IVFE for the first 7 days of TPN, regardless of when TPN is started in the critical illness. The availability of alternative IVFE products with fat sources, including olive oil, fish oil, and medium-chain triglycerides, is likely to change the approach to timing of IVFE use and help in the prevention of essential fatty acid deficiency. One such product has been successfully used in some pediatric populations. Vitamins and trace minerals should be added daily with additional selenium, zinc, and other vitamins as needed for specific clinical scenarios. The assistance of dietitians, pharmacists, and other nutrition experts is helpful in developing the appropriate formulation of calories, electrolytes, and minerals. Daily laboratory evaluations must be performed to guide the appropriate administration of electrolytes including calcium, phosphorus, and magnesium and glucose.

5.11 Summary

Critically ill children in the PICU pose a challenge on many levels. The determination of nutritional needs and the provision of appropriate calories, protein, and other nutrients are essential for wound healing and recovery from critical illness. Despite a general paucity of literature specific to pediatric critical care, the preponderance of available studies and opinion as well as information extrapolated from the adult literature emphasizes the importance of adequate nutrition for these vulnerable patients and the risks of malnutrition. The wide variety of disease states, the high level of acuity, and the ever-changing clinical status of the PICU population provide a challenge for practitioners to provide the appropriate nutrition to each individual patient.

Review Questions

1. A 7-year-old male is admitted to the pediatric intensive care unit with respiratory failure secondary to severe restrictive lung disease. He requires intubation and mechanical ventilation. Despite multiple interventions, he continues to have severe hypercarbia that has been fairly well compensated for by his kidneys. Which of the following feeding regimens should be avoided in this child?
   A. One with a relatively high carbohydrate content
   B. One with a relatively high fat content
   C. One with a relatively high multivitamin content
   D. One with a relatively high protein content
   E. One with a relatively high sodium content

2. Which of the following vitamins/minerals contributes to the biochemical functions of collagen formation, biosynthesis of bile, and catecholamines and demonstrates antioxidant properties?
   A. Selenium
   B. Vitamin B12
   C. Vitamin C
   D. Vitamin E
   E. Zinc

3. A 9-year-old female with acute myelogenous leukemia has been admitted to the pediatric intensive care unit for a week with alpha-streptococcal sepsis. The child is neutropenic recovering from myelosuppressive chemotherapy. She has no other organ system failures with adequate renal and hepatic function. Her only medications include antimicrobials, granulocyte colony-stimulating factor, and a proton pump inhibitor. Which of the following markers of adequacy of nutrition would be most helpful in assessing the acute nutritional state of this critically ill child?
   A. Serum albumin concentration
   B. Serum ferritin concentration
   C. Serum prealbumin concentration
   D. Serum transferrin concentration
   E. Total lymphocyte count

4. Which of the following has been associated with fatty infiltration of the liver, increased metabolic stress, and pulmonary compromise characterized by difficulty in weaning from the ventilator as the result of an unfavorable respiratory quotient?
   A. Continuous jejunal feedings
   B. Essential fatty acid deficiency
   C. Overfeeding
   D. Protein malnutrition
   E. Total parenteral nutrition

5. Which of the following conditions would represent a contraindication to enteral feedings?
   A. Acute respiratory distress syndrome
   B. Gastroesophageal reflux disease
   C. Infantile coarctation of the aorta
   D. The use of extracorporeal membrane oxygenation
   E. Traumatic brain injury

6. A 4-month-old develops a persistent left-sided pleural effusion. Thoracentesis reveals a milky-colored fluid with a high concentration of lymphocytes and triglycerides. Which of the following nutritional plans would be most appropriate for this infant?
   A. A diet high in fat
   B. A diet low in fat
   C. A diet high in protein
   D. A diet low in protein
   E. A diet with a normal balance of carbohydrate, fat, and protein

7. A typical standard enteral formula for healthy infants and children contains approximately what percentage of calories from carbohydrates?
   A. 30%
   B. 40%

C. 50%
D. 60%
E. 70%

8. In beginning total parenteral nutrition in a critically ill infant, a reasonable initial glucose infusion rate would be which one of the following?
   A. 5 mg/kg/min
   B. 10 mg/kg/min
   C. 15 mg/kg/min
   D. 20 mg/kg/min
   E. 25 mg/kg/min

9. Which of the following statements is false about nutrition support during adult or pediatric critical illness?
   A. The largest multicenter study of tight glucose control in pediatric critical illness demonstrated no benefit of tight glucose control.
   B. The most recent SCCM/ASPEN guidelines for adults recommend protein restriction with critical illness acute kidney injury in order to prevent significant increase in BUN.
   C. Calorie prescription for critically ill children based on standard equations results in frequent caloric overfeeding.
   D. The limited evidence available from study of enteral feeding in critically ill children is consistent with SCCM/ASPEN guidelines for adults with regard to emphasis on protein.
   E. Current SCCM/ASPEN guidelines for adults recommend against soy-based IVFE for the first 7 days of TPN, regardless of when TPN is started in the critical illness.

10. A 14-year-old male was admitted 10 days ago following motor vehicle accident during which he sustained closed traumatic brain injury, pulmonary contusion, liver laceration, and femur fracture. He is recovering from his injuries with discontinuation of ICP monitoring, improved neurological exam, and no signs of infection. Enteral feedings were initiated on day 4. To provide more protein than available in the standard pediatric product, he was placed on the adult formulation which provides 4 gm protein per 100 calories. What is the NPC:N_2 ratio of his tube feeding regimen?
    A. 89
    B. 156
    C. 183
    D. 131
    E. 250

Learning Objectives

- Differentiate between the concepts of pharmacokinetics, pharmacodynamics, and pharmaceutics
- Describe basic pharmacokinetic constructs and identify variability for each in critically ill pediatric patients, including:
  - Absorption
  - Distribution
  - Metabolism
  - Elimination
- Compare and contrast first- and zero-order elimination kinetics
- Describe the effects that organ dysfunction may have on the kinetics of drug disposition
- Identify pharmacokinetic challenges related to the use of extracorporeal membrane oxygenation in critically ill pediatric patients
- Summarize the pharmacokinetic parameters that influence the disposition of drugs in patients undergoing continuous renal replacement therapy
- List drugs and/or drug classes that exhibit variable pharmacokinetic parameters in the obese pediatric patient
- Summarize the impact of therapeutic hypothermia on the pharmacokinetic profile of medications commonly used in critically ill pediatric patients
- Explain how pharmaceutical factors influence medication pharmacokinetics and pharmacodynamics

6.1 Introduction

Pharmacokinetics is the science of how the body acts on a drug, while pharmacodynamics is the study of how a drug acts on the body or microorganism.

Pharmacology is the study of exogenous chemicals and their actions within the body. The science of pharmacology encompasses pharmacokinetics, pharmacodynamics, and pharmaceutics. Pharmacokinetics involves understanding the movement of a pharmacologic substance throughout the body. By studying a drug's pharmacokinetics, one can understand what the body does to the drug. Pharmacodynamics describes the effects of a drug and its mechanism of action on a body or infecting microorganism. Pharmaceutics is the science of pharmaceutical systems that focuses on drug preparation and dosage forms. An understanding of the effects of both age and illness on drug kinetics and dynamics is crucial to the practice of pediatric critical care.

6.2 Pharmacokinetics

ADME stands for **a**bsorption, **d**istribution, **m**etabolism, and **e**limination; this acronym represents a standard organization for describing a drug's pharmacokinetic properties.

Pharmacokinetics (PK) deals with the processes of absorption, distribution, metabolism, and elimination (ADME). Once a drug is administered, it must then be absorbed through cell membranes and distributed into different compartments in the body. The drug may be metabolized at various stages of absorption, with the most common site of metabolism being the liver. Many drugs are inactivated by these metabolic processes, while others are transformed and/or activated into molecules with additional activity. Elimination describes how and where a drug (or its metabolite) is removed from the body. The collective ADME processes represent a standard method for describing the pharmacokinetics of any drug.

A drug's pharmacokinetics may be analyzed by compartmental or physiologic models. **Compartmental pharmacokinetics** utilizes mathematical models to describe drug distribution. Using these models, it is assumed that after a drug is absorbed it is distributed into a system of connecting compartments

that are not anatomically based; the rate of transfer into and out of each compartment is represented by a constant, k. A drug may distribute according to a single compartment or a multi-compartment model (Fig. 6.1).

Single compartment pharmacokinetic models assume a drug achieves instantaneous distribution and equilibration throughout all the body's tissues. It is important to appreciate that this model does not imply the concentration of the drug will be equal throughout the body but rather that changes in the plasma concentration of the drug will result in a proportional change in all tissues. A multi-compartment model describes the concentrations of a drug in different tissue compartments as determined by rate constants that are specific to the interface between two given compartments. In a multi-compartment model, the plasma (bloodstream) is typically considered to be the central compartment. An example of a drug that distributes in the body according to a three-compartment model is the general anesthetic propofol. After intravenous (IV) administration directly into the bloodstream, propofol rapidly distributes into the central nervous system (CNS) where it exerts its anesthetic effects; however, it also distributes more slowly into the peripheral tissues which may become saturated during prolonged infusions (Fig. 6.2). The rapid rate of transfer from the plasma (compartment 1) to the CNS (compartment 2) is defined by the rate constant, k_{12}. The slower rate of transfer to the peripheral tissues (compartment 3) is described by k_{13}. Propofol may also distribute from the CNS and peripheral tissues back into the plasma, defined by the rate constants k_{21} and k_{31}, respectively. In compartmental PK models, if two given tissue beds have similar transfer rates and concentration profiles, they may be considered a single compartment for simplification. Elimination from the central compartment may occur via a variety of mechanisms and is defined by a given elimination rate constant, k_e.

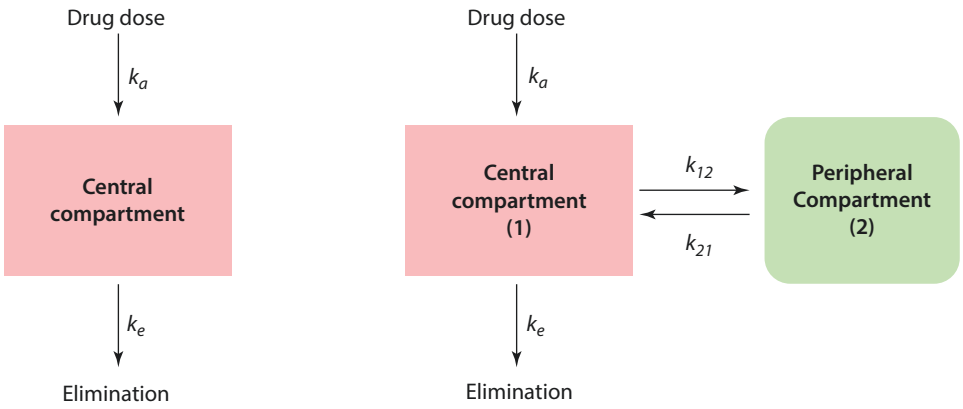

Fig. 6.1 One- and two-compartment pharmacokinetic models

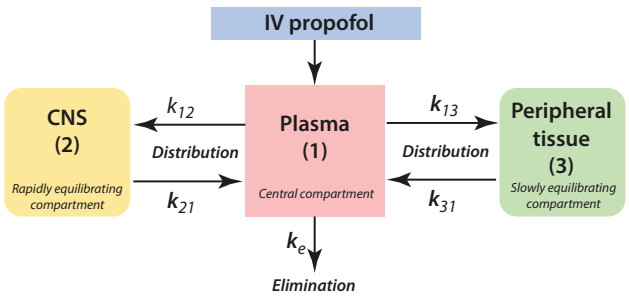

Fig. 6.2 A three-compartment pharmacokinetic model describing the distribution and elimination of propofol

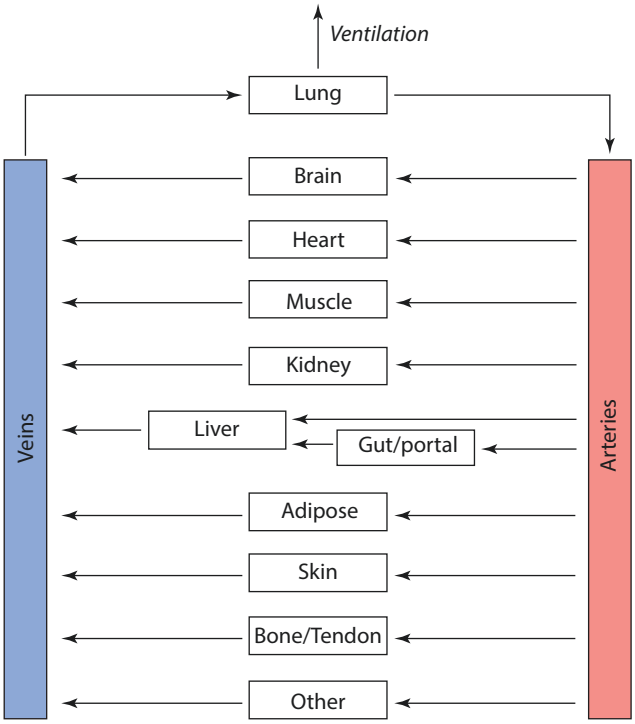

Fig. 6.3 Perfusion-based physiologic pharmacokinetic model

Vessel-rich organs such as the brain, kidney, lung, and heart may experience medication effects more rapidly than vessel-poor regions (e.g., adipose tissue), which may experience a delay in therapeutic concentration attainment.

In contrast to compartmental models, **physiologic models** use known physiologic and biochemical data to describe the distribution of medications throughout organ systems. These models separate the body into anatomically relevant compartments of defined volumes and perfusions that are connected in anatomical order (Fig. 6.3). Drug entry into each organ is based on the drug's partition coefficient and the organ's relative perfusion. "Vessel-rich" organs (e.g., brain, kidney, lungs, heart) may experience medication effects more rapidly, while "vessel-poor" regions (e.g., adipose tissue) may experience a delay in obtaining therapeutic drug concentration due to lower relative perfusion. Over time, vessel-poor tissues may serve as slowly filling depots for certain drugs. An example of this is the lipophilic drug diazepam. After initial administration of a single dose, CNS effects are seen relatively quickly due to the high degree of brain perfusion. Following early distribution to the brain, there is secondary redistribution to muscle and adipose tissue. With repeated or prolonged administration of diazepam, muscle and adipose tissue become a large drug reservoir that provides a source for continued action of the drug long after discontinuation.

Although compartment- and physiologic-based pharmacokinetic models may provide valuable theoretical information about a drug's behavior in the body, clinical applicability may be limited by the multiple assumptions made by each model. Regardless of which model is used, understanding fundamental pharmacokinetic concepts is required to appreciate how a drug moves throughout the body after administration.

6.3 Absorption

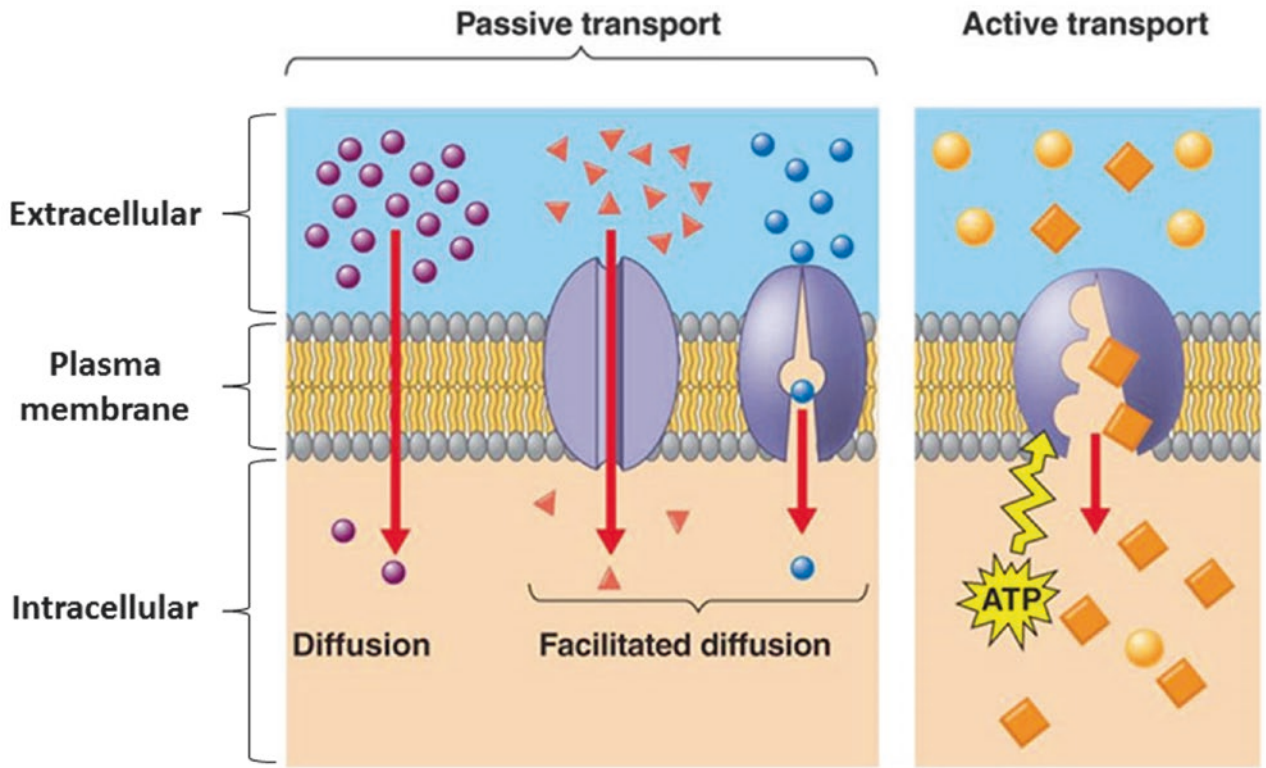
Absorption is the movement of a drug from its site of administration to the bloodstream. The route of administration may be categorized broadly as either **enteral**, if the drug is delivered via the alimentary tract, or **parenteral**, if any site outside the gastrointestinal tract is utilized.

A basic understanding of the cellular **plasma membrane** is essential when describing the processes involved in drug absorption. The plasma membrane consists of a phospholipid bilayer that is amphipathic (i.e., having both hydrophilic and hydrophobic regions; ◘ Fig. 6.4). This bilayer represents a barrier that prevents ions, proteins, and other molecules from moving into or out of the cell. The hydrophobic hydrocarbon chains are oriented inward; the polar, hydrophilic heads are oriented outward. Proteins and lipid molecules are embedded within the lipid bilayer and form the basis for various ion channels, receptors, and transporters. Most drug molecules can move across the cell membrane by passive diffusion, facilitated diffusion, or active transport.

Drugs may move across the cell membrane by passive diffusion, facilitated diffusion, or active transport.

Passive diffusion involves a molecule moving through the lipid bilayer, down its concentration gradient, and is dependent on the molecule being lipid soluble. **Facilitated diffusion** is also a passive process that relies on an electrochemical and/or concentration gradient and membrane proteins that form channels and transporters. Examples of substances transported into cells using facilitated diffusion include ions and glucose (when entering red blood cells). **Active transport** is an energy-dependent process that moves a substance against its electrochemical or concentration gradient. Primary active transport involves the hydrolysis of ATP to generate energy to move drugs or solutes across the plasma membrane (e.g., Na^+/K^+-ATPase pump), while secondary active transport utilizes an electrochemical gradient of one solute to move a second solute against its gradient (e.g., Na^+/Ca^{2+} antiporter). Most drugs are absorbed across the cell membrane by passive diffusion, although some substances (e.g., vita-

Most drugs are absorbed through the cell membrane by passive diffusion.



◘ **Fig. 6.4** Processes of drug movement across the plasma membrane. (Reece JB, Urry LA, Cain ML, Wasserman SA, Minorsky PV, Jackson RB. *Campbell's Biology*, 9th ed, ©2011. Reprinted with permission of Pearson Education, Inc., New York, NY)

mins, glucose, amino acids) are absorbed by active transport mechanisms. Multiple factors affect the rate and degree of drug absorption in a normal, healthy patient; critical illness may alter the absorption kinetics even more unpredictably depending on the type and severity of illness.

Bioavailability (F) describes the fraction of an administered drug dose that reaches the systemic circulation (central compartment). A drug administered enterally must first be absorbed from the gastrointestinal tract (stomach, intestine, etc.), and the final amount of drug delivered to the systemic circulation may be reduced by absorption kinetics and/or subsequent hepatic metabolism after it travels through the portal circulation.

$$F = \frac{\text{Amount of drug reaching the systemic circulation}}{\text{Dose of drug administered}}$$

where $0 < F \leq 1$

6

A drug administered intravenously should have 100% bioavailability.

A number of factors can influence the bioavailability of a medication including salt forms, first pass effect, pharmaceutical formulation, physiochemical properties, and patient-specific parameters. Due to direct delivery of the drug into the systemic circulation, intravenous administration usually results in 100% bioavailability ($F = 1$) unless extravasation occurs. Consider the following example:

» The bioavailability of intravenous (IV) ciprofloxacin is 100% (F = 1); therefore, a 400 mg IV dose results in 400 mg of ciprofloxacin being delivered to the systemic circulation (central compartment). The bioavailability of **oral** ciprofloxacin is only 80% (F = 0.8); therefore, in order to attain a similar serum concentration, a higher dose should be utilized. In this case, a 500 mg oral dose would be required in order to deliver 400 mg to the systemic circulation.

Following enteral administration, absorption of medications can occur at different sites along the gastrointestinal tract, including **oral**, **buccal**, **sublingual**, **gastric**, **jejunal**, and **rectal**. Most drugs are absorbed by passive diffusion, with lipid-soluble drugs moving across cell membranes and water-soluble drugs moving through aqueous channels. Drugs that resemble endogenous compounds (e.g., vitamins) require active transport to be absorbed. **Gastric pH** may affect enteral drug absorption significantly. Typically, weak acids are better absorbed from the stomach (pH 1.5–3.5) than the small intestine (pH 6–8) with the opposite being true for weak bases. Acid-labile compounds such as penicillin and pancreatic enzymes are degraded under acidic conditions and may have decreased bioavailability after prolonged exposure to stomach acid. The administration of H_2 antagonists or proton pump inhibitors increases gastric pH and may alter the absorption kinetics of drugs such as iron and itraconazole. Due to its larger surface area, the rate of absorption in the small intestine is generally much higher than in the stomach. If a drug moves too quickly (diarrhea) or too slowly (delayed gastric emptying) through the intestines, the rate of absorption may be reduced.

Changing the dosage form of a drug without understanding the pharmacologic implications can lead to supra- or subtherapeutic concentrations.

Some medications are commercially available in different salt forms. The **salt factor (S)** is the fraction of the administered dose (in salt form) that is the active drug. For example, aminophylline is the ethylenediamine salt form of the bronchodilator theophylline. Aminophylline has a salt factor of 80% ($S = 0.8$); thus, 1000 mg aminophylline is equivalent to 800 mg theophylline. Salt factors may vary based on dosage forms of the same drug. Phenytoin is manufactured as a parenteral injection of phenytoin sodium (which contains 92% phenytoin, $S = 0.92$), a chewable tablet of phenytoin acid (100% phenytoin, $S = 1$), or a suspension of phenytoin acid (100% phenytoin, $S = 1$). Changing only the drug form without a full understanding of the pharmacoki-

netic properties of the drug could lead to supra- or subtherapeutic drug concentrations. Small changes in phenytoin doses can produce large changes in serum concentrations, as this medication displays Michaelis-Menten pharmacokinetics (discussed later in this chapter).

The following equation is useful in determining the effect of a medication's salt form on the bioavailability:

$$\text{Amount of drug reaching the systemic circulation} = (\text{Dose})(S)(F)$$

where,

- S = salt factor
- F = bioavailability

If aminophylline ethylenediamine is 80% active theophylline ($S = 0.8$) and has an oral bioavailability of 100% ($F = 1$), the amount of active drug reaching the central compartment (plasma) after administering a 100 mg dose of aminophylline elixir is:

$$(100\text{mg aminophylline})(0.8)(1) = 80\text{mg theophylline}$$

Drugs absorbed in the stomach and small intestine enter the portal circulation and travel to the liver where they may undergo **first-pass metabolism** by hepatic enzymes before moving into the systemic circulation. First-pass hepatic metabolism may reduce the systemic bioavailability of many enterally administered drugs. For example, oral propranolol is almost completely absorbed through the intestine but is highly metabolized during its initial transit through the liver resulting in a bioavailability of only 30–40%. Other drugs that experience significant first-pass effect include lidocaine, opioids, midazolam, and nitroglycerin. In addition to hepatic metabolism, intestinal wall enzymes may metabolize portions of a drug prior to the drug reaching the circulation and may even pump a fraction of the drug back into the intestinal lumen. Cyclosporine, a calcineurin inhibitor used as an immunosuppressant after organ transplantation and to treat some autoimmune diseases, is an example of a drug metabolized by both the liver and the gut. Intestinal cytochrome p450 enzymes and p-glycoproteins may account for up to 50% of oral cyclosporine metabolism. Other enteral routes, such as sublingual or rectal, may bypass the portal circulation completely or partially. Venous drainage of the mouth to the superior vena cava bypasses the liver; thus, sublingual or buccal administration allows for direct absorption into the systemic circulation. The rectum is only partially drained by the portal circulation, and up to 50% of a drug absorbed rectally may bypass the liver completely. Drugs that undergo extensive first-pass metabolism may need to be given parenterally, sublingually, or in higher oral doses to achieve the desired effect. Conversely, some prodrugs require activation via hepatic metabolism, and their activity may depend on the first-pass effect. Valacyclovir is an example of an orally administered prodrug used to treat herpes simplex infections. It is converted to the active drug, acyclovir, by first-pass intestinal and hepatic metabolism with a resulting bioavailability of about 55% ($F = 0.55$).

First-pass hepatic metabolism may significantly reduce the bioavailability of an enterally administered drug.

Some prodrugs require activation by hepatic metabolism.

Drugs can be absorbed from the gut only when in solution. All other pharmaceutical formulations (capsules, tablets, etc.) must be converted into solution before being absorbed enterally. The formulation of a medication affects the rate of absorption and the time interval until it becomes available to the systemic circulation (Fig. 6.5). These differences may or may not be clinically significant and must be considered when changing formulations. For example, the difference in absorption rate between digoxin elixir and tablets is significant, while the difference between phenobarbital elixir and tablets is likely insignificant.

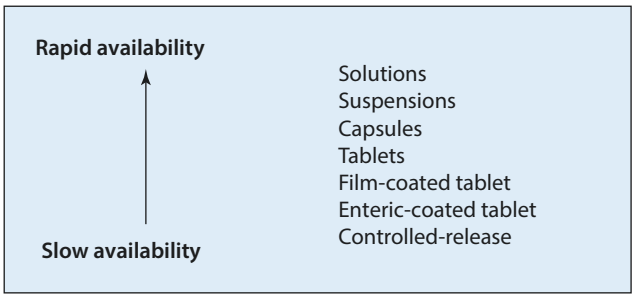


Fig. 6.5 Depiction of the continuum of rate of absorption of common enteral drug formulations

Once in solution, the solubility of the drug impacts its ability to be absorbed through the gut. Because of the electrochemical nature of the phospholipid bilayer, only lipid-soluble molecules (and some small molecules) passively diffuse through the cell membranes of the intestine. Ionized drugs are hydrophilic and therefore not well absorbed, preferring to stay in the aqueous medium of the gut lumen. As an example, vancomycin is a large, hydrophilic molecule resulting in very poor enteral absorption (its oral bioavailability is negligible in patients with healthy intestinal mucosa). For this reason, enteral vancomycin is utilized only to treat cases of bacterial enterocolitis where it may act locally on susceptible organisms (e.g., *Clostridium difficile* or *Staphylococcus aureus*).

Gastric emptying time can impact the rate and extent of enteral drug absorption.

Patient-specific parameters may also affect drug absorption. Depending on the drug, oral administration with food can increase, decrease, or have no effect on bioavailability. Delayed gastric emptying is often a complication of critical illness that may decrease the bioavailability of an intestinally absorbed drug. Decreased blood flow to the gastrointestinal tract can decrease enteral absorption, and patients with short bowel syndrome may have an impaired ability to absorb oral medications depending on which sections of bowel have been removed or are not functioning normally.

It is important to screen for intraluminal drug interactions in patients receiving enteral medications. Potential issues can be seen with fluoroquinolones, phenytoin, levothyroxine, and calcium, among others.

Drug interactions at the site of administration may also affect absorption. Drugs that slow gastric emptying may decrease the onset and/or rate of absorption of medications in the small intestine. Food components may also bind drug molecules, reducing their absorption through the gastrointestinal tract. Administration of phenytoin with enteral feeds results in **protein binding** that limits absorption. Levothyroxine may bind to fiber, calcium, iron, and even the feeding tube itself, thus reducing its bioavailability. Calcium compounds may act as chelators, binding to and decreasing enteral absorption of drugs such as ciprofloxacin. The chelation effect of calcium may also be utilized for therapeutic purposes: patients with chronic kidney disease may be prescribed oral calcium supplements to take both with meals to help prevent hyperphosphatemia (calcium acts as a phosphate binder) and on an empty stomach (to provide calcium supplementation).

Parenteral routes of administration refer to those outside the alimentary tract. As mentioned previously, **intravenous (IV)** administration has the benefit of complete bioavailability ($F = 1$) and rapid distribution. Irritating solutions may be delivered slowly or into a large, high-flowing vein in order to allow dilution by the blood. Some medications and/or concentrations should not be delivered into peripheral veins due to the risk of sclerosis or extravasation. Vasopressors or dextrose concentrations greater than 12.5% (12.5 g/100 mL) are preferably administered into large vessels via central venous catheters where they may be diluted by a larger volume of blood. The **intraosseous (IO)** route provides access to the systemic venous system comparable to the IV route. Care must be taken to ensure proper IO needle position within the bone marrow cavity, as significant extravasation and even acute compartment syndrome may occur with malpositioned needles. **Intra-arterial** administration is usually reserved for drugs with a targeted area of action, such as alteplase for arterial thromboses or che-

Parenteral administration is not limited to the IV route. Any site of administration outside the gastrointestinal tract is considered parenteral.

motherapy for certain solid-organ tumors. **Intramuscular (IM)** absorption of medications (e.g., epinephrine for anaphylactic shock) can be rapid but is dependent on blood flow to the muscles. Since fat is poorly perfused relative to muscle, muscle regions with higher adipose tissue content (such as the ventrogluteal region) are less preferred to the deltoid or vastus lateralis muscles. IM injections are limited by volume; thus, higher concentrations of certain medications may be required to deliver the required dose (e.g., IV ketamine 10 mg/mL vs. IM ketamine 100 mg/mL). **Subcutaneous (**formerly abbreviated **SC** or **SubQ)** injections also require smaller volumes and result in a slower, more sustained absorption of the drug due to less vascularity. **Topical** application is usually reserved for local activity (e.g., rashes, conjunctivitis), while **transdermal (TD)** patches are formulated for controlled release and systemic absorption of a drug. Transdermal absorption is dependent on the surface area of the patch, drug concentration, lipid solubility of the drug, use of an occlusive dressing, integrity of the skin, and temperature (damaged and/or higher temperature areas result in increased absorption). The **inhaled** route is a form of topical delivery that allows for both local activity in the lungs and some systemic absorption due to the large surface area of the pulmonary circulation. **Intranasal (IN)** delivery of sedatives/analgesics is increasingly used for procedural sedation due to the presence of dense capillary beds in the nasal mucosa that drain into the internal jugular vein, thus bypassing the liver and avoiding hepatic first-pass metabolism. The highly lipophilic nature of drugs such as fentanyl, midazolam, ketamine, and dexmedetomidine facilitates both transcellular absorption at the respiratory epithelium and penetration into the CNS. In intubated patients, the **endotracheal (ET)** route provides for limited absorption of certain lipid soluble drugs (lidocaine, epinephrine, atropine, and naloxone) in emergency situations where reliable IV/IO access cannot be established. Absorption through the alveolar capillary bed may result in substantially lower serum concentrations than achieved with IV administration and higher doses are usually recommended. **Intrathecal (IT)** administration of drugs is usually reserved for delivery of chemotherapy or antimicrobial drugs directly to the central nervous system. This route may be utilized to bypass the barriers between the blood, brain, and cerebrospinal fluid which often significantly limits the absorption of drugs.

The lipophilicity of drugs such as fentanyl, midazolam, ketamine, and dexmedetomidine facilitates both intranasal absorption and penetration into the CNS.

6.4 Distribution

Distribution is the reversible movement of a drug from the bloodstream to various sites in the body and is dependent on blood flow to a tissue bed, degree of plasma protein binding, capillary permeability, and lipophilicity of the drug. Once a drug has been administered and absorbed into the systemic circulation, it begins to distribute into peripheral tissues at rates governed by various rate constants (◘ Figs. 6.1 and 6.2). The rate of blood flow to a given tissue bed directly affects distribution to that compartment. Relative to tissue mass, the kidneys, heart, liver, and brain receive the highest blood flow, while the skeletal muscle, fat, and skin have much lower rates of blood flow.

The extent of **plasma protein binding** can impact drug disposition, including distribution and drug-drug interactions. To some degree, all drugs can bind to plasma proteins including albumin, α_1-acid glycoprotein, and lipoprotein. Albumin is a major carrier of acidic drugs, α_1-acid glycoprotein tends to bind basic compounds, and lipoproteins are known to bind several basic and neutral drugs. Reversible binding of drugs to plasma proteins affects the fraction of **free drug (i.e., active drug)**. Binding to plasma proteins is determined by the affinity of the drug for the protein, the availability of binding sites, and the plasma con-

centration of the drug. The extent of protein binding influences the rate and volume of distribution (discussed below). Drugs that are highly bound to plasma proteins may be displaced through competition with other compounds due to a finite number of sites available for binding free drug. This is the mechanism underlying several important drug interactions (e.g., sulfonamides and bilirubin, warfarin and phenytoin). Disease states such as hepatic or renal failure may reduce the availability of plasma proteins and thus decrease the extent of protein binding. If circulating plasma protein concentrations are lower than normal, the percentage of free drug increases. Even minor alterations in plasma protein binding may produce significant changes in therapeutic levels for highly bound drugs. For example, consider two hypothetical drugs ("A" and "B") that bind to a plasma protein ("X"). When drug A is administered alone, 99% binds to protein X, and the remaining 1% exists as free drug in the plasma. When drug B is introduced, it competes with drug A for binding sites on protein X and displaces an additional 1% of the total amount of drug A (Fig. 6.6).

For drugs that are highly protein bound, small changes in the degree of plasma protein binding may result in dramatic alterations in therapeutic drug levels.

The displacement of drug A from plasma protein X doubles the free fraction of drug A from 1% to 2%. This may also produce a doubling of therapeutic effect or, for drugs with a narrow therapeutic index (e.g., warfarin, phenytoin), a shift into the toxic range with potentially serious complications. When monitoring therapeutic concentrations of drugs such as phenytoin, it is crucial to distinguish between assays that report both total and free concentrations from those that report only the total serum concentration.

The **capillary permeability** of a drug is dependent upon the properties of the drug and structure of the capillary bed. **Lipophilic (hydrophobic) drugs** are generally lipid soluble, capable of dissolving into the capillary cell membranes without the aid of active transport mechanisms. **Hydrophilic drugs** are either charged or exhibit polarity and require either active transport mechanisms or slit junctions (fenestrations between capillary endothelial cells) to penetrate cellular barriers. The liver has capillary beds with large numbers of slit junctions through which small and/or ionized drugs may pass; in contrast, the capillaries of the CNS consist of endothelial cells with tight junctions that form the **blood-brain barrier** (Fig. 6.7).

Lipophilic drugs are able to dissolve through the cell membrane. Hydrophilic drugs require either active transport mechanisms or slit junction to penetrate cellular barriers.

Lipid-soluble drugs may pass directly through the cell membranes of the blood-brain barrier, while other drugs require specific transporters to facilitate entry into the CNS. Ionized drugs are generally unable to penetrate the endothelial cells of the blood-brain barrier due to the lack of slit junctions. A clinical example of this is the use of methylnaltrexone to treat opioid-induced constipation. The methylated form of naltrexone is a quaternary ammonium cation that cannot penetrate the blood-brain barrier, thus permitting peripheral opioid receptor antagonism without adversely affecting the CNS analgesic effects of any concurrently administered opioids (Fig. 6.8). While the blood-brain barrier is generally impermeable to hydrophilic drugs in healthy individuals, trauma or inflammatory disease states such as meningitis may alter the blood-brain barrier and increase its permeability.

After a drug reaches the plasma, the free (unbound) fraction may redistribute into other body compartments depending on the drug's size, structure, and

Fig. 6.6 The effect of protein binding and displacement on free drug levels

	Bound A (to protein X)	**Free A** (active)
Drug A (alone)	99%	1%

permeability. The **volume of distribution (V_d)** is a concept frequently used to describe a drug's distribution from the central compartment. V_d is not a true, measurable volume but rather a theoretical value indicating the fluid volume that would be required to contain the total amount of the drug in the body at the same concentration as measured in the plasma. V_d is dependent on the properties of the drug, including its lipid or water solubility and ability to distribute into different tissue compartments. V_d is defined by the following equation:

$$V_d = \frac{\text{Total amount of drug in the body}}{\text{Plasma concentration of drug}}$$

Volume of distribution is not a true, measurable volume; rather it is a theoretic value used to describe the extent of drug distribution to various tissues in the body.

Table 6.1 Drug characteristics affecting volume of distribution

Drug characteristics favoring large V_D	Drug characteristics favoring small V_D
Low molecular weight	High molecular weight
Low protein binding	High protein binding
High tissue binding	Low tissue binding
Increased membrane permeability	Decreased membrane permeability
Lipophilic	Hydrophilic
Uncharged	Ionized

Medications with a large V_d are widely distributed in the body, whereas those with a small V_d are mainly confined to the vascular space.

V_d is usually expressed in L/kg body weight. A large V_d indicates the drug is lipid soluble and/or highly concentrated into tissues, whereas a small V_d suggests the drug is more highly contained in the central compartment (plasma). An example of a medication with a small volume of distribution is warfarin. Because it is extensively bound to plasma proteins, warfarin has a V_d of 0.1–0.2 L/kg, indicating little of the drug is distributed beyond the vascular compartment. Conversely, amiodarone has a V_d of approximately 66 L/kg, resulting in tissue concentrations that are much higher than plasma concentrations.

Clinically, V_d is a useful parameter when calculating a **loading dose**. By rearranging the preceding equation, the following derivation is obtained:

$$\text{Loading dose} = V_d \times \text{Desired plasma concentration}$$

For example, if a phenobarbital level of 20 mcg/mL is desired for a neonate (population V_d = 1 L/kg), a 20 mg/kg load should be administered (20 mcg/mL • 1 L/kg = 20 mg/kg).

Knowledge of a drug's volume of distribution can guide decisions surrounding loading doses.

It is important to note that the volume of distribution is useful for initial loading and reloading doses, when calculating the amount of drug required to achieve a specific increase in plasma drug concentration starting from zero or from a known subtherapeutic concentration. These are often situations where one is "filling the tank." Volume of distribution alone is not useful for determining the frequency of maintenance or steady-state dosing. Factors that produce a small volume of distribution include those that prevent redistribution from the plasma to other tissue compartments such as low lipid solubility, high plasma protein binding, and decreased tissue binding (Table 6.1). Neonates inherently have a large V_d for most drugs due to a higher percentage of body water, lower levels of plasma proteins, and a relatively large liver and brain (highly perfused organs).

6.5 Metabolism

First-pass metabolism of an enterally administered drug may reduce the concentration reaching the systemic circulation. The liver and intestinal wall are the major sites of first-pass metabolism.

Drug metabolism includes all the processes that break down or transform drug molecules into inactive (or active) metabolites. Several organs and systems participate in drug metabolism, but the liver is the main site of metabolism for most drugs. A major function of the liver is to transform drugs via phase I and phase II reactions into water-soluble forms that can be excreted by the kidneys. Other sites of drug metabolism include the intestines, lungs, skin, plasma, and kidneys. **First-pass metabolism** of an enterally administered drug may reduce the concentration that reaches the systemic circulation. The liver and intestinal

wall are the major sites of first-pass metabolism. The amount of active drug molecules reaching the systemic circulation depends on the extent of metabolism in the liver and/or intestine.

Hepatic metabolism may include phase I and/or phase II reactions which transform the drug and enable it to be excreted by the kidney. **Phase I reactions** are *modification reactions* such as oxidation, reduction, hydrolysis, and cyclization/decyclization. These reactions serve to introduce reactive groups to the drug or to increase its polarity. Phase I reactions are frequently facilitated by the cytochrome p450 enzyme system located in the endoplasmic reticulum or inner mitochondrial membrane. If sufficiently polar, the metabolites may be ready for excretion after phase I reactions, otherwise they may undergo further metabolism via phase II reactions. **Phase II reactions** are *conjugation reactions* whereby the drug molecule is attached to polar or charged substrates such as a methyl group, acetyl group, glucuronic acid, sulfate, glutathione, or glycine group in order to enhance water solubility and renal elimination.

Phase I reactions modify a substrate to introduce reactive groups and/or increase its polarity. Phase II reactions conjugate a drug molecule with a polar or charged substrate, increasing its molecular weight and enhancing renal excretion.

A host of different cytochrome p450 enzymes act to oxidize or sometimes reduce drug and endogenous molecules. These enzymes are named in the following manner:

Isozyme: CYP3A4

CYP = cytochrome P450 enzyme
3 = family
A = subfamily
4 = individual member of the subfamily

Three families, CYP1, CYP2, and CYP3, are responsible for most drug transformations. CYP3A accounts for greater than 50% of phase I metabolism, predominantly via the CYP3A4 subtype. CYP3A4 is responsible for the metabolism of many drugs commonly utilized in the intensive care setting, including cyclosporine, methadone, acetaminophen, midazolam, diazepam, and tacrolimus.

CYP3A is one of the most important p450 isozymes, accounting for the majority of Phase I drug oxidation in the liver.

It is important to know which isozyme metabolizes a drug molecule to avoid clinically significant drug interactions which often result from the **induction** or **inhibition** of CYP enzymes (◘ Table 6.2). Information about the isozymes involved in the metabolism of a drug entity can be found in the drug's package insert, primary literature, or tertiary drug references. Additionally, many electronic medical records now include decision support software to alert ordering providers about potential drug-drug interactions.

An example of a potentially clinically significant drug interaction mediated by the p450 system is the interaction between midazolam and voriconazole. Midazolam is metabolized to a certain extent by CYP3A4, whereas voriconazole inhibits the action of CYP3A4. A patient receiving a midazolam infusion who is then started on voriconazole for a fungal infection may experience a clinically relevant increase in the concentration of circulating midazolam with potentially undesired effects.

Other tissues and systems that play considerable roles in drug metabolism include the gastrointestinal tract, lungs, skin, and kidneys. Lung tissue contains many CYP isozymes and other enzymes which participate in drug metabolism. For example, the inhaled steroid beclomethasone dipropionate is a prodrug which is metabolized to the active compound 17-beclomethasone monopropionate by lung esterases. In vitro studies of skin tissue have also demonstrated the presence of CYP isozymes and other drug-metabolizing enzymes. Topical propranolol, used to treat infantile hemangiomas, has been shown to undergo hydroxylation and dealkylation (phase I reactions) on skin biopsies. While the kidneys are routinely classified as organs of excretion or

elimination, they also play an important role in the metabolism of drugs such as acetaminophen, furosemide, and morphine, which all undergo some degree of renal glucuronidation (a phase II reaction). The clinical significance of this metabolism has not been fully elucidated but should be taken into consideration in patients with renal insufficiency.

Non-organ-dependent metabolism is an important pharmacokinetic feature of several neuromuscular blocking and analgesic agents.

Non-organ-dependent metabolism of certain drugs by peripheral enzymes may also occur. Two non-depolarizing neuromuscular blocking agents, atracurium and cisatracurium, undergo peripheral metabolism known as Hoffman elimination (exhaustive methylation). Although this is not the exclusive mechanism of elimination (some drug undergoes renal clearance), it is an important factor to consider when choosing a neuromuscular blocking agent in the setting of renal or hepatic dysfunction. Succinylcholine is rapidly degraded by plasma cholinesterases, accounting for its short duration of activity. These enzymes are produced by the liver and are responsible for hydrolyzing succinylcholine to inactive metabolites. Plasma cholinesterase deficiency can result in prolonged neuromuscular blockade after succinylcholine administration and this deficiency can be inherited or acquired. An additional example of non-organ-dependent metabolism occurs with the short-acting analgesic remifentanil, which is rapidly metabolized by nonspecific plasma and tissue esterases.

6.6 Elimination

Renal elimination of drugs occurs primarily by passive glomerular filtration and active tubular secretion.

Drugs are removed from the body by many potential routes including the urine, bile, sweat, tears, or saliva. The two principal organs responsible for drug clearance are the kidneys and the liver. Renal elimination of medications is accomplished primarily by one of two mechanisms: passive glomerular filtra-

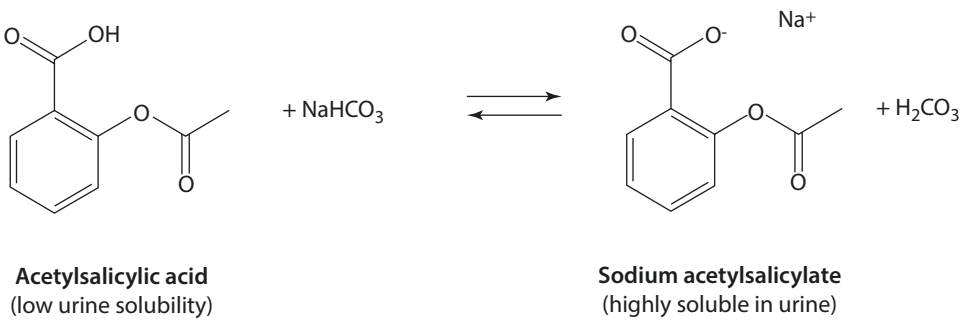

Fig. 6.9 Aspirin may be converted to its more soluble conjugate base (sodium acetylsalicylate) by the addition of sodium bicarbonate to IV fluids to alkalize the urine

tion or active tubular secretion. Most renal elimination is accomplished by passive **glomerular filtration**. Factors that determine the amount of drug filtered through the glomeruli include the size and charge of the drug, protein binding, and water solubility. Larger and more highly protein-bound drugs are not easily filtered, and anionic molecules are somewhat repelled by the negatively charged glomerular basement membrane. Estimations of glomerular filtration rate (GFR) commonly use 24-hour urine collection or estimation from serum creatinine measurement. In addition to filtration, drugs may be renally eliminated by **tubular secretion**. This is an active, energy-requiring elimination process occurring predominantly in the proximal tubule where active transport systems secrete organic acids and bases. Organic acids include most penicillins, cephalosporins, loop diuretics, thiazides, and nonsteroidal anti-inflammatory agents; organic bases include morphine and ranitidine. These drugs are secreted into the tubular fluid and then potentially reabsorbed at various sites in the nephron, depending on lipophilicity and urine pH. Alkalization of the urine may enhance renal elimination of weak acids such as aspirin via a process known as "ion trapping" (Fig. 6.9). Urine alkalization ionizes aspirin (acetylsalicylic acid, a weak acid with a pKa of 3.5) to its conjugate base, sodium acetylsalicylate, potentially increasing its elimination by enhancing urine solubility. The effectiveness of urine alkalization is debated, however, with some studies suggesting little to no benefit in enhancing urinary excretion of these substances.

Manipulation of urine pH may influence the elimination rate of certain drugs and metabolites.

Manipulation of urine pH also is used to modify the elimination rate of certain drugs and metabolites; for example, urine alkalization is used to limit methotrexate toxicity. Methotrexate demonstrates poor urine solubility at acidic pH, and its major metabolites, 7-OH-MTX and DAMPA, are six- to tenfold less soluble than the parent molecule, respectively. Increasing urine pH from 6.0 to 7.0 produces a five- to eightfold greater solubility of both methotrexate and its metabolites. These characteristics led to the recommendation for IV hydration containing 40–50 mEq sodium bicarbonate per liter of IV fluid prior to, during, and after the administration of high-dose methotrexate therapy.

The liver may also eliminate drugs via biliary excretion. After a drug is conjugated in the liver and excreted in bile, it may be reabsorbed via **enterohepatic recirculation** or eliminated in the feces. Medications that undergo biliary elimination include morphine, ceftriaxone, phenobarbital, and steroid and thyroid hormones.

6.6.1 Elimination Kinetics: First-Order vs. Zero-Order

When a drug is removed from the body as a *fixed percentage* of the remaining concentration over time, it is described as having **first-order elimination**. On a

linear plot, the decay curve will appear exponential (Fig. 6.10). First-order kinetics implies that the elimination mechanisms are not saturated. Since a fixed percentage of the drug is eliminated per unit time, a higher drug concentration should lead to a higher quantity eliminated over a specified time period. Because V_d and clearance are fixed in the setting of first-order kinetics, dose adjustments can be expected to produce proportional changes in serum concentration (e.g., doubling the gentamicin dose should double the serum concentration). Most drugs in use at therapeutic concentrations are eliminated via first-order kinetics.

Most drugs used clinically are eliminated via first-order kinetics.

Zero-order elimination occurs when a *fixed quantity* of drug (rather than percentage) is removed per unit time and the linear plot demonstrates linear decay. Zero-order kinetics implies a saturation of the elimination mechanisms. Many drugs exhibit first-order kinetics at therapeutic concentrations but then display zero-order elimination at higher concentrations when elimination pathways become saturated. Few drugs exhibit zero-order kinetics at therapeutic concentrations, one example being ethanol. Zero-order elimination may be seen in the setting of supra-therapeutic dosing or an overdose of some drugs. **Michaelis-Menten kinetics** describe the process of "saturable elimination" in which the rate of elimination approaches a maximum (V_{max}). Drugs that follow Michaelis-Menten kinetics will follow first-order elimination at lower serum levels, but as doses are increased and elimination mechanisms become saturated the rate of elimination approaches V_{max} and follows zero-order kinetics. When the rate of elimination is at V_{max}, further drug doses will lead to disproportionately elevated serum levels. This is especially important for drugs like phenytoin and fosphenytoin whose therapeutic serum levels are within the range of saturable elimination. Serum levels of these drugs should be monitored closely to ensure patients are not approaching toxic concentrations.

Many drugs exhibit first-order elimination kinetics at therapeutic dosing but then display zero-order kinetics at higher dosing when elimination mechanisms become saturated.

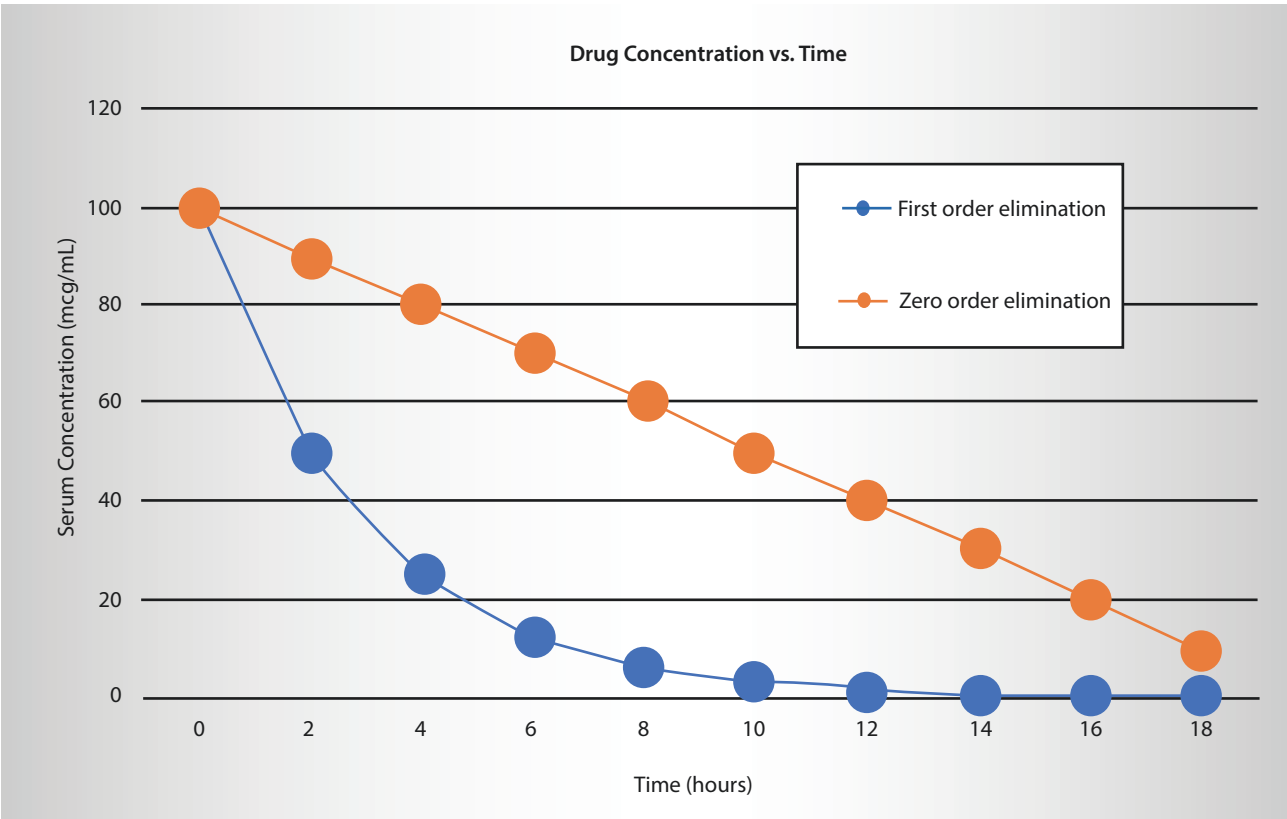

Fig. 6.10 Linear plot demonstrating first-order elimination (50% every two hours) vs. zero-order elimination (10 mcg/mL every two hours)

6.6.2 Half-Life and Steady-State

The elimination half-life is the amount of time required for the concentration of a drug to decrease by 50%.

The elimination **half-life ($t_{½}$)** is the amount of time required for the concentration of a drug in the body to decrease by 50%. Terminal half-life describes, more specifically, the time required for the plasma concentration of a drug to decrease by half. For example, gentamicin has a population half-life of approximately 2 hours in children. If the serum concentration of gentamicin was 10 mcg/mL after IV administration, the level 8 hours (four half-lives) later would fall to approximately 0.625 mcg/mL. Half-life is dependent on a drug's elimination constant (k_e), which can be determined from concentration-time plots. Drug half-lives reported in the literature are based on population variables and may be different in individual patients. The half-life of a drug in a particular patient may be affected by drug-drug interactions, genetic variables (rapid or slow metabolizers), organ dysfunction, etc. Assuming a drug has reached steady-state concentration, the half-life of a drug that follows first-order elimination can be calculated as follows:

$$t_{½} = \frac{0.693}{k_e}$$

Assuming consistent dosing, steady-state concentration is usually achieved after 4–5 half-lives of a drug have passed.

Related to half-life, **steady-state** concentration is reached when the amount of a drug entering the body is equal to the amount leaving the body. Assuming consistent dosing, steady-state concentration is usually achieved after 4–5 half-lives have passed (Fig. 6.11). In most clinical situations, it is important to ensure that steady-state concentrations have been achieved prior to making decisions about dosage adjustments to maintenance medication regimens. Loading doses for certain drugs (e.g., aminoglycosides, digoxin) may be used to achieve therapeutic serum concentrations more rapidly than waiting for 4–5 half-lives to pass.

Clearance (CL) is defined as the volume of plasma from which a substance is completely removed per unit time and is usually expressed as mL/min.

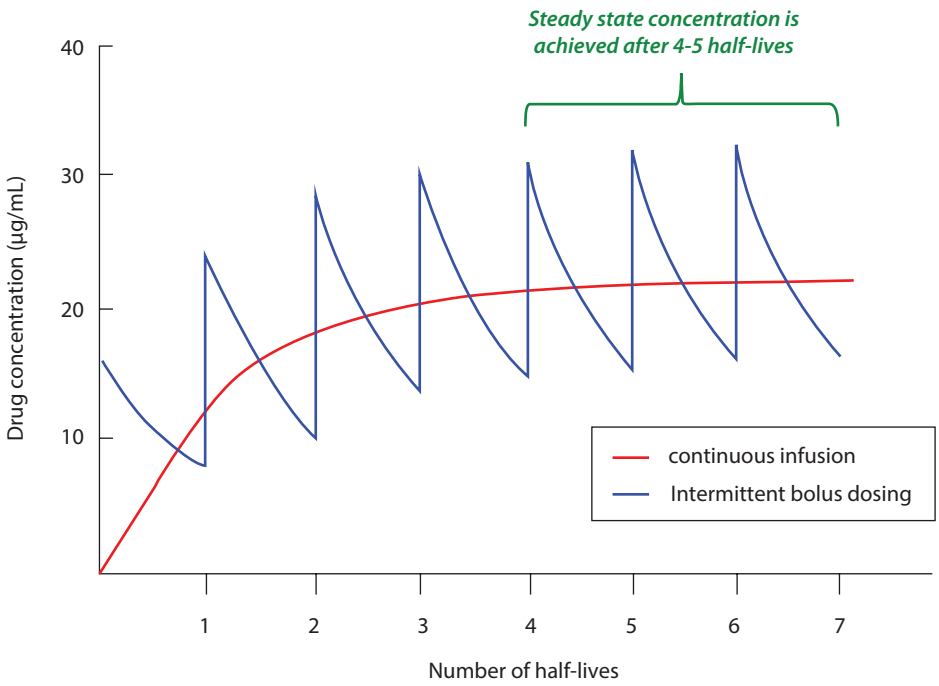

Fig. 6.11 Time to achieve steady state concentration of a drug. (Adapted from Australian Prescriber, 1996)

Clearance does not represent the amount of drug eliminated from the body; rather, it is the amount of plasma per unit of time from which the drug is cleared by the processes of metabolism and elimination. Mathematically, it is the product of the elimination constant and the apparent volume of distribution.

$$CL = k_e \times V_d$$

Clearance represents the fractional rate of drugs lost from the volume of distribution. The relationship between half-life and clearance can be understood by the equation below, in which k_e is equivalent to CL/V_d:

$$t_{½} = \frac{0.693 \times V_d}{CL}$$

Clearance represents the volume of plasma that is completely cleared of a drug by metabolism and elimination per unit time.

Of note, based on the equation above, drugs with a larger V_d will have longer terminal half-lives since more of the drug is distributed outside the central compartment. In the ICU setting, the relevance of this becomes apparent when short-acting drugs are administered as continuous infusions over prolonged periods of time. For example, the highly lipophilic drug propofol has a V_d of 5–10 L/kg in children. Bolus doses of propofol typically have a duration of action of 5–20 min; however, prolonged infusions lead to high concentrations of propofol in the peripheral tissues and a terminal half-life of up to 1–3 days. This accounts for the longer duration of action after discontinuation of prolonged propofol infusions.

Lastly, the total body clearance of a drug is the sum of individual organ clearances (hepatic, renal, other): $CL_{total} = CL_{hepatic} + CL_{renal} + CL_{other.}$

6.7 Pharmacodynamics

Pharmacodynamics describes the mechanism of action of a drug that produces physiologic and clinical effects. There are a myriad of mechanisms of action through which drugs exert their effects. Some drugs act directly without mediation by receptors. Examples include antacids that neutralize gastric secretions, cholesterol binding agents, and the osmotic diuretic mannitol. Receptor-mediated mechanisms are ubiquitous throughout human physiology and are the most extensively studied. A comprehensive discussion of these receptors and their mechanisms is beyond the scope of this chapter, but ◘ Table 6.3 provides a brief overview of commonly encountered physiological receptors and their pharmacodynamics related to drugs used in the ICU.

Pharmacodynamics may also describe how a drug acts on an infecting microorganism. The mechanisms of action of common antimicrobial agents are listed in ◘ Tables 6.4 and 6.5.

6.8 Pharmacokinetic and Pharmacodynamic Issues in the Pediatric ICU Setting

Many situations commonly encountered in the pediatric ICU have significant effects on pharmacotherapy. In particular, **organ failure** can have profound effects on both drug disposition and therapeutic response. In states of **fluid overload** such as **heart failure**, tissue injury with localized loss of capillary integrity, or generalized **capillary leak** from burn injury or sepsis, there may be significant expansion of the body's fluid compartments. This includes expansion of the extracellular fluid space with intravascular volume either increased or decreased. Fluid may accumulate in the third compartment (third space) such

Organ failure, fluid overload, and capillary leak all may contribute to the alteration of drug kinetics and require adjustments to drug dosing and/or frequency to ensure therapeutic levels.

Table 6.3 Physiologic drug receptors

Receptor type	Receptor example(s)	Drug example(s)[a]
G protein-coupled receptors are a large class of receptors formed by a single polypeptide chain with seven hydrophobic regions that represent transmembrane alpha-helices (also referred to as 7-TM receptors). The coupling of two G proteins occurs at the carboxy terminal within the cytoplasm, leading to downstream stimulation or inhibition of specific intracellular enzymes.	Adrenergic receptors ($ß_1$, $ß_2$, α_1) Opioid receptors	Epinephrine Dobutamine Norepinephrine Fentanyl, morphine
Enzyme-linked receptors have either intrinsic enzyme activity or are linked to cytosolic enzymes. These glycoproteins span the cell membrane only once and are activated through an extracellular receptor.	Tyrosine kinase	Imatinib
Nuclear receptors modulate gene expression. They are activated by lipophilic molecules that can diffuse across the plasma membrane and bind to intracellular nuclear receptors.	Steroid receptors Retinoic acid receptor Thyroid hormone receptor	Glucocorticoids ATRA T3, T4
Voltage-gated ion channels are involved in the regulation of cell membrane potential and the propagation of an action potential in excitable cells. They mediate Na^+, Ca^{2+}, K^+, and Cl^- conductance through membrane potential changes.	Na^+ channels Ca^{2+} channels	Lidocaine Phenytoin Nicardipine Gabapentin
Ligand-gated ion channels combine to form a binding site for neurotransmitters and an ion-conducting pore. These channels produce rapid changes in membrane permeability, modulating synaptic events in the nervous system.	GABA receptors NMDA receptor	Benzodiazepines Propofol Ketamine
Membrane transport proteins are integral transmembrane proteins involved in the transport of ions, proteins, or small molecules across the cell membrane. Two main types are *channels* and *carriers*.	Na-K-Cl cotransporter GLUT Gastric proton pump	Furosemide Glucose/dextrose Pantoprazole
Direct enzyme targets act upon one or more of the thousands of enzymes in the human body. Enzyme inhibition may be reversible or irreversible, depending on the reaction.	Phosphodiesterase Acetylcholinesterase Dihydrofolate reductase	Milrinone Neostigmine Methotrexate

[a]Drugs listed may be agonists/activators or antagonists/inactivators of a given receptor

as the pleural and peritoneal cavities. The net effect of the expansion of total body water in the critically ill is to increase the volume of distribution of all hydrophilic drugs that distribute widely throughout the body's water space. For example, the presence of significant edema and ascites may increase the V_d of highly water-soluble agents such as aminoglycoside antibiotics.

If a drug's dosing interval spans multiple half-lives, large peak-to-trough differences may occur and establishing adequate peak concentrations to ensure effectiveness may require significant increases in the individual dose. As a further consideration, if plasma clearance remains fixed but the size of the body's "tank" has markedly increased, half-life will increase because of the increase in

V_d (recall that $t_{½} = 0.693 \times V_d/CL$). As a result, it may be required to increase the dosing interval to achieve adequate peak levels without elevated trough levels.

The function of the gastrointestinal system may have significant effects on drug kinetics and toxicity. **Delayed gut motility** may slow the peak response to enterally administered medications. Drugs that undergo extensive first-pass metabolism may have a significantly higher oral bioavailability in patients with **liver failure** than in patients with normal hepatic function. The capacity of the liver to metabolize drugs depends on hepatic blood flow and liver enzyme activity. Certain p450 enzymes are more susceptible than others to liver injury, which may lead to general or selective impairment of drug metabolism. Decreased liver synthetic function can result in hypoalbuminemia or decreased glycoprotein levels that may affect the protein binding of acidic or basic drugs, respectively, leading to an increase in free serum drug concentrations. Furthermore, medications that are normally highly protein bound may also have increased tissue distribution due to reduced plasma protein concentrations.

An understanding of the primary and alternate pathways of elimination for all medications is essential for the daily management of the critically ill child. **Renal failure** may alter the elimination of many drugs utilized in the ICU and medications with significant renal clearance require dose reduction. It is essential to understand whether a drug produces active or toxic metabolites that may accumulate in the setting of organ failure. For example, morphine is metabolized by the liver to an active metabolite (morphine-6-glucuronide) that is subsequently excreted by the kidney and should therefore be dose reduced or avoided altogether in renal failure. This may not be readily apparent to the clinician who knows that morphine is a hepatically metabolized drug. The emergence of renal protection strategies to mitigate or reverse the nephrotoxic

Clinicians should be aware of any active or toxic metabolites produced by a drug's metabolism, as these may accumulate in the setting of organ failure.

effects of medications has added another dimension to this issue. A growing body of literature demonstrates that augmentation of intrarenal blood flow may have a protective effect on renal function in the context of specific threats. For example, both theophylline and fenoldopam are intrarenal vasodilators that favorably affect renal function and augment diuresis in the presence of renal impairment (intrarenal vasoconstriction) caused by calcineurin inhibitors. Furthermore, a recent meta-analysis of the effects of theophylline on radiocontrast nephropathy demonstrated a protective effect of theophylline on renal function when combined with IV hydration.

The medication list of any critically ill patient should be reviewed and evaluated frequently based on changing patient status, organ function, and new drug-drug interaction.

An important part of daily patient care is the review of all medications in the context of any changes in patient condition, organ function, and new drug interactions. The critical care physician is challenged to manage the interplay between physiologic impairments of organ function and drug-related organ injury. The threats to renal and hepatic function posed by critical illness (e.g., shock, sepsis, etc.) must be balanced against the potential organ toxicity caused by potentially lifesaving drugs such as cyclosporine, vancomycin, amphotericin, aminoglycosides, and various other agents. Furthermore, the need to preserve adequate intravascular volume for optimizing organ perfusion must be balanced against the morbidity and mortality associated with generalized fluid overload.

Certain drugs used in critically ill patients may require dose adjustment in the setting of ECMO.

The use of **extracorporeal membrane oxygenation (ECMO)** is known to affect the pharmacokinetics and pharmacodynamics (PK-PD) of many drugs used in the ICU. For most infants and children, the ECMO circuit represents a significant expansion of circulating blood volume; hence, the volume of distribution (V_d) for many drugs increases. This increase in V_d has been demonstrated in vivo with drugs such as vancomycin and gentamicin. Individual components of the circuit also have the ability to increase V_d through drug **adsorption**. Highly lipophilic drugs such as fentanyl and midazolam may be adsorbed extensively by the polyvinyl chloride (PVC) tubing and oxygenator components. A 2012 study compared drug recovery from ECMO circuits with controls (PVC-lined glass jars) and found that up to 70% of fentanyl and 50% of midazolam were lost in the ECMO circuit during the first hour of therapy (Table 6.6). For this reason, a less lipophilic drug such as morphine may be a better analgesic for patients supported with ECMO. Drug clearance may also be impaired in patients requiring extracorporeal support; however, as patients requiring ECMO frequently have multi-organ failure, it is unclear to what degree clearance is affected by the circuit versus underlying organ dysfunction. Extensive PK-PD studies for many drugs are lacking in the pediatric population but small studies and case series suggest some cardiovascular drugs (esmo-

Fentanyl and midazolam demonstrated extensive binding (adsorption) to components of the extracorporeal membrane oxygenation (ECMO) circuit.

Table 6.6 Average drug recovery from ECMO circuits vs. controls, relative to baseline starting dose

	Drug recovery at 24 h	
	Control[a]	ECMO circuit
Fentanyl	82%	3%
Morphine	97%	103%
Midazolam	100%	13%
Vancomycin	99%	90%
Meropenem	42%	20%

[a]Polyvinyl chloride (PVC) jars with fresh human whole blood

lol, amiodarone, and sildenafil), diuretics (bumetanide), antimicrobials, and analgesics/sedatives may require dosing adjustments while on ECMO. Notably, the PK of inotropes and vasoactive agents such as dopamine and epinephrine appear to be less affected by extracorporeal circuits. In addition to the interaction between drugs and circuit components, the altered blood flow patterns seen in ECMO may affect organ function and drug kinetics. Some studies suggest the lack of pulsatile blood flow often observed in venoarterial (VA) ECMO may lead to microvascular changes and renal dysfunction, with further potential for impaired drug clearance.

Similar to ECMO, the use of **continuous renal replacement therapy (CRRT)** may also impact the PK-PD of certain drugs. The small pores of the CRRT membranes generally limit clearance to the unbound fraction of a drug. Thus, drugs that are more extensively protein bound are less likely to be cleared by the circuit; conversely, hypoproteinemia is often seen in critical illness and may result in increased clearance due to a higher free fraction of drug in the plasma. Drugs with higher V_d (lower proportion of drug in the intravascular space) will not be cleared as extensively. As with ECMO, the circuit itself may adsorb drugs resulting in a higher V_d and further reducing clearance. In addition to patient- and drug-specific factors, the mode of CRRT used, blood flow rate (Q_b), and dialysate flow rate (Q_d) may also affect the clearance of drugs during renal replacement therapy.

The small pores of the CRRT membrane generally limit drug clearance to the free (unbound) fraction of a drug.

Body composition plays a significant role in drug disposition in both healthy and critically ill children. **Pediatric obesity** is on the rise in the United States and has implications for medication dosing and management in the critically ill child. Current Centers for Disease Control and Prevention (CDC) statistics suggest 13.7 million children and adolescents (nearly 20% of the pediatric population) are considered obese, defined as a body mass index (BMI) ≥ 95th percentile for the child's age and gender. Having a larger relative proportion of adipose tissue can affect the distribution of many drugs, but the effect remains difficult to estimate with indirect measures such as BMI and body surface area (BSA). Different methods of drug dosing in children include weight-based, age-based, allometric scaling, and BSA-based dosing. Weight-based dosing is used most commonly, followed by BSA-based dosing, which is frequently utilized for dosing chemotherapy. BSA is commonly calculated using the Mosteller equation:

$$\mathrm{BSA}\left(\mathrm{m}^2\right) = \sqrt{\frac{\mathrm{height}\left(\mathrm{cm}\right) \times \mathrm{weight}\left(\mathrm{kg}\right)}{3600}}$$

Weight-based dosing strategies include using total body weight (TBW), ideal body weight (IBW), or adjusted body weight (ABW or IBW-Adj). While TBW is measured, IBW is calculated based on height and is used to limit the risk of overdosing in overweight patients. Several methods for calculating IBW in children have been reported, but currently no gold standard equation has been identified. The ABW (IBW-Adj) is a calculated weight frequently used by dieticians to estimate caloric requirements but also may be considered for dosing certain drugs when a child's actual weight exceeds 120% of his/her calculated IBW. It is important to consider the pharmacokinetic information available when dosing medications in obese children and the risk of under- or overdosing medications (◘ Table 6.7). Much of the data regarding weight-based dosing strategies for obese patients is obtained from adult studies, and, as such, consultation with a pediatric pharmacist should be considered whenever dosing questions arise.

For obese children, weight-based dosing recommendations may be based on total body weight (TBW), adjusted body weight (ABW), ideal body weight (IBW), or body surface area (BSA) since there is no gold standard method to adjust dosing in obese children.

Opioids such as fentanyl, hydromorphone, and morphine are primarily metabolized by the liver and eliminated either intact or as metabolites in urine.

Table 6.7 Weight-based dosing strategies for obese pediatric patients

	Calculation	Suggested use
Total body weight (TBW)	Measured	Cephalosporins heparin (loading dose) propofol succinylcholine vancomycin
Ideal body weight (IBW)	*Moore method:* (1) Using growth chart, plot height-for-age (2) Obtain percentile (3) Identify corresponding weight at the same percentile	Acyclovir cisatracurium digoxin levothyroxine midazolam (infusion) remifentanil rocuronium vecuronium
	McLaren method: (1) Using growth chart, plot height-for-age (2) Obtain percentile and draw horizontal line to 50th percentile (3) Draw vertical line to weight at the 50th percentile for the corresponding age	
	Body mass index (BMI) method: (1) Using BMI-for-age chart, obtain BMI at 50th percentile for patients age (2) Multiple by the square of the patient's height	
Adjusted body weight (ABW or IBW-Adj)	IBW + 0.4 (TBW – IBW) *For patients whose weight exceeds 20–30% of the IBW*	Amikacin cisatracurium enoxaparin gentamicin heparin (infusion) rocuronium/vecuronium tobramycin

Dosing of these medications depends on pharmacokinetic parameters of the drug and the drug's properties (lipophilic vs. hydrophilic). While recommendations support the use of ABW to dose hydromorphone and fentanyl due to their lipophilic properties and IBW when dosing morphine due to its hydrophilic properties, clinicians often start with IBW or TBW dosing and titrate upward toward a typical adult dose, as needed.

Since antimicrobial agents are generally hydrophilic, they carry the risk of being underdosed in obese children who have an increased V_d due to increased total body water. The penicillins and cephalosporins are typically dosed based on TBW up to the maximum adult dosing. Aminoglycosides are water soluble and are primarily eliminated by glomerular filtration. ABW should be used to dose gentamicin and tobramycin in critically ill, obese children, and appropriate therapeutic drug monitoring (TDM) should be undertaken to allow for appropriate dose adjustments. Vancomycin distributes into fluid and tissues widely and is eliminated by glomerular filtration. Some studies recommend dosing vancomycin in obese children based on TBW while using a maximum vancomycin in dose and adjusting based on trough levels.

Heparin and low molecular weight heparins (LMWH) are also affected by weight and body composition. Heparin is highly protein bound and is cleared primarily via macrophages and the reticuloendothelial system and to a lesser extent by the kidneys. Pharmacokinetic data suggest obese children should receive heparin bolus doses based on TBW, but infusion rates should be based on ABW due to the hydrophilic properties of the drug and the water content of adipose tissue. LMWH are primarily eliminated by the kidneys; for critically ill obese children, the dosing recommendation is to utilize ABW and titrate to target a desired anti-Xa activity level. As in all situations involving pediatric patients with a diagnosis of obesity, consultation with published dosing guidelines and/or a pediatric pharmacist is recommended.

Therapeutic hypothermia is occasionally utilized in the PICU to limit brain injury after cardiac arrest or to treat severe, refractory status epilepticus. The putative benefit of this therapy, specifically the limitation of secondary neurologic damage, may be impacted by the effects of hypothermia on drug disposition (ADME) and effectiveness. Human and animal studies demonstrate a complex relationship between hypothermia and drug metabolism, elimination, and response. Hypothermia reduces the function of the hepatic cytochrome p450 system, thereby decreasing the metabolism and clearance of drugs that interact with this enzyme family. For example, PK analysis demonstrates a >100-fold decrease in systemic clearance of midazolam when the subject's core temperature was lowered below 35°C, likely due to impaired CYP3A4 and CYP3A5 activity. Similar reductions in clearance during hypothermia are observed for other hepatically metabolized drugs including fentanyl, morphine, barbiturates, propofol, vecuronium, propranolol, phenytoin, and many others. Proposed mechanisms for hypothermia-induced reduction in activity of the p450 enzymes include reduction in the rate of redox reactions, decreased substrate affinity for enzymes, and changes in enzyme binding pocket conformation. In addition to impairing metabolism, hypothermia may also reduce the effectiveness of certain drugs. Morphine is hepatically metabolized by phase II glucuronidation reactions primarily to morphine-3-glucuronide (no analgesic effect) and morphine-6-glucuronide (reduced analgesic potency compared to the parent drug). Hepatic metabolism of morphine may be impaired by hypothermia; however, animal studies have shown that both morphine and its active metabolite have reduced affinity for the μ-opioid receptor as body temperature decreases, thereby reducing their potency. The net impact of hypothermia on morphine may be different for each patient, warranting close monitoring for both inadequate drug response and adverse effects.

Hypothermia may decrease the activity of hepatic cytochrome p450 enzymes by reducing the rate of redox reactions, decreasing substrate affinity for enzymes, and changing the enzyme binding pocket conformation.

6.9 Pharmaceutics

Pharmaceutics is the science of pharmaceutical systems and focuses on drug preparations and dosage forms. There are a number of important applications of pharmaceutics to the critically ill child such as the physicochemical properties of drugs, which should be considered when contemplating the site of administration. When administering parenteral preparations, knowledge of the formulation pH, concentration, and osmolarity is critical. Agents with a non-physiologic pH should not be administered intramuscularly as tissue necrosis can occur. Phenytoin, for example, is soluble only at a pH of approximately 11; therefore, intramuscular administration may cause local hemor-

rhagic necrosis and should be avoided. The administration of phenytoin through peripheral catheters or peripherally inserted central catheters should also be avoided due to the risks of phlebitis and precipitation, respectively. Fosphenytoin, the phosphorylated prodrug of phenytoin, has a pH of 8.6, allowing for safer IV and IM administration due to its more favorable pharmaceutical properties.

Concentration, pH, osmolarity, and vasoconstrictive properties may limit the safety of peripheral administration of some drugs.

In addition to pH, drug properties such as concentration, osmolarity, vasoconstrictive potential, or predisposition to induce phlebitis may limit the safety of peripheral IV administration. **Hyperosmolar solutions** may cause vascular endothelial damage and thrombophlebitis when administered in small blood vessels and these agents should be administered via a central venous catheter whenever possible. It is prudent to avoid prolonged peripheral administration of medications with an osmolarity >900–1100 mOsm/L. When information regarding the osmolarity of medications is not readily available, the clinician must rely on published maximum concentrations to guide the decision regarding administration route. Vasoconstrictive medications such as norepinephrine and phenylephrine may pose a higher risk of limb ischemia when administered peripherally. Medications inherently more likely to induce phlebitis when administered into small, peripheral veins include nafcillin, amphotericin B, propofol, and vancomycin. Management of tissue extravasation is agent specific and may include warm or cold compresses, elevation, or the use of an antidote such as hyaluronidase to promote dispersion from the site. Vasoconstrictive agents such as phenylephrine and norepinephrine can cause significant tissue necrosis if extravasation occurs; treatment may include local instillation of a vasodilator such as phentolamine. Consultation with a pharmacist and, if indicated, plastic surgery should not be delayed.

When administering multiple medications concomitantly through the same catheter, physical and chemical compatibility should be investigated prior to initiation. Multiple tertiary references and charts exist to assist with assessment of drug-drug compatibility. When utilizing these references, note the specific medication concentrations that were studied as only those concentrations listed may be extrapolated to clinical practice. For example, dobutamine 1 mg/mL is compatible with a dilute KCl solution (20 mEq/L) but incompatible with a concentrated KCl solution (160 mEq/L).

Preservatives and solubilizing agents may pose a higher risk of toxicity and injury in young children.

Attention should also be paid to the content of **preservatives** and **solubilizing agents** in medications used in critically ill children, particularly when high doses are used or in the setting of organ dysfunction. Benzalkonium chloride, a bactericidal preservative found in many albuterol nebulizer solutions, may produce bronchoconstriction in some patients. Benzyl alcohol is a preservative found in some injectable drugs which may accumulate, resulting in serious toxicities and even death. High exposure to benzyl alcohol-containing products in neonates has been associated with an increased incidence of metabolic acidosis, neurological impairment, cerebral palsy, and intraventricular hemorrhage. If possible, preservative-containing medications should be avoided in patients less than 60 days of age or in those with severe renal impairment. Propylene glycol is a solubilizing agent found in formulations of drugs such as pentobarbital, diazepam, and lorazepam and is normally metabolized by the liver to lactic acid (◘ Fig. 6.12). When administered at high doses over a sustained period of time (e.g., during a pentobarbital-induced coma), both propylene glycol and lactic acid may accumulate resulting in a hyperosmolar state with an increased anion gap acidosis. Renal dysfunction may also exacerbate this state as the excretion of unchanged propylene glycol is impaired. Certain

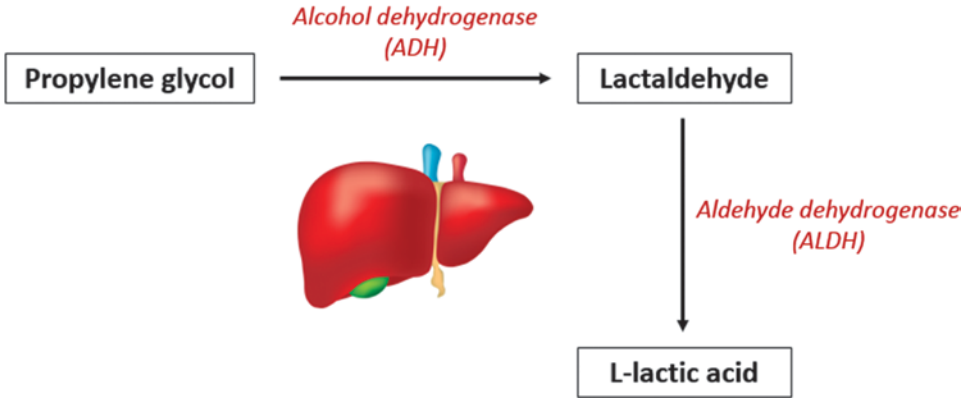

Fig. 6.12 Conversion of propylene glycol to lactic acid in the liver

drug formulations should also be avoided due to their excipients (diluents). For example, injectable itraconazole contains a solubilizing excipient that accumulates in patients with renal insufficiency and is contraindicated in children with a GFR <30 mL/min due to the increased potential for toxicity.

6.10 Summary

In the course of treating critical illness in children, the pediatric intensivist utilizes a broad variety of drugs and therapies. A strong understanding of the science of pharmacology including pharmacokinetic, pharmacodynamic, and pharmaceutical concepts is essential to the care of critically ill patients. Age, organ dysfunction, disease state, co-administered drugs, and therapeutic interventions can all affect drug disposition, effectiveness, and toxicity with potentially significant impacts on patient morbidity and mortality. Whenever uncertainty exists about using a new or infrequently used medication, consultation with a clinical pharmacist or reference resources will help to determine the optimal dosing strategy and to understand how altered organ function and drug interactions may affect the pharmacokinetic and pharmacodynamics properties of the agent.

Review Questions

1. Which of the following is true regarding volume of distribution (V_d)?
   A. V_d is used primarily to determine the frequency of drug dosing.
   B. V_d is typically small for drugs that are highly protein bound.
   C. For most neonates, V_d is smaller due to lower total body water content.
   D. A patient with significant fluid overload would be expected to exhibit a smaller V_d for a specific drug compared to a patient with normal fluid status.
   E. Drugs with a small V_d tend to be widely distributed in peripheral tissues.

2. Which statement best describes the differences between first-order and zero-order elimination?
   A. Zero-order elimination is characterized by a fixed amount of drug removed per unit time; first-order elimination is characterized by a fixed percentage of a drug removed per unit time.
   B. First-order elimination includes the linear Michaelis-Menten or "saturable elimination" model.
   C. Zero-order elimination is common in the initial phases of drug elimination, whereas first-order kinetic often follows after a steady state has been achieved.

D. Zero-order elimination is often seen in the setting of subtherapeutic dosing.
E. Zero-order elimination only occurs with highly protein-bound drugs.

3. Which of the following is a phase I hepatic metabolism reaction?
A. Glucuronidation
B. Methylation
C. Hydrolysis
D. Sulfation
E. Conjugation to glycine

4. Which one of the following statements regarding the effects of therapeutic hypothermia on drug disposition is true?
A. Hypothermia generally increases the effectiveness of medications.
B. The major effect of hypothermia on drug metabolism is caused by an increased affinity of drug molecules for the cytochrome p450 enzymes.
C. Hypothermia increases drug distribution into the central nervous system.
D. Hypothermia decreases hepatic metabolism by reducing the function of the cytochrome p450 enzymes.
E. The effects of hypothermia have been demonstrated mainly in the absorption and distribution phases of drug pharmacokinetics.

5. Which statement does *not* reflect the known effects of an extracorporeal membrane oxygenation (ECMO) circuit on drug disposition?
A. The ECMO circuit may decrease the plasma concentration of a drug by increasing its volume of distribution.
B. Free drug concentration may be decreased by binding to the polyvinyl chloride tubing of the ECMO circuit.
C. Free drug concentration may be decreased by adsorption to the ECMO oxygenator.
D. Patients who require ECMO often have coexisting organ failure which contributes to alterations in drug kinetics.
E. The ECMO circuit enhances hepatic drug metabolism by inducing cytochrome p450 enzymes.

Answers

1. B

Volume of distribution (V_d) is a theoretical value representing the plasma volume required to contain an entire administered dose of a drug based on its concentration in the plasma. Drugs that distribute extensively outside the intravascular space into peripheral tissues have a larger V_d. A high degree of binding to plasma proteins tends to keep drugs in the intravascular space; therefore, drugs with a high degree of protein binding have a smaller V_d. Volume of distribution is not particularly helpful in determining the frequency of drug administration; however, knowledge of V_d can assist with determining loading and reloading doses of certain medications. As neonates have a higher percentage of body water compared with older children and adults, V_d for many medications is higher in this population (e.g., gentamicin). A patient with severe edema or fluid overload would be expected to have a higher V_d for most hydrophilic medications as increased third-space and interstitial fluid provides a larger volume into which the drug may distribute.

2. A

A drug that is removed from the body as a fixed percentage over time is described as having first-order elimination. (see Fig. 6.10 in the text).

First-order kinetics implies that the elimination mechanisms are not yet saturated, so a higher concentration of drug should lead to a higher quantity eliminated in that time interval (the percent eliminated is a fixed quantity). Under first-order kinetics, dose adjustments are expected to produce proportional changes in serum concentration. Most drugs used at therapeutic concentrations are eliminated via first-order kinetics. Zero-order elimination occurs when a fixed amount of drug (rather than percentage) is removed per unit time, and the linear plot of drug concentration versus time demonstrates linear decay. Zero-order kinetics implies a saturation of the elimination mechanisms. Many drugs display first-order kinetics initially, but at higher concentrations when elimination pathways become saturated, removal of the drug becomes zero order; therefore, this type of elimination is often seen in the setting of supra-therapeutic dosing or an overdose. The Michaelis-Menten model describes enzyme kinetics that approach a maximum rate (V_{max}). At lower doses, drug elimination follows first-order kinetics but once the elimination mechanisms reach V_{max}, elimination becomes zero-order.

3. C

Hepatic drug metabolism is generally classified into either phase I or phase II reactions. Phase I reactions are *modification reactions* that include hydrolysis, reduction, oxidation, and cyclization/decyclization. These reactions serve to introduce polar groups to exogenous drug molecules, which limits transport through cellular membranes and enhances renal elimination. Phase I reactions may also convert a parent drug to an active metabolite. Phase II reactions are *conjugation reactions* whereby a charged or polar group (e.g., glutathione, sulfate, glycine, methyl, glucuronic acid) is added to the drug molecule. This serves to increase the metabolite's molecular weight and charge, making it less reactive and more likely to be excreted. Of the choices listed, only hydrolysis is considered to be a phase I reaction as it involves modification of the drug by reaction with a water molecule and not conjugation to a new functional group.

4. D

During therapeutic hypothermia, the function of the hepatic cytochrome p450 system is reduced, thereby decreasing the metabolism and clearance of drugs that interact with this enzyme family. Reductions in clearance during hypothermia are observed for many hepatically metabolized drugs including fentanyl, morphine, barbiturates, propofol, vecuronium, propranolol, and phenytoin, among others. Proposed mechanisms for hypothermia-induced reduction in activity of the p450 enzymes include a reduced rate of redox reactions, decreased substrate affinity, and changes in enzyme binding pocket conformation. In addition to impairing hepatic metabolism, hypothermia may also reduce the effectiveness of certain drugs. Morphine is hepatically metabolized by both phase I (p450 enzymes) and phase II (glucuronidation) reactions; thus, its clearance may be impaired by hypothermia. However, animal studies show that morphine has reduced affinity for the μ-opioid receptor as body temperature decreases, thereby reducing its potency. Hypothermia has not been described to increase drug transport into the central nervous system; rather, some animal studies have demonstrated hypothermia may provide a protective effect in preventing disruption in the blood-brain barrier.

5. E

The use of ECMO may be a lifesaving therapy for many patients with critical illness, but the circuit has well-described effects on drug disposition. The addition of an ECMO circuit to a patient's native circulation creates a larger

volume of distribution for many drugs that may require adjustments in loading and reloading doses. The circuit tubing and oxygenator may sequester drugs via adsorption of drug molecules, thus decreasing the plasma concentration of free drug. It is important to recognize that many patients who require ECMO also have coexisting failure of one or more organ systems, making the effects of the ECMO circuit on drug pharmacokinetics difficult to distinguish from the effects of critical illness. Finally, while induction of cytochrome p450 enzymes is known to enhance metabolism of many drugs, there is no known effect of ECMO on induction or inhibition of liver enzymes.

Learning Objectives

- Describe key points in human lung embryology
- Understand the transport of gas through the conducting airways to and from the alveoli
- Understand the structure of the airways and their properties
- Describe the two sources of blood supply to the lungs
- Understand and contrast dynamic and static compliance
- Understand compliance of lung, chest wall, and total respiratory system
- Describe hysteresis and its causes
- Understand the function of and unique properties of lung surfactant
- Understand the determinants of airways resistance and the differences between laminar and turbulent flow
- Understand and use the alveolar gas equation to assess oxygenation defects

This chapter will review how the normal lung should function while highlighting disease that disrupts normal function. A brief review of lung development will be presented, followed by lung anatomy and, finally, lung physiology. It is important to understand lung development in the context of lung anatomy because there can be disruptions in the development of the respiratory system that can contribute to disease. Furthermore, the arrangement of the respiratory system has important implications for how well the lungs function in the vital process of respiration, namely, oxygenation and ventilation.

7.1 Developmental Biology/Anatomy

An understanding of how the respiratory system develops supports a knowledge of anatomy of the lungs. It also allows for an understanding of how lung anomalies may arise if insults to the normal lung development occur during certain phases of gestation.

Lung development has its beginnings very early in fetal development. In week 4 of embryonic development, the lungs are formed by the projection of the lung bud (laryngotracheal groove) from the ventral foregut. By weeks 5 and 6, the left and right lungs push into what will be the pleural cavity and descend into the thorax. In gestational week 7, descent of lung and heart structures is curtailed by enlargement of the liver, and by week 17, all the airways have developed within the space that will be the thoracic cavity. The airways then continue to differentiate into respiratory bronchioles, and acinus formation occurs. The acinus is the basic unit of the lung and will be discussed in more detail in a subsequent section. From gestational age 26 weeks to adolescence, the lung develops into the organ with the primary responsibility of respiration. This stage of lung development is crucial for creating functioning alveolar units and increasing surface area needed for gas exchange. These stages of lung development are highlighted in ◘ Table 7.1.

The structure of the airways in the lung have developed by gestational week 17.

Gestational age 26 to adolescence is when alveolarization of the lung occurs.

In concert with lung parenchymal development, diaphragm, vascular, and thoracic cavity development occurs. This elegant coordination of lung and respiratory system development, when normally conducted, leads to a normally functioning respiratory system that allows for gas exchange and, most importantly, oxygen delivery to organs and working tissue. When lung and respiratory system development is disrupted, congenital anomalies and/or a deficiency of gas-exchanging units leads to disruption of oxygenation and ventilation. Therefore, understanding the embryologic development of the lung is important to identify why certain disease states occur.

Table 7.1 Stages of lung development

Gestational age	Developmental period	Developmental milestones
3–6 weeks	Embryonic	Lung bud forms and differentiates to segmental bronchi
7–16 weeks	Pseudoglandular	Subsegmental bronchi further differentiate to terminal bronchioles
17–25 weeks	Canalicular	Respiratory bronchioles differentiate and form acini
26–35 weeks	Saccular	Alveolarization and expansion of gas-exchanging units, surfactant production
36 weeks–postnatal maturation	Alveolar	Further alveolarization, maturation of alveolar/capillary interface, lung growth

Embryonic development of the respiratory system reaches a critically important phase encompassing the canalicular and saccular periods (listed in Table 7.1). It is during this phase that development, maturation, and thinning of alveolar structures allow for close approximation with pulmonary capillaries that will take up oxygen and deliver it to the rest of the body. It is also during this critical phase that surfactant production occurs in the type II epithelial cells of the lung. Surfactant is extremely important for promoting normal lung mechanics. Disruption of lung development by preterm birth in the canalicular and saccular periods leads to respiratory distress syndrome (RDS), pulmonary hypoplasia, and subsequent bronchopulmonary dysplasia (BPD) characterized by disrupted lung mechanics and gas exchange. This pathology is characterized by an inability to maintain adequate functional residual capacity (FRC). The importance of maintaining normal FRC will become clear in the subsequent sections of this chapter.

Disruption of gestation (preterm birth) in the canalicular and saccular periods lead to RDS. This is because pulmonary hypoplasia and surfactant deficiency limit the lungs' ability to function properly.

The lung continues to grow after birth both by further alveolarization (addition of and maturation of alveoli) as well as by somatic growth. It is because of this continued growth that neonates and infants with respiratory distress syndrome can recover a significant amount of lung function that similarly injured adults with acute respiratory distress syndrome (ARDS) are less likely to recover. This is one distinction between pediatric and adult lung anatomy and physiology that is dependent upon the development of the lung. Another distinction rooted in the development of the lung has to do with chest wall compliance. The neonate's and infant's chest wall is much more compliant than that of an adult which is supported by fully ossified ribs. This difference is evident both in healthy states and in lung disease as the compliant chest wall is less able to counteract lung elastic recoil. It is most pronounced in lung disease (acute and chronic) where thoracic excursion is limited leading to retractions with paradoxical thorax and abdominal movement. These forces acting upon and between lung and chest wall are important to understand in relation to alveolar ventilation and, ultimately, gas exchange which is the lung's primary task. The next sections of this chapter will focus on normal anatomy and physiology of the respiratory system (lung and thoracic cage) with important examples of aberrant lung pathology to highlight physiologic principles.

A neonate's compliant chest wall makes it difficult for adequate lung excursion to occur. Especially in the case of lung disease that results in non-compliant lung tissue.

7.2 Anatomy of the Lung

The respiratory system consists of the airspace (airways and alveoli) as well as lung parenchyma (interstitium and pulmonary vasculature). Both are acted upon and protected by the pleura, diaphragm, and chest wall. This anatomic arrangement allows for the important task of ventilation, ventilation/perfusion (V/Q) matching, and ultimately gas exchange. The subsequent sections will address how the respiratory system normally functions to perform this important physiologic task. This section will address the anatomic units involved in that task.

7.2.1 Airways

As the laryngotracheal groove buds anteriorly from the ventral foregut, it first forms the tracheobronchial tree. This tracheobronchial tree as it exists in the fully developed individual consists of the trachea that branches into the right and left main bronchi which subsequently branch 23 times until the airways terminate in respiratory bronchioles and alveoli. Larger airways are supported by cartilage to provide a scaffold that maintains airway patency. Disorders in cartilage growth and development such as tracheo- and bronchomalacia lead to airway obstruction, defects in V/Q matching, and defective mucus clearance. Airways distal to the trachea and main bronchi that reach further into the lung parenchyma are supported or tethered by acinar units (lung parenchyma with elastin fibers) and have airway smooth muscle that can contract and decrease the radii of conducting airways. Therefore, diseases which affect how acini are expanded (atelectasis) and smooth muscle contraction (asthma) can influence airway patency. The total cross-sectional area of the conducting airways increases as airflow moves distally allowing for, in a healthy state, unencumbered flow of oxygenated air to the alveoli. This seems somewhat counterintuitive because airways get smaller as air moves more distally. However, the cumulative number of airways leads to a significant increase in total cross-sectional area, and the total amount of conductive airspace is greater at the level of bronchioles in comparison to the trachea and bronchi.

As airways branch distally into the lung, the cumulative cross-sectional area for airflow increases even though airways are much smaller than trachea and bronchi. This cumulative increase in cross-sectional area is helpful in the healthy state as it allows for unencumbered airflow to alveoli. In obstructive airways disease, such as asthma, the cumulative narrowing of these small airways can have a significant impact on ventilation.

As airways branch and narrow, going from bronchi to bronchioles to respiratory bronchioles, they form primary units of the lung defined as the pulmonary lobule which contains acinar units. A terminal bronchiole and acinus together form a lobule. An acinus is a respiratory bronchiole with the alveoli it ventilates. These terms are important to comprehend as lung diseases have patterns that affect lobules and acini. Understanding the distinct anatomic units of the lung helps in interpreting radiographs and pathology specimens. The acinus as a distinct anatomic unit of the lung is important to understand as it has implications on gas exchange and lung compliance.

7.2.2 The Pulmonary Lobule and Acinus

The acinus is the working unit of the lung that completes the main task of the respiratory system; oxygen uptake and carbon dioxide removal.

Airways eventually branch to terminal bronchioles that feed a pulmonary lobule. The lobule contains the terminal bronchiole, respiratory bronchiole, and alveoli. The acinus is the unit of the lung that is supplied by a terminal bronchiole, and so it is comprised of the respiratory bronchiole and alveoli. It can be thought of as the working unit of gas exchange. This is where alveoli exist in close proximity to blood vessels that collect oxygen and dispense carbon dioxide. Every part of the respiratory system functions to ensure adequate

ventilation of the acinar structures for proper gas exchange. This is much like the mitochondria of working cells being supported by the cardiorespiratory system or how the nephron is the working unit of the kidney. Disruption of acinar structure or function can have great effects on the primary function of the lung, gas exchange, as well as lung expansion.

Within the acinus are not only alveoli but a rich network of pulmonary vasculature in the form of pulmonary capillary beds that envelope gas-exchanging alveoli. The arrangement of inflated alveoli to pulmonary capillaries is crucial to the main work of the lung and oftentimes only appreciated when this arrangement is disrupted by disease. Congenital conditions such as alveolar-capillary dysplasia represent a failure of the acinar structure to develop alveoli and capillaries in close proximity and thus result in gas exchange failure. Premature birth leads to a disruption in acinar development (airspace and vascular development) as well as surfactant deficiency which results in less surface area for gas exchange. Acute injury from infection or edema can lead to acinar dysfunction by making it more difficult to diffuse oxygen across diseased alveolar-vascular membranes or by destroying acinar units altogether. Chronic, diffuse disease that affects acinar units can also lead to less surface area for gas exchange.

7.2.3 Pulmonary Vasculature

The lung has 2 sources of blood supply; pulmonary arterial vasculature and systemic arterial vasculature.

The pulmonary vasculature develops along with branching airways, and this concerted development is crucial for ventilation and perfusion matching, necessary for adequate gas exchange. The lung has two sources of blood supply. The main blood supply to the lung comes from the right heart and pulmonary arteries. These vessels carry deoxygenated blood that has supplied working organs and mitochondria with oxygen. They branch along with branching airways and eventually form capillaries that envelop the alveoli (acini) allowing for gas exchange. Capillaries then feed pulmonary veins that return oxygenated blood to the left side of the heart.

The pulmonary vasculature (arterial and venous) is under low-pressure conditions in healthy states. Hypoxemia, disrupted lung development, and pulmonary vascular disease can all affect how blood supplies the lung and acinar units. In the case of hypoxemia, the pulmonary arteries limit blood flow to lung units (lobules and acini) that are not ventilated adequately. This is advantageous in acute disease as it can preserve ventilation and perfusion matching. It can be disadvantageous in chronic disease as this vasoconstriction can eventually lead to chronic vasoconstriction, arteriole wall thickening, and pulmonary hypertension (PH). In cases such as BPD where pulmonary vascular development is disrupted, pulmonary arterioles and capillaries can be in short supply for working acini to transfer oxygen to pulmonary blood. Finally, primary pulmonary hypertension (in contrast to secondary PH that develops from lung disease and chronic hypoxemia) can limit blood supply to working acinar structures, disrupting ventilation and perfusion.

The second source of blood to the lungs is from the left side of the heart. This blood source, like blood supply to other vital organs and working muscles, is oxygenated blood that supplies working tissue of the lungs. This blood supply consists mainly of bronchial arteries that feed the airways of the lungs. Bronchial arteries arise from the aorta and drain to the azygos veins. In chronic, suppurative lung disease like bronchiectasis, or disease states that cause pulmonary hemorrhage, understanding that the lungs have both pulmonary arterial blood flow that is under relatively low pressure and systemic, or bronchial,

arterial blood flow which is under relatively high pressure can be clinically relevant. In cases of pulmonary hemorrhage from pulmonary arterioles, the bleeding may not be particularly brisk. In fact, some individuals with pulmonary bleeding syndromes may not have hemoptysis as a presenting sign. In contrast, bleeding from bronchial artery supply is very significant and can cause massive hemoptysis. Understanding the severity of bleeding and the anatomy of pulmonary blood flow will allow the astute clinician to better localize the source of pulmonary bleeding.

7.2.4 Pleura/Chest Wall/Diaphragm

The pleura, chest wall and diaphragm are crucial for ventilation as well as protection of the lungs.

The lung and its components (airways, lobules/acini, blood vessels) are supported and acted upon by the thoracic cavity. The thoracic cavity consists of the pleura, chest wall, and diaphragm. These components are crucial for housing lung structures, protecting lung structures, and, most importantly, moving (ventilating) lung structures to bring oxygen containing air into the lung and to move the by-product of metabolism (carbon dioxide) out of the lung.

The next section of this chapter will highlight just how important the thoracic cavity is to the process of ventilating the lung. However, it is important to highlight again the difference between an infant thoracic cavity and that of an older child/adult thoracic cavity. The main difference is in the supporting cartilaginous and ossified ribs. In infants, the chest wall is supported by a significant amount of compliant/cartilaginous rib structure. Therefore, a more compliant chest wall can make it difficult to counteract lung elastic recoil especially in disease states. In acute disease, infants can display more signs of respiratory distress such as suprasternal and subcostal retractions than adults. In chronic disease, infants can have significant problems with failure to thrive because the metabolic demand of breathing can be amplified in an infant with difficulties breathing with a compliant chest wall. Merely maintaining adequate FRC can be a significant problem for infants with lung disease and noncompliant lungs. This should become clearer in the next section of lung physiology.

7.3 Lung Physiology

Up until this point, the anatomy of the respiratory system has been discussed. Again, understanding how the respiratory system is normally developed and arranged is important to understanding how the respiratory system works: respiratory physiology. An emphasis on normal physiology will be presented with examples of disease that disrupt normal function.

FRC is the “steady state” of the lung in which elastic recoil of the lung is equal and opposite to elastic recoil of the thoracic cavity. Disruption of FRC by disease leads to increased work of breathing and disruption of adequate ventilation.

The respiratory system without movement at end exhalation is in a balance between the chest wall and diaphragm pulling outward against the lung recoiling inward. This point at which the two forces are equally opposing is functional residual capacity (FRC). The respiratory system is only part of the time at FRC and the rest of the time it is in motion. When the lung is in motion and ventilating, the chest wall and diaphragm need to overcome forces in order to move air into and out of the lung. Understanding these forces helps clarify normal pulmonary physiology and how normal lung mechanics can be disrupted. These forces that impede ventilation/respiratory movement can be broadly broken down into two main categories: the elastic forces that impede chest movement (lung compliance) and the resistive forces that impede airflow or airways resistance.

7.3.1 Lung Compliance/Elastance

Lung compliance is a measure of how much of a change in pressure is needed to make a change in volume of air inspired/expired.

Lung compliance is a measure of how deformable the lungs are: a measure of the lungs' ability to move. It can be calculated as static or dynamic and is obtained by dividing the change in volume by the pressure needed to make that change ($C = \Delta V / \Delta P$). The measure of compliance of the whole lung is transmural pressure. This is the difference in pressure that is measured from the alveolar space to the pleural space. Transmural pressure equals alveolar pressure minus pleural pressure ($P_{tm} = P_{alv} - P_{pl}$).

Lung elastance is simply the reciprocal of compliance, and it is dependent upon elastin fibers in the parenchyma but, in the healthy lung, more dependent upon surface tension of the alveolus. Since there are over 300 million alveoli in the lung, the surface tension of alveoli has a profound impact on the overall compliance, or elastance, of the lung. The additive result of millions of alveoli with their individual surface tension characteristics can be analyzed as a whole. It is important to realize, however, that lung disease is not uniform, and variably affected areas of the lung will have differing surface tensions and, consequently, varying lung compliance. This is exemplified in ARDS. For the purposes of better understanding lung compliance, however, the cumulative effects of surface tension on lung compliance are important.

The law of Laplace relates the pressure over a liquid surface within a sphere or cylindrical vessel, to the area of that surface, and the surface tension of the liquid. It is represented in the following equation:

$$P = 2T / R$$

where P is pressure, T is surface tension, and R is the radius of a cylinder or bubble (or in the case of the lung, alveolus). In the case of the alveolus, the surface tension is very important in determining pressure required to maintain inflation of the alveolus. In the case of the lung, the pressure required for distention of the alveolus or many alveoli is very important in determining compliance of the lung. Lung compliance is dependent upon pressure gradients across the lung and the relationship of change in pressure to change in volume. Therefore, surface tension as a major component of alveolar pressure is critical in determining how well the lung functions. The components of alveolar surface lining liquid determine surface tension and the ease at which the lung inflates. The vital surface tension lowering component of the alveolar lining is surfactant.

One of surfactant's critical characteristics is its ability to vary its surface tension properties across varying radii/alveolar volumes. According to the Laplace equation, as surface tension increases, so should pressure in the alveolus. Pressure and surface tension are proportional. However, pressure and radius (or, in the case of the lung, pressure and alveolar volume) are inversely proportional. As the radius of the alveolus increases, the pressure inside should decrease, and as the radius of the alveolus decreases, the pressure inside should increase. If surface tension were to remain constant, then alveoli of smaller volume would have required higher distending pressures, and gas would preferentially move from smaller to larger alveoli. Smaller alveoli would be more difficult to remain open, and larger alveoli would tend to increase in size. This would be quite disadvantageous in the lung as poorly ventilated or atelectatic lung units would remain atelectatic, and larger or emphysematous lung units would become more and more emphysematous.

If surface tension in the lung were constant, alveolar volume of large alveoli would increase leading to emphysema, and alveolar volume of small alveoli would decrease leading to atelectasis. Surfactant is important to maintaining normal lung compliance because it can vary surface tension and, in turn, balance compliance across the lung.

Fortunately, surfactant has the special ability to decrease surface tension at low lung volumes and increase surface tension at high lung volumes. Therefore, surface tension is a variable, not a constant. This is shown in the equation below where pressure can remain constant in the face of varying radii (alveolar volumes):

$$2 \downarrow T / \downarrow R = P_{alv} = 2 \uparrow T / \uparrow R$$

Maintaining a constant alveolar pressure (P_{alv}) is highly important to maintaining a constant transmural pressure which determines how well the lung can perform its mechanical work (ventilate).

7.3.2 What Is Surfactant?

Surfactant is the substance produced in alveolar type II cells that allows surface tension to increase at high lung volumes and decrease at low lung volumes. How surfactant is composed allows this to happen. Surfactant is 90% lipid, and 70–80% of the lipid is dipalmitoyl phosphatidyl choline (DPPC). It is the nature of surfactant DPPC which gives its varying surface tension properties. Ten percent of the composition of surfactant is protein of which surfactant proteins comprise about 2%. These surfactant proteins B and C are very important and responsible for controlling the release and stabilization of surfactant in the alveoli. Infants born with the absence of surfactant protein B (SPB) and ATP-binding cassette member A3 (ABCA3) will have severe respiratory distress and failure. This will also occur to a lesser degree with other surfactant protein deficiencies. Surfactant proteins A and D belong to a family of immune proteins called collectins and are involved in pathogen recognition and immune cell regulation.

Other clinical situations in which surfactant function can be disrupted are neonatal respiratory distress syndrome, ARDS, and congestive heart failure (CHF). All are clinical entities that perturb the natural function of surfactant and lead to poor lung compliance, leading to inadequate ventilation.

Deficient, defective and displaced surfactant in the diseased lung leads to a state of non-compliant lung.

In neonatal RDS, a baby is born at a premature age prior to adequate lung development and maturation of alveolar type II cells. Hence, the premature neonate is born with a surfactant deficiency. As the baby transitions from a liquid environment in the uterus to an air environment, amniotic fluid in lungs needs to be expelled to replace fluid-filled alveoli with air-filled alveoli. As some alveoli do not completely expand, heterogeneity occurs among lung units, and gas will preferentially redistribute from smaller alveolar units to larger units in the absence of surfactant (Laplace's law). Volume loss in some lung units occurs in conjunction with overinflation in others. Atelectasis can occur in conjunction with emphysema or even air leak/pneumothorax.

The same may occur in ARDS but by a different mechanism. While in neonatal respiratory distress syndrome the problem is a lack of surfactant production, ARDS is a problem of a loss of functional surfactant. This loss of functional surfactant in conjunction with damage from inflammation leads to poor lung compliance and alveolar volume loss in some lung units with overinflation in other.

In CHF the problem is increased lung water. Surface tension of simple liquids (such as edema) is much higher and not variable like surfactant. With transudation of fluid into alveoli in CHF, the action of surfactant is diluted, and surface tension (T) increases which also increases the pressure (P) needed to distend alveoli. Increased P causes a decrease in lung compliance.

7.3.3 Transmural Pressure and Volume

Lung compliance, the ability to change volume based on a distending pressure, can be understood with regard to surface tension and surfactant. In the context of lung disease, it is important to understand how compliance affects the lung during ventilation, the lung that is changing volume from FRC to inflating volume and back. Fortunately, compliance is relatively constant in the healthy lung. This is important because it allows for varying transmural pressures to accommodate for varying lung volumes in the different zones of the lung. Looking at the equation, $C = \Delta V/\Delta P$, if C is relatively constant, this allows for ΔV to change relatively constant with ΔP.

At the apices, pleural pressure is more negative causing a greater transmural pressure gradient. At the bases, where pleural pressure is less negative, there is a smaller pressure gradient. Along with these differences in pressure gradients, there is a coincident change in volume, and so the compliance throughout the lung remains relatively constant in the healthy lungs among lung zones and within normal tidal breathing volumes. In $C = \Delta V/\Delta P$, if rearranged to $\Delta V = (C)\Delta P$, then ΔV is directly related to ΔP. This is very important in maintaining normal lung function and can be significantly disrupted in disease that affects lung compliance. If compliance (C) decreases, then the distending pressure (ΔP) needed to maintain a normal volume (ΔV) needs to increase.

ΔV is proportional to ΔP as long as lung compliance is preserved. Disease states that disrupt normal lung compliance disrupt the relationship between ΔV and ΔP, in that, higher pressures in a non-compliant lung are needed to maintain adequate ventilating volume.

In diseases like ARDS where there is heterogeneous damage that occurs, it is easy to see why a constant compliance throughout the lung is so important. If ARDS is a heterogeneous disease with differing compliances throughout the lung parenchyma, then differing pressure gradients will be needed to ventilate different areas. More compliant areas will require less pressure and run the risk of overinflation (air leak/pneumothorax), while less compliant areas will require higher pressure gradients (ΔP) to ventilate (ΔV) and are at risk for collapse if those areas are not adequately ventilated (atelectasis).

7.3.4 Hysteresis

Lung compliance has two components: static compliance and dynamic compliance. If the lung is inflated to a level and held, there is an initial peak pressure required to fully inflate and then a decline to a plateau where this new level of pressure maintains volume. Thus, there is a time dependence on the elastic behavior (compliance) of the lung. In other words, compliance changes during phases of breathing or lung inflation. Additionally, static compliance is measured at a point where flow has ceased and thus contains no component of airways resistance. Dynamic compliance is measured during inflation where airways resistance may contribute to inflation pressure requirement. The measured compliance during inspiratory/inflation and exhalation/deflation is dynamic, while the compliance at the inspiratory plateau and FRC is static compliance.

Static compliance at the same volume varies from inspiration to expiration. There is a difference in the transmural pressure gradient at the same lung volume. This is hysteresis. Interestingly, as tidal volume increases, these points become more distinct. What this means is that during inhalation/inflation, there is a greater required amount of pressure for a given volume than the pressure needed during exhalation (Fig. 7.1).

Hysteresis is the change in compliance related to the phase of breathing and lung volume.

Hysteresis occurs for a number of reasons. First, there are changes in surfactant activity. At high lung volumes, surface tension is higher due to the variation afforded by surfactant. With inspiration, surface tension also tends to be

Surfactant properties contribute to hysteresis because surfactant can vary alveolar surface tension depending on alveolar volume.

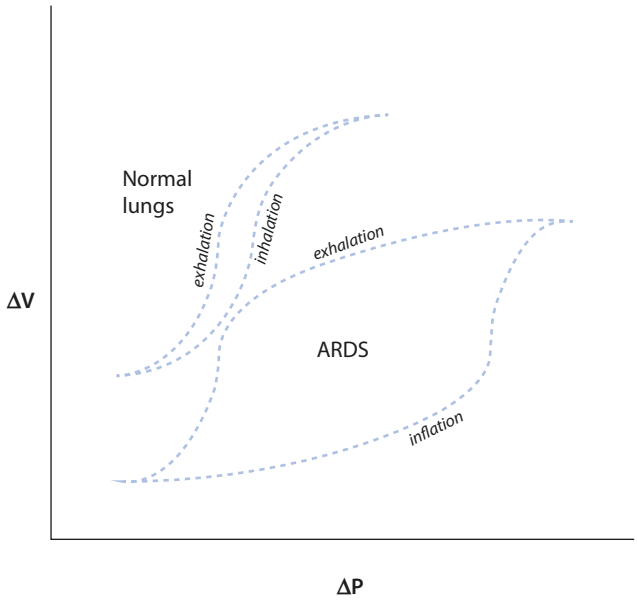

Fig. 7.1 Compliance curves for ARDS: Static compliance curves from a patient with ARDS in comparison to someone with normal lungs. Compliance, especially during inhalation/inflation, is reduced in ARDS as shown by the slope of the line and markedly so at low and high lung volumes

higher than in exhalation. A second component of hysteresis is stress relaxation. The initial pressure to move the lung at rest needs to be greater than the pressure needed to continue to move the lung in motion, much like the coefficient of static friction is often greater than the coefficient of kinetic or dynamic friction. A third component relates to time constants and redistribution of gas that occurs. This is based on airways resistance and lung compliance. Pulmonary time constants describe the amount of time taken to fill or empty a lung unit, and mathematically the time constant is the product of the airways resistance times the lung unit compliance. The units for airways resistance are mmHg/mL/second (or mmHg x second/mL), and the units for compliance are mL/mmHg; thus their product is seconds, the time for lung unit filling or emptying. A lung unit will fill to 63% of its capacity in one time constant and to 96% of its capacity in three time constants. Fig. 7.2 shows how different lung units fill and eventually redistribute air (volume) within the lung. Finally, and this situation likely only occurs in disease states and in the first few breaths of a neonate, recruitment of non-distended alveoli can make for a situation in which initial distending pressures need to be higher to "pop" open collapsed alveoli.

7.3.5 Factors Affecting Compliance

In the diseased lung, compliance can be affected by many factors. Both static and dynamic compliance can be affected.

First, lung volume affects compliance. In an emphysematous lung, compliance is increased, whereas in a lung with restrictive disease (e.g., pulmonary fibrosis), compliance is decreased. Acute respiratory distress syndrome is an example in which static compliance of the lung is greatly decreased in some areas and may be normal in others (Fig. 7.2). Adequate ventilation is challenging in ARDS because of the heterogeneity of compliance in the diseased lung.

Venous congestion within the lung decreases compliance in that more fluid in the lungs makes the lung denser and more difficult to expand. Higher pressures (ΔP) are needed to achieve a change in volume (ΔV). Bronchoconstriction affects dynamic compliance in that an initial high pressure is needed to over-

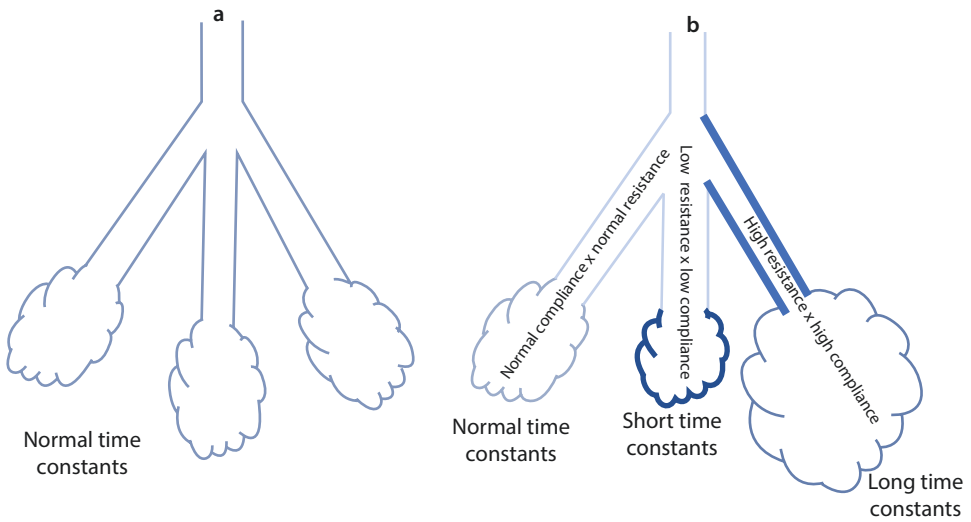

Fig. 7.2 Resistance/compliance characteristics of lung units: When considering airways resistance and lung compliance, the two factors together determine the filling time of the alveolar units (RC time constants). In the normal lung **a** with normal airways resistance and lung compliance, ideally all alveolar units would fill uniformly. With diseased lung **b**, some units may be normal, some may have increased resistance with increased compliance and fill slowly, while some may have decreased resistance with decreased compliance and fill quickly. This heterogeneity of lung units can make alveolar ventilation difficult and is seen in disease states such as ARDS and asthma

come resistance in airways that are constricted. If purely bronchoconstriction, then once the initial dynamic compliance defect is overcome (airways resistance), then static compliance should be normal. This can be seen in asthma. However, as is the case most of the time, there can be atelectasis or loss of lung volume in addition to bronchoconstriction, which can decrease static compliance. Likewise, air leak/pneumothorax can also lead to a loss of lung volume and decrease in static compliance. It is important to fully delineate whether dynamic compliance, static compliance, or both are affected to understand how to treat the problem that is causing poor lung compliance.

Understanding whether static compliance, dynamic compliance or both are disrupted can be useful in determining lung pathology and treatment.

7.3.6 Compliance of the Respiratory System

At this point, only compliance of the lung has been discussed. The thoracic cage itself has its own compliance, and the two (lung and thoracic cage) have a codependent relationship. Compliance of the thorax is also defined as the change in volume divided by the change in pressure. In the case of thoracic compliance, the pressure change is the change in the gradient between atmosphere and the intrapleural space: $C_{thorax} = \Delta V/\Delta(P_{pleura} - P_{atm})$. Compliance of the thorax is primarily dependent upon anatomic factors such as obesity or conditions that may restrict chest wall movement, as well as body position, since the diaphragm in the relaxed state will readily transmit pressure from the abdomen. Pressure from the abdomen, the resistance to diaphragm descent, increases when moving from upright to supine.

When compliance of the lung and compliance of the thoracic cage are considered together, compliance of the respiratory system can be determined. The lung pressure gradient, transmural pressure, is the gradient between alveolus and intrathoracic pressure, and thoracic cage pressure gradient is based on the gradient between intrathoracic and atmospheric pressure. Together, this defines the compliance across the whole respiratory system. When mathematically combining the two equations, the entity intrathoracic pressure drops out. This relationship can be represented as a change in volume over a change in pres-

The thoracic cage is compliant much like the lung is. Together, they both make up respiratory system compliance and is measured as the change in pressure from atmosphere to alveolus that is needed to make a change in volume ventilated.

sure, where the pressure gradient is the difference between alveolar and atmospheric pressure or $C_{total} = \Delta V/\Delta(P_{alv} - P_{atm})$. These various components that determine respiratory system compliance, in turn, have an important impact on FRC.

7.3.7 Determinants of FRC

Functional residual capacity is the volume in the lungs at end expiration when the respiratory system is at a steady state at the end of passive exhalation. It is determined by the thoracic cage forces leading to lung inflation that are equal and opposite to the lung tissue forces leading to deflation. This parameter, FRC, is heavily dependent upon elastic forces of both the lung and the thorax. Therefore, alterations in lung or chest wall compliance or, inversely, elastance can determine how well the lungs are expanded or overexpanded.

Alterations of FRC can occur in multiple different circumstances. Body size and gender can affect FRC. Height increases FRC, while obesity decreases it. Women have on average 10% less FRC compared to men. Reduced respiratory muscle tone can lead to decreased FRC with poor lung expansion and eventual atelectasis. Posture can affect FRC especially in the supine position when abdominal viscera exert pressure on the diaphragm and reduce lung expansion. Finally, disease can have significant effects on FRC. Most pronounced is disease that affects lung and thoracic compliance. It is in disease where one can see the consequences of inability to maintain normal FRC. In restrictive lung disease, FRC is diminished due to increased elastic forces causing the lung and alveoli to collapse if higher distending pressures are not generated to inflate the lung. Functional residual capacity can also be diminished if the thoracic cage is unable to generate enough force to change intrathoracic pressure. This is the case in neuromuscular weakness, where lower lung volumes and FRC will result in lung and alveolar collapse. Conversely, if lung tissue is highly compliant, as in the case of emphysema, FRC will be elevated.

Functional residual capacity can also be affected by airways resistance. If airways are obstructed, then the volume of gas expired from the lung is less and less with each tidal volume/breath. Eventually this will lead to a state of air trapping in the lungs which leads to an increase in FRC.

Restrictive lung disease causes a decrease in FRC. Obstructive lung disease causes an increase in FRC. Any alteration in FRC leads to increased work of breathing to maintain adequate ventilation.

Any deviation from normal FRC means that more work is needed for breathing to maintain adequate lung volumes. Understanding the factors that determine lung compliance, airways resistance, and, ultimately, FRC is important. Subsequent chapters will illustrate how the relationship between ΔV and ΔP (compliance) is so very important to understand in disease states when one is trying to maintain adequate volume expansion of the lung while carefully using and monitoring pressure to adequately ventilate.

7.3.8 Airways resistance

Before alveoli can be distended, air must travel through airways. Airways resistance must also be considered when evaluating how well ventilation occurs. To consider resistive forces to gas flow in the airways, it is important to illustrate and draw distinctions between the two forms of airflow, laminar and turbulent flow.

Laminar flow is defined as flow that consists of concentric cylinders that move over each other and form an advancing cone. The advantage of this flow is that fresh gas in the center of the cone may reach peripheral airways.

Therefore, alveolar ventilation may occur even when the volume of gas delivered is less than that of dead space. This can occur because the center of the "cone" of air depicted in Fig. 7.3 can reach distal airspaces. The disadvantage is that gas at the periphery of the advancing cone may not reach distal airways and may even be stationary. Therefore, with laminar flow, there is a loss of the ability to completely purge the airways of gas. In straight, unbranched tubes, where laminar flow can occur, the resistance to flow is largely dependent upon the radius of the tube as the relationship is dependent upon the fourth power of radius as demonstrated in Poiseuille's law:

The advantage of laminar airflow is that fresh gas may reach alveoli even if the volume of gas is less than dead space.

$$Q = \pi Pr^4 / 8\eta l$$

where flow (Q) is proportional to pressure (P) and radius (r) and inversely proportional to viscosity (η) and length (l). Even slightly decreasing radius (as would be the case in obstructive airways disease – asthma and bronchiolitis) leads to a significant decrease in flow. If the properties of the tube are held constant, and viscosity is the only variable, then changing the viscosity of gas may be advantageous in laminar flow. Viscosity must be distinguished from density of gas.

Turbulent flow is airflow that has a square front (Fig. 7.3). Its disadvantage is that no fresh gas enters distal airways until the full volume of gas is equal to at least dead space. The advantage of turbulent flow is that airways can be purged completely of gas. In turbulent flow, airways resistance is not constant and is proportional to flow rate. Therefore, the ΔP it takes to overcome airways resistance in turbulent flow is dependent upon three principles. First, ΔP is proportional to the square of the flow rate (not to the first order as seen in laminar flow). Second, ΔP is proportional to the density of gas (not viscosity). Third, the required ΔP (to move gas) is inversely proportional to the fifth power of the radius of the tube. As with laminar flow, any decrease in airway radius will have a great effect on airways resistance.

The advantage of turbulent airflow is that airways can be completely purged of gas with adequate ventilating volumes.

Knowing the difference in airways resistance properties between laminar and turbulent flow is clinically important. When trying to overcome airways resistance in a turbulent flow environment, manipulating gas density could be helpful. It is generally accepted that turbulent flow is primarily present in large

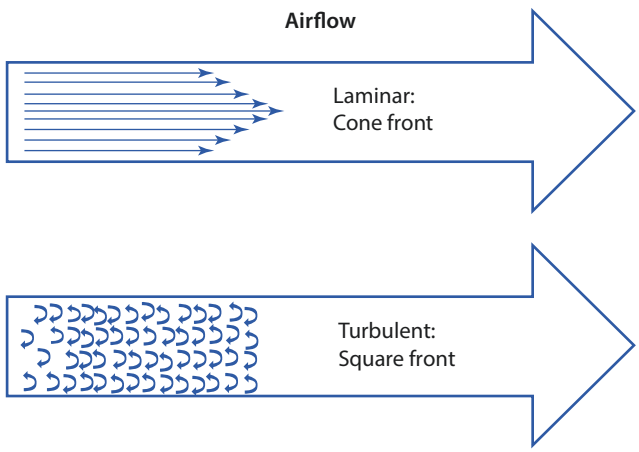

Fig. 7.3 Laminar vs. turbulent flow: Laminar flow (top) establishes a cone of airflow with the central portion of the cone reaching the alveoli even if all of the peripheral portion of the cone does not. In turbulent flow, all the air travels in a square front that necessitates flow all the way to the alveoli for gas exchange to occur. The advantage of laminar flow is that not all the air needs to reach distal alveoli for gas exchange to occur. The advantage of turbulent flow is that gas from the lungs may be completely purged with adequate ventilation

(not small) airways. However, in most clinical scenarios, there is a mixture of laminar and turbulent airflow that is present in all airways. Somewhat counterintuitively, airways resistance has a greater impact on large airways in comparison to the small airways because the total cross-sectional area in the smaller airways is much greater as airways branch distally. Even though the airways are much smaller distally, the vast number of smaller airways contributes to a much larger cross-sectional area for airflow in the smaller airways and bronchioles, greater than the cross-sectional area for airflow in the trachea and bronchi.

With both laminar and turbulent airflow, any decrease in the radii of conducting airways can cause a significant increase in airways resistance.

Other factors that affect airways resistance are lung volume and bronchomotor tone of the airways. Volume is inversely proportional to airways resistance. When there are high lung volumes, airways resistance is less. Higher bronchomotor tone leads to bronchoconstriction and decreased radii of the conducting airways. With decreased radii, the pressure needed to maintain flow through the airways needs to increase or flow will decrease. Clinically, this manifests as increased work of breathing.

7.3.9 Ventilation/Perfusion Matching and Gas Exchange

Knowledge of anatomy and physiology is important to understanding how the lungs perform their most important function: respiration or matching oxygenated air with pulmonary blood supply. This occurs at the level of the pulmonary acinus, and factors of pulmonary compliance and airways resistance greatly determine how oxygenated air gets to the blood supply of the lung at the level of the alveoli.

Gas exchange will be discussed in a separate chapter. However, the concept of ventilation/perfusion matching will be briefly touched upon here. Ventilation is the main purpose of the lung and is dependent upon adequate/normal lung compliance and airways resistance. It is the ability of the lung to deliver oxygenated air to the alveolus where the oxygen can be exchanged across the alveolar/capillary membrane for carbon dioxide, the by-product of metabolism. Understanding how well someone is ventilating and, subsequently, oxygenating can be illustrated in the alveolar gas equation which is

$$P_AO_2 = 0.21\left(P_B - P_{H20}\right) - P_aCO_2 / 0.8$$

Once it is understood how well oxygen is getting to the alveolus, then there can be a better understanding of why someone may not be ventilating adequately. Or it may be that the patient is adequately ventilating, but the acinus is not working properly to exchange gas.

The alveolar gas equation allows for a calculation of alveolar oxygen. Knowing the partial pressure of alveolar oxygen can help determine if hypoxemia is a result of inadequate oxygen delivery (poor ventilation) or inadequate gas exchange at the acinar level (V/Q mismatch, anatomic R→L shunt or diffusion defect).

The alveolar gas equation describes the causes of hypoxemia. Considering the components of the alveolar gas equation will allow for an understanding of how oxygen gets to the alveolar space and is available for diffusion across the membrane into the blood. Oxygen exists in the environment as a fraction of the air that is inspired (0.21). Because it is a partial pressure of oxygen, it is a fraction (0.21) of the pressure of air (P_B) that must also subtract out other molecules in ambient air from the environment and the airways. These other molecules are mostly water (P_{H2O}). When this fraction of oxygen reaches the alveoli, other gas particles are present, and this is primarily carbon dioxide (P_aCO_2). Because the displacement of O_2 by CO_2 in the alveolus cannot be measured directly, it must be calculated from the arterial CO_2 by dividing by the respiratory quotient (R, commonly estimated as 0.8). Once the amount of oxygen that is supplied to the alveoli (P_AO_2) is known, then it can be better

understood how well, or how poorly, the lungs are working in the act of gas exchange.

Consider the five main causes of hypoxemia (Table 7.2): ventilation/perfusion (V/Q) mismatch, anatomic shunt, diffusion defect, hypoventilation, and altitude (or decreased ambient air pressure). In the case of hypoventilation, the alveolar gas equation explains why hypoxemia occurs. It occurs because not enough oxygen is delivered to the alveolus. P_aCO_2 will rise because of inadequate ventilation, and subsequently P_AO_2 will fall. Likewise, in the case of altitude, not enough oxygen is delivered to the alveolus. In this case, a lower P_B decreases, and the amount of ambient oxygen inspired is decreased.

In the cases of V/Q mismatch, anatomic shunt, and diffusion defect, the lungs are able to ventilate and get oxygenated air to the alveolus (or at least some alveoli), but there is a problem at the acinar level with the oxygen. In V/Q mismatch, there is regional hypoventilation and physiologic shunting of blood through areas of the lung that are not well oxygenated. This is the case with atelectasis or pneumonia. One part of the lung is unable to ventilate well, and so hypoxemia may occur. This can be overcome by increasing ventilation and perfusion to healthy areas area of the lung that can compensate. Also, supplemental oxygen may help compensate for hypoxemia in areas of low V:Q ratio but not where V:Q = 0, defined as true or absolute shunt.

In anatomic right to left shunting, the alveoli are adequately ventilated, and P_AO_2 is normal, but blood flow is shunted around the alveoli either at the cardiac level or by pulmonary arteriovenous malformations. In this situation, supplemental oxygen will be ineffective in correcting the hypoxemia.

Finally, in diffusion defect, the alveolar-capillary interface is disrupted so that oxygen does not easily diffuse into the pulmonary blood supply. In this case, oxygen supplementation, to a degree, can help correct hypoxemia.

As illustrated above, when considering hypoxemia due to V/Q mismatch, anatomic shunt, or diffusion defect, supplementing oxygen can be beneficial in narrowing down the cause of hypoxemia. It should be stressed that supplementing oxygen should be carefully considered as a therapy only after hypoventilation as a cause of hypoxemia has been ruled out. Supplementing oxygen will have no benefit in the case of pure hypoventilation as the patient is unable to ventilate to get oxygen to the alveoli in the first place.

One can further narrow down the cause of hypoxemia by supplementing oxygen and assessing for a response. In the case of anatomic shunt, oxygen supplementation will have little to no effect on improving oxygenation.

In the situation where ventilation appears to be adequate, the problem is with inadequate oxygen delivery to the pulmonary capillary blood supply. In this case, an increased alveolar-arterial (A-a) gradient exists:

$$P_AO_2 - P_aO_2 = A - a\ \text{gradient}$$

Normal A-a gradients range from 3 to 8 mmHg for healthy children and adolescents. If oxygen is adequately delivered to the alveolar level (A) but not adequately delivered to pulmonary capillaries and subsequently systemic

Elevated A-a gradient indicates that there is poor oxygen delivery to the vascular bed at the level of the acini/alveoli.

Table 7.2 The five causes of hypoxemia with effects on P_aO_2 and A-a gradient

Five causes of hypoxemia	P_AO_2	A-a gradient
V/Q mismatch	Normal/↓	↑
Anatomic R → L shunt	Normal	↑
Diffusion defect	Normal	↑
Hypoventilation	↓	Normal
Altitude (↓FiO2)	↓	Normal

arteries (a), then an increased gradient exists, and hypoxemia occurs. In the case of inadequate ventilation or altitude, the A-a gradient should be normal because arterial oxygen (P_aO_2) is low because alveolar oxygen tension (P_AO_2) is low. Of course, in practice, there is often a combination of inadequate ventilation and alveolar gas exchange. So the alveolar gas equation and the A-a gradient must always be interpreted with clinical context. Nevertheless, understanding how oxygen is delivered to the alveolus (ventilation) and how it is subsequently delivered to the pulmonary vasculature (oxygenation) will be very important when evaluating and treating patients with respiratory distress and hypoxemia.

Knowing how respiratory compliance and airways resistance affect ventilation is essential for evaluating a child with increased work of breathing and impending respiratory failure. Finally, knowing the difference between inadequate ventilation and alveolar gas exchange (oxygenation) is essential for assisting children with respiratory distress and respiratory failure. Subsequent chapters that discuss respiratory failure, ARDS, and mechanical ventilation will highlight these important physiologic principles.

7.4 Summary

The lung and respiratory system arise early in gestation and give rise to an anatomic structure that allows for normal physiologic function. Disruption of normal development can affect normal anatomic structure and, ultimately, function. Normal respiratory physiology has its roots in normal developmental anatomy. Neonatal respiratory distress syndrome and BPD are prime examples of how disruption of normal developmental anatomy can have a significant impact on normal lung physiology. There are other examples of lung disease that impact normal physiologic function as well. A knowledge of lung physiology is important for the clinician when treating pediatric lung disease. First, it must be appreciated that lung physiology in children differs from adults mainly because lung and chest wall compliance in children is different from adults. Second, understanding how the forces of respiratory system compliance and airways resistance impede ventilation is critical because disease states only augment the factors that impede normal ventilation. Finally, understanding how gas exchange at the acinar level is affected by ventilation (or inadequate ventilation) allows for a better understanding of why patients with lung disease have respiratory insufficiency or failure. With this understanding, the clinician will be equipped to identify and treat the cause of respiratory disease.

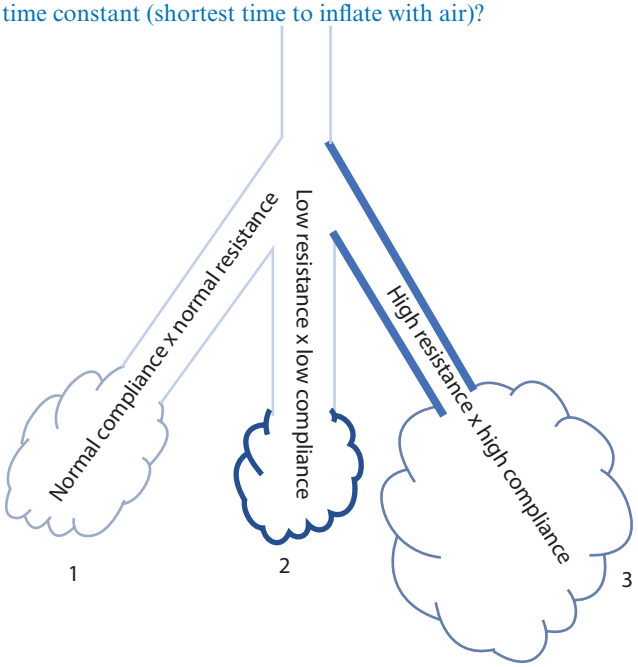
Five Multiple Choice Questions

1. The saccular stage of lung development continues the development of alveoli and is the initiating phase of surfactant production. At what point in gestation does the saccular stage begin?
   A. 4 weeks
   B. 17 weeks
   C. 26 weeks
   D. 36 weeks
   E. 40 weeks

2. What level of the airways presents the least resistance to airflow in healthy lungs?
   A. Nose
   B. Oropharynx

C. Trachea
D. Large airways
E. Small airways

3. Which of the following acini in the diagram below would have the shortest time constant (shortest time to inflate with air)?



A. 1
B. 2
C. 3
D. 1 and 3
E. 2 and 3

4. A 14-year-old with history of BPD is admitted to Floating Children's Hospital in Boston with a right lower lobe pneumonia. He has an oxyhemoglobin saturation of 86% breathing room air. His respiratory rate is 44, and he has nasal flaring. You obtain an arterial blood gas while he is breathing room air, and the values are pH 7.42, P_aCO_2 40, P_aO_2 50. What is his A-a gradient?
A. 18
B. 36
C. 50
D. 100
E. 110

5. In the patient above, you supplement oxygen with 50% face mask via venturi valve. His oxyhemoglobin saturation improves to 96%, and you obtain another arterial blood gas. The values are pH 7.44, P_aCO_2 36, P_aO_2 296. In this scenario, what is the most probable cause of his hypoxemia?
A. Hypoventilation
B. Decreased inspired oxygen tension
C. Anatomic right→left shunt
D. Diffusion defect
E. Ventilation/perfusion mismatch

Answers

1. C – 26 weeks. The saccular stage begins around gestational age 26 weeks. This is when respiratory bronchioles and alveoli develop in the acini and type II pneumocytes begin to produce surfactant. Disruption of gestation in the canalicular period (which precedes saccular) and saccular period leads to RDS. What results is pulmonary hypoplasia because of acinar and vascular immaturity as well as surfactant deficiency. Surfactant is critically important for maintenance of normal lung compliance. At 4 weeks gestation, the ventral groove of the foregut buds to initiate respiratory tree formation. By 17 weeks, the majority of airways have been formed. At 36 weeks begins the alveolar phase when alveoli develop and mature into adolescence.
2. E – small airways. The cross-sectional area of all the small airways is cumulatively larger than either trachea, bronchi, or upper airways. Therefore, the overall resistance to airflow at the level of small airways (generally believed to be the 11th generation and beyond) is lower than that of the nose, oropharynx, trachea, or bronchi.
3. B – 2. A lobule/acinus with poor compliance (low compliance) and low airways resistance will have the shortest filling time (RC time constant). This is because airways resistance is low allowing for faster transit time through the airway, and lung compliance is low causing rapid filling of the airspace. Both airways resistance and lung compliance being low lead to a short time constant. In ARDS, which is a heterogeneous lung disease, there are varying resistances and compliances (RC time constants) throughout the lung. This makes treating ARDS with mechanical ventilation a challenge.
4. C – 50. If breathing room air, the fraction of inspired oxygen is 0.21. Barometric pressure at sea level would be 760 mmHg and partial pressure of H_20 47 mmHg. Using the alveolar gas equation, this child has a P_AO_2 of 100 ($P_AO_2 = 0.21(760–47) – 40/0.8$). If his P_AO_2 is 100 and his P_aO_2 is 50, then his A-a gradient is 50.
5. E – ventilation/perfusion mismatch. V/Q mismatch is the most common cause of hypoxemia in children with lung disease (acute and chronic). In this case, V/Q mismatch is most likely because of a widened A-a gradient that improves oxygenation with supplemental oxygen. Diffusion defect is also a possibility for someone with a widened A-a gradient that improves with oxygen, but in this clinical scenario, with a child who has a lobar pneumonia, ventilation and perfusion mismatch is more likely because of regional disruption of ventilation accompanied by preserved or diminished perfusion.

Fundamentals of Gas Exchange and the Assessment of Oxygenation and Ventilation

John S. Sullivan and Toah Nkromah Alafita

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_8

Learning Objectives

- Present and explain the alveolar gas equation and describe the changes in the partial pressure of oxygen from the atmosphere to the bloodstream.
- Define dead space (alveolar and anatomic) and describe its quantification and describe the compensatory mechanisms invoked with increased dead space.
- Describe the distribution of ventilation and pulmonary blood flow.
- Describe how ventilation and perfusion are coupled and detail common causes of their uncoupling.
- Describe the alveolar/arterial oxygen gradient and demonstrate its calculation.
- Describe the transport of gases within the body and focus especially on the hemoglobin/oxygen dissociation curve and carbon dioxide transport.
- Describe the differences between oxygen and carbon dioxide transport.
- Describe the mechanics of, uses, and limitations of pulse oximetry, end tidal carbon dioxide monitoring, and transcutaneous oxygen and carbon dioxide measurement.

8

8.1 Introduction

The basic function of the respiratory system is to supply oxygen (O_2) to, and remove carbon dioxide (CO_2) from, the body. The essential steps in this process include the exchange of gas between the atmosphere and the alveoli (ventilation), the diffusion of these gases across the alveolar capillary membrane, the transportation of gases in the blood, and the diffusion of the gases to and from the tissue capillaries.

8.2 The Process of Gas Exchange

8.2.1 Alveolar Ventilation and the Oxygen Cascade

In normal lungs, because carbon dioxide diffuses so readily across the alveolar capillary membrane, the alveolar CO_2 (P_ACO_2) is essentially equal to the arterial carbon dioxide ($PaCO_2$).

The cardiorespiratory system functions to extract oxygen from the atmosphere and deliver it to the tissues where it is required for aerobic metabolism. Alveolar ventilation is the volume of fresh gas each minute that reaches the alveoli and takes part in gas exchange. It is the first step in the oxygen cascade and the most important factor in determining the partial pressure of oxygen in the arterial blood (PaO_2). Alveolar ventilation is also responsible for the amount of CO_2 that is exhaled from the alveoli. In normal lungs, because carbon dioxide diffuses so readily across the alveolar capillary membrane, the alveolar CO_2 ($PACO_2$) is essentially equal to the arterial carbon dioxide tension ($PaCO_2$).

The oxygen cascade begins as oxygen enters the alveoli on inspiration (Fig. 8.1). Oxygen diffuses across the alveolar capillary membrane into the pulmonary capillary blood down a pressure gradient created by a pressure difference across the membrane. Diffusion is a passive process defined as the transfer of a gas from an area of higher pressure to an area of lower pressure. This diffusion of oxygen across the alveolar capillary membrane is accounted for by *Fick's first law of diffusion*, which asserts that the amount of gas diffusing through a membrane is *directly* proportional to the surface area available for diffusion but inversely proportional to the distance it has to diffuse. The diffusion capacity for the pulmonary vascular bed is optimal for achieving gas exchange because the membrane is exceedingly thin, and the surface area is

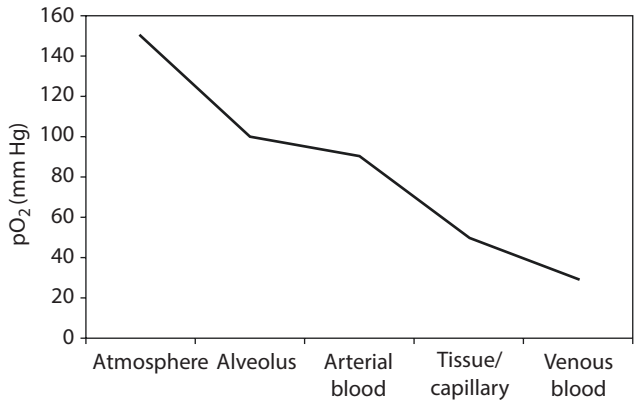

Fig. 8.1 The oxygen cascade

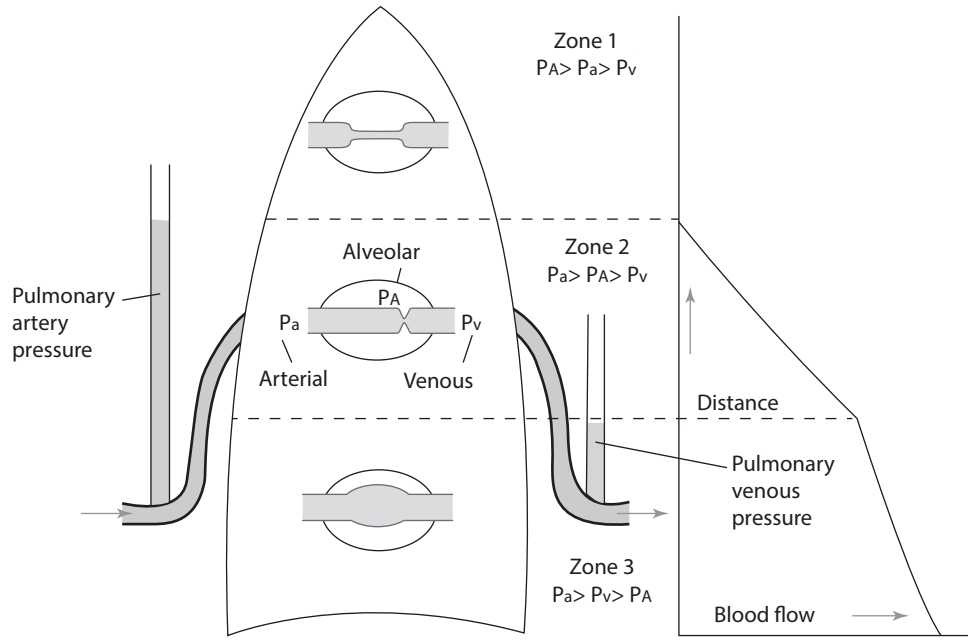

Fig. 8.2 West zones of pulmonary perfusion and ventilation. *Pa* arterial pressure, *PA* alveolar pressure, *Pv* venous pressure

vast due to the structure and arrangement of approximately 400 million alveoli. In addition, in the setting of increased O_2 demand, additional capillaries may be recruited which help to maintain adequate O_2 supply by decreasing diffusion distances.

The diffusion capacity for the pulmonary vascular bed is optimal for achieving gas exchange because the membrane is exceedingly thin, and the surface area is vast due to the structure and arrangement of approximately 400 million alveoli.

8.2.2 Distribution of Alveolar Ventilation

Both alveolar ventilation and perfusion pressures increase progressively from the apex of the lung to its base due to the effects of gravity. However, blood flow increases more rapidly than does ventilation. Therefore, the ventilation-perfusion (*V*/*Q*) ratio is highest at the apex of the lung and lower toward the base giving rise to what has come to be known as the West zones of perfusion and ventilation (Fig. 8.2). West described three theoretical zones of the lung from the apex to the base according to their relative distribution of ventilation and pulmonary blood flow. In Zone I, the least amount of blood flow occurs because alveolar pressure is greater than both pulmonary artery pressure and pulmonary venous pres-

sure. In Zone II, pulmonary arterial pressure is greater than alveolar pressure, and blood flow is determined by the difference between alveolar and arterial pressures independent of venous pressures. In Zone III, pulmonary arterial pressure exceeds pulmonary venous pressure which exceeds alveolar pressure. Consequently, flow is a function of both pulmonary arterial and venous pressures, and because pulmonary arterial pressure is higher, blood flow is down this gradient.

8.2.3 Carbon Dioxide Elimination

In general, blood holds more CO_2 than O_2, in part, because CO_2 is carried in three forms. Five to 10% of CO_2 is dissolved in the bloodstream, 5–20% is bound in the form of carbamino compounds, and the remainder (the vast majority) exists in the form of H_2CO_3.

Once oxygen reaches the bloodstream, it is delivered to the tissues where it is consumed in both the processes of cellular respiration and in a number of non-energy-producing oxidative reactions. During cellular respiration, which occurs in the mitochondria, oxygen is consumed generating energy in the form of adenosine triphosphate (ATP), with CO_2 being produced as a by-product. Alveolar ventilation is necessary to ultimately eliminate the CO_2 that is produced. Carbon dioxide exists in equilibrium with carbonic acid, H_2CO_3, a weak acid. Thus, the accumulation of carbon dioxide produces acidosis. In general, blood holds more CO_2 than oxygen, in part, because CO_2 is carried in three forms. Five to 10% of CO_2 is dissolved in the bloodstream, 5–20% is bound in the form of carbamino compounds, and the remainder (the vast majority) exists in the form of H_2CO_3. Carbon dioxide freely and efficiently diffuses from the tissues into the blood and then across the capillary alveolar membrane into the alveolar gas so that it can be eliminated through exhalation.

When CO_2 is not effectively eliminated by the lungs, hypercapnea results. In the face of hypercapnea, CO_2 freely diffuses into the cell, decreasing the intracellular pH by combining with H_2O to release H + as delineated in the following equation:

$$CO_2 + H_2O \leftrightarrow H_2CO_3 \leftrightarrow H^+ + HCO_3^-.$$

The resulting acidemia initially triggers a sympathetic and adrenal response with endogenous catecholamine stimulation. Subsequently, the body has several compensatory mechanisms that are activated in order to surmount and counteract this acidosis.

1. Chemoreceptors in the brainstem and in the carotid body rapidly detect changes in the $PaCO_2$. In a spontaneously breathing, non-sedated patient with normal neuromuscular function, there is generally an initial increase in the minute ventilation in an attempt to increase carbon dioxide elimination and normalize the pH.
2. Deoxygenated hemoglobin molecules bind hydrogen ions as well as carbon dioxide to form carbaminohemoglobin in order to buffer the pH and prevent substantial changes in pH.
3. The kidneys increase the excretion of ammonium ion (NH_4^+) (thereby eliminating hydrogen ions) and chloride while retaining HCO_3^- and sodium (Na^+) after being exposed to hypercapnia for at least 6 h. The result is an increase in the plasma HCO_3^- concentration by approximately 3.5–4 mEq/L for every 10 mm Hg increase in the $PaCO_2$. The HCO_3^- then serves as a buffer for the existing free hydrogen ions.

8.2.4 Assessing Adequacy of Gas Exchange

Under normal conditions, the partial pressure of oxygen in the alveolus (PAO_2) is only slightly higher than that in the arterial blood (PaO_2), reflecting a nearly balanced equilibrium between the alveolar gas and the pulmonary capillary

blood. A significant gradient between the alveolar and arterial blood (A-a gradient) suggests a degree of lung injury causing a limitation of gas exchange. The composition of the alveolar gas depends on:

1. The oxygen content of both inspired air and the mixed venous blood
2. The quantity of air and blood reaching the alveoli
3. The ratio of alveolar ventilation to perfusion
4. The extent to which equilibrium is reached between the alveolar gas and the pulmonary capillary blood

While the arterial pO_2 is measured and reported in a blood gas analysis, it is more difficult to accurately measure the alveolar pO_2. The PAO_2 may be calculated from the following equation:

$$PAO_2 = PiO_2 - PaCO_2/RQ$$

where PiO_2 is the partial pressure of inspired oxygen and RQ is the respiratory quotient, the ratio of CO_2 produced to O_2 consumed in oxidative metabolism. The PiO_2 is determined by the atmospheric barometric pressure and the percent of oxygen being inspired. At sea level, where oxygen accounts for 21% of air, and atmospheric pressure is approximately 760 mm Hg, the partial pressure of inspired $O_2 = 760 \times 0.21$. However, that equation does not account for the displacement of oxygen and nitrogen by water vapor, which humidifies inspired air and thereby reduces the proportion of barometric pressure containing oxygen and nitrogen by 47 mm Hg. Therefore, the PiO_2 can be further defined by the following equation:

$$PiO_2 = \left(P_B - P_{H2O}\right) \times FiO_2 = 160\,\text{mm Hg}$$

At sea level, the PiO_2 will be approximately equal to 150 mm Hg (i.e., (760 mm Hg – 47 mm Hg) × 0.21 = 150 mm Hg). At altitude (e.g., on the top of Mount Everest, where the barometric pressure is 380 mm Hg), the PiO_2 will be significantly lower [e.g., (380 mm Hg – 47 mm Hg) × 0.21 = 70 mm Hg]. In hyperbaric oxygen chambers, where the barometric pressure is much higher than atmospheric, the PiO_2 will be higher.

The sum of the partial pressures of alveolar gases must equal ambient pressure. Therefore, an increase in one gas must result in a decrease in another. As gas moves down the airway into the alveolus, the partial pressure of oxygen is progressively reduced by the presence of carbon dioxide in the alveolar gas. The partial pressure of arterial carbon dioxide is utilized in the equation in place of alveolar carbon dioxide because carbon dioxide is so readily diffusible that arterial and alveolar carbon dioxide quickly equilibrate. However, to account for the fact that more oxygen is usually consumed than carbon dioxide is eliminated, this value is divided by the respiratory quotient. The respiratory quotient (RQ) is the ratio of the amount of CO_2 being produced and excreted to the amount of oxygen being consumed and utilized. It also reflects the oxidation of carbohydrates relative to fats. Under normal circumstances, the RQ approximates 0.8, but it can range between 0.67 and 1.3, depending on the clinical scenario and the relative composition of lipids (RQ = 0.7), carbohydrates (RQ = 1.0), and proteins (RQ = 0.8) being metabolized. Consequently, assuming a $PaCO_2$ of 40 mm Hg, a normal diet, and sea level barometric pressure, the PAO_2 is approximately 100 mm Hg.

$$PAO_2 = PiO_2 - PaCO_2 / RQ$$

$$PAO_2 = \left[\left(760\,\text{mm Hg} - 47\,\text{mm Hg}\right) \times 0.21\right] - 40\,\text{mm Hg} / 0.8$$

$$\left[\sim 150\,\text{mm Hg}\right] - 50\,\text{mm Hg} = \sim 100\,\text{mm Hg}$$

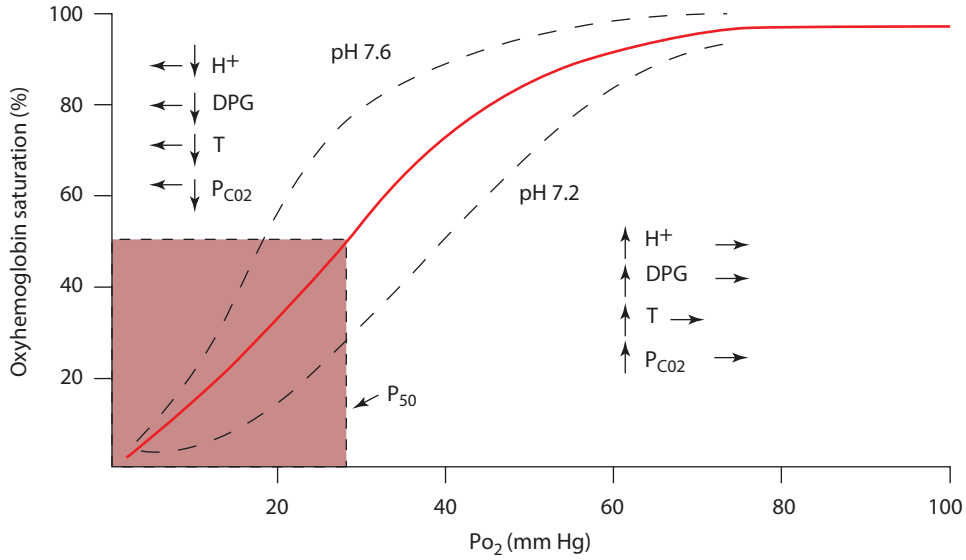
Under ideal conditions, the partial pressure of oxygen in the alveolus (P_AO_2) and in the arterial blood (PaO_2) should be nearly equal, and no gradient should exist, reflecting a balanced equilibrium between the alveolar gas and the pulmonary capillary blood. A significant gradient between the alveolar and arterial blood (A-a gradient) suggests a degree of lung injury causing a limitation of gas exchange.

The P_AO_2, may be calculated from the following equation:

$$PAO_2 = PiO_2 - PaCO_2/RQ$$

The PiO_2 is defined by the following equation:

$$PiO_2 = \left(P_B - P_{H2O}\right) \times FiO_2 = 160\,\text{mm Hg}$$



8

Fig. 8.3 The oxygen-hemoglobin dissociation curve. *DPG* 2,3-diphosphoglycerate, *T* temperature

The PAO_2 is higher than the partial pressure of oxygen in the pulmonary artery and capillary blood, leading to the diffusion of oxygen from the alveoli into the bloodstream.

8.2.4.1 In the Bloodstream

In the bloodstream, oxygen molecules combine with hemoglobin to form oxyhemoglobin, the primary form in which oxygen is delivered to the tissues. The affinity that hemoglobin has for oxygen determines the degree of binding and the availability of oxygen for release to the tissues.

Several factors have been identified that influence the degree of binding of oxygen to hemoglobin. The oxygen-hemoglobin dissociation curve graphically depicts the relationship between the partial pressure of oxygen and the saturation of hemoglobin (Fig. 8.3). This graph describes the affinity of hemoglobin for oxygen and thus depicts the relative avidity of oxygen at the tissue level. The P_{50} is often used as a measure of this affinity. The P_{50} is defined as the PaO_2 at which hemoglobin is 50% saturated with oxygen. For normal adult hemoglobin (Hb A), the P_{50} is 27 mm Hg.

Various clinical conditions alter the affinity of hemoglobin for oxygen (Table 8.1). Conditions that produce a leftward shift of the curve as the result of an increase in the affinity of hemoglobin for oxygen have a lower P_{50} (a lower PaO_2 at which hemoglobin is 50% saturated with oxygen). This is most commonly seen with alkalosis and hypothermia. Hemoglobin F, the predominant form of hemoglobin in fetuses and neonates, has a lower P_{50} than hemoglobin A; therefore, the curve for hemoglobin F exists to the left of that of hemoglobin A. Conditions which cause a decrease in the affinity of hemoglobin for oxygen result in a higher P_{50} (a higher PaO_2 at which hemoglobin is 50% saturated with oxygen). These conditions cause a *rightward shift* of the oxygen-hemoglobin dissociation curve; common, clinically important examples include acidosis and hyperthermia.

The Bohr effect is a property of hemoglobin whereby its affinity for oxygen changes depending on the concentration of H+ or carbon dioxide. Increasing concentrations of H+ or carbon dioxide will reduce the affinity of hemoglobin

Table 8.1 Clinical factors that influence shifts in the oxygen-hemoglobin dissociation curve

Leftward shifts of the dissociation curve (increased oxygen affinity, lower P_{50})	Rightward shifts of the dissociation curve (decreased oxygen affinity, higher P_{50})
Decreased hydrogen ion (H^+) concentration	Increased hydrogen ion (H^+) concentration
Decreased RBC 2,3-diphosphoglycerate	Increased RBC 2,3-diphosphoglycerate
Decreased temperature	Increased temperature
Decreased partial pressure of carbon dioxide	Increased partial pressure of carbon dioxide
Increased pH	Decreased pH
Hemoglobin F (as compared to hemoglobin A)	

for oxygen. The Bohr effect provides part of the mechanism for the transfer of oxygen from the alveolus to the bloodstream and, subsequently, from the bloodstream to the tissues. In the lungs, the PCO_2 is low, and the pH is high. Under these conditions, the affinity of hemoglobin for oxygen is high, enhancing the uptake of oxygen from the alveoli into the bloodstream and on to the hemoglobin molecule in the red blood cell. By contrast, in the tissues, the high tissue PCO_2 and low pH favor the release of oxygen (Fig. 8.4). Similarly, the Haldane effect describes a property of hemoglobin whereby deoxygenated blood has an increased ability to carry carbon dioxide, and oxygenated blood has a decreased affinity for hydrogen ions and carbon dioxide. Therefore, in the lungs where oxygen is abundant, carbon dioxide is unloaded from the hemoglobin and made available to the alveolus for exhalation. Thus, the Bohr and Haldane effects represent molecular-level salutary enhancement of the already remarkable respiratory functions of hemoglobin.

The Bohr effect is a property of hemoglobin whereby its affinity for oxygen changes depending on the concentration of H+ or carbon dioxide. Increasing the concentration of H+ or carbon dioxide will reduce the affinity of hemoglobin for oxygen. The Bohr effect provides the mechanism for the transfer of oxygen from the alveolus to the bloodstream and, subsequently, from the bloodstream to the tissues.

The Haldane effect describes a property of hemoglobin whereby deoxygenated blood has an increased ability to carry carbon dioxide, and oxygenated blood has a decreased affinity for hydrogen ions and carbon dioxide. Therefore, in the lungs where oxygen is abundant, carbon dioxide is unloaded from the hemoglobin and made available to the alveolus for exhalation.

8.2.4.2 To the Tissues

From the pulmonary capillary blood, oxygen returns to the heart via the pulmonary veins. From there, oxygen travels in the systemic arterial blood, into the systemic capillaries, and, ultimately, into the mitochondria of the tissues. At each level of the oxygen cascade, the PO_2 progressively decreases until it reaches its clinically measurable nadir in the mixed venous blood returning to the heart. The PO_2 of mixed venous blood is determined by several factors, including the amount of oxygen delivered to the tissues (the oxygen supply), the amount of oxygen required by the tissues (the oxygen demand), and the capacity of the tissues to extract oxygen. If there is any impediment to oxygen delivery, organs will become deprived of oxygen. Oxygen consumption is defined by the following equations:

$$VO_2 = DO_2 \times O_2\text{extraction} = A - VDO_2 \times CO \times 10\,dL/L$$

where VO_2 is the oxygen consumption, DO_2 is the oxygen delivery, O_2 extraction is the fractional difference between arterial and venous O_2 content, the A-VDO_2 is the arteriovenous difference in oxygen content, and CO is the cardiac output.

$$\begin{aligned} DO_2\,\text{ml/min} &= CO\,\text{L/min} \times CaO_2\,\text{ml}\,O_2/\text{dL} \times 10\,\text{dL/L} \\ O_2\text{extraction} &= \left(1 - CvO_2/CaO_2\right) \\ \text{A-V}DO_2 &= \left(CaO_2 - CvO_2\right)\text{ml/dL} \\ 10\,\text{dL/L} &= \text{unit reconciliation} \end{aligned}$$

8.3 Mechanisms of Hypoxemia

Hypoxemia is a decrease in the oxygen content in the arterial blood reflecting a limitation of pulmonary gas exchange. There are four major causes of arterial hypoxemia: hypoventilation, ventilation-perfusion mismatch, shunted blood flow, and diffusion limitation.

Hypoxemia is a decrease in the oxygen content in the arterial blood reflecting a limitation of pulmonary gas exchange. The arterial oxygen content (CaO_2) is defined by the following equation:

$$CaO_2 = 1.34 \times Hb \times SaO_2 + 0.003 \times PaO_2$$

where 1.34 represents the oxygen combining capacity or the amount of oxygen in milliliters (mL) that a fully saturated gram of hemoglobin can carry, Hb represents the hemoglobin concentration in grams per deciliter, SaO_2 represents the arterial oxygen saturation of hemoglobin, and 0.003 represents solubility coefficient of oxygen in milliliters of oxygen in a deciliter of blood for each mm Hg partial pressure. The units for the arterial content of oxygen are milliliters of oxygen per deciliter of blood as mathematically illustrated below:

$$CaO_2\left(\text{mL}\,O_2/\text{dL}\right) = \frac{1.34\ \text{mL}\,O_2}{\text{g}} \times \frac{Hb\,\text{g}}{\text{dL}} \times SaO_2 + \frac{0.003\,\text{mL}\,O_2/\text{dL}}{\text{mm Hg}} \times PaO_2\,\text{mm Hg} = \frac{\text{mL}\,O_2}{\text{dL}}$$

Hypoxemia may therefore be the result of anemia or abnormalities of oxygenation. There are four major abnormalities of pulmonary gas exchange that may contribute to arterial hypoxemia: hypoventilation, ventilation-perfusion mismatch, shunted blood flow, and diffusion limitation.

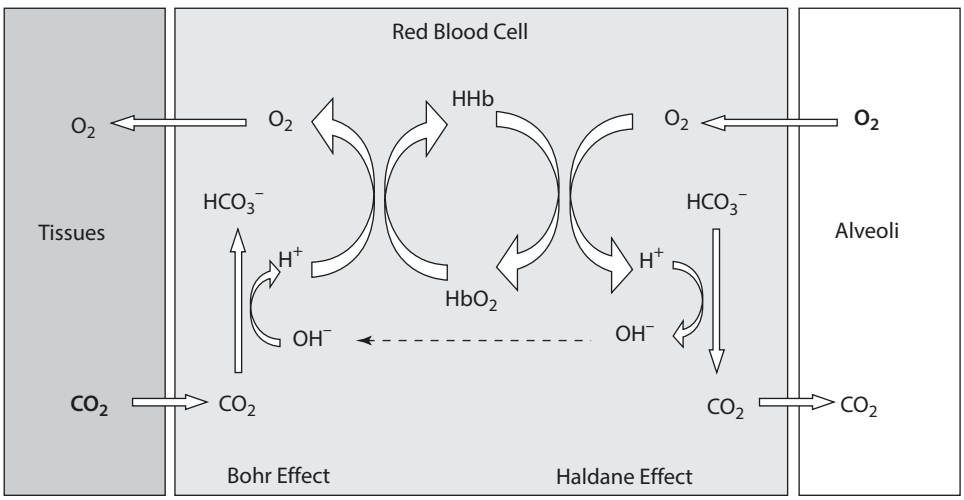


Fig. 8.4 The Bohr effect and the Haldane effect on oxygen transfer

8.3.1 Hypoventilation

Hypoventilation is an inadequate minute ventilation to maintain a normal $PaCO_2$ resulting in respiratory acidosis. Hypoventilation is not an oxygenation diffusion abnormality. Therefore, the A-a gradient usually does not increase. Rather, PAO_2 falls in accordance with the alveolar gas equation in response to increased $PACO_2$. The two main causes of hypoventilation are (1) *abnormal respiratory mechanics* causing increased airway resistance or decreased pulmonary compliance and (2) ventilatory control abnormalities such as ineffective muscles of respiration as in the case of neuromuscular disorders or *damaged neural sensing and signaling* as occurs in brain injury or deep sedation.

8.3.2 Ventilation-Perfusion Mismatch

The most common cause of hypoxemia is ventilation-perfusion mismatch. Gas exchange in the lung is best achieved when ventilation and perfusion are well matched. The degree to which ventilation matches perfusion determines how adequately gas exchange occurs. When alveolar ventilation matches pulmonary blood flow, carbon dioxide is appropriately eliminated, and the blood becomes fully saturated with oxygen. The ventilation-perfusion ratio can be determined using the following equation:

$$V/Q = \left[8.63 \times R\left(CaO_2 - CmvO_2\right)\right] / PACO_2$$

where V/Q represents the ratio of ventilation to pulmonary perfusion, 8.63 is a constant that reconciles the units and conventional conditions of expression, R is the respiratory exchange ratio, CaO_2 is the arterial content of oxygen, $CmvO_2$ is the mixed venous content of oxygen, and $PACO_2$ is the alveolar partial pressure of carbon dioxide.

When the V/Q ratio significantly exceeds one, ventilation is wasted because it does not participate in gas exchange. This is referred to as dead space ventilation. The most extreme example is the patient in cardiac arrest who is being ventilated but is no longer perfusing the lung. Anatomical dead space consists of the conducting airways (i.e., nasopharynx, trachea, subsegmental bronchi, terminal bronchioles) within which approximately 25% of each tidal volume is lost. Alveolar dead space consists of the alveoli not participating in gas exchange due to inadequate perfusion. The PCO_2 in these alveoli is relatively low since CO_2 is not added from the circulation. Physiological dead space is defined as the combination of both anatomical and alveolar dead space. The causes of increased dead space ventilation include tachypnea (anatomic dead space is fixed, thus rapid shallow breathing increases relative dead space), obstructive lung disease, and pulmonary emboli. The Bohr equation (not to be confused with the aforementioned Bohr effect) may be used to calculate the amount of physiological dead space:

$$V_d / V_t = \left(PaCO_2 - EtCO_2\right) / PaCO_2$$

V_d is the volume of dead space ventilation, V_t is the total ventilation volume, $PaCO_2$ is the arterial partial pressure of carbon dioxide, and $EtCO_2$ is the end tidal carbon dioxide.

As the V/Q ratio decreases below one, the PaO_2 decreases, and the $PaCO_2$ increases. When the V/Q ratio is less than one throughout the lung, hypoxemia is responsive to supplemental O_2. The normal compensatory response is

The Bohr equation may be used to calculate the amount of physiological dead space: $V_d/V_t = [PaCO_2 - EtCO_2]/PaCO_2$ where V_d is the volume of dead space ventilation, V_t is the total ventilation volume, $PaCO_2$ is the arterial partial pressure of carbon dioxide, and $EtCO_2$ is the end tidal carbon dioxide.

to increase the minute ventilation, producing either a low or normal $PaCO_2$. When ventilation ceases, the *V*/*Q* ratio reaches zero, and mixed venous blood enters the arterial circulation unchanged.

8.3.3 Shunting of Pulmonary Blood

A shunt is another cause of arterial hypoxemia. It can be thought of as the most extreme form of ventilation-perfusion mismatch where *V*/*Q* approaches zero. Shunts may occur at either the cardiac level with right to left intracardiac shunts or at the pulmonary level. The shunt fraction equation is

$$Q_s / Q_T = \left(CcO_2 - CaO_2\right) / \left(CcO_2 - CvO_2\right)$$

When the intrapulmonary shunt exceeds 30%, hypoxemia does not improve with supplemental oxygen because the shunted blood does not come in contact with enough of the high alveolar oxygen content.

where Q_s is the shunt blood flow, Q_T is the total blood flow, and the Cc, Ca, and Cv are the O_2 contents of the idealized alveolar capillary, measured arterial, and measured mixed venous blood, respectively. Under normal conditions, the percentage of intrapulmonary shunt is less than 10%. When the intrapulmonary shunt exceeds 30%, hypoxemia does not improve with supplemental oxygen because the shunted blood does not come in contact with enough of the high alveolar oxygen content. The PaO_2 levels fall proportionately to the degree of shunted blood flow.

8.3.4 Diffusion Limitation

A final, though infrequent, cause of arterial hypoxemia is diffusion limitation. Diffusion limitation occurs when there is disequilibrium between the partial pressure of a gas in the alveoli and the pulmonary capillaries causing an increase in the A-a gradient. Hypoxemia can occur due to a diffusion limitation because of a decreased driving force to push oxygen across the alveolar capillary membrane. Hypoxemia usually results when the diffusion capacity of the lung decreases to less than 50%. Increasing the FiO_2 may be enough to improve the driving pressure and enhance the transfer of oxygen from the alveoli into the blood. Most causes of decreased oxygen diffusion are caused by diffuse parenchymal lung diseases, which result in thickening of the alveolar capillary membrane. It has been estimated that blood passing through the lungs remains in a pulmonary capillary for only 0.75 s. Despite this brief time and a progressively decreasing alveolar capillary oxygen gradient (as the capillary blood becomes progressively more oxygenated), it has been estimated that pulmonary capillary blood approximates alveolar oxygen in only a third of this available time. This allows ample time for diffusion in clinical states of impaired perfusion.

8.4 Monitoring of Gas Exchange

8.4.1 Arterial Blood Gas Determination

An arterial blood gas (ABG) provides valuable data to help determine the acid-base status of a patient, the cause of any imbalance, as well as the degree of lung injury. Taken together, it is quite useful in assessing the adequacy of oxygenation and ventilation. The following parameters are provided in any ABG: pH, $PaCO_2$, PaO_2, HCO_3, and the base excess or deficit.

The pH describes whether acidemia or alkalemia is present. If the pH of the arterial blood is <7.35, then the patient is acidemic. If the pH of the arterial blood is >7.45, then the patient is alkalemic. The $PaCO_2$ is measured and may be used to determine the respiratory component of the pH. As a general rule, for every 10 mm Hg acute change in the $PaCO_2$, there is an inverse change of 0.08 pH units. Thus, accepting a $PaCO_2$ of 40 mm Hg and a pH of 7.40 as "normal" baselines, a patient with a $PaCO_2$ of 50 mm Hg should have a pH of 7.32 if the acid-base alteration is exclusively respiratory in origin. The $PaCO_2$ may also be used to determine the extent of dead space ventilation by the Bohr equation (as previously described):

As a general rule, for every 10 mm Hg acute change in the $PaCO_2$, there is an inverse change of 0.08 pH units.

$$V_d / V_t = \left(PaCO_2 - EtCO_2\right) / PaCO_2$$

In addition to assessing the respiratory component, the arterial blood gas can be used to assess the metabolic component of the acid-base alteration. Most blood gases provide a measurement of the bicarbonate concentration (either by direct measurement or determined from the measured pH and $PaCO_2$) and a calculated base excess or deficit. Because the carbon dioxide bicarbonate system accounts for only 75% of the buffering effect in the blood (the remainder being due to hemoglobin, phosphate, and plasma proteins), the base excess (or deficit) is a calculation used to compare the buffering capacity of the patient relative to normal. It is determined using the Siggaard-Andersen nomogram which relates pH, pCO_2, and HCO_3 while factoring in the contributions of the other blood buffers. There are equations to approximate the base excess (deficit) and its impact on pH that the pediatric critical care provider should understand. Specifically, the base excess can be approximated by the following equation:

$$\text{Base Excess} = \left(-1.2\right) \times \left(24 - \text{measured bicarbonate concentration}\right).$$

Moreover, for every change of 10 mEq/L in the base excess, there should be a 0.15 unit change in the pH. Conversely, for every 0.01 unit change in pH from expected, there will be a change of 0.67 mEq/L in the base excess.

This equation can be used in the interpretation of a blood gas to assess the metabolic component of an acid-base alteration. For example, a patient with a pH of 7.27 and a PCO_2 of 60 mm Hg should have a pH of 7.24 based solely on the respiratory component (carbon dioxide). This is based on the principle described above that every 10 mm Hg acute change from 40 mm Hg in the carbon dioxide should result in an inverse change of 0.08 in the pH. A $PaCO_2$ of 60 mm Hg is 20 mm Hg greater than 40 mm Hg, and consequently, the pH should be 0.016 less than 7.40, or 7.24. However, the pH in the example is 7.27. Remembering that for every change of 10 mEq/L in the base excess, there should be a 0.15 unit change in the pH, it can be stated that for every 0.01 change in pH from expected, there will be a corresponding 0.67 change in the base excess. In the example described above, the pH is 0.03 pH units higher than the expected pH based on the respiratory component alone. Since there is a 0.67 change in the base excess for every 0.01 change in the pH, the base excess in this patient would be $3 \times 0.67 = +2$. This would suggest that the patient has some metabolic compensation for his respiratory acidosis. Most simply stated, the base excess (or deficit) roughly quantifies the change in pH not accounted for by any change in $PaCO_2$.

For every change of 10 mEq/L in the base excess, there should be a 0.15 unit change in the pH.

The PaO_2 is also measured in the arterial blood gas and provides useful data reflecting the degree of hypoxia. The PaO_2 is utilized in a number of equations assessing the degree of lung injury. For example, the PaO_2 is utilized in the A-a gradient equation:

$$\text{A - a gradient} = PAO_2 - PaO_2$$
$$= \left[PiO_2 - PaCO_2 / RQ\right] - PaO_2$$
$$= \left[\left(\left(P_{BAR} - P_{H_2O}\right) \times FiO_2\right) - PaCO_2 / RQ\right] - PaO_2$$

The oxygen index (OI) is a marker of lung injury and is determined by the equation [(Mean airway pressure * FiO_2)*100] / PaO_2.

In addition, the PaO_2 is also used in determining the oxygen index (OI):

$$\frac{\left(\text{Mean airway pressure} \times FiO_2\right) \times 100}{PaO_2}$$

The OI has been used in a number of studies as a means to quantify and compare the degree of lung injury. It can be thought of as the magnitude of potentially injurious therapeutic interventions to the alveoli (pressure and fraction of inspired oxygen) over the result (the partial pressure of arterial oxygen achieved from delivering such interventions). As therapy (the numerator) increases to treat a declining PaO_2 in the denominator, the OI rises, indicating more severe lung injury.

The PaO_2 can also be used to determine the ratio of the partial pressure of oxygen and the fraction of inspired oxygen (P/F ratio). This P/F ratio has also been used extensively in both clinical and research work. In fact, the P/F ratio has been incorporated into the definitions of severity of acute respiratory distress syndrome (ARDS). In the Berlin definitions, P/F ratio > 200 and ≤300 mm Hg is considered mild ARDS, P/F ratio >100 and ≤200 is considered moderate ARDS, and P/F ratio ≤100 is considered severe ARDS. In contrast to the OI, the P/F ratio does not incorporate mean airway pressure and, therefore, can be utilized to assess the degree of lung injury in non-intubated patients. Although useful for that reason in the non-intubated patient, it may provide misleading assessments in patients receiving positive pressure ventilation. Since the P/F ratio often improves with increasing mean airway pressure, using it alone as an index of severity of lung disease will be misleading. An improved P/F ratio in response to the application of higher mean airway pressure does not mean that the patient has less lung injury. The oxygenation index, on the other hand, accounts for the increase in mean airway pressure, thereby balancing the improvement in PaO_2 which would itself decrease the calculated OI. The OI, and variations utilizing oxygen saturation in lieu of PaO_2, is the preferred severity grading tool for pediatric acute respiratory distress syndrome (PARDS) (▶ Chap. 11).

8.4.2 Pulse Oximetry

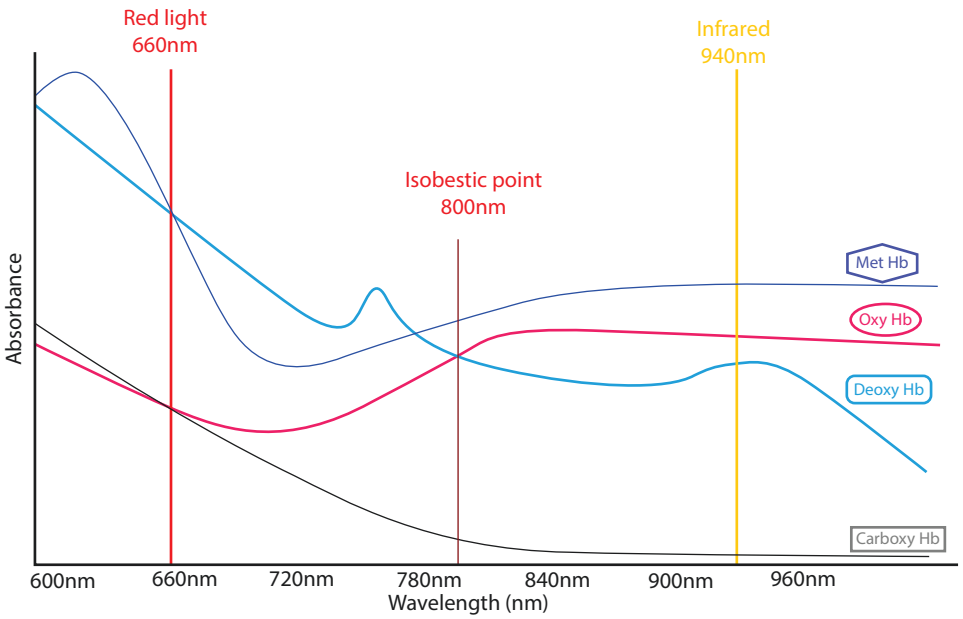
The use of pulse oximetry has become universally accepted for providing instantaneous information regarding the oxygen saturation of arterial blood. This technology is based on the light absorption characteristics of different forms of hemoglobin and utilizes two principles. First, the attenuation of light passing through tissues changes with the pulsation of arterial blood, and second, the degree of attenuation is based on the composition of the arterial blood. Present-day pulse oximeters utilize two wavelengths of light, visible red (660 nm) and near-infrared (900–940 nm), to discriminate between oxyhemoglobin and deoxyhemoglobin. Oxygenated hemoglobin reflects red light much better than other hemoglobin species resulting in the much "redder" appearance of oxygenated blood. As arterial blood is pumped through a tissue bed, the absorption of light changes in a pulsatile manner. The light absorption of the tissues, the venous blood, and the capillary blood does not change. Therefore, the degree of light absorption from these components can be subtracted from

the total light absorption to yield the amount of light absorption of the arterial blood alone. Because the absorption of light in the near-infrared range is relatively constant over a wide range of oxygen saturations, changes in the absorption at the 660 nm wavelength of the arterial blood reflect oxygenation and can be referenced to the near-infrared absorption. In this way, the arterial blood oxygen saturation may be determined using predetermined algorithms.

The ratio of the oxygen saturation ascertained from pulse oximetry to the fraction of inspired oxygen (the S/F ratio) is now being used in lieu of the P/F ratio as a marker of lung injury, in risk stratification, and for research purposes. Although there are limitations to this application, the S/F ratio may be beneficial for use in children with acute hypoxic lung injury, as it is a noninvasive measurement.

Pulse oximetry has been found to be very accurate for oxygen saturations greater than 70% with confidence limits of 2–4%. However, for saturations below 70%, the accuracy is substantially less. Moreover, there are clear limitations to the use of pulse oximetry. Motion artifact is probably the most common example of erroneous data being generated by pulse oximetry. This is easily recognized and often results in frequent triggering of the oximeter alarms. Pulse oximeters have been developed that attempt to minimize the effect of motion artifact. In addition, environmental light may interfere with pulse oximetry accuracy. Although this has not been found to be applicable to all oximeters, shielding the pulse oximeter probe from external light may result in improved performance. Other limitations of pulse oximetry include any factor that might interfere with the ability to detect and monitor a pulse such as hypoperfusion, vasoconstriction, and hypothermia. In these circumstances, the pulse oximeter will often not record at all or display an inaccurate reading.

In addition to the potential for error described above, clinical situations in which hemoglobin binds to substances other than oxygen may also result in erroneous pulse oximetry values. For example, in the setting of carbon monoxide poisoning, hemoglobin binds with great affinity to carbon monoxide to form carboxyhemoglobin. As can be seen in ◘ Fig. 8.5, carboxyhemoglobin has a very similar light absorption as oxyhemoglobin at 660 nm. Consequently, The pulse oximeter inappropriately interprets carboxyhemoglobin to be oxyhemoglobin and, therefore, overestimates the true oxygen saturation of hemoglobin in the setting of carbon monoxide poisoning.



◘ **Fig. 8.5** Light absorbance characteristics of various forms of hemoglobin

the pulse oximeter will inappropriately interpret carboxyhemoglobin to be oxyhemoglobin and, thereby, overestimate the true oxygen saturation of the hemoglobin. This may occur in the setting of significant hemolysis where significant amounts of carbon monoxide are formed and bind to hemoglobin to form carboxyhemoglobin. In the setting of carboxyhemoglobinemia, blood gas analysis with co-oximetry, which measures other forms of hemoglobin (carboxyhemoglobin, methemoglobin, oxyhemoglobin, deoxyhemoglobin), is necessary to truly ascertain the oxygen saturation of the blood.

The situation is different in the setting of methemoglobinemia. Initially, as methemoglobin levels increase, the pulse oximetry saturation will decrease to 80–85%. However, because methemoglobin adsorbs light equally well at 660 and 940 nm, the absorbance of light in pulsatile blood and baseline nonpulsatile reference tissue will increase at an equal pace. The ratio between the two points of light absorbance will be one resulting in a displayed oxygen saturation of approximately 85%. Consequently, even with further increases in the methemoglobin, the pulse oximeter saturation reading will remain approximately 85%. As with carboxyhemoglobinemia, blood gas analysis with co-oximetry is necessary in the setting of methemoglobinemia to accurately determine the percentage of oxyhemoglobin.

Finally, pulse oximetry may not be completely accurate in the setting of high concentrations of sickle hemoglobin (hemoglobin S). In addition to the abnormal shape of sickled red blood cells that potentially alter the normal absorption of light, a rightward shift of the oxygen-hemoglobin dissociation curve may result in lower pulse oximeter readings for any given partial pressure of arterial oxygen. In addition, significant hemolysis associated with sickle cell disease may result in carboxyhemoglobinemia and erroneous pulse oximeter values as described above.

8.4.3 Capnometry

Capnometry has become a standard of care to confirm appropriate endotracheal intubation.

Capnometry is the measurement of carbon dioxide in expired gas. Capnometers measure carbon dioxide using one of two techniques, each with its own advantages and disadvantages. The more common form of capnometry in intubated patients is referred to as mainstream. The mainstream capnometer is placed in line with the endotracheal tube circuit. It utilizes a light-emitting detector that is positioned on either side of an airway adaptor attached to the top of the endotracheal tube. It uses infrared light absorbance to detect carbon dioxide. Because of its in-line positioning, it allows for rapid breath-to-breath analysis of carbon dioxide. Although it does not depend on the aspiration of gas, it is susceptible to interference by respiratory secretions or humidity. Moreover, because of the need of an adaptor, additional dead space is added to the circuit. This is usually not problematic except in the smallest of infants. Finally, the sensor used by some mainstream capnometers may be large and heavy relative to the endotracheal tube and, thus, may place undue tension on the tube.

Sidestream sampling is the other form of capnometry. It is less commonly used in intubated patients but is increasingly being utilized in non-intubated circumstances. The sidestream technique continuously aspirates a small amount of gas as the patient ventilates either spontaneously or through a ventilator circuit. The advantage of this method is that the apparatus adds no additional dead space or weight to an endotracheal tube. The disadvantage, particularly in smaller patients, is that it may decrease minute ventilation due to the aspiration of gas. Also, because of the method of sampling, mucous and water may be inadvertently aspirated into the monitoring device obstructing optimal gas

flow. Finally, because the gas has to be pulled out of the endotracheal tube/ventilator circuitry, there is a delay in the response time to changes in carbon dioxide. It should be noted, however, that some gas aspirating systems utilize an adapter positioned between the ventilator circuit and the endotracheal tube, adding to system dead space similar to mainstream capnometers.

Capnometry has become an important component of pediatric critical care monitoring. First, and perhaps foremost, it has become a standard of care to confirm correct placement of an endotracheal tube after intubation. This may be accomplished in one of two ways. The simplest involves attaching the endotracheal tube to a colorimetric capnometer that will change colors when exposed to carbon dioxide, usually from purple to yellow. The colorimetric capnometers contain a disc that when exposed to carbon dioxide produces hydrogen ions. The increase in hydrogen ions and the resultant change in pH result in the color change of the disc. If no carbon dioxide is detected, the colorimetric capnometer will remain purple. If carbon dioxide is detected, the disc will change color from purple to yellow. This method may only be used for short-term confirmation of exhaled carbon dioxide. The second method involves graphically displaying the detected level of carbon dioxide. The second method, capnography, may be used to quantify the amount of carbon dioxide detected and may reflect the level of carbon dioxide at any given point in the respiratory cycle.

There are situations in which capnometry/capnography may provide misleading information regarding the appropriate positioning of an endotracheal tube. Tube placement above the vocal cords in the hypopharynx may allow for sufficient ventilation such that carbon dioxide may be detected despite the tube not being positioned in the trachea. In contrast, in the setting of cardiac arrest or extreme hypoperfusion, carbon dioxide may not be delivered to the lungs, resulting in little to no carbon dioxide in the exhaled breaths. Consequently, the capnometer/capnograph will not detect carbon dioxide even though the endotracheal tube may be properly positioned in the trachea. Large air leaks around the endotracheal tube or obstructed tubes may also result in diminished amounts of carbon dioxide being detected despite appropriate positioning of the endotracheal tube. It is recommended that capnometry/capnography be assessed over at least the first six breaths of ventilation to minimize the risk of misinterpretation.

In addition to confirming endotracheal intubation, capnometry may be used to monitor arterial carbon dioxide content noninvasively. Carbon dioxide readily diffuses across the alveolar capillary membrane such that the concentrations of arterial and alveolar carbon dioxide quickly equilibrate. Consequently, the partial pressure of carbon dioxide in the alveolus closely approximates the partial pressure of carbon dioxide in the arterial blood. Leaving the alveolus, gas is exhaled by traversing a terminal bronchiole, a subsegmental bronchus, a main bronchus, the trachea, the endotracheal tube, and into the expiratory limb of the ventilator circuit. During that entire transit, which is essentially dead space, very little additional gas exchange occurs. Consequently, under ideal circumstances, by measuring the peak concentration of carbon dioxide (end tidal) as it exits the endotracheal tube or nasopharynx, it is possible to estimate the concentration of carbon dioxide in the alveolus and, therefore, the partial pressure of carbon dioxide in the arterial blood. This is the foundation upon which the development of capnometry was developed. In the patient without cardiopulmonary disease, the system works well, and exhaled end tidal carbon dioxide approximates $PaCO_2$. In fact, the end tidal carbon dioxide is usually 2–5 mm Hg lower than the $PaCO_2$ because of anatomic dead space ventilation and the expected, mild ventilation-perfusion mismatch in the upper

Under ideal circumstances, by measuring the peak concentration of carbon dioxide (end tidal) as it exits the endotracheal tube or nasopharynx, it is possible to estimate the concentration of carbon dioxide in the alveolus and, therefore, the partial pressure of carbon dioxide in the arterial blood.

lung fields (West Zone I). In those upper lung fields, ventilation is slightly greater than perfusion because of the gravitational forces favoring blood flow to the lower, more dependent lung fields (see Fig. 8.2).

As the end tidal carbon dioxide ($EtCO_2$) represents the average partial pressure of ventilated alveoli and the $PaCO_2$ represents the same for perfused alveoli, any alteration in ventilation-perfusion matching will result in an inaccurate $EtCO_2$ estimate of the $PaCO_2$.

However, as might be anticipated, there are many clinical situations common to the pediatric intensive care unit where the premise of balanced ventilation and perfusion is invalid; thus, capnometry no longer provides reliable estimates of arterial carbon dioxide. As the end tidal carbon dioxide ($EtCO_2$) represents the average partial pressure of ventilated alveoli and the $PaCO_2$ represents the same for perfused alveoli, any alteration in ventilation-perfusion matching will result in an inaccurate $EtCO_2$ estimate of the $PaCO_2$. For example, in any setting of an increased ventilation to perfusion ratio (e.g., increased dead space secondary to decreased cardiac output, pulmonary embolus), the $EtCO_2$ will underestimate the $PaCO_2$. For example, if the $PaCO_2$ is 40 mm Hg, and only half of the alveoli are being effectively perfused, the carbon dioxide coming out of the perfused alveoli will be 40 mm Hg. However, if the other 50% of alveoli are not being perfused at all, the carbon dioxide coming out of these alveoli would be zero. When the gas from the two sets of alveoli meet and mix in the trachea, the resulting concentration of carbon dioxide detected at the capnometer would be 20 mm Hg (as opposed to the true arterial value of 40 mm Hg).

Capnography may be used to estimate the percentage of dead space ventilation.

In light of this, end tidal carbon dioxide monitoring is being utilized as a method to help assess adequacy of cardiac output, chest compressions, and pulmonary perfusion during cardiopulmonary resuscitation, as well as minimizing the chance of potentially deleterious hyperventilation. Although PALS Guidelines have recommended improving CPR quality if $ETCO_2$ levels are consistently less than 15 mm Hg, a specific value at which to maintain the $ETCO_2$ for optimal outcomes has not been uniformly defined. What does seem to be evident in recent studies is that attempting to maintain higher end tidal carbon dioxide levels does seem to be associated with better outcomes. Similarly, but conversely, in the setting of a decreased ventilation-perfusion ratio, where alveoli are being perfused, but not ventilated, the carbon dioxide in these non-ventilated alveoli will never be detected by the capnometer. Therefore, the $EtCO_2$ detected by capnometry will reflect only those alveoli that are actively participating in ventilation.

In addition to the absolute numbers provided by the capnogram, the waveform may also be used to detect problems within the cardiopulmonary system. A normal capnogram consists of four stages (Fig. 8.6a). First, there is an inspiratory baseline (I) where atmospheric air at the sensor has little to no carbon dioxide thereby providing a baseline value of zero. Once exhalation begins, and the air from the anatomic dead space is cleared (no or minimal carbon dioxide present), the second stage is characterized by a rapid rise (steep) in the measured carbon dioxide as alveolar air rich with carbon dioxide rushes past the sensor (III). During exhalation, the concentration of carbon dioxide quickly stabilizes, and the level of carbon dioxide roughly flattens. The highest recorded value of carbon dioxide at the end of exhalation is recorded as the end tidal carbon dioxide. During the final stage of the respiratory cycle, inspiration occurs. With the fresh rush of carbon dioxide-free air across the sensor, the carbon dioxide level quickly plummets to zero (IV). Monitoring of the capnogram allows for the continuous monitoring of airway obstruction, apnea, hypercarbia, and return of spontaneous circulation (Fig. 8.6b–d). It also allows for a more exact measurement of the respiratory rate than traditional thoracic impedance devices. The capnogram waveform may also be used to detect conditions associated with increased airway resistance. For example, waveforms associated with a wider angle between the upslope and the plateau

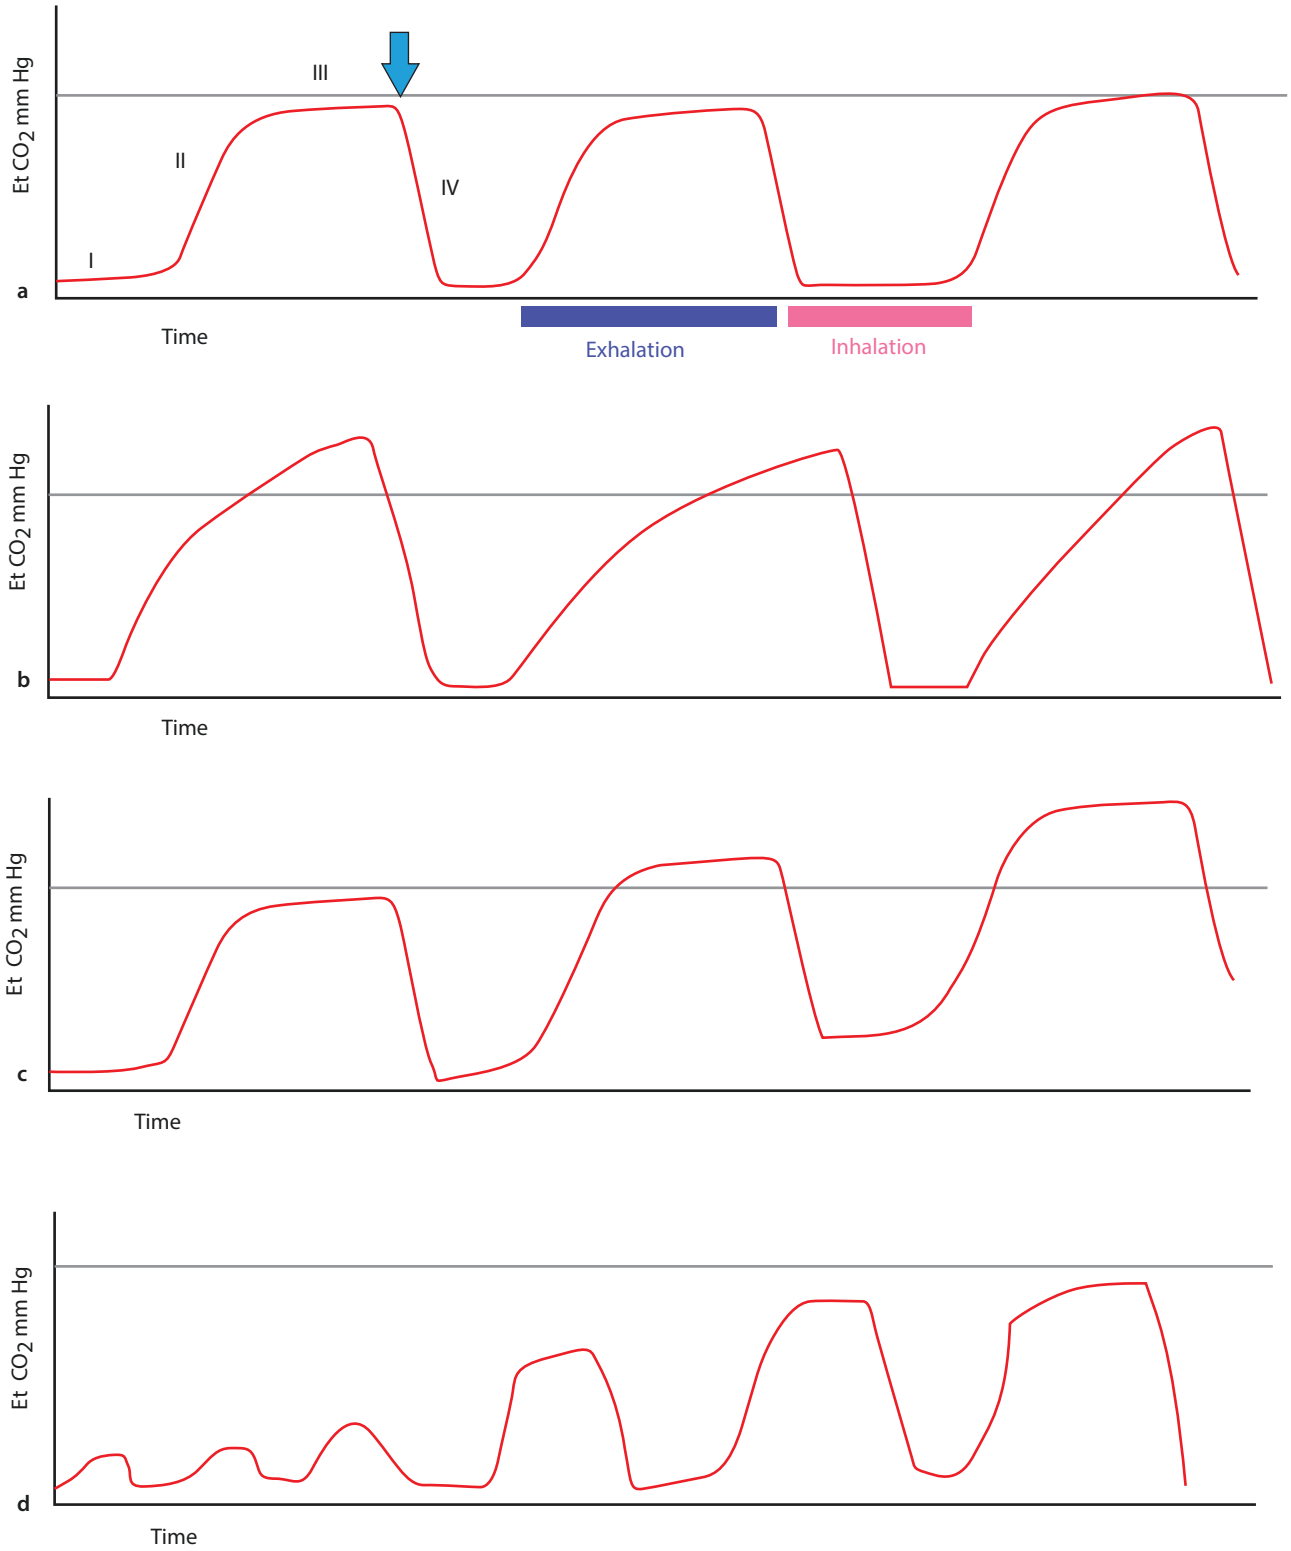


Fig. 8.6 **a** A normal capnogram consists of four stages: I. Inspiratory baseline where atmospheric air at the sensor has little to no carbon dioxide thereby providing a baseline value of zero. II. Start of exhalation and rapid rise in the measured carbon dioxide as alveolar air rich with carbon dioxide rushes past the sensor. III. Plateau phase where the concentration of carbon dioxide quickly stabilizes and the level of carbon dioxide roughly flattens. The highest recorded value of carbon dioxide at the end of exhalation is recorded as the end tidal carbon dioxide (arrow). IV. During the final stage of the respiratory cycle, inspiration begins, and the carbon dioxide level quickly returns to zero. **b** Capnogram demonstrating exhalatory obstruction as seen in bronchospasm ("shark fin capnogram"). **c** Capnogram demonstrating carbon dioxide rebreathing as would be seen in insufficient expiratory time or with a blocked exhalatory valve. **d** Capnogram during CPR demonstrating return to spontaneous circulation

stages of exhalation suggest slower carbon dioxide removal and increased airway resistance. The same is true for an uptrending stage III plateau.

Capnography is also useful for the monitoring of the non-intubated patient to monitor the respiratory status in the setting of seizures, altered mental status, overdoses, and particularly in the setting of procedural sedation. Because the medications required for such sedation may be associated with respiratory compromise, close monitoring of the respiratory system is of paramount importance. Traditionally, oxygenation has been monitored with pulse oximetry, and ventilation has been assessed with clinical observation alone. Sidestream capnography, by means of a nasal oral cannula which simultaneously monitors exhaled carbon dioxide and delivers low flow oxygen, allows for a more precise and detailed assessment.

8.4.4 Transcutaneous Oxygen and CO_2 Monitoring

The monitoring and trending of oxygen and carbon dioxide can also be accomplished using transcutaneous technology. This technology has been used since the late 1970s and the early 1980s and has largely been replaced by newer, more reliable technology (described above) which has overcome some of the limitations of transcutaneous monitoring. The use of the transcutaneous technology requires warming of the skin to promote hyperperfusion allowing the monitors to electrochemically detect O_2 and CO_2 levels. In this way, frequent blood draws are avoided, and a mode of continuous monitoring is achieved. The limitations, however, prevent practical regular and reliable use. The electrodes frequently need to be recalibrated; the measurement is inaccurate when the skin is not optimally perfused, as in the case of edema, acidosis, shock, or hypothermia. Furthermore, in order to achieve hyperperfusion, the skin is warmed, and burns have been reported. Finally, the response time is much slower than with the other noninvasive techniques described above. The clinical scenario in which transcutaneous CO_2 monitoring may be of particular benefit is in the child on high-frequency oscillatory ventilation in which end tidal CO_2 monitoring is not possible. Transcutaneous O_2 monitoring has been utilized to monitor the adequacy of tissue perfusion following vascular surgery.

8.5 Summary

The effective transfer of oxygen from the atmosphere into the body and ultimately to the various tissues is essential to maintaining life, as is the efficient transfer of carbon dioxide from the body to the environment. The exchange of these gases occurs via a series of complicated physiological processes. Abnormalities in the effective transfer of oxygen from the atmosphere into the bloodstream have been categorized into four pathophysiological mechanisms: hypoventilation, ventilation-perfusion mismatch, intrapulmonary shunt, and diffusion limitation. An understanding of each of these pathophysiological processes will facilitate therapeutic interventions to improve oxygenation. Moreover, close monitoring of the status of gas exchange is essential for the care of critically ill children. Both invasive and noninvasive methods exist to effectively monitor gas exchange in children. A clear understanding of these techniques will foster effective management of critically ill children with impaired gas exchange.

Review Questions

1. You arrive to a code for a child in septic shock who has just experienced a cardiac arrest. The code has been going on for ~10 min without return of spontaneous circulation. He has been intubated and is being ventilated at a rate of 8 bpm. Chest compressions are ongoing. The most helpful reason to request that an end tidal CO_2 monitor is placed at this time is:
   A. To have an objective way to estimate the efficacy of chest compressions by estimating pulmonary perfusion
   B. To avoid having to perform an arterial puncture
   C. To better assess the degree of airway restriction
   D. To be able to detect when the spontaneous respirations resume
   E. To assess the degree of acidosis and therefore need for administration of sodium bicarbonate administration

2. Intrapulmonary shunt
   A. Is the most severe form of dead space ventilation.
   B. Occurs when the ratio of ventilation to perfusion of lung units approaches infinity.
   C. Is the quotient of the difference in the idealized alveolar capillary O_2 content and the measured arterial O_2 content and the difference in the idealized alveolar capillary O_2 content and the measured mixed venous O_2 content.
   D. Under normal conditions the percentage of intrapulmonary shunt is >10%.
   E. In excess of 30% can only be overcome by administering 100% FiO_2.

3. A 15-month-old is admitted to the PICU with acute respiratory failure with bronchiolitis secondary to rhinovirus. What objective data can you obtain that may help you in risk stratification in determining the likelihood of requiring intubation?
   A. Respiratory rate
   B. Degree of wheezing
   C. Procalcitonin level
   D. SaO_2/FiO_2 ratio
   E. Time of last meal

4. A 10-year-old girl is in acute hypoxemic respiratory failure and is being managed with conventional invasive ventilation. O_2 saturation is 90% on an FiO_2 of 60% and a PEEP of 10 cm H_2O. Peak inspiratory pressure is 35 cm H_2O. Mean airway pressure is 18 cm H_2O, and $EtCO_2$ is reading 45 with a ventilator rate of 22 breaths per minute.
   You are debating whether to place an arterial catheter and decide that it would be helpful for the following reason:
   A. It allows you to measure the PaO_2 which is the only way to calculate the partial pressure of O_2 in the alveoli.
   B. The more data that helps drive patient care, regardless of invasiveness, the better the long-term outcome for the patient.
   C. It will enable you to calculate an oxygenation index which will help you prognosticate likelihood of survival.
   D. The continuous blood pressure measurement will help you mitigate against barotrauma.
   E. It will allow you to obtain a PaO_2 which can be utilized to help you trend the degree of lung injury.

5. A 2-year-old male is admitted with uncompensated shock. He is tachypneic, tachycardic, and hypotensive and had 90% O_2 saturation on RA. His labs are significant for a lactic acidosis. Which of the following statements explain his hypoxemia despite absence of lung disease?
   A. The elevated CO_2 levels in his blood are causing the tachypnea and therefore increasing the oxygen affinity of his hemoglobin molecules.
   B. His acidotic state has caused a rightward shift of the oxygen-hemoglobin dissociation curve causing his hemoglobin molecules to have a lower affinity for O_2.
   C. He still has a predominance of hemoglobin F.
   D. He has become hypothermic slowing his metabolic rate and improving the efficiency of O_2 delivery.
   E. His tachycardia is ensuring adequate pulmonary blood flow.

Learning Objectives

- Describe the anatomic differences in the airway of a child as compared to an adult
- Recognize the signs and symptoms of a child with upper airway obstruction
- Understand the approach to safe diagnostic evaluation of the infant or child with upper airway obstruction
- Understand the differential diagnosis of a child with upper airway obstruction in the context of age at presentation, congenital versus acquired, and chronic versus acute
- List and describe clinical differences in infectious etiologies of acute upper airway obstruction
- Understand the approach to stabilization and management of the child with upper airway obstruction
- Know the mechanism of action of the major therapies aimed at treatment of upper airway obstruction
- Know the indications for endotracheal intubation (including a clinical plan for intubation) and tracheostomy in a child with upper airway obstruction
- Outline a plan for the child with upper airway obstruction with an "unintubatable" airway (including laryngeal mask airway and cricothyroidotomy)

9.1 Introduction

The degree of airway obstruction is not proportionate to the amplitude of the stridor. Severe obstruction with poor airflow may occur with minimal stridor.

Acute upper airway obstruction presents an immediate threat to life. Following loss of the upper airway, hypoxemia with resultant cardiac arrest and death can ensue within minutes. Inspiratory stridor, a harsh, usually high-pitched sound, is the hallmark of upper airway obstruction. However, upper airway obstruction cannot occur in the absence of stridor, because profound degrees of obstruction may manifest silently if airflow is nearly absent. When confronted with a child who has acute upper airway obstruction, the practitioner must assess the degree of obstruction quickly and accurately. The possibility of progression to complete airway obstruction with hypoxemia and cardiac arrest must be appreciated. Delaying intervention in a child whose airway is unstable may be costly, but unnecessary instrumentation in a child who has stable upper airway obstruction may precipitate a crisis.

9.2 Anatomic and Physiologic Considerations

The extrathoracic upper airways are narrower during inspiration due to the relatively lower (negative relative to atmospheric) pressure within the lumen as air is being drawn through by the actions of the respiratory muscles. This lower luminal pressure in combination with the highly compliant nature of upper airway tissue creates a predilection toward inspiratory obstruction; this is especially true in infants. Pressure within the extrathoracic upper airways varies from mildly positive relative to atmospheric during quiet expiration to markedly greater than atmospheric during forced expiration. Thus, the internal diameter of extrathoracic airways is augmented somewhat during expiration, lessening the obstruction. Hence, airflow limitation from upper airway narrowing is greater during inspiration, and symptoms are apparent predominantly during inspiration.

The predominance of expiratory sounds suggests obstruction at the level of the intrathoracic trachea or lower airways.

Stridor is primarily, though not exclusively, an inspiratory phenomenon. The presence of mainly expiratory symptoms, regardless of the acoustic nature of the sound, should warn one to the presence of airway obstruction at the level of the intrathoracic (lower trachea and distal) airways. One exception is

the behavior of dynamic subglottic lesions, such as a soft subglottic cyst, which may move upward against the undersurface of the glottis causing expiratory noise but fall away from the glottis with no inspiratory sound.

The narrowest point of the airway of an infant or small child is at the level of the cricoid ring. This results in a funnel shape to the glottis and subglottic area. In contrast, the narrowest part of the airway of an older child or adult is vocal cord opening. There is no circumferentially narrow area of the adult upper airway which would correspond to the cricoid ring in the small child. Because of the fourth-power relationship between airway diameter and airway resistance (Poiseuille equation for nonturbulent flow), the same amount of airway encroachment or edema in millimeters causes a far greater physiological obstruction in a small child than in an adult. In addition, airways affected by edema may change flow dynamics from laminar to turbulent which is especially important at high flow rates and at locations where the diameter or angle of the airway changes abruptly. The pressure gradient to support turbulent flow is proportional to the square of the gas flow rate (as opposed to the first order with laminar flow) and is also proportionate to gas density. This effect of gas density on flow dynamics in the presence of turbulent flow is the rationale for the use of helium-oxygen gas mixtures in the treatment of some forms of upper airway obstruction.

In the absence of hypoxemia, a previously healthy infant or child can tolerate significant degrees of hypercapnia without organ damage.

The cause of death in patients who have airway obstruction is progressive hypoxemia and cardiac arrest. The oxygen consumption of a small child, approximately 7 ml/kg/min, is much greater than that of an adult (3 ml/kg/min) relative to body size. The progression to irreversible organ injury in the face of hypoxemia may be more rapid than for the adult. Thus, the immediate concern when first assessing the child is to provide oxygen and assess the degree of oxygen saturation. Carbon dioxide retention is a secondary concern relative to hypoxemia. An otherwise healthy infant or child can tolerate significant degrees of hypercapnia without organ damage. In addition, the degree of hypercapnia can vary over a matter of minutes as a result of factors such as the child's level of agitation, the degree of airway obstruction, the response to palliative therapies, and the onset of fatigue. For these reasons, arterial blood gas (ABG) measurement, which provides an assessment of pH and $PaCO_2$ for but one moment in time, generally is not considered sufficiently worthwhile, as the amount of distress it causes the child has the real potential to worsen the degree of airway obstruction for the reasons stated above. However, pulse oximetry monitoring is an extremely valuable objective assessment and is required except in rare cases where the probe placement worsens the symptoms due to agitation.

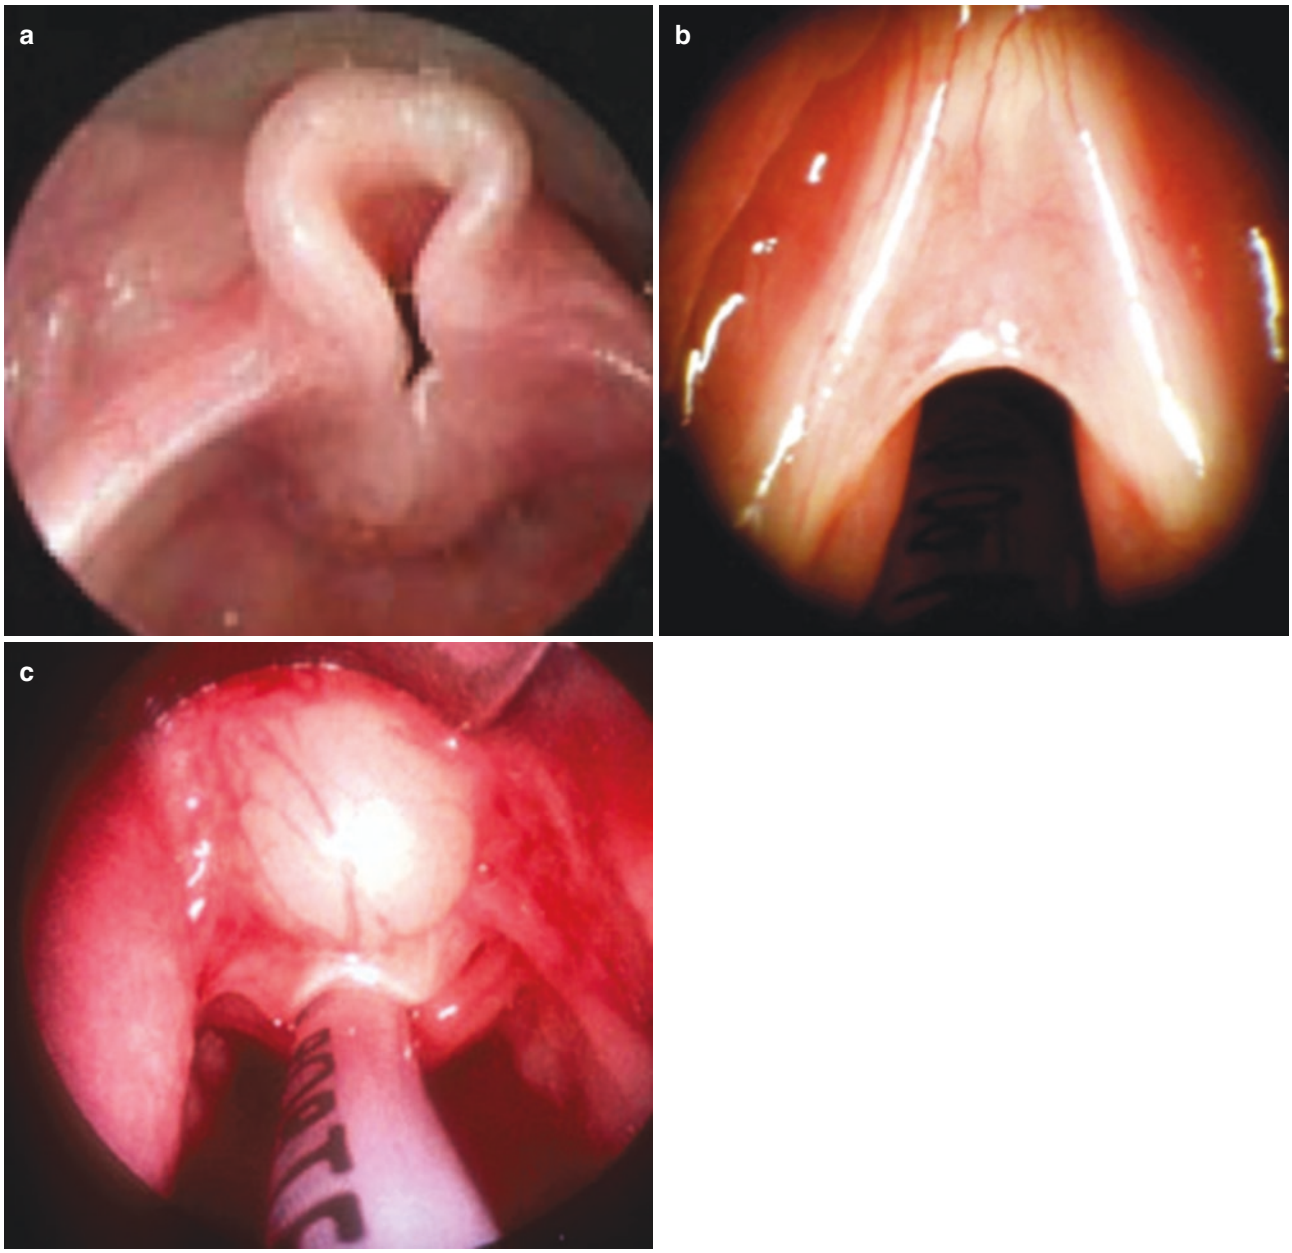
9.3 Differential Diagnosis of Upper Airway Obstruction

For the purpose of offering a diagnostic framework, the causes of upper airway obstruction have been divided into three categories: those occurring in early infancy secondary to congenital, developmental, or birth events; those acquired later in childhood from infectious etiologies; and those acquired later in childhood from noninfectious causes.

9.3.1 Early Infancy

Laryngomalacia is the single most common cause of stridor that begins in early infancy.

Congenital abnormalities of the airway may manifest with airway obstruction and stridor starting early in infancy and occasionally in the immediate newborn period (◘ Fig. 9.1) *Laryngomalacia* is the single most common cause of



9

Fig. 9.1 Congenital causes of upper airway obstruction **a** Laryngomalacia. **b** Anterior glottic web. **c** Vallecular cyst. (Photographs courtesy of pediatric otolaryngologist Aileen Wertz, MD)

stridor that begins in early infancy. Most patients have a history of stridor that is audible whenever the child is excited, agitated, or crying, beginning from the first days of life. This is commonly a self-limiting, developmental disorder in that the "floppy" larynx becomes more rigid and less obstructing with time. Endoscopically, the epiglottis is seen to fold over the larynx on inspiration. Another finding is varying degrees of prolapse of the arytenoid cartilages into the center of the larynx on inspiration. These infants may have feeding problems, and the stridor often worsens with minor respiratory tract infections. Through continuous noninvasive monitoring, it has been demonstrated that infants who have laryngomalacia are more likely than age-matched controls to have transient episodes of hypoxemia and hypercarbia, although these

episodes are usually not life-threatening. As the disorder improves over time, these infants rarely require an artificial airway or other surgical intervention.

Unilateral or bilateral *vocal cord paralysis* may occur in otherwise healthy newborns and has been associated with birth trauma. The prognosis for eventual recovery is very good for idiopathic and birth-related vocal cord injuries. However, vocal cord paralysis also may be associated with other neurological diseases and increased intracranial pressure. Restoration of abductor function has been variable with most affected patients recovering provided that the inciting event is resolved.

The prognosis for recovery of vocal cord function is good for patients with birth related paralysis.

Craniofacial dysmorphism (as in Pierre Robin and Treacher Collins syndromes) causes stridor as a result of micrognathia with posterior displacement of the tongue. *Midface hypoplasia* can contribute to upper airway obstruction in Pfeiffer, Crouzon, and Apert syndromes. *Macroglossia* (as in Beckwith-Wiedemann syndrome, congenital hypothyroidism, glycogen storage diseases, Down syndrome, and other conditions) also may cause stridor in the newborn period.

Choanal atresia presents as the neonate who makes ineffective respiratory movements with poor or absent air entry, no stridor, and deep retractions with the mouth closed yet has good air entry during inspiration when the mouth is open (e.g., during crying). Nearly half of affected neonates have other congenital anomalies (e.g., CHARGE syndrome). Unilateral choanal atresia or choanal stenosis may also occur and presents variable degrees of stridor, retractions, and poor air entry during closed mouth breathing, accompanied by resolution of symptoms with the mouth open.

Congenital laryngeal webs and *subglottic stenosis* may cause critical airway obstruction in the immediate newborn period. Some of these children may not be diagnosed correctly at presentation because endotracheal intubation in the newborn period not only provides a lifesaving airway but also temporarily bypasses the abnormality. With subsequent scarring, the child may manifest the condition again later in infancy during an upper respiratory tract infection.

Vascular rings and *slings* may cause airway obstruction in infancy. An infant who has a vascular ring may have persistent wheezing if the obstruction is in the lower trachea near the carina. Conversely, stridor is typically the major symptom when the obstruction is at a higher level of the extrathoracic trachea.

Vascular rings and slings may cause persistent wheezing if the obstruction is in the lower trachea near the carina or stridor if the obstruction is higher up in the extrathoracic trachea.

Laryngeal clefts are rare and may manifest with either stridor or symptoms of recurrent aspiration. They represent a posterior midline defect and can be difficult to visualize during flexible bronchoscopy due to the anterior angulation of the scope during laryngeal passage. Congenital *cysts* and *laryngoceles* also are uncommon causes of stridor in early infancy. As mentioned earlier, soft subglottic cysts may cause primarily expiratory sounds due to dynamic impingement on the undersurface of the glottis in expiration. These are easily visualized at flexible laryngoscopy/bronchoscopy.

Congenital *tracheal stenosis*, a rare disorder, may be limited to one or more tracheal rings but also has an extreme form in which the entire trachea may have circumferential cartilaginous rings much like lobar and segmental bronchi. It generally presents in infancy, precipitated by a respiratory infection, and may manifest with inspiratory or expiratory airflow obstruction depending on the location of the most significant narrowing. A pulmonary artery sling is present in approximately one third of patients, and less commonly cardiac anomalies are associated. Flexible bronchoscopy is very useful in delineating the extent of the stenosis, but the diagnosis may be missed without a thorough bronchoscopic exam, beyond a cursory look limited to the larynx and subglottis in the stridulous infant.

Pulmonary artery sling is an associated anomaly in patients with congenital tracheal stenosis.

Hemangiomas may develop at any level of the airway in infancy, and these may be associated with cutaneous hemangiomas. In the author's experience, these lesions are easily discernable with flexible bronchoscopy, undertaken with

sedation and topical anesthetic, with little risk of precipitating bleeding even when advancing the scope beyond the first lesion in order to examine for additional lesions. Corticosteroids (systemic or intralesional) may promote shrinkage. Prednisone and methylprednisolone may confer particular advantage due to a receptor-mediated antiangiogenic action. Interferon alpha, an inhibitor of angiogenesis, may be utilized with hemangiomas which do not demonstrate a response to corticosteroids. These hemangiomas generally regress spontaneously in the years following infancy.

9.3.2 Acquired Infectious Causes of Airway Obstruction

The most common cause of acute infectious airway obstruction is viral *laryngotracheobronchitis* (croup). The typical child is between 3 months and 4 years of age, has had a preceding upper respiratory tract infection, and has a barking cough and loud inspiratory stridor. Parainfluenza type 1 is the most common etiologic agent. Adenovirus, respiratory syncytial virus, and influenza are also causative. Pathogenically, there is edema of the subglottic airway with pale discharge. An important immunogenetic component is the demonstration of virus-specific IgE and histamine in the airways of children who develop the croup syndrome.

Bacterial tracheitis has become the most common cause of acute infectious upper airway obstruction resulting in respiratory failure.

Tracheostomy is not required for management of airway obstruction from bacterial tracheitis.

The incidence of membranous croup, also called *bacterial tracheitis*, has increased, and it has become the most common cause of acute infectious upper airway obstruction culminating in respiratory failure and requiring referral to a tertiary care pediatric intensive care unit. The prevailing belief is that this condition represents a bacterial superinfection of viral croup. The most common offending agents are *Staphylococcus aureus* and *Moraxella catarrhalis*, although *Streptococcus* and *Haemophilus* organisms have been implicated. The child usually has an initial croup-like illness that progresses in severity, with rising fever and increasing toxicity, culminating in respiratory failure, with thick purulent secretions noted upon intubation. This disorder usually is visually diagnosed at the time of laryngoscopy during intubation. Contrary to initial reports, tracheostomy generally is not necessary for treatment, and mortality should be very uncommon in children who have not suffered cardiac arrest before admission to an appropriate intensive care setting. Bacterial tracheitis has been reported as a feature of toxic shock syndrome caused by *S. aureus* and scarlet fever caused by group A *Streptococcus*.

Acute spasmodic croup manifests with recurrent nighttime onset of inspiratory stridor and croupy cough. Patients generally are afebrile, and episodes are short-lived. Recurrent episodes of croup may be misdiagnosed as spasmodic croup and instead may be manifestations of an underlying airway abnormality such as subglottic stenosis (SGS) or gastroesophageal reflux-related airway inflammation.

Retropharyngeal abscess (RPA, ◘ Fig. 9.2) is a relatively rare infectious cause of stridor in children. It usually occurs in children under the age of 5 years, characterized by high fever and difficulty swallowing, with airway obstruction to a far lesser degree than initially believed. Two large retrospective reviews reported the incidence of UAO in children with RPA as less than 5%. Computed tomography demonstrating a contrast-enhancing abscess is often diagnostic. Not all cases require surgical drainage.

Lemierre disease is a rare syndrome wherein infection from the oropharynx causes septic thrombophlebitis of the internal jugular vein and metastatic abscesses in the lung. It is caused by the anaerobe *Fusobacterium necrophorum*

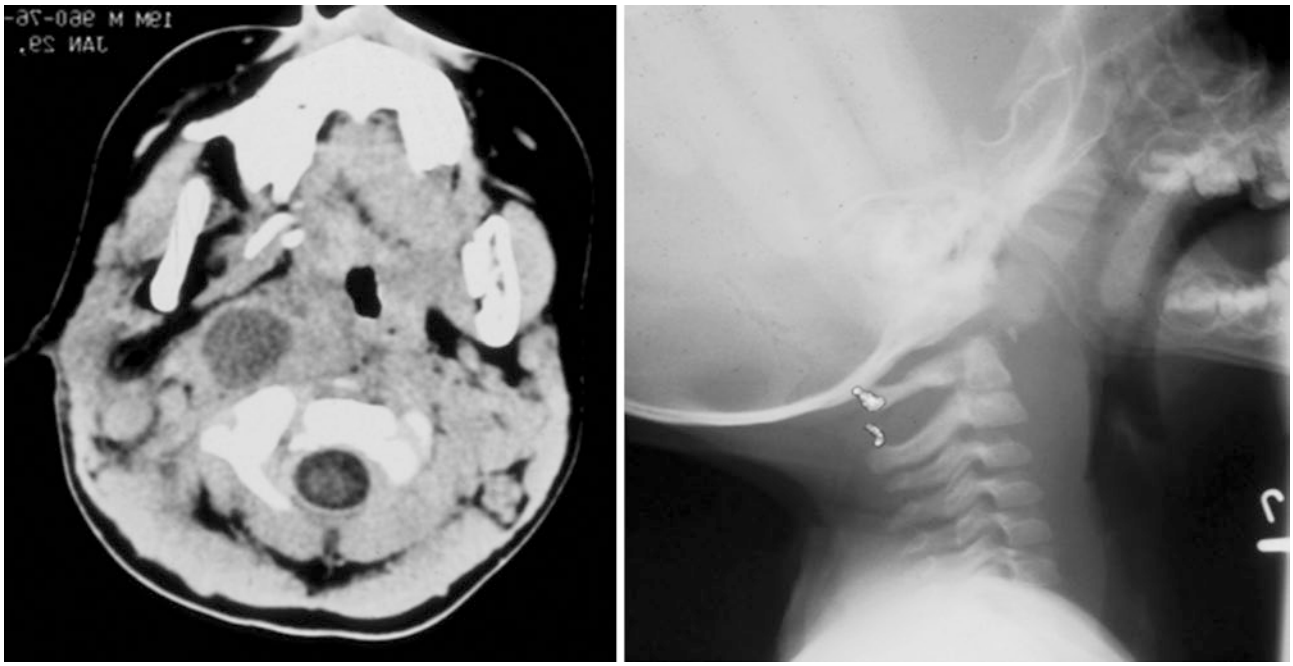


Fig. 9.2 Diagnostic imaging of a patient with retropharyngeal abscess: CT image demonstrating hypodense retropharyngeal abscess. Lateral plain radiograph demonstrating thickening of the prevertebral space

and afflicts teens and young adults with upper airway obstruction and signs of sepsis.

Acute epiglottitis (Fig. 9.3) is most commonly due to infection with *Haemophilus influenzae* type b. This disease has been seen less frequently in the past 20 years, as the result of the development of an effective vaccine. It may occur at any age, including in adulthood. Stridor, fever, and rapidly progressive respiratory distress are hallmarks of the infection. Immunocompromised hosts may develop epiglottitis from atypical organisms including *Pseudomonas aeruginosa* and *Candida* species. Noninfectious causes include trauma from instrumentation, thermal injury, and caustic ingestion.

Acute infectious mononucleosis may cause significant upper airway obstruction as a result of tonsillar hypertrophy. This condition rarely leads to respiratory failure, and the airway obstruction generally responds promptly to a short course of corticosteroids. The level of the obstruction is amenable to placement of nasopharyngeal airway with significant alleviation of airflow obstruction.

Airway obstruction from acute infectious mononucleosis rarely leads to respiratory failure and is amenable to relief with nasopharyngeal airway placement and a short course of corticosteroids.

Laryngeal papillomatosis may cause persistent stridor in children and adults at any age. Multiple, recurrent, rough-surfaced laryngeal tumors are caused by infection with the human papillomavirus (HPV). Repeated surgical excision generally is required to maintain a patent airway. Most recently, immunological therapy with interferon alpha and local treatment with the antiviral cidofovir has demonstrated beneficial effects on these tumors. The use of photodynamic therapy has shown promise but not yet demonstrated superiority in randomized trials. Likewise, case reports and small series suggest benefit from multivalent human papillomavirus vaccination. The condition tends to improve with time, presumably as the child develops immunity to the virus.

Diphtheria, caused by the gram-positive bacillus *Corynebacterium diphtheriae*, is an extremely rare infection in the United States, but it still may occur in unimmunized children.

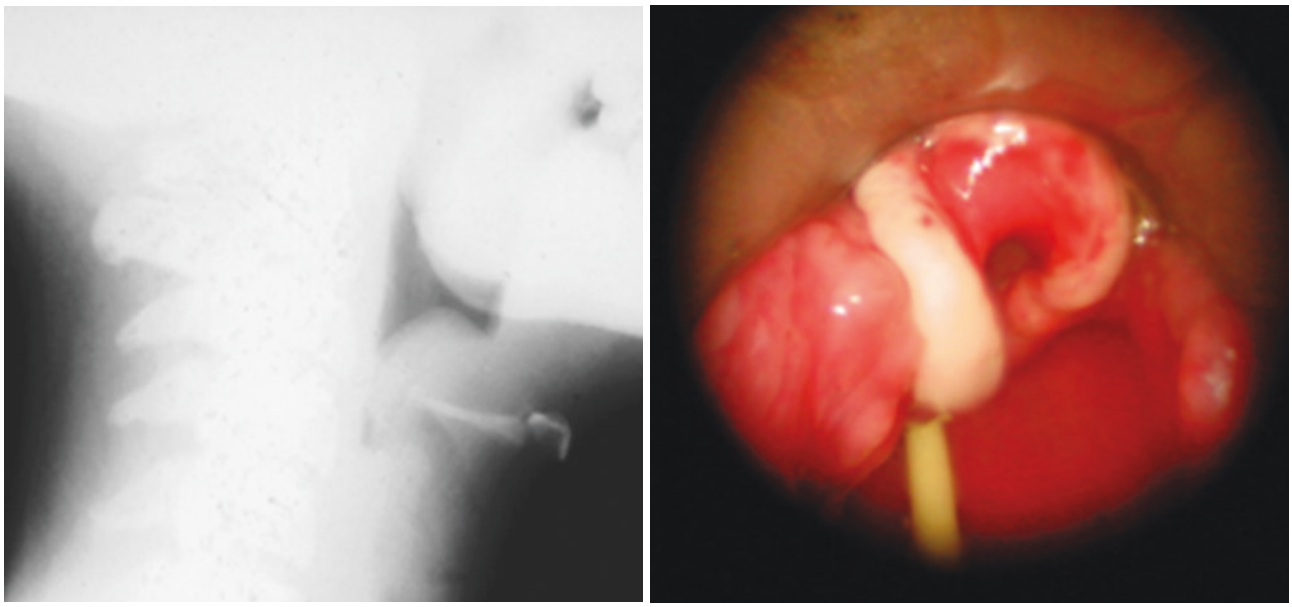

Fig. 9.3 Epiglottitis: Lateral plain radiograph demonstrating the shadow of a swollen epiglottis and direct laryngoscopy demonstrating inflamed and swollen supraglottic structures

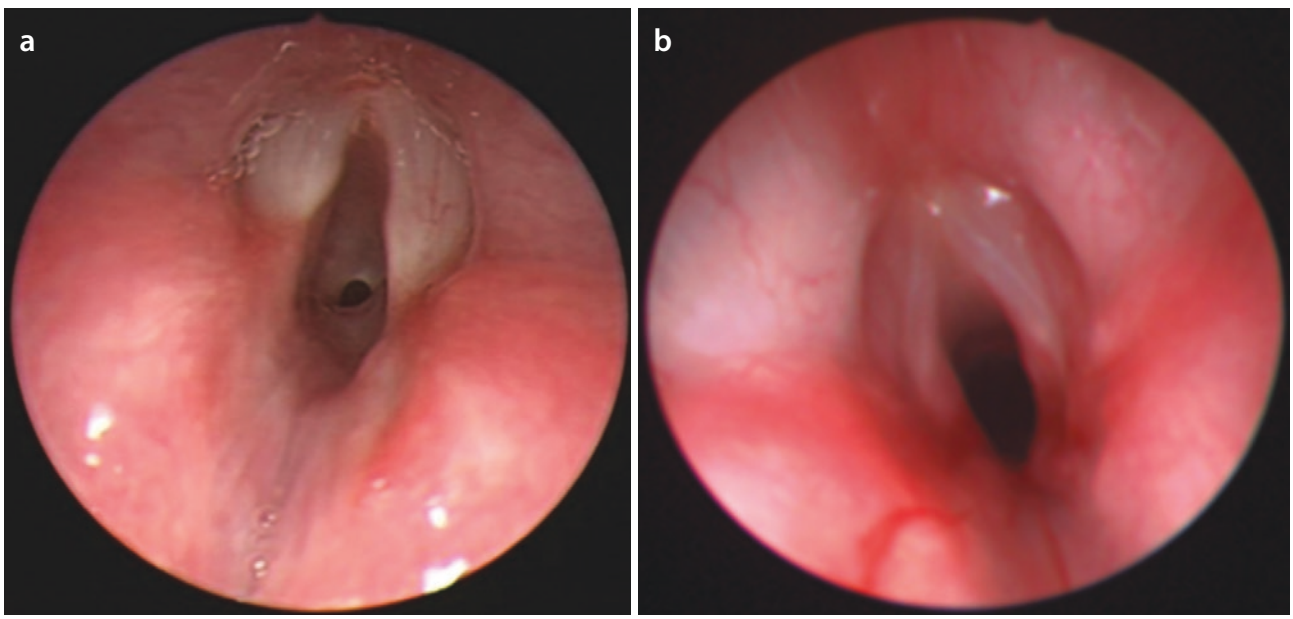

Fig. 9.4 **a** Acquired subglottic stenosis after prolonged intubation. **b** Bilateral fixed vocal folds due to posterior glottic stenosis and arytenoid scarring following prolonged intubation. (Photographs courtesy of pediatric otolaryngologist Aileen Wertz, MD)

9.3.3 Other Acquired Causes of Airway Obstruction

The pediatric intensivist must appreciate the risk of acquired subglottic stenosis (Fig. 9.4) due to endotracheal intubation. The narrowest and most susceptible area of the subglottic region is just below the vocal cords and is circumscribed by the cricoid cartilage. If this area is injured during intubation, clinical presentation of SGS can be variable in the timing and severity of UAO. Acute edema and inflammation may cause the child to become symp-

tomatic shortly after extubation. Alternatively, slow accumulation of granulation tissue in the injured subglottic region may delay symptoms for weeks following extubation.

Multiple factors contribute to the development of SGS and include the duration of intubation, traumatic intubation, reintubation, presence of an infection while intubated, undersedation, and concomitant gastroesophageal reflux. Although counterintuitive, it appears, most neonates tolerate longer periods of intubation without subglottic injury than do older children. Unlike congenital SGS, acquired SGS typically does not improve over time, and a tracheotomy may be required in severe cases. Tracheostomy often is unable to be reversed without definitive airway reconstruction. Tracheostomy carries a risk for all children, and definitive repair should be considered if possible. Tracheostomy dependence is associated with a 1–2% risk of tracheotomy-related death each year.

CNS-induced airway obstruction is complex and often multifactorial. *Bulbar dysfunction* refers to abnormalities of the control and strength of the laryngeal and pharyngeal muscles increasing resistance to airflow. Children who have suffered brain injuries may have upper airway obstruction secondary to poor supraglottic motor control and hypotonia. The tongue may obstruct the airway, or the pharynx may collapse on inspiration. This can occur as the result of long-standing severe psychomotor retardation or may be acquired as a result of hypoxic, infectious, or traumatic brain injury. It is also seen less commonly in pediatrics as a result of neuromuscular disease. *Laryngeal dystonia* is a less common condition involving the tonic adduction of the vocal cords with diminished inspiratory abduction seen in patients with hypertonicity secondary to acute (hypoxic-ischemic) or long-standing (cerebral palsy) CNS insults. *Vocal cord paralysis* with paradoxical inspiratory adduction may occur as a consequence of a variety of serious intracranial injuries. Typical patients have required a tracheostomy, although vocal cord function may improve over ensuing months, allowing decannulation.

Brain injured children may have upper airway obstruction secondary to poor supraglottic motor control and hypotonia.

Chronic upper airway obstruction with hypercarbia and apnea may occur in otherwise healthy children with *trisomy 21* or morbid obesity. The consequences of long-term indolent hypercarbia include pulmonary hypertension and congestive heart failure.

Foreign body aspiration may manifest with airway obstruction at almost any level of the pediatric airway. Stridor may be one of the presenting symptoms when a foreign body lodged in the upper esophagus has caused progressive airway obstruction secondary to localized edema that develops over days to weeks. Foreign bodies lodged in the upper airway itself often cause sudden death. Foreign bodies aspirated into the lower airway generally manifest with a combination of wheezing, cough, and infection. Clinical suspicion can be confirmed by appropriate roentgenographic studies. The definitive therapy is removal of the foreign body using rigid bronchoscopy techniques in an operating room, thereby permitting tracheostomy or thoracotomy if either of these becomes necessary.

Corticosteroid therapy is not beneficial for an inhalational or caustic injury to the airway.

Thermal or *chemical trauma* of the airway may cause swelling and upper airway obstruction significant enough to precipitate acute respiratory failure. Flash burns of the face from injudicious use of volatile liquids to start fires commonly cause oropharyngeal and laryngeal edema that may seriously compromise the airway. Ingestion of corrosive substances likewise may cause burns of the oropharynx and larynx that produce acute obstructing edema that requires placement of an artificial airway. Empirical use of parenteral corticosteroids is not beneficial for an inhalational or caustic injury. In the case of flash burn injuries to the face, early intubation prior to the development of maximal oropharyngeal swelling may be lifesaving.

External trauma to the head and neck may cause upper airway obstruction by dislocating the laryngeal cartilages or by causing a hematoma or edema. This type of injury is rare in the spectrum of pediatric traumatic injury.

In the oncology population, *severe mucositis* secondary to chemotherapy can on rare occasions lead to upper airway obstruction with pseudomembranes.

Upper airway swelling can develop suddenly after ingestion of an allergen, an insect sting, or an environmental exposure. This may occur with highly allergic individuals *(anaphylaxis)* or with hereditary *angioneurotic edema*, an extremely rare condition. The treatment goal for these children is rapidly securing an airway, in which case the prognosis is good.

9.4 Assessment

9.4.1 Examination

Airflow becomes more turbulent, and the pressure gradient necessary to support flow increases when flow rate increases as during excitement and crying.

The clinician first should assess the child's level of distress in a manner that contributes least to the child's fear and anxiety. Airflow becomes more turbulent, and the pressure gradient necessary to support flow increases when flow rate increases as during agitation and crying. Thus, the clinician should attempt to obtain as complete an assessment as possible in the least threatening manner because agitation and crying worsen the relative degree of airway obstruction and the attendant work of breathing. For the child who remains alert and aware, a useful approach is to obtain a brief history from the parents or transporting personnel while merely observing the child from a nonthreatening distance. After noting all physical signs that do not require direct physical contact with the patient, the examiner should gently approach the child to auscultate the chest and assess the circulation.

The child's appearance gives important clues to the degree of respiratory compromise. The degree of the child's anxiety can be an important clue to the severity of the airway obstruction. Many children who have croup appear quite calm and content sitting in their parent's arms when not being "threatened" by an examiner. Although these children may have significant stridor, their level of comfort indicates that they are not significantly hypoxic or hypercarbic. Conversely, a child who remains persistently anxious or who has become somnolent to the point of no longer interacting with those around him may be significantly hypoxic or hypercarbic.

Stridor needs to be assessed in the context of the quality of inspiratory breath sounds. Diminished stridor may indicate severe restriction of airflow.

Use of accessory muscles indicates the degree of inspiratory effort. Stridor needs to be assessed in the context of the inspiratory breath sounds. Generally, stridor becomes louder as airway obstruction worsens. However, in extreme cases, stridor may become barely audible as inspiratory flow almost ceases. It is the quality of the inspiratory breath sounds that differentiates improvement (breath sounds clearly heard) from rapid deterioration (breath sounds barely audible) as the reason for diminishing stridor. Respiratory rate has been reasonably well correlated with hypoxemia, but little correlation has been established with hypercapnia. The degree of hypoxemia is easily assessed by pulse oximetry monitoring, which most children tolerate well. In the differential diagnosis of acute infectious upper airway obstruction, the presence of fever, drooling, cough, a forward-leaning posture, or the appearance of toxicity is useful in leading toward a specific diagnosis and approach to therapy.

A variety of scoring systems have been proposed to aid in assessing the degree of upper airway obstruction. Such systems help focus observation and provide a guide to the effects of therapy. However, the usefulness of scoring

systems is limited because the symptoms of airway obstruction are highly dependent on the level of arousal which will vary with hypoxia and hypercarbia but also with wakefulness, hunger, fearfulness of strangers, and other variables not directly related to the level of airway obstruction. Rather, it is observation of the typical waxing and waning course over time and in response to therapies which is key to assessment.

The usefulness of scoring systems is limited because the symptoms of airway obstruction are highly dependent on the level of arousal which is affected by circumstances not directly related to the level of airway obstruction.

The quality of the inspiratory stridor can help to identify the level of obstruction. Supraglottic obstruction commonly results in a sonorous, low-pitched stridor (stertor) with muffled voice, whereas laryngeal obstruction (particularly abductor vocal cord paralysis) is most commonly characterized by high-pitched stridor and weak voice or cry. Finally, with subglottic obstruction, the stridor is loud, moderately high pitched, and the voice hoarse.

9.4.2 Diagnostic Evaluation

Clinical findings in bacterial tracheitis seem to evolve over time from those of more typical croup to those suggestive of epiglottitis

With acute, infectious upper airway destruction, diagnostic assessment and initial treatment should occur in a rapid and orderly manner. Depending on the cause, the child's condition may deteriorate quickly. Diagnosis is relatively straightforward when a young child has the classic symptoms of viral croup: upper respiratory tract infection prodrome with subsequent development of stridor, a barking cough, and a mildly elevated temperature. Likewise, an older child who has the classic presenting features of epiglottitis (acute onset of a sore throat, a high fever, a muffled voice, unwillingness to swallow, a toxic, distressed appearance, and rapidly progressive respiratory distress) is also readily diagnosed. In practice, however, many children have varying combinations of these features. Indeed, the emergence of membranous laryngotracheobronchitis (bacterial tracheitis) has complicated the diagnosis because this disorder's clinical findings seem to evolve over time from those of more typical croup to those suggestive of epiglottitis.

Controversy still exists over whether roentgenographic neck examinations should be done in a moderately ill child of any age who has acute upper airway obstruction. The need to rapidly differentiate croup from epiglottitis has markedly diminished since the success of *Haemophilus influenzae* type b vaccination. Roentgenographic confirmation of the diagnosis of croup is often unnecessary. In an uncooperative child who has classic croup, it is not uncommon for a lateral neck roentgenogram to be of such poor quality (usually an oblique view) that a misinterpretation of epiglottis is not uncommon. This usually results in an unnecessarily high level of anxiety and referral to a tertiary care pediatric center. The more important scenario, which has now become rare, is that of the child with epiglottitis who develops acute upper airway obstruction and respiratory arrest while being positioned for roentgenographic evaluation, necessitating emergency resuscitation in a suboptimal environment.

Finally, membranous laryngotracheobronchitis has no specific roentgenographic features. Because of these considerations, many pediatric institutions forgo routine roentgenographic evaluation of the upper airway for the child with significant distress if bacterial infection (epiglottitis, retropharyngeal abscess, and membranous laryngotracheobronchitis) is suspected. Rather, the airway is visualized in the operating room by a pediatric anesthesiologist with surgical backup and provisions for emergency tracheostomy if necessary. This approach affords maximal safety for children who have the most dangerous

disease, mainly epiglottitis; it also affords an opportunity for early diagnosis and intervention in cases of membranous laryngotracheobronchitis.

Flexible laryngoscopy and bronchoscopy allow direct diagnostic evaluation and videotaping of airway dynamics for patients with subacute or chronic stridor and can be performed safely at the bedside.

In the case of a neonate or child who has subacute or chronic stridor and no significant respiratory embarrassment, several diagnostic approaches can be taken. A barium swallow or fluoroscopic evaluation of the airway can be helpful in demonstrating congenital lesions. Flexible laryngoscopy and bronchoscopy also allow direct diagnostic evaluation and recording of airway dynamics. With experienced personnel and appropriate monitoring, this procedure can be done safely at the bedside.

Blood sampling is a low priority in a child who has acute infectious upper airway obstruction. Noninvasive pulse oximetry is a more appropriate way to monitor hypoxemia.

Blood sampling is a low priority in a child who has acute infectious upper airway obstruction because the crying and struggling elicited by this painful procedure increase both the metabolic rate and the inspiratory work of breathing through the obstructed airway. Children who have croup or epiglottitis may have mild hypoxemia in room air, which may be due to atelectasis or early secondary pneumonia. Noninvasive pulse oximetry is a more appropriate way to monitor hypoxemia than intermittent sampling of blood gases. Progressive hypoxemia in supplemental oxygen is a serious warning sign. Blood gas monitoring may be useful in cases of more subacute exacerbations of chronic upper airway obstruction as in the neurologically impaired child or the child with chronic upper airway obstruction with trisomy 21 or morbid obesity. In such cases, blood gas analysis can reveal useful information concerning the relationship of the current episode to baseline function (e.g., acute on chronic respiratory acidosis) and has implications regarding the urgency of intervention.

If an artificial airway is required, cultures of blood, purulent tracheal secretions, or the surface of the epiglottis can be obtained.

9.5 Management

9.5.1 Triage and Initial Stabilization

A child who has significant airway obstruction from any cause, as well as any child suspected of having foreign body aspiration or an acute airway injury, should be hospitalized immediately. These children should be placed in a pediatric intensive care unit or in a continuously monitored area in an institution that contains a pediatric intensive care unit to which the child can be transferred immediately should deterioration occur. A child who has mild croup and does not have stridor during quiet breathing need not be hospitalized. A child who has croup and has stridor at rest but who responds well to specific therapies does not necessarily require transfer to a pediatric tertiary care center.

Children suspected of having epiglottitis should not be transported to another facility prior to endotracheal intubation.

A child who has significant airway obstruction should be transported by ambulance (air or ground, depending upon the distance and geography) and receive oxygen continuously. The child must be accompanied at all times during transport by personnel skilled in airway management. Children suspected of having epiglottitis should not be transported before endotracheal intubation because of the risk, well documented in the medical literature, of cardiorespiratory arrest during transport when the airway has not been secured beforehand. It is a rare circumstance when a community hospital cannot assemble a team for controlled endoscopic examination and nasotracheal intubation in the operating room before transport.

Any child with signs of progressive airway obstruction should have cardiopulmonary and pulse oximetry monitoring and receive humidified oxygen in an intensive or intermediate care unit that has a central alarm station or transmission of alarm parameters to nursing staff. The theory of withhold-

ing oxygen so that desaturation can be used to detect early hypoventilation is not recommended since the child may have mild hypoxemia due to ventilation perfusion mismatching independent of hypoventilation. Additionally, hypercapnia is likely quite variable in these patients, and it is of little physiologic consequence, and thus risking hypoxemia in order to detect it is unwise.

The alert child should be allowed to maintain the position that is most comfortable. Most children who have an obstructed airway prefer to sit up if they are developmentally capable of doing so, and the position of most comfort (and therefore least airway obstruction) may be on the lap of a caregiver. For the somnolent or neurologically impaired child with upper airway obstruction due to abnormalities of dynamic control of the supraglottic or pharyngeal airway, the lateral recumbent position with neck extension may afford some relief of airway obstruction.

For the somnolent or neurologically impaired child with upper airway obstruction, the lateral recumbent position with neck extension may afford some relief of airway obstruction.

Nasopharyngeal airways can provide both relief of obstruction and a conduit for nasopharyngeal and nasotracheal suctioning. These are most useful with obstruction at a level above the laryngeal cartilages, such as when due to the tongue, tonsils, or pharyngeal walls. The length of the nasopharyngeal airway insertion should be equal to the distance from the nostril to the tragus and can be confirmed clinically with auscultation. While soft rubber catheters are minimally traumatic, on occasion they are not firm enough to avoid compressive obstruction by adjacent soft tissues. A trimmed uncuffed endotracheal tube may also be used as a nasopharyngeal airway in such circumstances. Oropharyngeal airways are rarely useful for any longer than brief resuscitative efforts due to the difficulty with long-term stabilization and tendency to induce gagging in all but the most neurologically depressed patients.

The length of the nasopharyngeal airway insertion should be equal to the distance from the nostril to the tragus and can be confirmed clinically with auscultation.

The effectiveness of nebulized epinephrine in the management of acute laryngotracheobronchitis is well established. Its vasoconstrictor properties at the site of inflamed swollen mucosa make it useful for the treatment of any inflammatory lesion of the airway including post-extubation upper airway swelling. Aerosolized racemic epinephrine (2.25%, 0.5 ml in 2.5 ml of saline) or L-epinephrine (1%, 0.5 ml in 2.5 ml of saline) in oxygen via face mask provides prompt temporary improvement in airflow. The dose is prescribed as a fixed volume and ratio of drug to saline, since the child's minute ventilation will proportion the dose received to his/her size. The most recent multi-study review shows no difference in efficacy between the two forms of nebulized epinephrine and no advantage of administration by IPPB (intermittent positive pressure breathing) over simple nebulization. The most significant toxicity of aerosolized epinephrine in a healthy child is tachycardia, which is well tolerated. At times, the heart rate declines after administration of epinephrine aerosol, coincident with the improvement in airflow and reduction of dyspnea. Aerosol treatments may be repeated every 15–30 min, as necessary, for palliation of upper airway obstruction.

The effectiveness of aerosolized epinephrine has been demonstrated for treatment of upper airway obstruction due to acute laryngotracheobronchitis, post-extubation airway edema, angioedema, and anaphylaxis.

It should be noted that a response to aerosolized epinephrine may not be long-lasting as the duration of action is only up to 2 h, at which point the child may "rebound" back to the previous state and require further therapy. Children who require repeated dosing should be hospitalized in a monitored intensive or intermediate care unit.

9.5.2 Definitive Therapy

The definitive therapies for the three most common causes of upper airway obstruction—viral croup, epiglottitis, and membranous laryngotracheobronchitis (bacterial tracheitis)—are each distinct. Most patients who have croup

respond to supportive medical treatment, which includes humidified oxygen, inhalation of epinephrine aerosol, and systemic corticosteroids. It is the unusual patient who has laryngotracheobronchitis to require an artificial airway. A diminishing response to epinephrine or the development of hyperpyrexia and toxicity may be evidence of bacterial superinfection, heralding the onset of membranous laryngotracheobronchitis (bacterial tracheitis).

Corticosteroids have been demonstrated to be effective for treatment of upper airway obstruction of multiple etiologies.

Corticosteroids have become an accepted component of therapy for inflammation-related upper airway obstruction. Inhaled budesonide has been shown to be equally effective as parenteral or enteral dexamethasone in the treatment of upper airway obstruction due to acute laryngotracheobronchitis. A meta-analysis of multiple studies has demonstrated the effectiveness of systemic corticosteroids in the treatment of post-extubation upper airway obstruction and prevention of the need for reintubation. Corticosteroids are also effective for upper airway obstruction due to infectious mononucleosis and hemangioma.

Helium-oxygen gas mixtures lower the density of inspired gas significantly, reduce airway resistance during turbulent airflow, and may temporarily relieve and palliate airflow obstruction.

Helium can be used to replace nitrogen as the carrier gas for oxygen (heliox) to reduce the work of breathing in patients who have critical narrowing of the upper or lower airway. Helium concentrations of 60% or greater (i.e., oxygen concentration of 40% or lower) will effectively lower the density of inspired gas and reduce airway resistance during turbulent airflow. Recent multi-study review has demonstrated the efficacy of helium-oxygen gas mixtures in the treatment of croup. Although helium-oxygen gas mixtures may temporarily relieve and palliate airflow obstruction, it is not definitive therapy in itself and cannot be used effectively in children requiring oxygen concentrations above 40%. Heliox should not be used in cases of acute epiglottitis.

9.5.3 Mechanical Support of the Upper Airway

The distensibility of the upper airway structures can be taken advantage of in the palliation of some forms of obstruction. Recall that the extrathoracic airway is narrowest during inspiration due to the collapsing effect of relatively negative intraluminal pressure. Continuous positive airway pressure (CPAP) can be used to distend the supraglottic airway and relieve obstruction. Nasal prongs or mask can be used to deliver CPAP.

The use of high-flow humidified oxygen via nasal cannula has gained popularity as a means to comfortably deliver distending pressure to the airways. The development of reliable humidification systems for high-flow gas delivery has overcome the damaging drying effects of high gas flows when delivered to the nares or trachea. Such systems deliver high flows of variable oxygen concentrations (up to 100%) to the proximal airway and provide an unquantifiable distending pressure which can be more comfortable than conventional CPAP delivery systems. High-flow humidified oxygen also decreases dead space ventilation and resistance forces which ultimately reduces the work of breathing. The added comfort makes the use more easily applied to pediatric patients than CPAP.

Optimal treatment in all cases of acute epiglottitis is securing the child's airway, preferably by endotracheal intubation. Tracheostomy for treatment of acute epiglottitis is unusual. Inspection and intubation are carried out in the operating room, with the patient undergoing general anesthesia and a pediatric anesthesiologist managing the airway. A surgeon must be present to perform either rigid bronchoscopy or tracheostomy if intubation is not possible.

Intubation for epiglottitis generally lasts 18–36 h, until parenteral antibiotics effective against *H. influenzae* have controlled the infection. A second- or third-generation cephalosporin generally is used because of the prevalence of ampicillin-resistant strains. Repeated visualization of the epiglottitis is not necessary for determining the timing of elective extubation, as success with empiric extubation is nearly 100%.

Many cases of bacterial tracheitis require endotracheal intubation to secure an adequate airway. Consequently, most diagnoses are made at the time of intubation. More recent case reports suggest that early diagnosis and initiation of appropriate antimicrobial therapy can ameliorate the course of milder cases, preventing progression to respiratory failure. The most common infectious agents that cause bacterial tracheitis are *S. aureus*, *H. influenzae*, *S. pneumoniae*, *M. catarrhalis*, and *S. pyogenes*. Empiric antibiotic coverage should consist of antistaphylococcal coverage (with consideration of vancomycin for possible methicillin-resistant isolates) paired with a second- or third-generation cephalosporin active against *Moraxella* and *Haemophilus* organisms. Antimicrobial coverage should be narrowed after identification of the causative organism. Generally, extubation is attempted only after thick, purulent secretions have diminished markedly and an air leak is heard on inspiration around the endotracheal tube. The requirement for an air leak is arbitrary because some children have a successful trial of extubation after intubation even without an air leak. The relationship of the patient's endotracheal tube diameter to the usual size for age is an additional consideration.

For the child intubated secondary to airway obstruction from bacterial tracheitis, extubation is attempted only after thick, purulent secretions have diminished markedly. The presence of an air leak around the endotracheal tube is encouraging but may not preclude a trial of extubation.

Another scenario encountered in the emergency department involves a child with long-standing, mild upper airway obstruction who has a sudden exacerbation of obstruction. This may be an infant with mild to moderate laryngomalacia who has increasing difficulty with oropharyngeal secretions arising secondary to a viral infection. Or it may be a child with poor supraglottic muscle tone as a result of severe psychomotor retardation who has an increase in upper airway obstruction due to increased volume of secretions or further decrease in mental status secondary to seizures or the effects of antiepileptic medications. Noninvasive methods of supporting upper airway patency with positive pressure or minimizing turbulence with helium-oxygen mixtures can be effective and obviate the need for airway instrumentation. These children may have chronic hypercapnia of varying degrees and generally will not precipitously lose their airways, and their treatment may be guided by judicious sampling of blood gas parameters to avoid extreme hypercapnia and acidosis.

The application of positive airway pressure to distend the supraglottic airway may be successful in the child with long-standing, mild upper airway obstruction who has a sudden exacerbation of obstruction.

Most children who have tracheobronchial foreign bodies are not in respiratory distress on arrival because the foreign bodies usually are not located in the proximal airway. In the very rare instance in which the patient is moribund, back blows, chest thrusts, or Heimlich abdominal thrusts may be performed (as appropriate for age) if foreign body aspiration is deemed likely. If these procedures are unsuccessful, direct examination of the airway with a laryngoscope is warranted. If a foreign body is seen to be wedged in the larynx or subglottic space, an emergency cricothyroidotomy may be necessary. If no foreign body is seen, endotracheal intubation should be performed because a foreign body may have migrated to the distal trachea. The only recourse in such circumstances is to push the foreign body forcibly into the right mainstem bronchus and ventilate the left lung. This situation is exceedingly rare.

The clinician is guided in responding to the needs of all these children by remembering the "ABCs" of basic life support—*airway, breathing*, and *circulation.* Initial assessment of the child's upper airway function focuses on the degree

of airway obstruction and the efficiency of ventilation. The clinician must determine whether the airway is *stable* and patent (which requires no intervention) or *maintainable* (the airway is compromised but can be maintained with basic interventions of oxygen, suctioning, and positioning). The third possibility is that the airway is judged to be *unstable*—this requires immediate placement of an artificial airway to maintain patency. Nasopharyngeal and endotracheal airways are the airway adjuncts of choice to maintain patency of an unstable airway.

The clinician must determine whether the airway is stable and patent, maintainable, or unstable which requires immediate placement of an artificial airway to maintain patency

9.6 The Difficult Airway

The intensivist, being the clinician charged with caring for the most compromised patients, will inevitably be confronted at some time with the child requiring intubation who possesses an anatomically challenging airway. Even the normal infant and small child present a challenge to airway management due to the relatively larger tongue and more anterior and cephalad placement of the larynx relative to the adult. It is imperative that a plan of action is in place that describes the approach to the child with an unanticipated difficult airway.

Nasopharyngeal and endotracheal airways are the airway adjuncts of choice to maintain patency of an unstable airway.

Effective airway management begins with assessing the child for the potential of a difficult airway. Several anatomic features are predictive of a difficult airway (Table 9.1) and include congenital, developmental, or acquired anomalies of the airway. Goldenhar syndrome, Pierre Robin sequence, Pfeiffer syndrome, Crouzon syndrome, Apert syndrome, Treacher-Collins syndrome, Klippel-Feil syndrome, arthrogryposis multiplex, and the mucopolysaccharidoses are often associated with difficult airways. Micrognathia or mandibular hypoplasia combined with relative or absolute macroglossia can make visualization of the structurally normal larynx difficult. Conversely, the progressive soft tissue infiltration with glycosaminoglycans occurring in the mucopolysaccharidoses can lead to supraglottic and glottic structures that are so thickened and distorted as to render them unrecognizable.

9.6.1 Pharmacologic Considerations

The American Society of Anesthesiologists has published updated practice guidelines for the management of the difficult airway. The initial key decision point in dealing with the difficult airway is the choice between awake intuba-

Table 9.1 Conditions associated with difficult intubation

Anatomic abnormality	Associated conditions
Small mouth (microstomia)	Freeman-Sheldon syndrome, Hallermann-Streiff syndrome
Mandibular hypoplasia (micrognathia)	Pierre Robin sequence, Treacher-Collins syndrome, Goldenhar syndrome, Apert syndrome
Large tongue (macroglossia)	Down syndrome, Beckwith-Wiedemann syndrome, mucopolysaccharidoses, anaphylaxis, trauma
Limited neck mobility	Klippel-Feil syndrome, cervical spine immobilization
Abnormal head size	Apert syndrome, Crouzon syndrome, microcephaly, macrocephaly

tion and intubation attempts after the induction of anesthesia. While attempting to intubate the awake child preserves the patient's strength and ventilatory drive, the presence of distress with struggling and unsuppressed airway reflexes substantially increases the difficulty of successful intubation. A basic tenet in approaching a potentially difficult airway is to avoid burning one's bridges by using the shortest lasting sedatives or neuromuscular blockers to facilitate intubation. None of the non-depolarizing agents is of sufficiently short duration to allow the resumption of spontaneous ventilation within minutes of unsuccessful intubation attempts. The shortest acting non-depolarizing agent (rocuronium) has a duration of action of 30–40 min. Succinylcholine has the pharmacokinetic profile to afford very brief relaxation with rapid recovery if intubation fails. However, the use of succinylcholine requires the use of a vagolytic medication in the very young. Its use may result in muscle fasciculations, occasionally resulting in transiently increased masseter tone or vomiting. Succinylcholine carries the risk of hyperkalemia in at-risk groups who not uncommonly will be the patients with difficult airways. These include children with chronic skeletal muscle disease (e.g., Becker or Duchenne muscular dystrophy) and denervating neuromuscular disease (e.g., cerebral palsy with paralysis). These concerns make succinylcholine a less than optimal choice.

An appropriate sedative agent must be given prior to the use of neuromuscular blockade. Propofol offers the advantage of rapid onset of titratable relaxation and complete suppression of airway reflexes, coupled with very short duration of action should airway attempts fail. Induction of anesthesia with incremental doses of 1–2 mg/kg up to a total of 3–5 mg/kg can afford an optimal first look at the difficult airway with the ability to return to spontaneous ventilation within 5 min. The only significant risk is for hypotension in the hemodynamically unstable child. This can be ameliorated with fluid administration prior to intubation. Alternative sedative agents include ketamine, fentanyl, and/or midazolam. Etomidate, if used, should be avoided in children with sepsis.

Multiple randomized controlled trials have demonstrated longer times to desaturation thresholds of 93–95% oxygen concentration after 3 min of preoxygenation. Recent data from the National Emergency Airway Registry for Children has demonstrated arterial oxygen desaturation to less than 80% in 19% of all PICU intubations, 23% of those children with respiratory indication for intubation. Moderate and severe desaturations (SaO_2 < 70%) were independently associated with the occurrence of adverse hemodynamic events.

The initial key decision point in dealing with the difficult airway is the choice between awake intubation and intubation attempts after the induction of anesthesia.

When uncertain of the ability to secure intubation of the airway, one should use the shortest lasting sedatives or neuromuscular blockers to facilitate intubation.

9.6.2 Ventilation Without Intubation

For the child who cannot be intubated in the conventional manner under direct laryngoscopic visualization yet requires assisted ventilation, the ASA recommends several alternate techniques and devices to provide ventilation in the absence of endotracheal intubation. The methods applicable to children at the bedside include two-person mask ventilation, oral and nasopharyngeal airways, laryngeal mask airway, retroglottic devices (King tube), and transtracheal jet ventilation.

Two-person mask ventilation can overcome high upper airway resistance in the child with severe upper airway obstruction. Oral and nasopharyngeal airways are useful in allowing BMV in the child who has failed intubation.

One can achieve short-term ventilation of the unintubatable child using oral and nasopharyngeal airways and bag-mask positive pressure ventilation.

The laryngeal mask airway (LMA) has been the most successful and widely accepted form of supraglottic artificial airway, offering some of the advantages of endotracheal intubation without the need to visualize and intubate the larynx. It has become the consensus second-line airway. The LMA consists of an

inflatable mask or bowl portion attached at the distal end of the airway tube. Rotational technique with partially inflated cuff is reported to have the highest rate of successful insertion. On insertion, the operator's index finger, placed at the junction of the airway shaft and the mask, guides the LMA along the posterior structures from the palate down the posterior pharyngeal wall into the hypopharynx to rest with the tip at the upper esophageal sphincter where it can advance no further. Inflation of the anterior-facing mask provides a low pressure seal against the glottis allowing positive pressure ventilation. Ease of insertion is the greatest advantage of the LMA. It has found widespread application in the routine use for anesthetic management of patients of all ages and has also been successfully used in the delivery room resuscitation of newborns. It can be used with reliable success by personnel not trained in endotracheal intubation. In the hands of individuals trained for either procedure, the LMA provides an airway with less potential for trauma and stress response than laryngoscopic intubation. One of the primary disadvantages of the LMA is its inability to separate the respiratory and alimentary tracts with the risk of aspiration in the event of vomiting. Finally, the LMA affords no means of suctioning the airway below the glottis. Thus, in patients with significant lung disease, the LMA can provide only temporary support through positive pressure ventilation. The LMA has found widespread use in anesthetic management of patients with normal lungs and in resuscitation of neurologically depressed neonates. Most recent systematic review demonstrated superiority of laryngeal mask airway (LMA) over bag-mask ventilation for neonatal resuscitation and the ability to rescue failed bag-mask ventilation with LMA without resorting to endotracheal intubation in this population.

The laryngeal mask airway (LMA) has been the most successful and widely accepted form of supraglottic airway.

Retroglottic devices are laryngeal tubes that allow ventilation without tube intubation through the vocal cords. When the tube is placed in the upper airway, a large pharyngeal balloon seals the oropharynx, and a smaller balloon seals the esophagus. The net effect of these seals is the direction of airflow to the glottic opening while blocking airflow into the esophagus or out the oropharynx. There are several iterations of these laryngeal devices (Combitube, King tube) that are now available in pediatric sizes.

One of the primary disadvantages of the LMA is the inability to separate the respiratory and alimentary tracts with the risk of aspiration in the event of vomiting.

Transtracheal jet ventilation uses either specialized ventilator or high-pressure-driven valve circuit via a catheter passed through the cricothyroid membrane. Required equipment includes a high-pressure oxygen supply (wall outlet), flow regulator and supply tubing, jet injector, oxygen tubing, Luer lock connector, and an intravenous catheter (14- or 16-gauge). Specialized, reinforced catheters are less likely to kink after removal of the needle. A 14- or 16-gauge catheter is introduced through the cricothyroid membrane, and air is aspirated from a syringe. The catheter is advanced into the trachea and connected to the oxygen tubing using a Luer lock connection. Gas flow is controlled using the jet injector. Adequacy of ventilation is judged by listening for breath sounds and observing chest rise. Transtracheal jet ventilation has the advantage of rapid institution of ventilation in the patient with a difficult airway if the components are previously assembled and allows ventilation during airway placement. It has the disadvantages of requiring a high-pressure gas source and depends on patency of the upper airway for ventilation. In small children, bag ventilation through 14- or 16-gauge catheter may be possible. The catheter can be connected to a 3 ml syringe which then can be connected to a 7.0 ETT tube connector. The bag (Mapleson or self-inflating) can then be connected, and ventilation can be attempted. Complications include subcutaneous emphysema, pneumomediastinum, pneumothorax, or other types of barotrauma. The use of transtracheal ventilation is limited to situations where intubation and supraglottic devices have failed (e.g., severe maxillary and or facial trauma, angioedema) (Fig. 9.5).

In patients with significant lung disease, the LMA can provide only temporary support through positive pressure ventilation. It is a tool that can be very useful in the difficult to visualize airway provided there is no obstruction at the level of the glottis or below.

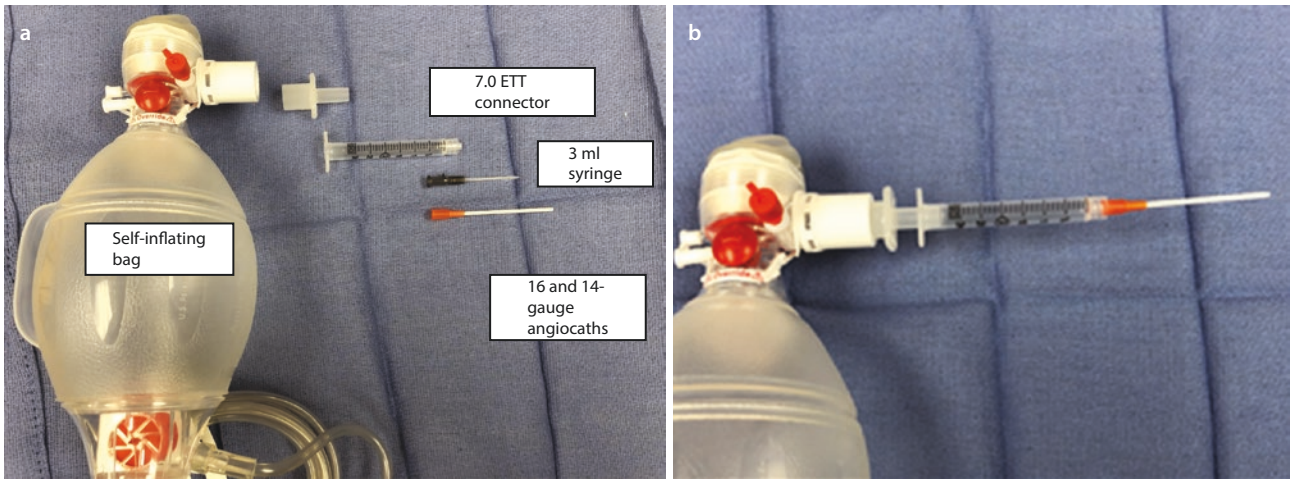

Fig. 9.5 Components of needle cricothyrotomy **a** and assembled allowing for bag ventilation **b**

9.6.3 Nonconventional Intubation Techniques

Techniques to facilitate intubation of the difficult pediatric airway following failure of conventional direct laryngoscopic visualization include fiber-optic intubation, indirect video laryngoscopes, light wand-assisted intubation, laryngeal mask airway as a conduit to intubation, retrograde intubation, and surgical or percutaneous invasive airways access. These techniques are best performed in conjunction with pediatric anesthesia and/or pediatric otolaryngology.

Passage of an endotracheal tube over a flexible fiber-optic laryngoscope is a useful technique for the difficult to visualize larynx due to extreme anterior location or supraglottic anomalies of the mandible or oral cavity. For ease of advancement of the endotracheal tube, its inner diameter must approach 1 mm greater than the outer diameter of the laryngoscope/bronchoscope. In the spontaneously breathing child, laryngoscopy with a blade is not necessary, and the endotracheal tube is placed via one of the nares to the pharynx. The scope is advanced through the endotracheal tube to the pharynx and thereafter into the trachea to the carina to assure against dislodgement. Advancement of the endotracheal tube over the scope is hindered by laryngeal reflexes and the tendency for the bevel of the tube to catch on the right vocal cord. Rotation of the tube 90° can facilitate passage. In the deeply sedated or paralyzed patient, blade laryngoscopy may be required to open the pharyngeal airway. The fiber-optic scope can be passed nasally as above or orally and the larynx intubated under direct fiber-optic visualization. Again, a 90° rotation of the endotracheal tube may be necessary to traverse the vocal cords.

Passage of an endotracheal tube over a flexible fiber-optic laryngoscope is a useful technique for the difficult to visualize larynx due to extreme anterior location or supraglottic anomalies of the mandible or oral cavity.

Video laryngoscope devices are available for intubation of the airway that cannot be visualized with line-of-sight direct laryngoscopy. Videolaryngoscopy is increasingly used as a standard intubation technique. It is also commonly used as a rescue device for the anticipated or unanticipated difficult airway. Videolaryngoscopy, if available, should be considered prior to more invasive techniques such as needle or surgical cricothyrotomy. In addition, the devices allow for real-time guidance when supervising learners.

The increasing use of videolaryngoscopy has been documented within the National Emergency Airway Registry for Children. Videolaryngoscopy has been associated with a lower incidence of tracheal intubation adverse events but not with a lower incidence of severe tracheal intubation adverse events or

with fewer attempts. However, even with adjustment for recorded patient level covariates in this retrospective analysis, it is likely that the videolaryngoscopy was used more commonly for the anticipated more difficult scenarios, and the populations were not equivalent.

Videolaryngoscopy devices include the GlideScope (Verathon Medical) and the CMAC (Karl Storz). The hyperacute angulation of the tip of the GlideScope blades precludes its use for standard direct laryngoscopy and requires training and experience to achieve proficiency. The CMAC blades are based on original blade designs used for direct laryngoscopy. Since the blades are very similar, no modification in laryngoscopy technique is required. The blades are available in traditional Macintosh and Miller sizes.

A light wand can be used as the stylet for the endotracheal tube, curved 90° toward anterior. The ability to see the transilluminated light in the anterior neck confirms location above the larynx. Blind advancement is attempted with the loss of transilluminated light indication passage into the esophagus behind the trachea. Persistence of transillumination on advancement signals successful tracheal intubation. This is essentially a blind technique with reported success rates from 65% to 90%.

The laryngeal mask airway can be used as a conduit for transglottic passage of an endotracheal tube. The smallest conventional intubating LMA is appropriate for school-age children. Small endotracheal tubes can be advanced though modified or shortened LMAs. Alternatively, a fiber-optic bronchoscope can advance through the LMA into the trachea with an endotracheal tube advanced over it. The end result of these techniques is a fairly small for age endotracheal airway.

The retrograde intubation technique utilizes a wire passed retrograde from a puncture in the cricothyroid membrane to the mouth to allow passage of an endotracheal tube into the trachea. The placement of the wire through the cricothyroid membrane should ensure passage of the endotracheal tube into the trachea. The technique does not require visualization of the larynx and may be performed rapidly by skilled practitioners. Risks attendant with the puncture of the tracheal are appreciable in the small child.

Emergency surgical airway can be accomplished via percutaneous puncture through the cricothyroid membrane with a 16–14-gauge catheter.

Emergency surgical airway can be accomplished via percutaneous puncture through the cricothyroid membrane with a 14–16-gauge catheter. Conversely, bedside tracheostomy can be accomplished in minutes when proper equipment and personnel are available. Figure 9.6 depicts an example of an algorithm for the approach to the unexpected difficult intubation.

9.7 Further Care

The focus of care in a pediatric intensive care unit revolves around vigilant provision of adequate sedation (and paralysis if necessary) to prevent additional trauma to the airway or even its inadvertent loss.

After a critically impaired airway has been diagnosed and appropriate therapy has been started, the issue of where the child will be cared for must be addressed. A child whose life depends on the patency and stability of an endotracheal tube, nasotracheal tube, or newly created tracheostomy requires the constant attention of nurses, respiratory therapists, and physicians experienced in pediatric intensive care. No amount of monitoring equipment can substitute for experienced personnel. Hence, *it is only in dire circumstances that a child with upper airway obstruction or who is intubated should be cared for in an intensive care unit that deals primarily with adults.* The focus of care in a pediatric intensive care unit revolves around vigilant provision of adequate sedation (and neuromuscular blockade if necessary) to prevent additional trauma to the airway or even its inadvertent loss. The unplanned and thus ill-timed loss of the artificial airway in a child with upper airway obstruction can be rapidly fatal and must be avoided. Airways can be kept patent by suctioning and chest

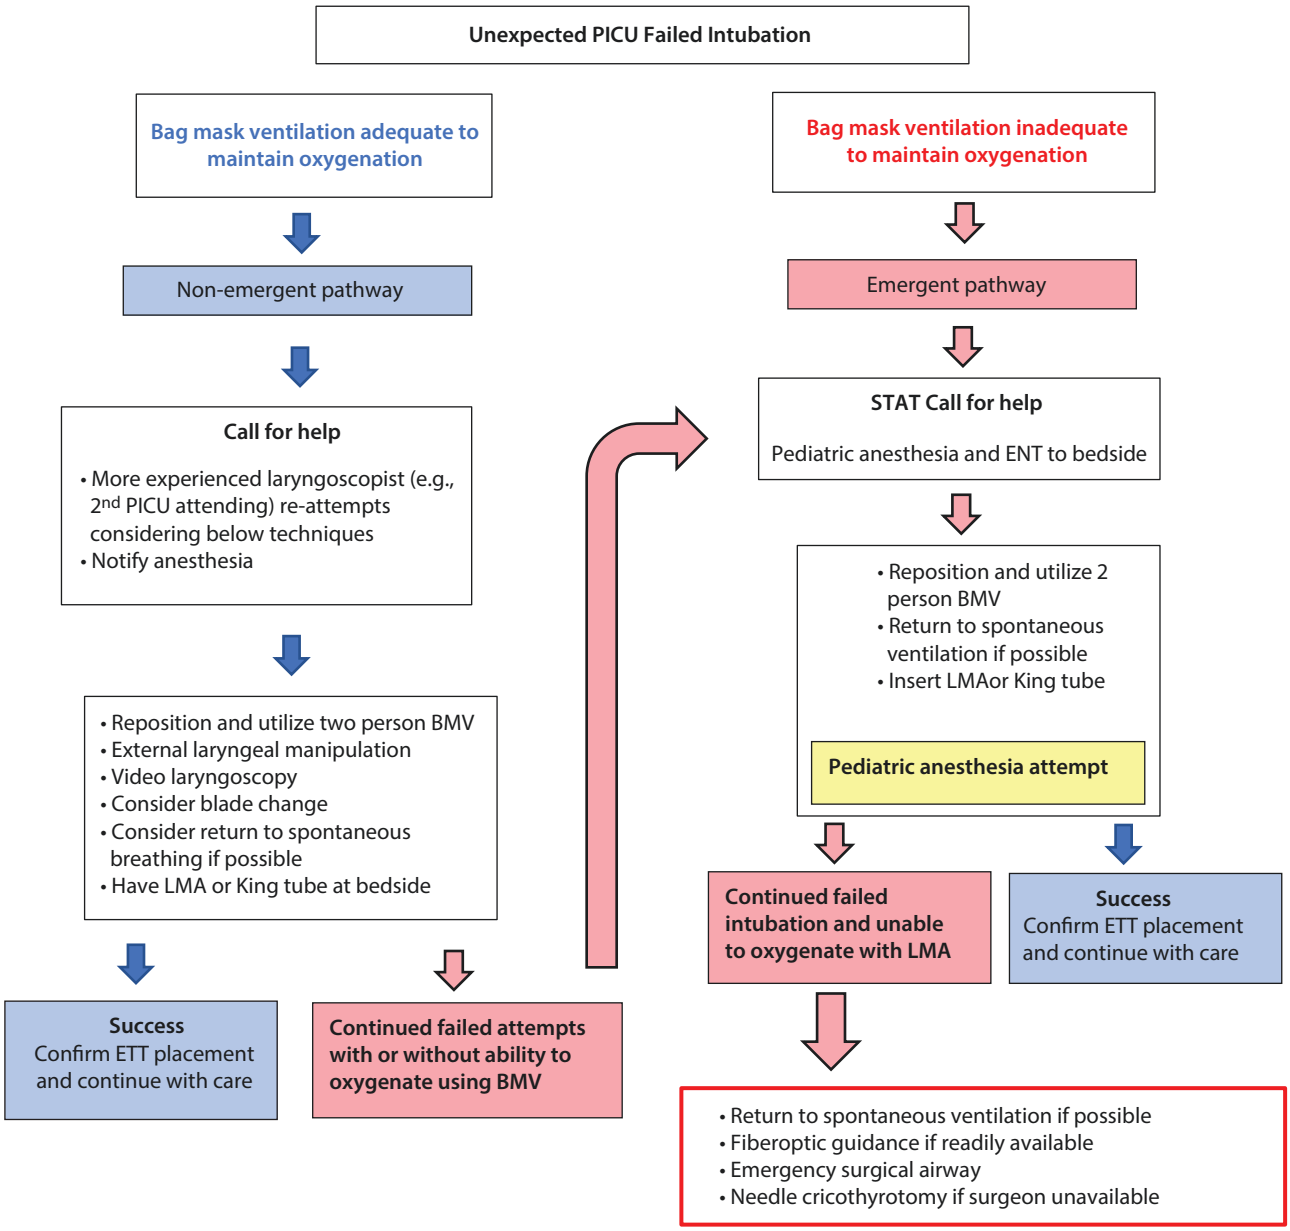

Fig. 9.6 An algorithm for the approach to the unexpected difficult intubation

physiotherapy. Providing adequate ventilation and lung expansion will prevent parenchymal complications. Attention to other organ system derangements, as well as to the routine needs of a critically ill child, also is essential. When it becomes appropriate to do so, extubation is performed only by personnel experienced in the care of the pediatric airway.

9.8 Summary

Upper airway obstruction presents a potentially life-threatening scenario to the pediatric intensivist. Characteristics of the pediatric airway including size in relation to metabolic rate, shape as relates to location of least cross-sectional area, and rigidity as relates to deformability contribute to the increased susceptibility of infants and small children to upper airway obstruction. There

are several congenital and developmental causes of upper airway obstruction which do not generally possess the danger of rapid deterioration and which afford the time for thoughtful and thorough diagnostic evaluation. The infectious causes of acquired upper airway obstruction present a much more urgent situation that must be approached with caution due to the inherently unstable nature of the infected and inflamed airway. These conditions must be addressed in an expeditious manner due to the unpredictable rate of progression of the diseases. Finally, there is a population of children with chronic compromise of upper airway function, who are prone to episodic exacerbations and whose approach to therapy can often be more measured requiring the discrimination of acute from chronic physiologic findings.

Review Questions

1. *Which of the following statements regarding bacterial tracheitis is true?*
   - A. Bacterial tracheitis commonly represents a primary invasive bacterial infection of tracheal soft tissue.
   - B. Bacterial superinfection of viral laryngotracheobronchitis is the most common cause of infectious upper airway obstruction requiring an artificial airway.
   - C. Antimicrobial agents are not effective in the treatment of bacterial tracheitis.
   - D. The most common offending agents are anaerobic bacteria of the oropharynx.
   - E. Tracheostomy is the preferred airway for small children with bacterial tracheitis because of difficulties with thick tracheal secretions.

2. *A 15-month-old male presents with acute laryngotracheitis. Upon arrival to the PICU, he has audible stridor, increased work of breathing, and a pulse oximeter reading of 88% on a simple face mask. In considering the use of heliox in this child, which of the following is true?*
   - A. The use of heliox would require monitoring of arterial blood gases because of the associated lower FiO2.
   - B. A supervised trial of heliox in the PICU may improve both ventilation and oxygenation.
   - C. A supervised trial of heliox in the PICU may improve ventilation but is unlikely to improve oxygenation.
   - D. Heliox cannot be used in this child because of the high oxygen requirement and the inability to provide a significant fraction of helium.
   - E. Heliox is a reasonable alternative as it will also lower pulmonary vascular resistance.

3. *The monitoring of serial arterial blood gases may be useful in which of the following upper airway obstruction scenarios?*
   - A. A 14-month-old with sudden onset of cough and stridor while playing with a Lego building set with his 4-year-old sibling.
   - B. An 18-month-old with acute laryngotracheobronchitis.
   - C. A 4-year-old with acute epiglottitis while considering whether to transport to a tertiary care children's hospital prior to intubation.
   - D. A 6-year-old with static encephalopathy requiring nocturnal BiPAP who has worsening upper airway obstruction during an acute upper respiratory infection.
   - E. A 5-year-old with peanut allergy with acute upper airway obstruction after exposure to nuts to assess the response to an injection of epinephrine.

4. *Which of the following statements is true regarding the administration of supplemental oxygen to children with and upper airway obstruction?*
   A. Supplemental oxygen should be administered to avoid hypoxemia; however, its use mandates periodic blood gas analysis (arterial or venous) to assess for evidence of hypoventilation and hypercapnia.
   B. Supplemental oxygen administration can exacerbate atelectasis in the child with laryngotracheitis, and, therefore, the lowest possible concentration of oxygen that maintains the pulse oximeter reading just above 90% should be administered.
   C. Supplemental oxygen should be readily administered because the threat to life from upper airway obstruction comes from hypoxemia and cardiac arrest.
   D. Supplemental oxygen administration can mask hypoventilation and hypercapnia in the child with laryngotracheitis, and, therefore, its use should be avoided to allow for more effective monitoring of the patient.
   E. Supplemental oxygen should *not* be administered via positive pressure systems (i.e., high-flow nasal cannula, continuous positive airway pressure, bi-level positive airway pressure) because the positive pressure may displace the epiglottis posteriorly exacerbating airway obstruction.

5. *Which of the following statements is true regarding differences in the airway anatomy and physiology between the infant and the adult?*
   A. The infant possesses a relatively larger tongue in contrast to the adult.
   B. The infant airway is relatively longer than that of the adult.
   C. The narrowest portion of the airway of the infant is at the vocal cord opening.
   D. The oxygen consumption (mL/kg/min) of the infant is approximately half that of the adult.
   E. The infant airway is more posterior and caudal relative to the adult.

6. *The primary disadvantage of the use of a laryngeal mask airway (LMA) is which of the following?*
   A. The proper utilization of the LMA requires individuals with extensive training in the technique.
   B. The LMA is associated with a greater potential for airway trauma and stress than a laryngoscopic intubation in the hands of individuals trained for either procedure.
   C. The LMA is unable to fully protect the respiratory tract from aspiration in the event of vomiting.
   D. The LMA is placed with insertion by hand into the pharynx, and, therefore, airway anatomy is not visualized.
   E. The LMA has limited use in the airway management of small children because of differences in their airway from the adult.

7. *A 6-month-old male with Pierre Robin sequence presents with signs and symptoms of viral bronchiolitis. He is admitted to the PICU with increased work of breathing and with mild hypoxemia (SpO_2 92%). He is placed on continuous positive airway pressure (CPAP) via nasal prongs with improved oxygenation and decreased work of breathing. You are called to the bedside for an acute deterioration (SpO_2 78%) requiring bag-mask ventilation. The oxygenation improves in response to the bag-mask ventilation. What is the most appropriate next intervention?*
   A. Continue bag-mask ventilation and prepare for intubation using ketamine sedation.
   B. Administer heliox via the CPAP circuit.
   C. Convert the CPAP to bi-level positive airway pressure (BiPAP).
   D. Discontinue bag-mask ventilation and monitor to assess if he is able to maintain adequate oxygenation.
   E. Continue bag-mask ventilation while mobilizing difficult airway personnel and equipment.

8. *A 2-year-old male develops pneumococcal pneumonia complicated by empyema and ARDS. He is currently intubated with a 4.5 cuffed ETT and is being weaned from mechanical ventilation. He has a respiratory rate is 24–30 breaths per minute and has spontaneous tidal volumes of 7 ml/kg while on pressure support of 5 cm H_2O. His FiO_2 is 30%, and he is saturating 98%. He is extubated on day 18 after successful spontaneous breathing trials. Within 30 min of extubation, he develops stridor and increased work of breathing. He has an acute desaturation to 50% and requires emergent reintubation. His vocal cords are easily visualized using GlideScope videolaryngoscopy, but the ETT cannot be passed easily through the cords. A 3.5 cuffed ETT is passed on the third attempt. Which of the following is true?*
   A. The child should have undergone an ETT leak test. The lack of a leak would have been highly predictive of extubation failure.
   B. The child has developed subglottic stenosis as a result of concomitant pneumococcal bacterial tracheitis.
   C. The child has developed subglottic stenosis as a result of prolonged intubation with a cuffed tube, and definitive treatment is a tracheostomy.
   D. The child has developed subglottic stenosis which is far more common in neonates after prolonged intubation.
   E. The child developed subglottic stenosis as a result of multiple contributing factors which may have included undersedation during prolonged mechanical ventilation.

Learning Objectives

- Discuss the impact of asthma on the pediatric population
- Review the pathophysiology of status asthmaticus
- Review the usual triggers of asthma and appreciate potential iatrogenic triggers of bronchospasm in the PICU
- Describe the evaluation of a child admitted to the PICU with status asthmaticus
- Outline a tiered treatment algorithm for asthmatic patients requiring critical care
- Review the major tiered therapies for status asthmaticus
  - Inhaled beta-agonists
  - Inhaled anticholinergic agents
  - Corticosteroids
  - Magnesium
  - Helium/oxygen mixture
  - Intravenous beta-agonists
  - Methylxanthines
  - High-flow nasal cannula
  - Noninvasive ventilation
  - Mechanical ventilation
  - Ketamine
  - Inhalational anesthetics
  - ECMO
- Mechanical ventilation strategies in severe asthma
  - Review the theoretical and practical difficulties with mechanical ventilation in patients with status asthmaticus
  - Discuss the complications that may occur with status asthmaticus during positive pressure ventilation

10.1 Introduction

Asthma remains one of the most common chronic childhood diseases. Asthma affects nearly 7 million children and is a frequent cause of emergency department visits and hospitalizations. Over the past few decades, the prevalence of childhood asthma has increased at a rate of 1.4% per year. For the period 2008–2010, average annual prevalence was higher in children <18 years of age (9.5%) compared to adults (7.7%) (Fig. 10.1). Population-based asthma exacerbation prevalence rates were higher in children (range 5.2–5.8%) as compared with adult rates (range 4.4–5.4%).

The majority of children with asthma can be safely managed in the outpatient setting using preventative measures which include trigger avoidance and compliance with controller medications. However, a small subset of children may have severe asthma with recurring exacerbations that, at times, may be life-threatening (status asthmaticus). Although severe asthma likely affects less than 5% of all asthmatic children in the United States, the resource utilization of patients with severe pediatric asthma is disproportionate to disease prevalence. Annual total medical expenditures of childhood asthma are estimated at greater than $10 billion, with severe asthma accounting up to 50% of those costs.

Status asthmaticus is defined as an asthma exacerbation that does not respond to first-tier therapy (nebulized beta-agonists, nebulized anticholinergics, and system corticosteroids) requiring inpatient admission. Children with status asthmaticus are at risk of progressing to respiratory failure.

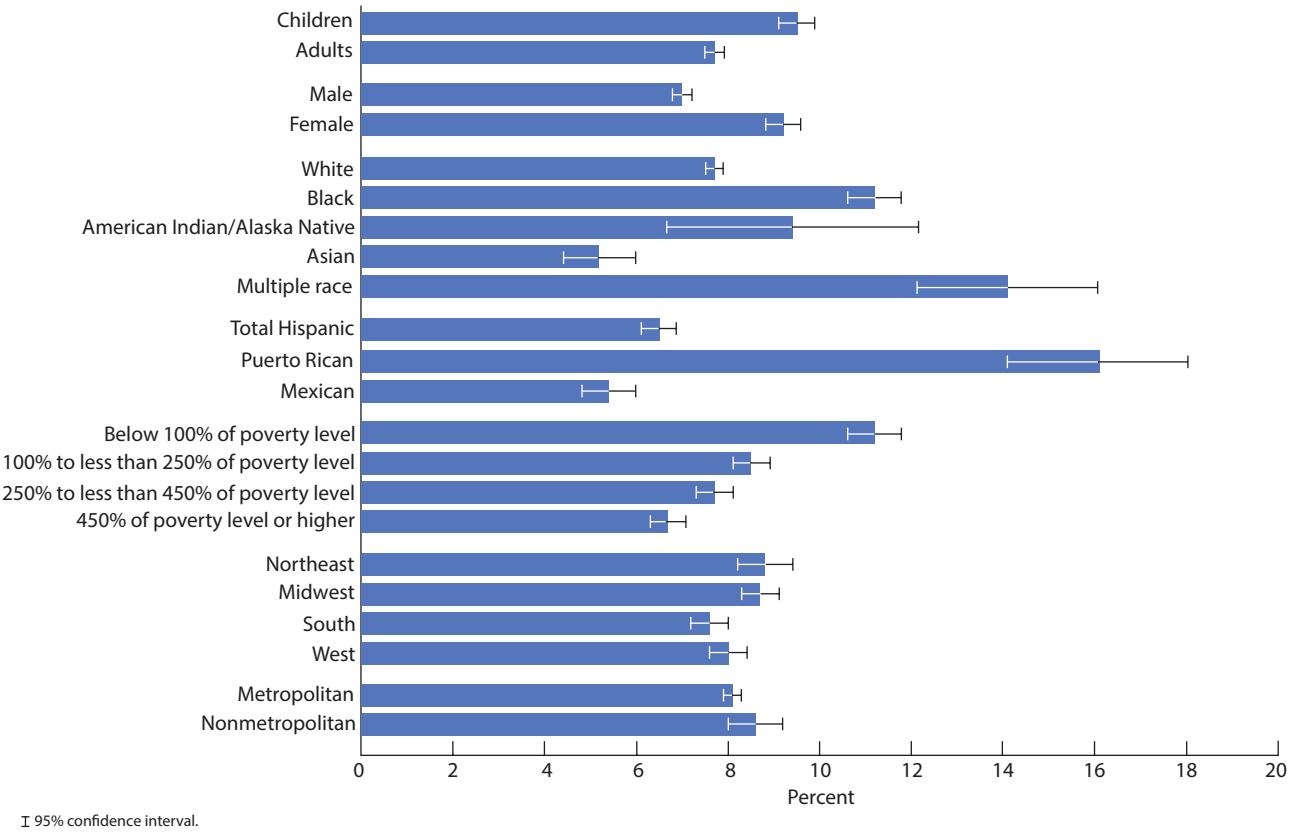

Fig. 10.1 Current asthma prevalence, by age group, sex, race and ethnicity, poverty status, geographic region, and urbanicity: United States, average annual 2008–2010. (Source: CDC/NCHS, National Health Interview Survey and Health Data Interactive)

Diagnosing and managing severe asthma require an understanding of the underlying pathophysiologic framework. Asthma is a complex heterogeneous inflammatory disorder that is characterized by variable and recurring symptoms of airflow obstruction due to inflammation, bronchospasm, and mucous plugging. Multifactorial interactions between host (polygenetic) and environmental factors determine clinical manifestations, severity of asthma, and response to treatment (Fig. 10.2).

10.2 Genetic Factors

Although inheritable factors are clearly important, it is unlikely that a single gene is responsible for the various asthma phenotypes. Children with a family history of asthma are at increased risk of developing asthma, but transmission of the disorder does not follow simple Mendelian inheritance. Several genes (polygenic) interacting with each other offer a more plausible explanation. Several candidate genes have been proposed through genetic linkage analysis, genetic association analysis, and genome-wide association studies. These studies confirm that asthma is both a genetically and phenotypically heterogeneous disorder.

A growing list of over 100 genes has been associated with asthma. For example, a disintegrin and metalloproteinase 33 (ADAM33) gene is located on chromosome 20p13, and the protein is expressed in bronchial smooth muscle cells and lung fibroblasts. It is shown to be strongly linked to asthma, bronchial hyperresponsiveness, and airway remodeling.

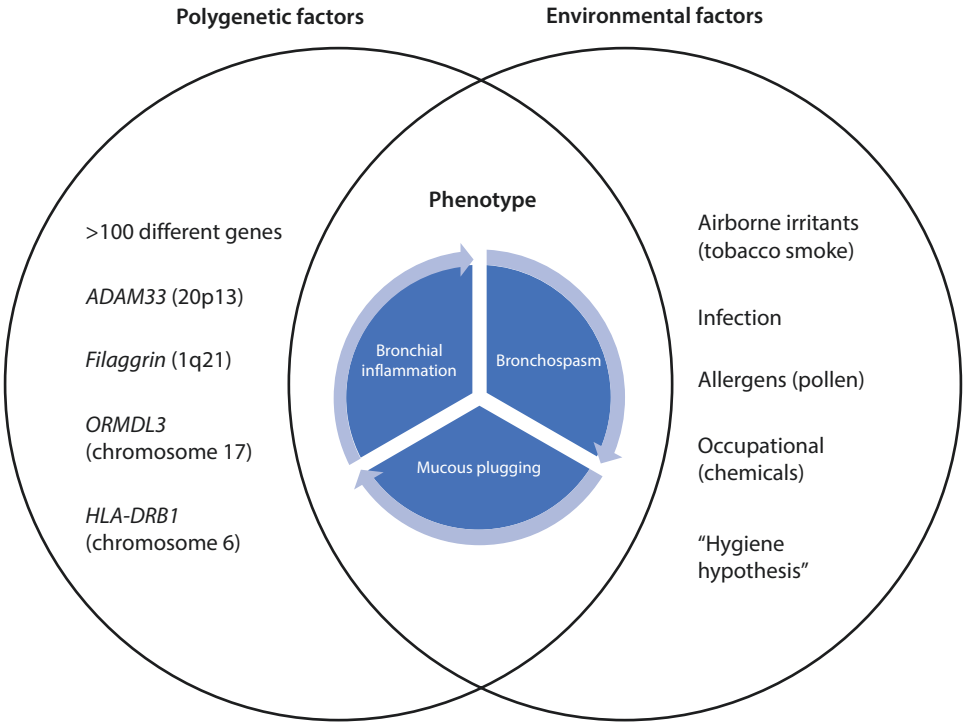

Fig. 10.2 Multifactorial interactions resulting in the pathophysiologic symptoms of asthma

10

The phenotype of asthma is likely due to a complex multifactorial gene-environment interaction.

Filaggrin is a protein involved in maintaining an effective skin barrier. The gene is located on chromosome 1q21, and loss-of-function mutations are associated with the development of allergic sensitization, hay fever, and asthma. That development only occurred in patients with atopic dermatitis. Dysfunction of the skin barrier enhances sensitization to allergens and leads of systemic allergic responses including increased IgE levels and airway hyperresponsiveness. It appears that absorption of allergens through the skin of patients with this loss-of-function mutation is a prerequisite for the development of asthma. The importance of polygenetic interactions leading to the development of asthma should not be underestimated.

Asthma genome-wide association studies (GWAS) are used to identify single-nucleotide polymorphisms (SNPs) across the genome. The GABRIEL consortium, a large-scale GWAS of asthma, reports associations between asthma and numerous SNPs found on chromosomes 2, 6, 9, 15, 17, and 22. There are multiple makers on chromosome 17q21 strongly associated with childhood-onset asthma. Variation in the expression of *ORMDL3* (17q21), a member of a gene family that encodes transmembrane proteins, contributes to the risk of childhood asthma. *GSDMB* (17q21) also demonstrates a strong genetic linkage to asthma. It is highly expressed in lung bronchial epithelium and regulates airway remodeling and hyperresponsiveness. While genetic factors play an important role in the development and severity of asthma, further study is necessary to delineate the clinical importance of these genes and their polymorphisms especially as they relate to the clinical response to pharmacological treatments.

10.3 Environmental Factors

Numerous theories have been considered to explain the increase in asthma prevalence. Many of which continue to be sharply debated. One hypothesis is based on the apparent association between exposure to irritants (e.g., second-hand

tobacco smoke, viruses, and pollen) and the subsequent development of asthma in childhood. This theory can be extended to early infection with respiratory syncytial virus which has been linked to the development of asthma. However, this theory is speculative, as it is unclear whether the exposure to an asthma trigger during a time of rapid lung growth leads to airway remodeling or whether the respiratory symptoms that occur with these early exposures are simply the initial presentation of a child who is "prone" to the development of asthma.

In contrast, the "hygiene hypothesis" postulates that increased hygienic conditions and declining family size in industrialized nations have led to reduced microbial exposure in early childhood. The functional counter-regulatory T cell subsets, T helper 1 (TH1) and T helper 2 (TH2), have provided the immunologic paradigm to study this hypothesis. The paradigm suggests that reduced microbial exposure early in life directs the maturing immune system toward proallergic TH2 responses and suppresses counter-regulatory TH1 imprinting. TH2 is critical in cytokine production including interleukin (IL)-4, IL-5, IL-9, and IL-13. These cytokines mediate the initiation, maintenance, and amplification of cellular inflammation in the asthmatic lung.

The immunologic paradigm also emphasizes the importance of regulatory T (Treg) cell classes. Treg cells may dampen allergen-specific TH2 responses, and the lack of stimulation of the immune system reduces activation of Treg cells. Despite extensive study, it is unlikely that the hypothesis alone can explain the increase in asthma prevalence.

Asthma prevalence continues to increase, but the etiology of this increase is still unknown.

10.4 Triggers of Asthma

There are many known stimuli that can incite severe asthma exacerbations. The most well-understood mechanism is *IgE-mediated allergic asthma*. This immediate type of hypersensitivity occurs when IgE molecules bound to resident mast cells interact with the allergic antigen and lead to the inflammatory response governed by lymphocytes. This stimulus can lead to immediate airway obstruction that is generally short-lived but may be followed by a late reaction which can be more severe and persistent.

While *infections* from both viral and bacterial sources can trigger severe asthma in children, viruses appear to be the major infectious trigger. In the very young child, respiratory syncytial and parainfluenza virus predominate, while in older children, influenza and rhinovirus become more prevalent. Human metapneumovirus and bocavirus have recently been implicated in viral-induced asthma exacerbations in children.

In all age groups, but particularly noteworthy in infants, *gastroesophageal reflux disease* can produce bronchospasm. The etiology is likely due to direct irritation of the airways by refluxed gastric material or, alternatively, by neurally induced bronchospasm secondary to irritation of vagal nerve fibers located in the distal esophagus. The control of reflux and gastric acidity remains an important component of asthma treatment.

Environmental irritants including air pollution and second-hand smoke may predispose children with bronchial hypersensitivity to severe asthma exacerbations. In children, second-hand smoke from caretakers is known to play a major role in triggering asthma and may contribute to the severity of the exacerbation.

In addition to the aforementioned triggers for asthma, older children and adolescents may have asthma induced by exercise, emotional stress, cigarette smoking, and inhalant abuse.

Exercise is a common trigger of severe asthma, especially in the adolescent. The worsening of airway obstruction may occur after exercise and not during it. Pretreatment with inhaled therapies may have some success in preventing exacerbations of exercise-induced asthma.

Bronchoconstriction secondary to vagal efferent nerve activity can also be triggered by *emotional stress* in the older child. This trigger is particularly important when tailoring treatment for a child requiring intensive care. It is possible that an external stimulus may initiate an exacerbation, but increasing emotional distress can worsen its severity. Therefore, the judicious use of low-dose sedation may be required in children admitted to the PICU with status asthmaticus who are not mechanically ventilated.

There are many external triggers of asthma that require careful assessment by history upon PICU admission. Common triggers include IgE-mediated allergic asthma, infections, air pollution, exercise, and GERD.

At times, a trigger for a severe asthma exacerbation cannot be readily identified. Symptoms can appear abruptly and progress quickly. A rapid-onset, severely progressive form of asthma exacerbation in older children has been appreciated. Acute asphyxial asthma (AAA), or rapid-onset near-fatal asthma, is well described in adults. AAA has a predilection for young adult males and is characterized by a brief duration of symptoms (usually less than 6 h), few identifiable triggers, and a rapid progression to respiratory failure. Often, the patient will present in extremis, cyanotic, with little to no air movement, and obtundation. Despite the severity of presentation, response to therapy is prompt. When mechanical ventilation is warranted, its duration is usually short, due to rapid improvements in gas exchange. The pathophysiology of AAA may be distinct. An initial neurogenic event that mediates intense bronchospasm may be of primary importance and be independent of the submucosal cellular profile.

Iatrogenic triggers of bronchospasm include medications, airway manipulation (e.g., bronchoscopy), and mechanical ventilation. Medications that are of particular importance are beta-adrenergic antagonists. These agents have been demonstrated to incite bronchospasm and should be avoided or used with caution in a child with a known history of asthma. Cardio-selective beta-1 adrenergic antagonists may induce less bronchospasm but should still be used with caution. Other agents such as aspirin, nonsteroidal anti-inflammatory drugs, and sulfating agents can also incite bronchospasm. Children with a history of asthma are at increased risk for developing bronchospasm after the initiation of mechanical ventilation for processes unrelated to the lungs (e.g., neurologic or cardiovascular support).

10.5 Pathophysiology

Despite the many triggers of status asthmaticus, the underlying pathophysiology remains constant and is composed of three mechanisms: *bronchial inflammation/edema*, *airway smooth muscle spasm* (bronchospasm), and *airway mucous plugging*. All these mechanisms lead to a reduction in airway diameter, increased airway resistance, and severe airflow obstruction.

10.5.1 Inflammation

Even in asymptomatic asthmatic children, the airway is in a state of low-grade persistent inflammation.

Bronchial inflammation induced by resident airway inflammatory cells or infiltrating inflammatory cells characterizes asthma. Children with severe asthma, even when asymptomatic, have airways that are in a state of low-grade persistent inflammation. Although a variety of inflammatory cells contribute to this airway inflammation, cells most active during an acute exacerbation include infiltrative lymphocytes, eosinophils, resident mast cells, and airway epithelial cells.

During asthma exacerbations, *lymphocytes* (specifically the TH2 subtype) are drawn to infiltrate the airway by signaling from a variety of chemokines, with eotaxin being the most studied. Once activated, lymphocytes

release a host of inflammatory cytokines (e.g., IL-4 and IL-5) that further stimulate the inflammatory response, leading to increased edema. Other inflammatory mediators, such as granulocyte-macrophage colony-stimulating factor (GM-CSF), regulated on activation, normal T cell expressed and secreted (RANTES), and IL-8, contribute to the ongoing inflammatory response that occurs during status asthmaticus.

Eosinophils play a major role in this upregulated inflammation, leading to release of leukotrienes and the formation of oxygen free radicals, all of which worsen airway edema and mucus production. A study of adults with asthma demonstrated that the number of eosinophils found in bronchoalveolar lavage fluid is directly proportional to asthma severity.

Lymphocytes and eosinophils are important infiltrative cells in asthma pathogenesis.

Mast cells are resident airway cells that are upregulated when stimulated by allergens. Activation occurs after an allergen binds with an IgE antibody attached to the mast cell surface. Once induced, mast cells are pro-inflammatory and release a variety of granule-associated mediators including histamine, proteases, and cytokines. Mast cell activation also induces de novo synthesis of leukotrienes. IgE-mediated mast cell activation is an important component of the inflammatory response in asthma and has become a therapeutic target. A humanized IgG monoclonal antibody (omalizumab) has been developed which binds circulating IgE. Once bound to the monoclonal, IgE can no longer associate with mast cell surface receptors, and thus activation and degranulation are inhibited. Omalizumab has been proven as an effective maintenance therapy to prevent allergen-induced asthma exacerbations in children older than 6 years with poorly controlled asthma. However, it currently does not have a role in acute exacerbations.

Airway epithelial cells produce several cytokines and chemokines that regulate inflammation during severe asthma. IL-1-beta is the most intensely studied. Bronchoalveolar lavage fluid IL-1-beta concentrations have been correlated with asthma severity in adults. The IL-1-beta inflammatory pathway has been manipulated in attempts to gain control over the inflammatory response that triggers worsening asthma with some success in vitro.

Mast cells and airway epithelial cells are important resident cells in asthma pathogenesis.

Given the importance of inflammation, some experts suggest that methods to noninvasively measure inflammation may have a role in chronic asthma therapy. An inflammatory product that is increased and readily measurable is exhaled nitric oxide (NO). L-arginine and L-citrulline are oxidized by NO synthases (NOS), which synthesize NO. The measurement of fraction of exhaled NO (FeNO) has become a useful clinical point-of-care marker of inflammation in asthma. The FeNO has been found to decrease after steroid therapy in asthmatics. It has also been found to be useful in predicting asthma exacerbations in adults.

The fraction of exhaled nitric oxide may be a clinically useful marker for airway inflammation in children with asthma.

10.5.2 Bronchospasm and Airway Resistance

The airway smooth muscle (ASM) cell is the end effector of bronchospasm. Airways may constrict too much (airway hyperresponsiveness) or too easily (airway hypersensitivity) in response to a trigger. Although airway hyperresponsiveness and hypersensitivity have been described empirically in asthmatics, the underlying mechanisms are not fully elucidated. It is thought that remodeling leading to increased ASM mass is the primary derangement as opposed to decreased load against which the ASM must contract. Increasing evidence suggests that the bronchodilating response to periodic stretch and deep inspirations is impaired in asthma leading to ASM to be shortened and frozen in a "latch" state (Fig. 10.3).

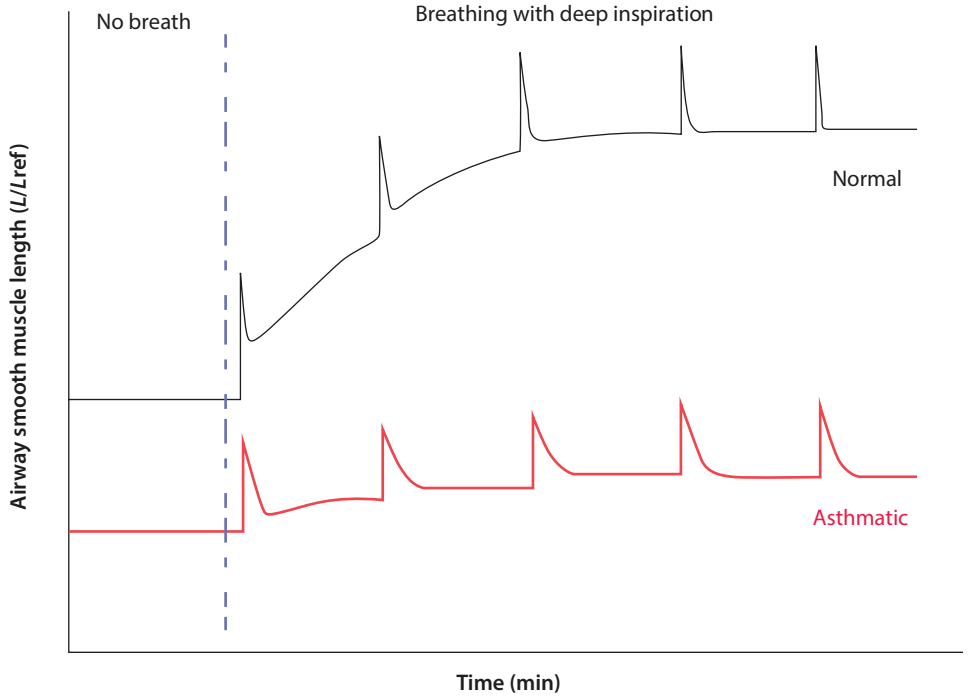

Fig. 10.3 In vitro airway smooth muscle length (averaged over duration of one breath) vs time. The normal airway remains dilated in response to deep inspiration, while the asthmatic airway only dilates by a smaller amount and returns to a static constricted state

The three mechanisms responsible for airway obstruction in asthma are bronchial mucosal inflammation/edema, airway smooth muscle spasm (bronchospasm), and airway mucus plugging from copious secretions.

Decreasing the airway radius by 50% leads to a 16-fold increase in resistance.

As the diameter of pediatric airways is proportionally smaller than an adult, a child has greater vulnerability to bronchospasm and, therefore, more likely to demonstrate symptoms of respiratory distress. At times, this distress can have an abrupt onset and rapid progression.

The effect of a reduction in airway diameter is best appreciated when considering Poiseuille's equation, which states:

$$R = 8\eta L$$

where R = resistance, η = viscosity of the air (or fluid), L = length of the tube (airway), and r = radius of the tube (airway).

Accordingly, decreasing the radius by 50% (as can occur readily in the small airway of a child) will result in a 16-fold increase in airway resistance.

10.5.3 Mucous Production

Mucous hypersecretion has long been recognized as a significant component of airway obstruction in asthma. Increased mucous production coupled with impaired clearance can significantly worsen airway obstruction in asthma. Recently, improved understanding has evolved regarding the pathophysiology of mucous production during asthma exacerbations.

In the nonpathological state, airway epithelium is covered by a mucus gel layer approximately 5–50 μm thick. Ciliary motion within this layer promotes movement of mucous proximally to the pharynx where it is swallowed together with entrapped particles and pathogens. MUC5B is the principal gel-forming mucin produced during homeostasis and provides this essential particle clearance function.

Inflammation in asthma induces airway epithelial remodeling and changes in intracellular mucin production. Under pathological conditions, mucin secretion

increases, and its composition changes. There is an increase in goblet cell number (hyperplasia) and a phenotypic change in the mucin-producing cells (metaplasia). This transformation results in a dramatic increase in the production of MUC5AC, the principal mucin upregulated during asthmatic inflammation. A proposed pathologic mechanism of MUC5AC mucin is its ability to increase tethering of mucous to the luminal epithelium causing accumulation of mucous and increased plugging.

Studies have demonstrated that concentrations of MUC5AC are elevated compared to MUC5B in individuals with asthma. In children, a similar high ratio of MUC5AC to MUC5B has been noted. Interestingly, increased MUC5AC has been found in children with both stable and acute asthma versus healthy controls. Currently, there is no convincing evidence for the use of mucolytics or agents that inhibit mucous production in children with asthma exacerbations. However, MUC5AC gene transcription or MUC5AC goblet cell differentiation may provide future therapeutic targets.

10.5.4 Cardiopulmonary Interactions

It is important to consider the pathophysiology of cardiopulmonary interactions that occur during asthma exacerbations. Pulsus paradoxus, the expected small decrease in systolic blood pressure during inspiration, can be greatly accentuated during forceful inspiration and the air trapping seen in severe asthma. These amplified interactions can have profound hemodynamic effects.

A deleterious cycle (Fig. 10.4) leading to a biventricular increase in afterload and relative reduction in preload can occur during severe asthma.

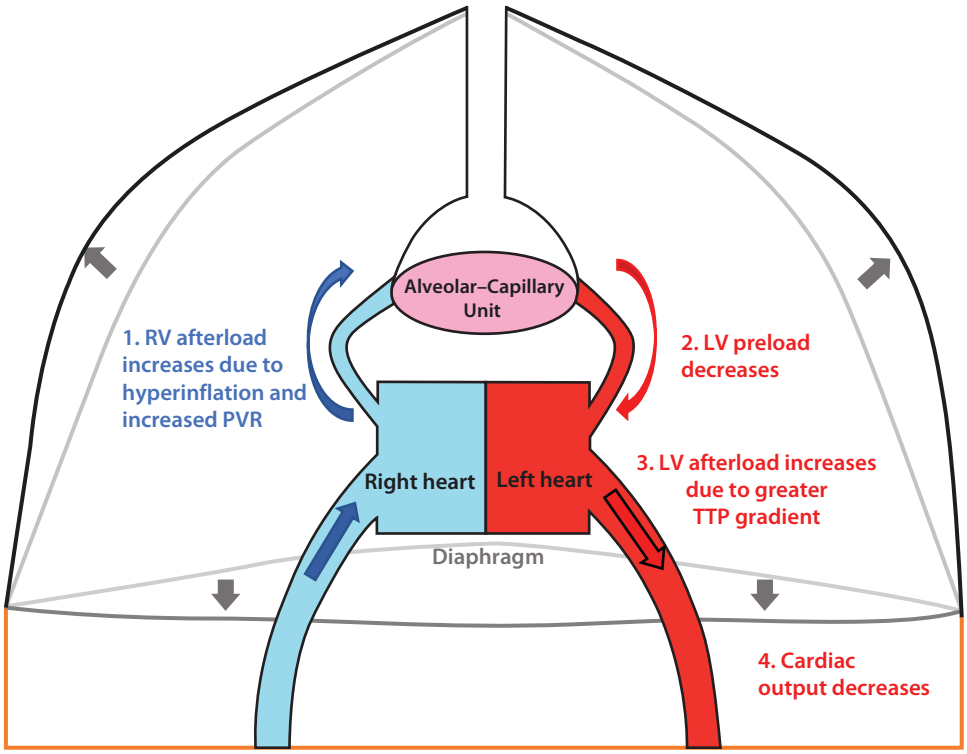

Fig. 10.4 Cardiopulmonary interactions during severe asthma. Air trapping leads to dynamic hyperinflation and diaphragmatic flattening (gray arrows). Right ventricular afterload increases due to hyperinflation-induced compression of alveolar vessels and hypoxia-induced increased PVR. Pulmonary venous return is compromised, and left heart preload is reduced. RV preload may also be decreased due to poor intake and increased insensible losses. LV afterload increases due to greater transthoracic gradient. The net effect of these hemodynamic changes can lead to a reduction in cardiac output. *RV* right ventricle, *PVR* pulmonary vascular resistance, *LV* left ventricle, *TTP* transthoracic pressure

Forceful negative pressure inspiration and ongoing expiratory obstruction lead to dynamic hyperinflation. Hyperinflation and hypoxia lead to an increase in pulmonary vascular resistance and right ventricular afterload. Left atrial filling and left ventricular (LV) preload are subsequently reduced.

The effect on left ventricular afterload is of particular importance. During forceful inspiration, the intrathoracic pressure (ITP) surrounding the left ventricle decreases markedly, while the pressure surrounding the extra-thoracic arterial compartment remains constant. LV afterload increases as the left ventricle must overcome a greater pressure gradient to eject blood. Increased LV afterload combined with decreased LV preload can severely compromise LV ejection and reduce cardiac output.

Additionally, children may present with hypovolemia secondary to increased insensible losses and poor fluid intake. Tachycardia secondary to stress, hypovolemia, and bronchodilators may further reduce ventricular filling time and preload.

These cardiopulmonary interactions place the asthmatic child in a tenuous hemodynamic state. Cardiac output can be reduced at presentation or may progressively decline after the institution of positive pressure ventilation. Although positive pressure can reduce LV afterload, the institution of positive pressure in the failing asthmatic can dramatically reduce RV preload, thus negating any favorable effects on LV afterload. In addition, medications used for intubation often are cardiac depressants. Medication effects coupled with a sudden reduction in right heart preload can produce profound hypotension. If intubation seems imminent, appropriate volume expansion is often necessary to reduce the risk of hemodynamic instability.

10.6 Evaluation of Status Asthmaticus

A severe asthma exacerbation, also termed "status asthmaticus," is characterized by a lack of response to repetitive or continuous administration of short-acting inhaled beta-2 adrenergic receptor agonists and steroids. Exacerbations can be variable in severity and response to treatment.

The initial assessment of exacerbation severity is based on a thorough *examination* of the child. A visual assessment of work of breathing may reveal accessory muscle use, paradoxical thoracoabdominal breathing, and nasal flaring. Expiratory wheezing is commonly heard and can be graded as mild, moderate, or severe. The absence of wheezing may signify severe airflow obstruction. Expiratory prolongation is common and may be truncated due to air trapping. Cerebral function should be monitored closely as children with carbon dioxide retention or hypoxia may exhibit alterations in mental status such as agitation or lethargy. Lethargy, inability to phonate, cyanosis, and a silent chest are ominous signs that often precede respiratory arrest.

An underappreciated examination finding is the presence and severity of a *pulsus paradoxus*. When measured in a normal child, the decrease in systolic blood pressure during inspiration is generally 5 mmHg. In moderate asthma, a decrease of 10–20 mmHg is often noted. A systolic pressure decrease of >20 mmHg during inspiration is seen in children with severe exacerbations. The hemodynamic impact of this accentuation has been previously discussed.

Serial physical examinations remain the cornerstone for the ongoing assessment of the child with severe asthma. Using a validated scoring system allows the clinician to objectively assess the response to treatment and adjust interventions accordingly. As with any clinical scoring tool, interobserver

variability and the subjective nature of some variables may limit the clinical usefulness of certain tools.

Several reliable clinical scoring systems have been developed to help gauge the severity of asthma exacerbation, including the Pediatric Asthma Score (PAS), Wood-Downes asthma score, Becker asthma score, Acute Asthma Intensity Research Score, and Pediatric Pulmonary Index Score. The Pediatric Asthma Score is outlined in ◘ Table 10.1. The clinical asthma score allows multiple caregivers to assess progression or improvements in a child with severe asthma.

Serial clinical examinations are of paramount importance in the child with severe asthma.

Measurement of expiratory airflow with a peak flow meter is very useful in older children who can reliably perform this maneuver. This measurement is safe and inexpensive, and it also can be performed repeatedly, allowing the clinician to assess therapy effectiveness.

A *chest radiograph* (◘ Fig. 10.5) allows the clinician to detect hyperinflation, concomitant pneumonia, pneumothorax, or pneumomediastinum. A large pneumothorax warrants chest tube or pigtail catheter placement. In a mechanically ventilated child, the radiograph is also used to determine appropriate depth of the endotracheal tube.

An *arterial blood gas* will aid in determining alterations in gas exchange but must be interpreted in the context of the clinical examination. A $PaCO_2$ of greater than 45 mmHg in a child with a severe asthmatic exacerbation likely warrants PICU admission and serial arterial blood gas monitoring. In a child with severe tachypnea, increasing work of breathing, and hypoxia, a "normal" $PaCO_2$ may not be physiologically appropriate and indeed may signify worsening gas exchange. Clinical symptoms, such as the ability to speak, mental status, and diaphoresis, are likely as reliable if not more reliable to determine respiratory failure when compared to arterial blood gas data.

It is important to remember the old adage, "All that wheezes is not asthma," and clinicians should consider alternative diagnoses. The differential diagnosis of lower airway obstruction includes tracheomalacia and bronchomalacia (especially in children less than 2 years of age), cystic fibrosis, viral bronchiolitis, for-

◘ **Table 10.1** Pediatric asthma score

Pediatric asthma score (PAS)	1	2	3
	Respiratory rate		
2–3 years	≤ 34	35–39	≥ 40
4–5 years	≤ 30	31–35	≥ 36
6–12 years	≤ 26	27–30	≥ 31
>12 years	≤ 23	24–27	≥ 28
Oxygen requirements	>95% on room air	90–95% on room air	<90% on room air or on any oxygen
Auscultation	Normal breath sounds to end-expiratory wheeze only	Expiratory wheezing	Inspiratory and expiratory wheezing to diminished breath sounds
Retractions	None or intercostal	Intercostal and substernal	Intercostal, substernal, and supraclavicular
Dyspnea	Speaks in sentences, coos, and babbles	Speaks in partial sentences, short cry	Speaks in single words/short phrases/grunting

Fig. 10.5 Post-intubation findings on chest radiograph of a teenager with status asthmaticus include hyperinflation, left-sided subsegmental atelectasis, and air leaks which lead to pneumomediastinum and subcutaneous air

eign body aspiration (usually a sudden onset of wheezing in a previously healthy child), cardiac wheezing secondary to congenital heart disease or myocardial failure, viral croup, bacterial tracheitis, psychogenic wheezing, and vocal cord dysfunction. Congenital fixed anatomic obstructions can also mimic bronchiolitis and asthma, especially in the first year of life. These include vascular rings, airway hemangiomas, and tracheal webs. A thorough history and physical examination will often exclude many of these disorders that can mimic severe asthma.

Vocal cord dysfunction can be challenging to differentiate from lower airway obstruction, and episodes have been mistakenly treated as a severe asthma exacerbation. Vocal cord dysfunction (VCD) is defined as the paradoxical adduction of vocal cords during inspiration. It may be precipitated by emotional stress, exercise, and extrinsic or intrinsic irritants. All of which are known triggers for an asthma exacerbation. VCD tends to present as exertional dyspnea in an adolescent female. Differentiating VCD from asthma based on history alone is often not possible. Examination findings suggestive of VCD include auscultation of inspiratory wheezing or stridor over the larynx and a lack of hypoxia. Diagnosis of VCD can be made using pulmonary function testing confirming extra-thoracic inspiratory obstruction or, more definitively, with direct visualization of inspiratory adduction of vocal cords through fiberoptic rhinolaryngoscopy.

10.7 Treatment Algorithm for Severe Asthma in Children

Asthma therapy must be tailored for each child, considering disease severity, response to therapeutics, and adverse effects of therapies.

Asthma therapy in the PICU must be tailored to disease severity, age, comorbidities, host response, and adverse therapeutic effects. Figure 10.6 outlines a general algorithm for the treatment of severe asthma in children. The key to the treatment of severe asthma is reassessment after each therapeutic intervention, noting both efficacy and adverse events. The algorithm outlines possible therapeutic strategies.

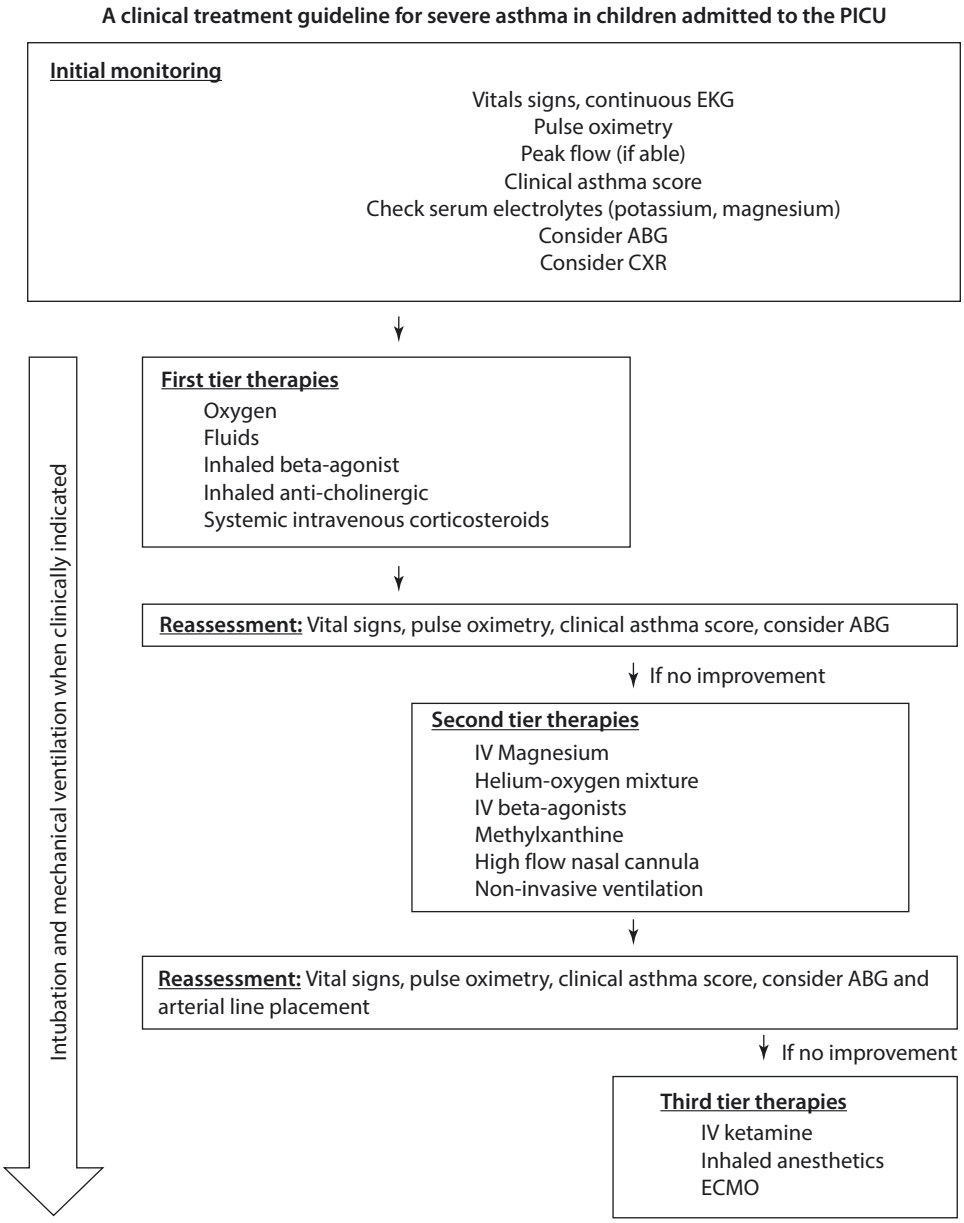

Fig. 10.6 Algorithm for the step-wise approach to escalating therapy in acute asthma

10.8 Therapies for Status Asthmaticus (Table 10.2)

10.8.1 First-Tier Therapies

10.8.1.1 Oxygen

Oxygen delivery is the key treatment goal in caring for a child with severe asthma.

Avoidance of hypoxia remains the primary goal in status asthmaticus. Ventilation/perfusion mismatch routinely develops with severe asthma due to air trapping, atelectasis, and mucous plugging. Contrary to adults with chronic obstructive pulmonary disease, supplemental oxygen will not suppress the respiratory drive in children with asthma. Therefore, oxygen therapy at high concentrations can be administered. Refractory hypoxia is the

Table 10.2 Tiered medications for severe asthma

	Mechanism of action	Adverse effects
First-tier therapy		
Inhaled beta-agonists	Bronchodilation: Stimulation of beta-2 receptors leading to bronchodilation by adenosine 3′,5′-cyclic monophosphate (cAMP)	Stimulation of beta-1 that can result in tachycardia Excitability/hyperactivity Tremor Hypokalemia
Inhaled anticholinergics	Bronchodilation: Inhibits parasympathetic-mediated bronchoconstriction by blocking muscarinic receptors of acetylcholine	Pupillary dilation if agent comes in contact with the eye
IV Corticosteroids	Anti-inflammatory	Glucose intolerance Peptic ulcer Long-term therapy: Suppression of hypothalamic-pituitary-adrenal axis, bone demineralization, myopathy, growth failure
Second-tier therapy		
IV Magnesium	Bronchodilation: Inhibits calcium intake into airway smooth muscle cells	Hypotension Flushing Arrhythmia Weakness CNS depression
Helium/oxygen mixture	Biologically inert gas that reduces Reynolds number thus favoring laminar flow	Patients with oxygen requirements may not tolerate helium/oxygen mixture
IV Beta-agonists	Bronchodilation: Same as inhaled beta-agonists	Tachycardia/dysrhythmias Cardiac ischemia
Methylxanthines	Bronchodilation: 1. Non-selective inhibitors of phosphodiesterases thus increasing intracellular cAMP and downregulating pulmonary cell inflammatory burst 2. Inhibition of adenosine-induced bronchoconstriction	Nausea/emesis Agitation Tachycardia Toxic levels: Urinary retention, arrhythmias, irritability, seizure
Third-tier therapy		
IV Ketamine	Bronchodilation (possible mechanisms): 1. Catecholamine release stimulating beta-2 adrenergic receptors 2. Inhibition of vagal pathways to produce anticholinergic effect on bronchial smooth muscle	Hallucinations Bronchorrhea Laryngospasm Tachycardia Hypertension Seizures
Inhaled anesthetics	Bronchodilation (possible mechanisms): 1. Beta-adrenergic receptor stimulation 2. Impede antigen-antibody-mediated enzyme production and the release of histamine from leukocytes	Myocardial depression Arrhythmias Intrapulmonary shunting Cerebral vasodilation

primary reason to rapidly escalate therapies including the need to initiate mechanical ventilation.

10.8.1.2 Intravenous Fluids

Children with severe asthma may have hypovolemia due to poor oral intake and increased insensible fluid losses. Fluid replacement with a goal of euvolemia should be undertaken. Appropriate volume expansion may be necessary in the peri-intubation period, but aggressive overhydration should be avoided due to the risk of transpulmonary edema. Potassium replacement may be required due to beta-agonist-induced hypokalemia.

10.8.1.3 Inhaled Beta-Agonists

In the United States, albuterol is the most commonly used selective beta-2 agonist. Stimulation of the beta-2 receptors on bronchial smooth muscle cells leads to bronchodilation by the adenosine 3′,5′-cyclic monophosphate (cAMP)-mediated pathway. When delivered by aerosol, its effectiveness is dictated by distal drug delivery to the bronchial smooth muscle cells. Therefore, albuterol delivery is dependent upon dose, spontaneous tidal volume, gas flow, device used to deliver the gas, and the child's respiratory effort. Even under ideal conditions, only a small percentage of drug reaches the target cells. Therefore, dosing must be titrated accordingly. While the use of serial, fixed-dose, inhaled beta-agonist treatments is appropriate for moderate exacerbation, multiple studies support the use of continuous nebulization in severe cases. Continuous beta-agonist therapy is well tolerated by most patients and is less labor-intensive, thereby leading to a degree of cost-effectiveness when compared to many intermittent treatments.

Albuterol is an equal mixture of stereoisomers, (R)-albuterol, and (S)-albuterol. (R)-albuterol (also known as levalbuterol) is a therapeutically active component and selectively binds beta-2 receptors resulting in airway smooth muscle relaxation. Previously thought to be an inert enantiomer, in vitro studies now show that (S)-albuterol activates eosinophils, increases intracellular calcium in ASM cells enhancing airway hyperresponsiveness, and increases immune cell proliferation and cytokine production. The (S) enantiomer persists longer in plasma and lung tissue than the (R) enantiomer which results in accumulation of the (S) enantiomer with repeated dosing of albuterol.

Inhaled beta-agonists are the mainstay of therapy for the child with severe asthma.

Studies of (R)-albuterol in the severe pediatric asthma remain limited. The use of levalbuterol as an alternative to albuterol is not strongly supported by the literature. A randomized, double-blind trial in 2009 found no benefit in substituting high-dose continuous levalbuterol for albuterol and did not reduce the time on continuous therapy in children aged 6–18 years old. A 2012 meta-analysis of seven trials evaluating levalbuterol and albuterol for acute asthma in all age groups found that levalbuterol was not superior to albuterol in regard to respiratory rate, oxygen saturation, percentage change in FEV1, clinical asthma score, heart rate, side effects, and duration of ED care outcomes.

10.8.1.4 Inhaled Anticholinergic Agents

Ipratropium bromide is often used in combination with beta-agonists in severe asthma. Ipratropium exhibits bronchodilator effects through inhibiting parasympathetic-mediated bronchoconstriction and has the advantage of less cardiac toxicity than beta-agonists. Unlike the parasympatholytic atropine, ipratropium bromide does not impede mucociliary function. Although the evidence supporting the routine use of ipratropium has not been compelling, its relative safety can justify its use as an adjunct in severe asthma exacerbations. Clinicians should be aware of the potential for concomitant pupillary dilation (unilateral or bilateral) if the inhaled anticholinergic agent inadvertently contacts the eye.

10.8.1.5 Corticosteroids

Corticosteroids are required therapy in severe asthma due to their potent anti-inflammatory effects. In addition, corticosteroids may decrease mucous production and potentiate the effect of beta-agonists by upregulating beta-receptors. Children with severe asthma should receive their first dose of steroids upon presentation as the anti-inflammatory effect may be delayed up to 6 h.

Although oral corticosteroids are appropriate for most children presenting with severe asthma, children requiring PICU admission often require intravenous administration. Delayed gastric absorption, intestinal dysmotility, and/or vomiting can reduce the bioavailability of orally administered corticosteroids. There are several intravenous corticosteroid preparations available. Methylprednisolone is commonly used; however, dexamethasone and hydrocortisone are acceptable alternatives.

Intravenous corticosteroids should be administered as soon as possible to a child with severe asthma.

The adverse effects of short-term corticosteroid therapy include hyperglycemia, gastritis, sodium and water retention, hypertension, and increased susceptibility to infection. Muscle weakness and myopathy are possible, especially if a neuromuscular blocking agent is used concomitantly in children who require mechanically ventilation. If long-term therapy is required for children with asthma, suppression of the hypothalamic-pituitary-adrenal axis, demineralization of bones, myopathy, and growth failure may occur. Tapering of corticosteroid should be considered if the duration of systemic corticosteroid use is >2 weeks.

10.8.2 Second-Tier Therapies

10.8.2.1 Magnesium

Magnesium is an intracellular cation that is a key cofactor for cellular homeostasis. Inhibiting calcium intake into the smooth muscle cell prevents smooth muscle contraction and promotes bronchodilation. Magnesium reduces histamine and prostaglandin release by inhibiting mast cell degranulation. In addition, magnesium decreases acetylcholine release at motor nerve endings, which results in decreased muscle fiber excitability and bronchoconstriction.

Magnesium has been shown to produce a bronchodilator effect in a dose-dependent manner in children with mild to severe asthma. Studies have found that use of intravenous magnesium decreased hospital admission rate, reduced the need for mechanical ventilation, reduced hospital length of stay, improved short-term lung function, and reduced clinical symptom scores. Intravenous dosing of 25–50 mg/kg given over 30 min is the most common method of administering magnesium for severe asthma. Higher doses or rapidly infused magnesium may cause vasodilatation with resultant hypotension, and, therefore, close hemodynamic monitoring is required. Some authors have suggested the use of continuous infusions of magnesium for patients who are responsive to initial bolus dosing. Infusion rates of 15–25 mg/kg/h (not exceeding 2 g/h) have been safely used; however, infusions lasting greater than 4 h have not been formally evaluated. With repeated dosing or infusions, studies have suggested targeting serum magnesium levels to 4 mg/dL.

Inhaled magnesium has been evaluated in several large studies with mixed results. Nebulized magnesium appears to be safe, but it is unclear whether inhaled magnesium provides any clinical advantage over intravenous administration.

Potential side effects of magnesium administration include hypotension, flushing, arrhythmia, weakness, and CNS depression.

10.8.2.2 Helium/Oxygen Mixture

Helium is a biologically inert gas without inherent bronchodilatory or anti-inflammatory properties. Its use in the therapy of severe asthma is directly related to its physical properties that produce favorable gas flow characteristics. Normally, gas flow in the lung periphery is laminar because the large cross-sectional area of the distal bronchioles allows for slow, streamlined flow. In

contrast, upper airway flow is turbulent resulting in a high velocity and chaotic flow pattern. Although the diameter of the upper airway is far greater than an individual bronchial, the total cross-sectional area available for flow is far less in the upper airway.

In small airway disease, heliox is predicted to be much less effective because of the large cross-sectional area of the smaller airways. However, the pathophysiologic changes that asthma produces in the lower airway (edema, constriction, and mucous plugging) result in a reduction in the cross-sectional area available for flow. It is postulated that the favorable effects of heliox on gas flow reduce the pressure gradient that is required to achieve a given flow rate.

Turbulent flow can be predicted based upon the Reynolds number (Re) of a gas. Flow is turbulent when the $Re > 2500$. The formula for the Reynolds number is

$$Re = VD\rho$$

where V is gas velocity, D is the diameter of the airway, ρ is gas density, and μ is gas viscosity. Since helium possesses a lower gas density (approximately seven to eight times less dense than air), it results in a lower Reynolds number and, thus, reduces the likelihood of turbulent gas flow through narrowed airways. The conversion of turbulent to laminar flow allows distal gas delivery with a lesser pressure gradient and reduced velocity. Clinically, this results in improvement in gas exchange and a reduction in the work of breathing. In addition, helium/oxygen mixtures may inherently improve ventilation as carbon dioxide diffuses at a four times faster rate when compared to an oxygen/nitrogen mixture.

The potentially advantageous effects and the high safety profile of helium/oxygen mixtures have led its incorporation into acute asthma treatments. The most beneficial mixture (i.e., the lowest Reynolds number) is a mixture of 80% helium and 20% oxygen. Persistent hypoxia may lead to the need to increase the oxygen concentration to 30%. Utilizing mixtures with lower than 70% helium may compromise the ability to reduce turbulent flow.

Using a helium/oxygen mixture as a vehicle to deliver aerosolized beta-agonists may increase distal bronchial delivery and hasten the resolution of bronchospasm. A large systematic review of heliox-driven nebulized beta-agonist therapy showed an increase in peak expiratory flows and a reduction in hospital admissions, with a trend toward greater benefit in patients with severe exacerbations. Caution should be taken when heliox is delivered to a mechanically ventilated child. The mixture may cause erroneous flow and pressure measurements from most conventional ventilators, which are calibrated with only oxygen/nitrogen mixtures.

Helium/oxygen mixtures have a lower Reynolds number, leading to less turbulence through narrowed airways.

10.8.2.3 Intravenous Beta-Agonists

Theoretically, intravenous rather than aerosolized beta-agonists may be a superior method of drug delivery if bronchial constriction is so severe that aerosolized drug is prevented from reaching the distal airways. Intravenous beta-agonists such as terbutaline or salbutamol have been utilized to obtain beta-agonist bronchodilation via the systemic route. A loading dose of terbutaline 2–10 mcg/kg IV can be started prior to initial infusion rates of 0.1–0.4 mcg/kg/min. The infusion may be titrated by 0.2–0.4 mcg/kg/min every 30 min based on clinical response and adverse drug reactions. These parenteral agents are also more likely than inhaled albuterol to produce beta-agonist-induced adverse effects such as tachycardia, tremor, hypokalemia, and rarely cardiac ischemia.

Despite the paucity of evidence to support the routine use of intravenous beta-agonists, their use can be considered in children who are unresponsive to

increasing doses of inhaled bronchodilators. Limited data suggests these parenteral beta-agonists agents may decrease the need for intubation or shorten the course of mechanical ventilation for severe asthma. However, due to the potential for cardiac side effects, intravenous beta-agonists should be utilized only in children without concomitant heart disease.

10.8.2.4 Methylxanthines

Medications known as methylxanthines, most notably theophylline and aminophylline, have been long known to be potent bronchodilators. They are nonselective inhibitors of phosphodiesterase (PDE), including type 4, which is expressed in bronchial smooth muscle. Intracellular cAMP is metabolized to AMP by the PDEs. By inhibiting PDE, the intracellular concentration of cAMP increases which causes a decrease in phospholipase C-induced smooth muscle contraction. PDE inhibition is also thought to downregulate the inflammatory burst from pulmonary inflammatory cells. In addition, methylxanthines inhibit adenosine-induced bronchoconstriction, increase diaphragmatic contractility, stimulate endogenous catecholamine release, and promote diuresis and inhibition of afferent neuronal activity. Most notable is all these effects are mediated through pathways that are not beta-receptor dependent.

Despite multiple favorable mechanisms of action and a long history of use in asthma, methylxanthines are considered second-line therapy for acute exacerbations. Methylxanthines have been found to improve clinical asthma scores and airflow during acute exacerbations but have not consistently been shown to reduce PICU or hospital length of stay. Their narrow therapeutic window, and significant adverse effect profile (nausea, vomiting, agitation, tachycardia, decrease seizure threshold), has limited their use. Drug concentrations can also increase or decrease due to multiple interactions with medications that interact with the hepatic cytochrome P450 enzymes.

Methylxanthines may have a role in the treatment of some children with severe asthma, but they possess a small therapeutic window.

Clinicians should consider the use of methylxanthines in the beta-agonist refractory asthmatic while closely monitoring for the potential for drug toxicity. A 5–6 mg/kg loading intravenous dose of aminophylline over 20 min is needed to achieve a therapeutic concentration. Each 1.2 mg/kg dose raises the serum theophylline concentration by approximately 2 mg/L. Serum drug concentrations should be checked approximately 6 h after completing the loading dose and prior to starting an infusion. Serum target levels should be between 12 and 15 mcg/mL. After the loading dose is given, the recommended continuous aminophylline infusion rate is dependent upon the patient's age since methylxanthine drug clearance is decreased in neonates and infants. Clinician should be aware that methylxanthine clearance can be decreased in patients with pulmonary edema, congestive heart failure, hepatic disease, hypothyroidism, and sepsis with multiorgan failure.

10.8.2.5 High-Flow Nasal Cannula

High-flow nasal cannula (HFNC) is a device that allows the delivery of humidified oxygen via of supraphysiologic flow rates. Its use as noninvasive respiratory support for a variety of pulmonary disorders has increased dramatically. Current applications include neonatal respiratory distress, bronchiolitis, and pneumonia.

Mechanisms of action include dead space washout, reducing metabolic expenditure and providing some degree of positive pressure. By delivering gas at high inspiratory flow rates, nasopharyngeal dead space is replaced with warmed and humidified oxygen. This reduces both carbon dioxide rebreathing and the inspiratory work of breathing. Providing the airways with humidified and heated gas reduces the metabolic energy that would otherwise be expended to produce this gas conditioning. The amount of positive pressure provided

to distal airways is highly variable with a maximal end-expiratory pressure of 6–8 cm H_2O. The airway pressure is determined by the flow rate but also by how much flow leakage occurs at prong-nostril interface and from an open mouth. Flow rates range from 1 to 2 L/kg/min with maximal flow rates of 6 L/min in infants and 30 L/min in older children.

Complications related to HFNC are rare. Air leak syndromes including pneumothorax and pneumomediastinum have been reported in small infants and are likely related to higher than predicted delivery of distal airway positive pressure.

The favorable mechanisms of action and safety profile make HFNC an attractive modality for respiratory support in the child with moderate to severe asthma. Case reports and several observational studies suggest the HFNC is safe and effective in pediatric asthma. Further studies are required to determine its overall efficacy in the treatment of moderate to severe pediatric asthma.

10.8.2.6 Noninvasive Ventilation

Noninvasive ventilation (NIV) provides positive pressure, either synchronized with negative pressure breaths (spontaneous) or with a set backup rate (timed). Positive pressure is delivered via tight fitting facial or nasal mask. The set pressure can be either continuous positive airway pressure (CPAP) or bi-level inspiratory and expiratory airway pressures (BiPAP). This mode of ventilation is frequently used as an early intervention in children with impending hypoxic respiratory failure and may have a safe role in moderate to severe asthma exacerbations.

NIV positive pressure can reduce airway resistance by stenting distal airways, thereby increasing distal beta-2 agonist delivery. In addition, NIV can reduce respiratory muscle work, improve atelectasis, and promote collateral ventilation. The use of this mode of respiratory support requires patient cooperation and may require mild to moderate sedation in some children. Other limitations include an inability to clear oral secretions and a potential to increase gastric distention and risk of aspiration.

NIV may be considered in children with moderate to severe asthma not responsive to first-tier therapies (e.g., continuous bronchodilators). However, current evidence is not conclusive in determining if NIV reduces rates of endotracheal intubation or shortens length of stay in children with moderate to severe asthma.

10.8.3 Third-Tier Therapies

10.8.3.1 Ketamine

Ketamine is a sedative-hypnotic that has been used extensively to facilitate intubation in asthmatic children. Its current use has been expanded to provide sedation in both the pre-intubation and post-intubation period. The increasing preference to use ketamine as a sedative for children with moderate and severe asthma has been due to its potential to provide some degree of bronchodilation.

Ketamine produces bronchodilation by several proposed mechanisms of action. These include (1) potentiating endogenous catecholamine release, thereby further stimulating beta-2 adrenergic receptors, (2) inhibition of vagal pathways producing anticholinergic effects on bronchial smooth muscle, (3) inhibition of NMDA receptor-induced bronchoconstriction, (4) reversal of histamine-induced bronchoconstriction, and (5) downregulation of inducible nitric oxide synthetase in pulmonary tissue.

Ketamine has notable adverse effects which include hallucinations, bronchorrhea, laryngospasm, tachycardia, hypertension, and lowering seizure

threshold. Use of anti-sialagogues (atropine or glycopyrrolate) may be required if to reduce airway secretions.

Due to the sedative and bronchodilatory effects of ketamine, it is the preferred medication to facilitate intubation in the asthmatic child with impending respiratory failure.

Ketamine should be the sedative of choice to facilitate endotracheal intubation. Low-dose ketamine may play a role in avoiding mechanical ventilation and facilitating NIV in the child with severe asthma. Due to a paucity of high-quality data, ketamine infusions should be used with caution as a sedative in a spontaneous breathing or mechanically ventilated asthmatic children. Further studies are warranted to determine the efficacy of ketamine in pediatric patients with severe asthma.

10.8.3.2 Inhaled Anesthetics

A child with a refractory exacerbation and progressive hypoxemia despite maximal therapy and mechanical ventilation warrants a trial of inhalational anesthetic agents as a rescue maneuver. Halothane, isoflurane, and sevoflurane have all been found to have bronchodilatory effects which are thought to be due to beta-adrenergic receptor stimulation, reduction of vagal tone, and decreasing histamine release. Halothane has both significant negative inotropic and arrhythmogenic properties and should be avoided. Operationally, anesthetic delivery may be difficult. Anesthesia machines often do not have the capacity to ventilate the severe asthmatic for prolonged periods. A standard ICU ventilator can be fitted to deliver anesthesia, but ongoing delivery requires the presence of an anesthesiologist at the bedside.

10.8.3.3 Extracorporeal Membrane Oxygenation (ECMO)

In severe refractory respiratory failure secondary to asthma, ECMO remains a viable rescue option. The institution of ECMO may allow time for therapeutics (bronchodilators, glucocorticoids) to take effect. Once on ECMO support, pulmonary hygiene and lung rest can be facilitated while avoiding ventilator-induced lung injury. ECMO requires a multidisciplinary team not only proficient in managing the circuit but also capable of addressing the multiorgan derangements that can occur during mechanical cardiopulmonary support. Small case series have reported success utilizing ECMO. Further data is required to determine the optimal timing of ECMO relative to increasing support on mechanical ventilation.

10.9 Mechanical Ventilation for Severe Asthma in Children

The goal of mechanical ventilation during asthma is to provide adequate oxygenation and ventilation and allowing respiratory muscles to rest.

Most children who are treated promptly and aggressively for severe asthma will improve and not progress to respiratory failure requiring mechanical ventilation. However, a rare subset of children may have progressive or rapid respiratory deterioration that requires endotracheal intubation and mechanical ventilation. These patients represent a clinical challenge, both in the decision and process of endotracheal intubation and in the strategies utilized to provide ongoing ventilatory support. The goal of mechanical ventilation of the child with severe asthma is to provide adequate oxygenation and ventilation until the airway obstruction subsides and to allow respiratory muscles to rest by assuming the work of breathing.

Preparation is paramount during intubation, as most morbidity and mortality of childhood asthma occur during or shortly after endotracheal intubation.

Indications for the initiation of mechanical ventilation in severe asthma include respiratory or cardiac arrest, refractory hypoxemia, or a rapidly worsening sensorium. The presence of a respiratory acidosis should not be the sole prompt for intubation. However, rapidly rising carbon dioxide in the setting of obvious fatigue and/or progressive hypoxia is a clear indication for intubation. There are relative indications for endotracheal intubation, in which the deci-

sion must be made in the context of disease progression and therapy refractoriness. Relative indications include a rapidly increasing pulsus paradoxus, the loss of the ability to speak, and increasing serum lactate levels.

Once the decision is made to intubate, careful preparation is essential. A significant portion of morbidity and mortality due to severe asthma occurs in the peri-intubation period. Due to the predictable hemodynamic response to the initiation of positive pressure and the likelihood of concomitant volume depletion, appropriate fluid resuscitation should commence prior to intubation. Ketamine with a benzodiazepine is an effective combination to provide sedation. Use of atropine or glycopyrrolate should be considered to decrease bronchorrhea due to asthma or secondary to ketamine. Propofol is an acceptable alternative sedative if hypotension is not present. Neuromuscular blockade can be achieved with the use of a rapidly acting nondepolarizing paralytic such as rocuronium. Due to the potential side effects of histamine release and hyperkalemia, succinylcholine is generally avoided, especially in infants. Opioid agonists such as morphine can worsen bronchospasm secondary to a release of histamine and should be avoided. Fentanyl causes less histamine release and may be considered if analgesia is required.

Mechanical ventilation of the severe asthmatic can be challenging due to rapid changes in airflow dynamics during ventilation. The asthmatic may experience acute airway plugging from copious secretions and severe bronchoconstriction during agitation or may develop a pneumothorax secondary to air trapping. A pneumothorax should be considered with any acute hemodynamic or respiratory deterioration.

Multiple ventilatory modes have successfully supported children with respiratory failure due to asthma. No consensus exists in terms of what is the optimal mode of ventilation. Synchronized intermittent mandatory ventilation (SIMV) delivered with either pressure control (SIMV/PC) or volume control (SIMV/VC) are common choices. Pressure-regulated volume control (PRVC) uses a decelerating flow rate and combines elements of pressure and volume ventilation. PRVC guarantees a set tidal volume to be delivered with the lowest peak pressure possible to minimize barotrauma.

Mechanical ventilator settings should be adjusted to provide a physiologically acceptable level of oxygenation and ventilation while avoiding excessive airway pressure and dynamic lung hyperinflation. General guidelines on initial settings include an initial tidal volume set at approximately 6–10 mL/kg to maintain an inspiratory plateau pressure of <30 cm H_2O, a ventilation rate between 6 and 14 breaths/min depending on the age of the patient, a relatively short inspiratory time that allows a prolonged inspiratory to expiratory ratio (1:4 or higher depending on the rate), and possibly the application low positive end-expiratory pressure (PEEP) while monitoring auto-PEEP closely. Initial oxygen concentration is set at 100% and weaned as tolerated.

Adjusting the respiratory rate is best done with careful attention to the physical exam and exhalation flow pattern. The clinician should auscultate breath sounds and visualize chest excursion after multiple breaths. Full exhalation should occur prior to commencement of the next breath. If not, residual volume from each breath will lead to breath stacking, hyperinflation, and an increased risk of pneumothorax and hemodynamic compromise (Fig. 10.7).

If the exhaled flow is not completed, then either the mechanical respiratory rate must be decreased or the expiratory time must be increased. However, to obtain minute ventilation enough for carbon dioxide removal, higher tidal volumes and peak inspiratory pressures may need to be tolerated. Normal carbon dioxide levels are not necessary and indeed may lead to preventable barotrauma. Clinicians should allow "permissive hypercapnia" to limit

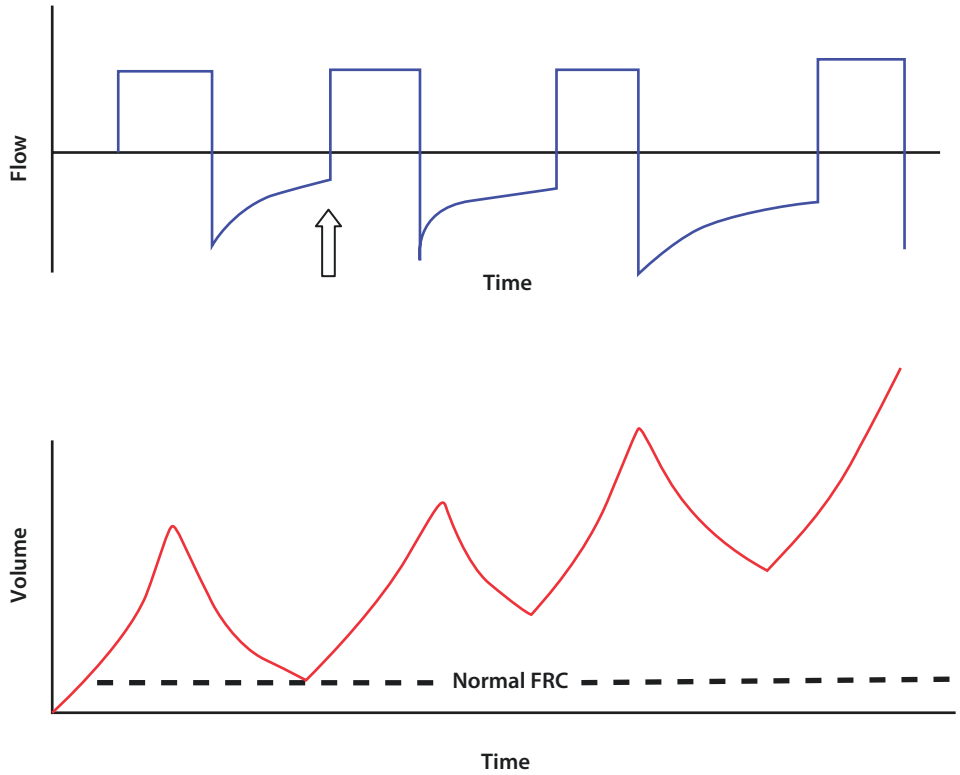

Fig. 10.7 Progressive dynamic hyperinflation in the setting of severe expiratory airflow obstruction. Inspiration begins prior to completion of exhalation (arrow) as seen on flow versus time graph. Air trapping above FRC ensues, as seen on the volume versus time graph

ventilator-induced lung injury. $PaCO_2$ levels as high as 90 mmHg may need to be tolerated during the early phases of mechanical ventilation.

10.10 Monitoring During Mechanical Ventilation

Although mechanical ventilation may be lifesaving in the asthmatic with respiratory failure, multiple challenges can occur after the institution of positive pressure. Monitoring changes in airway dynamics during the mechanical ventilation of a child with severe asthma is essential. Serial measurements of peak inspiratory pressures (PIP) and plateau pressures and monitoring for the development of progressive hyperinflation enable the clinician to respond to dynamic airway changes that are common during mechanical ventilation for asthma.

Peak inspiratory pressure often is used as a proxy for distal alveolar pressure. However, elevated airway resistance causes the measurement of peak inspiratory pressure to be poorly reflective of peak alveolar pressure. Instead, measurement of both peak inspiratory pressure and plateau pressures provides a better assessment of changes in compliance and resistance in the mechanically ventilated asthmatic. These measurements can aid clinicians in rapid troubleshooting and in monitoring worsening or improving disease.

Dynamic compliance is derived from measuring the tidal volume in relation to the delta of the PIP and PEEP and is affected by gas flow.

$$\text{Dynamic compliance} = \text{tidal volume}$$

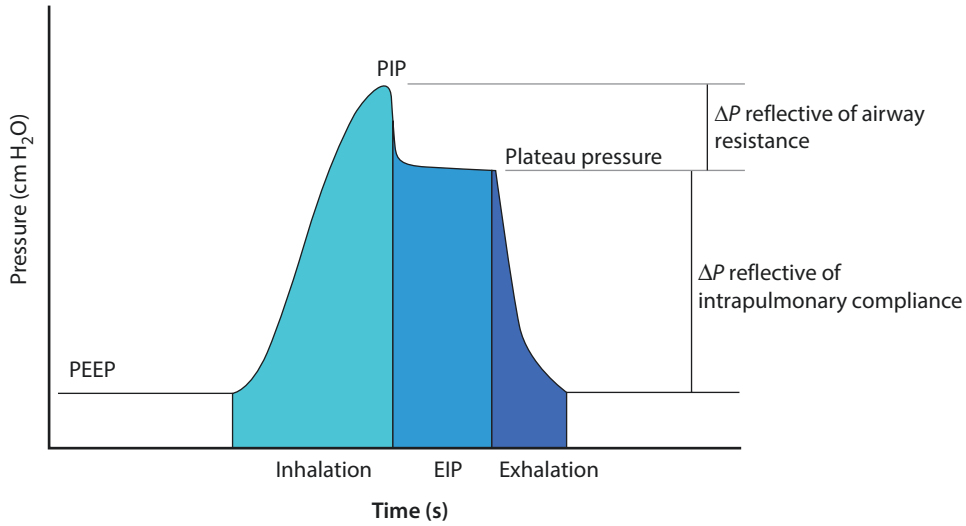

Fig. 10.8 Pressure during end inspiratory pause. Note the delta between the peak and plateau (*EIP* end inspiratory pause)

Static compliance utilizes plateau pressure in place of PIP. The plateau pressure is measured at the termination of inspiratory flow and therefore is unaffected by gas flow.

$$\text{Static compliance} = \text{tidal volume}$$

Because PIP is measured during ongoing gas flow, it may be reflective of both lung compliance and resistance to airflow in proximal and distal airways. To differentiate reduced compliance and increased resistance, a plateau pressure should be measured by instituting a 3 s flow pause at the end of inspiration (Fig. 10.8). An increasing PIP in the setting of an elevated plateau pressure reflects a reduction in dynamic compliance of the lung. This may be due to worsening parenchymal disease but may also be due to asynchrony, hyperinflation, or a pneumothorax. An increased PIP in the setting of a low plateau pressure (< 30 cm H_2O) reflects increased airway resistance.

Increased peak inspiratory pressure with little change in plateau pressure usually reflects increased airway resistance.

In summary, normally PIP is slightly greater than plateau pressure. Increasing PIP should prompt troubleshooting (Fig. 10.9). Concomitant elevations in PIP and plateau pressure are usually reflective of hyperinflation due to auto-PEEP or developing parenchymal disease. Increased PIP with little change in plateau pressure usually reflects increased airway resistance. It is not uncommon for peak inspiratory pressures to be much higher than plateau pressures during mechanical ventilation for asthma. An increased PIP-plateau pressure delta is reflective of increased airway resistance (bronchospasm, plugging). A decreasing PIP-plateau pressure delta can serve as useful marker for clinical improvement.

Auto-PEEP occurs if an insufficient expiratory time impedes full exhalation of alveolar and is reflective of air trapping.

Auto-PEEP can occur if insufficient expiratory time impedes full exhalation of alveolar gas. Auto-PEEP is reflective of air trapping and is not uncommon in mechanically ventilated asthmatic children. Auto-PEEP can be quantified by occluding the expiratory port of the ventilator at end expiration. The proximal airway pressure will equilibrate with alveolar pressure and permit measurement of auto-PEEP. Of note, auto-PEEP measured by the end-expiratory occlusion maneuver can have inconsistent results and requires paralysis as expiratory muscle contraction can cause artificial elevation. Auto-PEEP can underestimate the severity of hyperinflation if there is poor communication between the distal alveoli and the proximal airways. This can occur if pre-

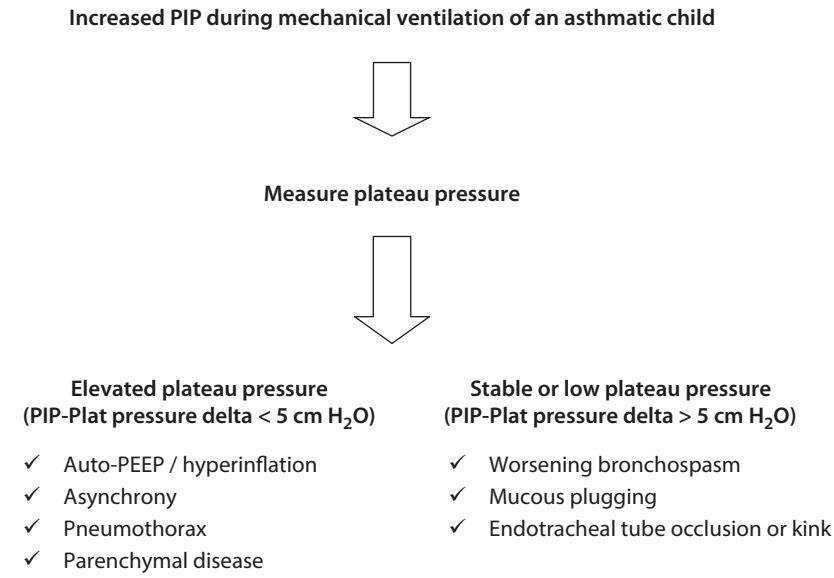

Fig. 10.9 Algorithm for evaluation of increasing PIP during mechanical ventilation

mature airway closure occurs prior to end expiration. Therefore, elevations in plateau pressures may be a more reliable and practical method to monitor lung hyperinflation.

Although counterintuitive, the application of extrinsic PEEP may provide some benefit during positive pressure ventilation of the asthmatic. Extrinsic PEEP (usually about 80% of the baseline auto-PEEP) can improve inspiratory muscle effectiveness. Use of low levels of extrinsic PEEP in mechanically ventilated children with spontaneous breaths may decrease the inspiratory work of breathing by stenting open airways and decreasing the pressure gradient required to overcome auto-PEEP. Therefore, when selecting a PEEP setting, the intrinsic auto-PEEP must be carefully considered. The extrinsically applied PEEP should always be lower than the auto-PEEP. Adding excessive PEEP may result in overinflation, air leak, and hemodynamic compromise from increased intrathoracic pressure.

The airway obstruction that occurs in severe asthma can be detected and monitored by several flow waveforms. A flow-volume loop (Fig. 10.10) can demonstrate increased airway resistance causing a decrease in maximum expiratory flow. This results in a concave shape to the expiratory limb on the flow-volume loop.

End tidal carbon dioxide tracings may also display evidence of expiratory obstruction and prolongation. There will be a delayed upstroke prior to reaching the peak expired carbon dioxide level transforming the waveform into a "shark fin" appearance. Normally, a plateau is maintained after reaching the end tidal carbon dioxide value (Fig. 10.11).

10.11 Complications During Mechanical Ventilation of Asthma

Many complications can occur during the initiation and maintenance of mechanical ventilation in severe asthma. These complications include air leak due to positive pressure-induced barotrauma (pneumomediastinum, pneumo-

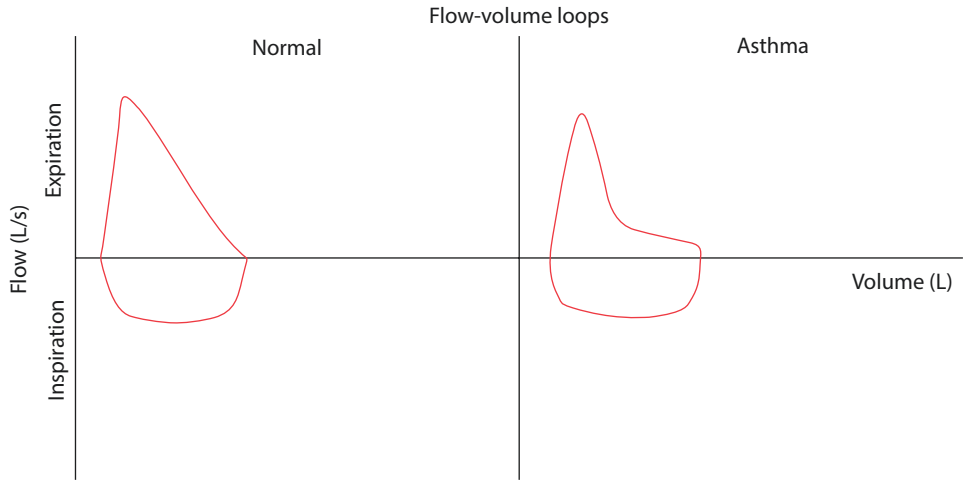

Fig. 10.10 Concave expiratory flow pattern seen with lower airway obstruction

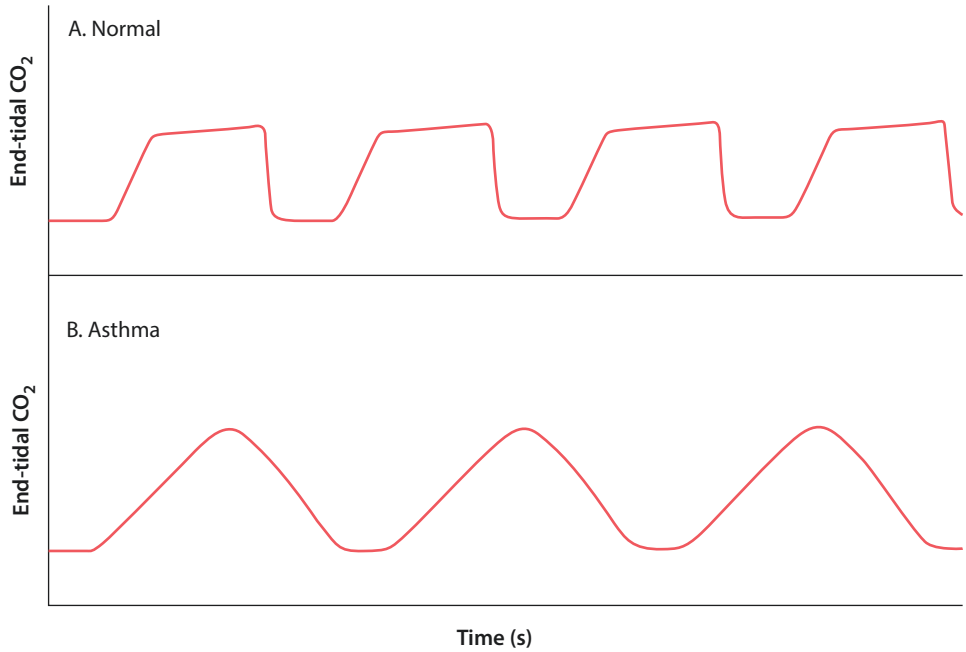

Fig. 10.11 **a** Normal capnograph revealing normal early expiratory upstroke followed by alveolar plateau phase. **b** Capnograph during bronchospasm revealing prolonged expiratory phase, poor plateau, and elevated end tidal CO_2 level

thorax, subcutaneous emphysema), nosocomial tracheitis and pneumonia, and mucus plugging and atelectasis. Complications such as pneumothorax and hemodynamic compromise can be limited if plateau pressures are maintained less than 30–35 cm H_2O and auto-PEEP is less than 15 cm H_2O. Marked hemodynamic compromise can occur and has been discussed in detail above. Prolonged weakness may occur in children ventilated for severe asthma. The risk of myopathy appears to increase with the concomitant use of steroids and neuromuscular blocking agents. The etiology of this myopathy is not completely understood but may be related to a loss of protein synthesis or altered electrical excitability of muscle fibers. Weakness may be protracted and require inpatient physical rehabilitation after PICU discharge.

Review Questions

1. Which of the following statements regarding the epidemiology of childhood asthma is correct?
   A. A child with asthma has a high likelihood of requiring intubation and mechanical ventilation if hospitalization is required for his/her care.
   B. Although the prevalence of pediatric asthma has increased, the associated mortality has sharply decreased due to improved critical care services.
   C. The "hygiene hypothesis" which suggests that the early exposure to microbial infections results in asthma has become accepted as the sole explanation for the increased prevalence of asthma.
   D. The phenotype of asthma is likely the result of a complex interaction between environmental factors and a single gene mutation.
   E. Prevalence of childhood asthma has increased, and average annual prevalence is higher in children <18 years of age as compared to adults.

2. A 14-year-old girl is admitted to the PICU for status asthmaticus. It is her third admission in 5 years, each occurring in late fall. Her parents inquire about potential triggers and how best to avoid them. Which statement is appropriate to include in your response?
   A. Exacerbations often have unidentifiable triggers.
   B. Exacerbations often have triggers that cannot be modified.
   C. Exacerbations in adolescent females are often misdiagnosed. An evaluation for vocal cord dysfunction is required.
   D. Environmental irritants including second-hand smoke may predispose children with bronchial hypersensitivity to severe asthma exacerbations.
   E. Viral infection is a common trigger for exacerbation but usually only in infants.

3. Poiseuille's equation is used to explain the laminar flow rate of an incompressible fluid down a column. Which component of this equation best explains why children are at greater risk for airway obstruction than adults?
   A. The airway radius
   B. The density of gas
   C. The distance of the airways
   D. The laminar flow of air
   E. The pressure gradient from the trachea to the alveolus

4. Which statement is true regarding the underlying pathophysiology of asthma?
   A. Asymptomatic asthmatic children may have low-grade persistent inflammation.
   B. Neutrophils play a major role in mediating inflammation and releasing of leukotrienes and histamine.
   C. Mucin production is increased due to goblet cells hyperplasia, but the composition of mucin remains unchanged.
   D. The fractional excretion of nitric oxide decreased due to the inflammatory response seen in asthma.
   E. Remodeling leads to increased airway smooth muscle mass but does not contribute to airway hyperresponsiveness and hypersensitivity.

5. An important component of the pathophysiologic cardiopulmonary interactions that can lead to decreased cardiac output during severe asthma exacerbation is:
   A. Right ventricular preload increase
   B. Right ventricular afterload decreases due to hyperinflation

C. Increased left ventricular afterload due to greater transthoracic pressure gradient
D. Increased left ventricular preload
E. Overall myocardial ischemia due to inadequate oxygenation

6. A 4-year-old male is admitted to the pediatric intensive care unit with respiratory distress secondary to an acute exacerbation of asthma. He was started on albuterol as a continuous nebulized solution of 15 mg/h in the ED but was unable to tolerate oral prednisone. He is awake and speaks in short sentences. His oxygen saturation is 92% on 40% face mask oxygen, and he has normal inspiratory sounds. He has marked expiratory wheezing with maximal accessory muscle use. Considering these clinical findings, it would be *most* important to initiate which of the following medications?
A. IV azithromycin
B. Nebulized ipratropium
C. IV magnesium
D. IV solumedrol
E. IV theophylline

7. A 9-year-old male is transferred to the pediatric intensive care unit with respiratory distress secondary to an acute exacerbation of asthma. He has marked expiratory wheezing with maximal accessory muscle use. Despite aggressive therapy consisting of intravenous steroids, continuous β-agonist aerosol therapy, and anticholinergic aerosols, the child continues to deteriorate and requires intubation. Which of the following induction medications for the intubation would be *most* appropriate?
A. Etomidate
B. Fentanyl
C. Ketamine
D. Propofol
E. Thiopental

8. A 13-year-old male with severe status asthmaticus was evaluated in the emergency department and admitted to the PICU. His initial arterial blood gas data is pH 7.23, PCO2 58, PO2 79 on room air. In the ED, he was started on NC 4 lpm, received nebulized albuterol × 3, and IV methylprednisolone. He continues to have inspiratory and expiratory wheezes with decreased air entry. You recommend starting nebulized ipratropium with the next dose of albuterol. Of the following, which best explains the mechanism by which nebulized ipratropium may be of benefit in this patient?
A. Inhibition of calcium intake into smooth muscle cell of the airway
B. Increase of intracellular cyclic guanosine monophosphate
C. Blockage of nicotinic receptors
D. Antagonism of airway leukotriene receptors
E. Blockade of muscarinic acetylcholine receptors

9. A 14-year-old male with bicuspid aortic valve stenosis is admitted to PICU with his first asthma exacerbation. His response to continuous albuterol, ipratropium bromide, and steroids is minimal. Terbutaline is started at 1 mcg/kg/min and increased to 4 mcg/kg/min with some improved response. During the increased titration, the pulse pressure starts to widen along with increasing tachycardia. The patient then goes into cardiac arrest after complaining of back and chest pain. The *most* likely explanation for his cardiac arrest is
A. Acute asphyxial asthma
B. Impaired cardiac filling
C. Aortic dissection

D. Severe hypokalemia
E. Myocardial ischemia

10. On day 2 of mechanical ventilation of an asthmatic child, the respiratory therapist reports a sudden increase in peak inspiratory pressure from 19 to 29 cm H_2O. You perform an inspiratory hold to measure the plateau pressure. The plateau pressure is 18 cm H_2O. What is the most likely explanation for elevated PIP?
A. Parenchymal disease
B. Auto-PEEP
C. Pneumothorax
D. Asynchrony
E. Mucous plugging

11. Which of the following medications used in the treatment of status asthmaticus exerts its effect by inhibiting the inward movement of calcium into smooth muscle, thereby preventing further bronchoconstriction?
A. Albuterol
B. Aminophylline
C. Helium
D. Ipratropium
E. Magnesium

12. Which of the following medications used in the treatment of status asthmaticus exerts its effect via a combination of inhibition of phosphodiesterase and adenosine-induced bronchoconstriction?
A. Albuterol
B. Aminophylline
C. Helium
D. Ipratropium
E. Magnesium

13. A 16-year-old female with status asthmaticus has failed to respond to first-tier therapies when admitted to the PICU. The pediatric intensivist decides to start a helium/oxygen mixture of 80% helium/20% oxygen. Which of the following characteristics *best* describes the mechanism of action for helium/oxygen mixtures in this setting?
A. Increased Reynolds number, creating conditions that favor laminar flow
B. Decreased Reynolds number, creating conditions that favor laminar flow
C. Less viscous than oxygen/nitrogen mixtures
D. Higher mass density than oxygen/nitrogen mixtures
E. Less gas velocity than oxygen/nitrogen mixtures

14. A 12-year-old male with a known history of refractory asthma is transferred to the pediatric intensive care unit (PICU) with a severe exacerbation. He is placed on a non-rebreather oxygen mask because his oxygen saturation ranges 84–89%. He is promptly started on intravenous solumedrol, continuous inhaled albuterol, and intermittent ipratropium bromide. A few hours into his admission, his respiratory distress persists. Intravenous magnesium and an aminophylline infusion are added to his therapeutic regimen. His vital signs reveal a temperature of 37.8 °C, heart rate of 152 bpm, respiratory rate of 36 breaths/min, and a blood pressure of 125/82 mmHg. His air exchange is fair with expiratory wheezing and marked retractions. He has bounding pulses. The nurse reports that he has anisocoria with his right pupil 7 mm and his left 4 mm. He answers questions appropriately in two-word sentences. Which of the following is the *most* appropriate course of action?

A. Perform a thorough neurologic exam, and if reassuring, continue his current care with frequent monitoring of his neurologic exam and serum drug levels.
B. Perform a thorough neurologic exam, and if reassuring, decrease the dose of albuterol as its high-dose effect may be resulting in a tachycardia that is potentially compromising CNS perfusion.
C. Perform a more thorough neurologic exam, and if reassuring, obtain an EEG as aminophylline may be associated with subclinical seizures.
D. Prepare for immediate intubation using neuroprotective strategies.
E. Perform a more thorough neurologic exam, and if reassuring, order a stat head computerized axial tomogram.

15. A 7-year-old male with a severe asthma exacerbation has a rapidly deteriorating level of consciousness. An arterial blood gas reveals a pH 7.26, $PaCO_2$ 56 mmHg, and PaO_2 52 mmHg. Pulse oximetry reveals saturations persistently below 85%. A decision is made to urgently intubate the child. The child receives ketamine (1 mg/kg), glycopyrrolate, and rocuronium (0.9 mg/kg) to facilitate the intubation. The child is intubated on the first attempt with end tidal carbon dioxide confirmation. While taping the endotracheal tube, he becomes profoundly hypotensive with significant respiratory variation in his arterial pressure waveform. He has decreased air entry in all lung fields. Which of the following most likely represents the primary pathophysiology of the hypotension?
A. A tension pneumothorax secondary to the initiation of positive pressure
B. Decreased cardiac output due to myocardial ischemia
C. Decreased cardiac output secondary to ketamine effect
D. Inaccurate zeroing of the arterial catheter pressure transducer as the bed was raised to facilitate intubation of the child
E. Relative intravascular volume depletion secondary to increased insensible losses, decreased oral intake, and increased intrathoracic pressure

16. A 9-year-old, 30 kg young girl with an acute exacerbation of severe asthma has required intubation and mechanical ventilation. She is placed in a pressure-regulated volume control mode with the following ventilator settings:
- IMV rate: 24 breaths/min
- Peak end-expiratory pressure (PEEP): 5 cm H_2O
- Tidal volume: 300 mL
- I-time: 1.0 s
- Fraction of inspired oxygen: 0.40

In addition, she has an auto-PEEP of 5 cm H_2O, a peak inspiratory pressure of 42 cm H_2O, a plateau pressure of 34 cm H_2O, and an end-expiratory flow of 3 L/min. Her most recent arterial blood gas reveals:
- pH: 7.34
- $PaCO_2$: 49 mmHg
- PaO_2: 72 mmHg

Which of the following is an appropriate ventilator adjustment?
A. Increase the I-time
B. Increase the PEEP
C. Increase the tidal volume
D. Decrease the respiratory rate
E. Increase the fraction of inspired oxygen

Pediatric Acute Respiratory Distress Syndrome

Garrett Keim and Nadir Yehya

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_11

Learning Objectives

- Define pediatric acute respiratory distress syndrome (PARDS).
- Understand how the alveolar-endothelial barrier maximizes gas exchange while minimizing fluid flux.
- Understand the mechanisms for the pulmonary edema seen in PARDS.
- Describe the important biochemical events that mediate inflammatory lung injury seen in PARDS.
- Identify how changes in compliance and functional residual capacity lead to intrapulmonary shunting and hypoxemia seen in PARDS.
- Recognize the distinct temporal pathologic changes in PARDS necessitating specific targeted therapies.
- Describe how the "open-lung model" maximizes oxygen exchange while minimizing ventilator-induced lung injury.
- Understand the roles for prone positioning, HFOV, APRV, corticosteroids, surfactant, and nitric oxide in the treatment of PARDS.

11.1 Introduction

Clinicians have long known the severe pulmonary complications that can accompany life-threatening illness or injury. In 1967, Ashbaugh and colleagues described what has now become known as the acute respiratory distress syndrome (ARDS). Their initial description of the syndrome in civilian patients was further appreciated in victims of nonthoracic trauma during the Vietnam War. ARDS has been known by other terms: Da Nang lung, shock lung, noncardiogenic pulmonary edema, and wet lung. Comparison was made with neonatal respiratory distress syndrome, acquired surfactant deficiency was postulated, and management with mechanical ventilation was described. ARDS was subsequently reported in pediatric patients, and the term "acute respiratory distress syndrome" came to be used in place of "adult respiratory distress syndrome." We describe here the epidemiology, pathogenesis, and management of pediatric ARDS (PARDS). As much of the evidence comes from adult ARDS, we liberally reference adult data and make specific references to pediatric considerations when appropriate.

In 1994, the European-American Consensus Conference formalized the first widely accepted definition for both acute lung injury and ARDS: acute onset of bilateral infiltrates on chest radiograph, no clinical evidence of left atrial hypertension or wedge pressure <18 mmHg, and a $PaO_2/FiO_2 \leq 300$ for acute lung injury and ≤200 for ARDS. The definition was refined and updated in 2012 with the publication of the Berlin ARDS definition. Berlin ARDS is divided into mild, moderate, and severe based on PaO_2/FiO_2 (eliminating the confusing "acute lung injury/non-ARDS" category) and removes the need for documenting a wedge pressure given the declining incidence of pulmonary artery catheterization. In neither 1994 nor 2012 were pediatric considerations addressed in the definitions of ARDS.

11.1.1 PALICC Definition of PARDS

In 2015, the Pediatric Acute Lung Injury Consensus Conference (PALICC) group published the first pediatric specific consensus definition of PARDS (Table 11.1). PALICC utilizes the more commonly used (in pediatrics) metrics of oxygenation index (OI) and oxygenation saturation index (OSI) to define

Table 11.1 Comparison of PALICC PARDS and Berlin ARDS

Characteristic	PALICC PARDS	Berlin ARDS
Oxygenation	*Mild*: 4 ≤ OI < 8 (5 ≤ OSI < 7.5) *Moderate*: 8 ≤ OI < 16 (7.5 ≤ OSI < 12.3) *Severe*: OI ≥ 16 (OSI ≥ 12.3)	*Mild*: 200 < P/F ≤ 300 mmHg (PEEP or CPAP ≥ 5 cm H_2O) *Moderate*: 100 < P/F ≤ 200 mmHg (PEEP ≥ 5 cm H_2O) *Severe*: P/F ≤ 100 mmHg (PEEP ≥ 5 cm H_2O)
Timing	Within 7 days of clinical insult	Within 1 week of clinical insult or worsening respiratory symptoms
Pulmonary edema	Judged not to be caused by cardiac failure or fluid overload	Not explained by cardiac failure or fluid overload; requires objective assessment such as echocardiography to exclude hydrostatic edema
Chest radiograph	New infiltrate(s) consistent with acute pulmonary parenchymal disease (can be unilateral)	Bilateral opacities not explained by effusion or lung collapse
Noninvasive ventilation criteria	Full-face bi-level positive pressure ventilation with CPAP ≥ 5 cm H_2O PF ≤ 300 SF ≤ 264	CPAP 5 ≥ cm H_2O only for mild ARDS

and stratify PARDS. Uses of OI (mean airway pressure (mPaw) × FiO_2 × 100/PaO_2) and OSI (mPaw × FiO_2 × 100/SpO_2) were considered more appropriate stratification variables due to the incorporation of mPaw rather than PaO_2/FiO_2, the preferred metric of hypoxemia in adult ARDS. PALICC also explicitly has alternative stratification using SpO_2 when PaO_2 is unavailable (i.e., OSI) and has less restrictive radiographic criteria (unilateral versus bilateral). Prospective validations of the PALICC definition have demonstrated good performance of these OI- and OSI-based severity categories for predicting mortality, suggesting good face validity.

11.1.2 Epidemiology

PARDS has a distinct epidemiology, including a lower mortality, than adult ARDS.

There are significant differences between the adult ARDS and PARDS epidemiology, risk factors, and mortality rates. Adult ARDS is comprised of patients with multiple medical comorbidities and has mortality rates reported between 27% and 45%. PARDS, on the other hand, has a lower mortality (18–27%). A history of prematurity, with its unique effects on physiology, is a comorbidity specific to children. Other important comorbidities in PARDS include congenital diseases, immunodeficiencies, hematologic malignancies, and bone marrow transplantation. As survival has improved in recent years, post-ARDS outcomes have been of growing interest. A follow-up study of a cohort of ARDS survivors demonstrated a 1-year mortality of 11%, as well as continued functional limitations and impaired quality of life out to 5 years post-ARDS. Survivors of ARDS have shown effects on ability to return to work out to 5 years and effects on psychological well-being. Post-PARDS outcomes are

much less understood. A single-center cohort study showed that 1-year mortality of PARDS survivors is 5.5%. More work is needed to better understand the post-ICU course for survivors of PARDS.

11.1.3 Etiology, Initiation, and Subtypes of PARDS

ARDS is a heterogeneous disease based on etiology, genetic predisposition, underlying mechanisms of disease, and response to therapy.

ARDS and PARDS are defined as clinical syndromes representing a heterogeneous disease based on etiology, genetic predisposition, and underlying mechanisms of disease. The varying etiologic events vary widely and are postulated to affect severity of disease and mortality. This has led to attempts to divide both ARDS and PARDS into broad categories that are more useful for prognostication and targeting future therapeutic interventions. Most commonly, these divisions have been between direct (pulmonary) versus indirect (non-pulmonary) etiologies, infectious versus noninfectious etiologies, and focal versus non-focal distribution (based on lung imaging). Direct lung injury is a result of damage at the level of the alveolar epithelium from conditions such as pneumonia, gastric aspiration, and drowning. Conversely, indirect lung injury is a result of systemic processes such as sepsis, burns, blood transfusion reactions, and non-pulmonary trauma that cause secondary lung injury by damage initially to the vascular endothelium. Recent publications looking at these different categories have shown unique clinical presentations of indirect and direct PARDS. Indirect PARDS is associated with a higher severity of illness, while direct PARDS has worse oxygenation. Despite these differences, no difference in mortality was seen between these two categories. Significant work is required to better understand and delineate how and which etiologic models are utilized in future PARDS trials.

Despite the fact that ARDS is a multifactorial, heterogeneous disease, there exists some degree of genetic predisposition to the development of ARDS. This predisposition is likely multigenic and, at present, there are multiple candidate genes that have demonstrated association with development of ARDS in adults. There are no studies to date in children investigating whether specific genes are implicated in the development of PARDS.

11.2 Anatomic and Physiologic Considerations in PARDS

Pulmonary interactions essential to the understanding of the pathogenesis and treatment of PARDS include:

- Starling's hypothesis
- Alveolar surface tension
- Lung compliance
- Functional residual capacity (FRC)
- Intrapulmonary shunt

11.2.1 Starling's Hypothesis and Lung Fluid in PARDS

Starling's forces: Capillary hydrostatic and colloid osmotic pressure determine fluid flux across the alveolar-endothelial barrier.

The lung's endothelial-alveolar barrier is a highly complex and efficient system, maximizing gas exchange and minimizing fluid flux (Fig. 11.1). The alveolar epithelium and capillary endothelium form a barrier in which fluid flux is determined by forces outlined in Starling's hypothesis. The force tending to push fluid *out* of the capillary and *into* the interstitium is the capillary hydro-

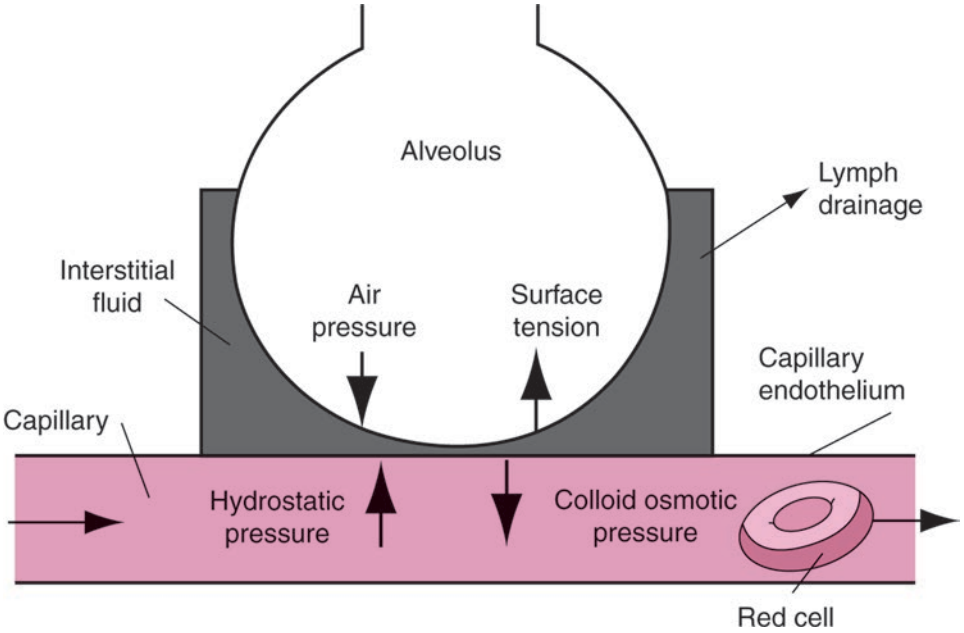

Fig. 11.1 Starling's forces determining fluid flux across the lung's endothelial-alveolar barrier. (From Rhoades and Tawner (1995))

static pressure minus the interstitial hydrostatic pressure ($P_c - P_i$). The force tending to pull fluid *into* the capillary is the capillary oncotic pressure minus the interstitial oncotic pressure ($\pi_c - \pi_i$). This net oncotic force also depends on the effectiveness of the capillary wall in preventing the flow of proteins, which is referred to as the reflection coefficient (σ). The relationship between the sum of these forces and fluid movement is the inherent permeability of the endothelium to water, and the surface area available for fluid flux also affects this relationship. The filtration coefficient accounts for these factors and is referred to as K. Thus:

$$\text{Fluid flow across capillary} = J_v = K\left[\left(P_c - P_i\right) - \sigma\left(\pi_c - \pi_i\right)\right]$$

Disruption of the alveolar-endothelial barrier leads to the accumulation of proteinaceous edema fluid in alveoli of the PARDS lung.

On balance, there is a net egress of fluid out of the capillary. Fluid pushed out of the capillary will be reabsorbed by perivascular lymphatics until the lymphatic capacity is overwhelmed, at which point alveolar fluid accumulates. The pulmonary edema associated with ARDS and PARDS is *not primarily* due to increased capillary hydrostatic pressure. It is "noncardiogenic" in nature. After an initial insult, a pro-inflammatory cascade is set in motion that ultimately compromises alveolar-endothelial integrity (disrupts the filtration coefficient K) and favors edema formation. As the barrier is now more permeable to larger proteins, there is an efflux of proteinaceous fluid into the interstitium, and if the alveolar epithelia are damaged, into the airspace. The plasma proteins in the edema fluid further contribute to lung injury by causing surfactant dysfunction with loss of surface tension. The protein-rich edema fluid that has been quantified in the alveoli of ARDS patients confirms that barrier disruption and loss of oncotic balance are initially responsible for edema formation. Increased capillary hydrostatic pressure may occur later due to hypoxic pulmonary vasoconstriction, microvascular thrombosis, and even subsequent cardiac dysfunction. Note that cardiac dysfunction can coexists with ARDS and PARDS but cannot be the primary driver of pulmonary edema. This is often difficult to differentiate in clinical practice and is a shortcoming of the syndromic definitions used.

11.2.2 Alveolar Surface Tension

A soap bubble serves as an excellent model to explain the physiologic force of surface tension. The spherical bubble has both outer and inner moist surfaces that are in direct contact with air. A bubble maintains its spherical shape because water molecules are more attracted to each other than to the surrounding air molecules. This creates surface tension, the inwardly directed force that reduces surface area while maintaining the integrity of the sphere. Pressure is maintained within the sphere to counter the natural forces favoring collapse. Laplace described these forces mathematically with the following equation:

$$P = 4T / R$$

P = pressure within the sphere, T = surface tension, R = radius.

When both inner and outer surfaces are in contact with air, the constant 4 is used; if only one surface is in contact with air, the constant 2 is used. The alveolus can be thought as an incomplete sphere where the moist inner surface is in contact with air and the moist outer surface is in contact with tissue. The Laplace relationship when applied to an alveolus is therefore:

$$P = 2T / R$$

Surfactant's ability to reduce surface tension is amplified as the size of the alveoli is decreased. This allows for equalization of pressures among interconnected alveoli of varying sizes. Without functional surfactant, alveoli are prone to collapse and fluid influx, leading to regional atelectasis and worsening pulmonary edema.

A problem arises when the principle is applied to interconnected alveoli with different dimensions. According to Laplace, the pressure in the smaller alveoli would exceed that of the larger alveoli (since it has a smaller radius, thus higher P), causing escape of air from the smaller unit into the larger unit. This would create an unstable lung with a propensity for smaller units to become atelectatic (Fig. 11.2). This would indeed be the case if the alveolus were coated with interstitial fluid instead of surfactant. Surfactant is secreted by type II pneumocytes and is made up of lipids (primarily dipalmitoyl phosphatidylcholine) and proteins that are spread over the inner surface of the alveoli. Surfactant dramatically reduces surface tension with its effects becoming greater as the diameter of the alveolus decreases (lower T as radius decreases). Surfactant's ability to stabilize surface tension allows equalization of pressure in large and small alveoli and thus prevents atelectasis. Surfactant also reduces the tendency of fluid to move from the tissue to the alveolus. Without surfac-

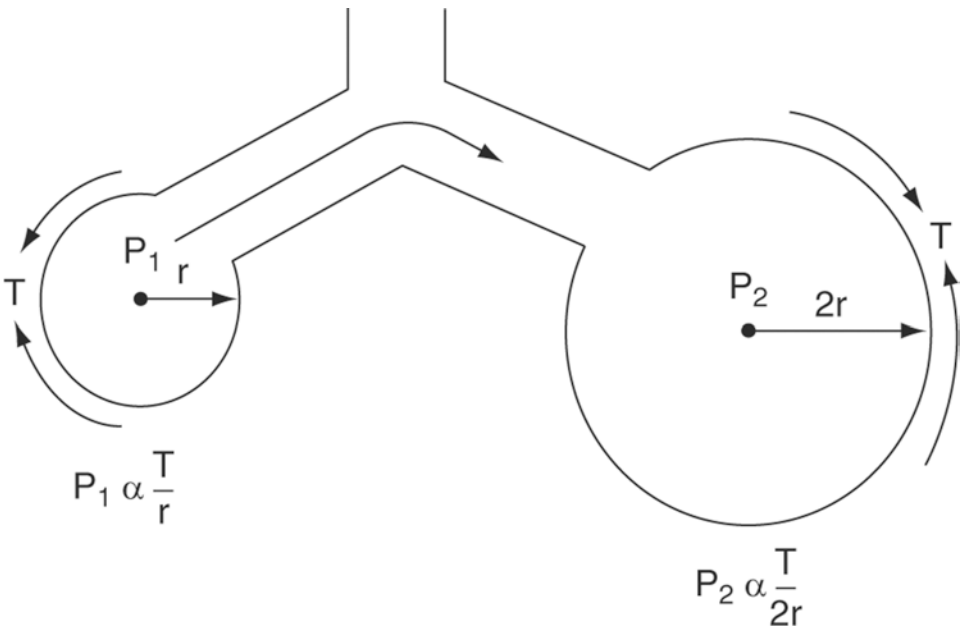

Fig. 11.2 According to Laplace's law, the pressure in the smaller alveolus exceeds the larger one causing air to empty into the larger alveolus with subsequent collapse of the smaller alveolus. This is not the case because the lung is lined with surfactant, and the alveoli are structurally linked to each other. Surfactant's ability to reduce surface tension is amplified as the diameter of the alveoli is decreased. This allows for equalization of pressures among interconnected alveoli of varying sizes

tant, surface tension forces would be greater at a given pressure causing fluid to be drawn into the alveolus. In effect, surfactant preserves the intra-alveolar pressure available to resist fluid influx into the alveolus.

Surfactant's ability to reduce surface tension is greatly compromised by the protein-rich edema fluid that accumulates in the alveoli of the ARDS lung. This results in both alveolar collapse and further edema formation. Macroscopically, this leads to dramatic changes in lung mechanics. Of particular importance are the reductions in lung compliance and functional residual capacity.

Without functional surfactant, alveoli are prone to collapse and fluid influx, leading to regional atelectasis and worsening pulmonary edema.

11.2.3 Compliance

The volume change per unit pressure change is known as the compliance of a system.

$$\Delta V / \Delta P$$

Lung compliance can be measured by calculating the slope of the pressure-volume curve. The pressure-volume curve of ARDS lungs is less steep than a healthy lung, indicating that a greater change in pressure is needed to produce the same change in volume (Fig. 11.3). ARDS lungs are functionally smaller and less compliant and are often referred to as being "small and stiff." Accompanying this reduction in compliance is a dramatic fall in the functional residual volume of the lung.

The ARDS lung requires a far greater change in pressure to produce the same incremental change in lung volume as a healthy lung.

Elastance is the reciprocal of compliance and is defined mathematically as $\Delta P/\Delta V$. It is the tendency of a hollow structure (i.e., lung) that is under pres-

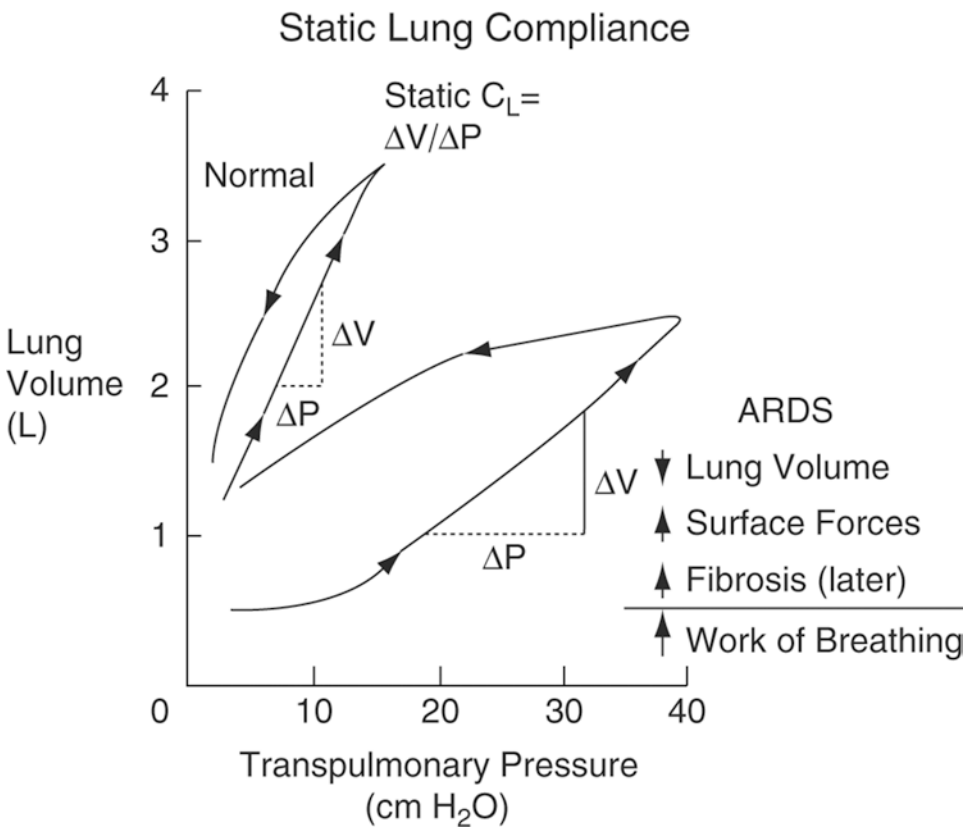

Fig. 11.3 Change in pressure-volume curve due to multifactorial pathology causing decreased lung compliance. The ARDS lung requires a far greater change in pressure to produce the same incremental change in lung volume as a healthy lung

sure to recoil to its original dimensions upon removal of the distending pressure. The lung, chest wall, and total respiratory system have individual compliance and elastance properties. The compliance-elastance relationship can be simplified as compliance determines the inspiratory pressure required to distend the lung, and its reciprocal elastance determines the expiratory volume the lung will return to when the distending pressure is removed.

Distinctive differences in pulmonary biomechanics, specifically elastance, have been described between PARDS resulting from direct lung injury and PARDS from indirect lung injury. Studies have found that the elastance of the *lung* is higher in direct lung injury as compared to indirect (non-pulmonary) PARDS. Conversely, the elastance of the *chest wall* was more than twofold higher in indirect PARDS than in direct lung injury, likely because the generalized inflammatory process causing edema formation in the lung is also occurring in the skin, muscle, and fat layers of the chest wall. The high elastance of the chest wall is consistent with a stiffer and noncompliant chest wall. The increased elastance of the chest wall in indirect PARDS may be also related to increased intra-abdominal pressure, which is seen commonly in patients with indirect PARDS.

11.2.4 Functional Residual Capacity (FRC)

FRC is the volume of the lung at which the inherent forces of the chest wall to maintain expansion balance the lung's inherent tendency to collapse. FRC is greatly reduced in the child with PARDS due to alveolar collapse and edema.

FRC is the volume of gas that remains in the lung after normal expiration. It is at this volume that the inherent forces of the chest wall to maintain the expanded shape of the thorax balance the lung's inherent tendency to collapse. FRC is reduced in PARDS due to alveolar filling with edema fluid and alveolar collapse secondary to surfactant destruction/dysfunction. Although upon gross inspection the postmortem lung of a child with PARDS is large and edematous, physiologically, the lung is operating at a reduced FRC and thus is functionally small. In adult ARDS, this is referred to as the "baby lung": the concept that the functionally available lung in ARDS is reduced to a much smaller volume. This reduction in FRC results in a diminished surface area available for gas exchange and is associated with hypoxemia. Recruitment of these nonfunctional alveolar units by mechanical ventilatory strategies that open lung and attempt to regain a normal FRC improves gas exchange largely due to restoring surface area and decreasing intrapulmonary shunting.

11.2.5 Intrapulmonary Shunting in PARDS

When considering ventilation-perfusion (V/Q) relationships, it is useful to appreciate the extremes of V/Q mismatching (◘ Fig. 11.4). Dead space ventilation represents one extreme; an alveolus receives ventilation without perfusion. The V/Q ratio approaches infinity in such cases. Large conducting airways exemplify normal anatomic dead space. The other extreme, intrapulmonary shunt (IPS), exists when the alveolar unit is unventilated but remains perfused (V/Q → 0). This "intrapulmonary shunt" blood returns to the left side of heart without the benefits of gas exchange and thus appears as mixed venous blood. A small anatomic shunt exists in the normal state (approximately 3% of blood returning to the left heart). This is made up of blood returning from the bronchial circulation (thebesian veins) and coronary venous blood draining directly into the left ventricle. This normal anatomic shunt partially accounts for the fact that the partial pressure of arterial O_2 is slightly less than the partial pressure of alveolar O_2.

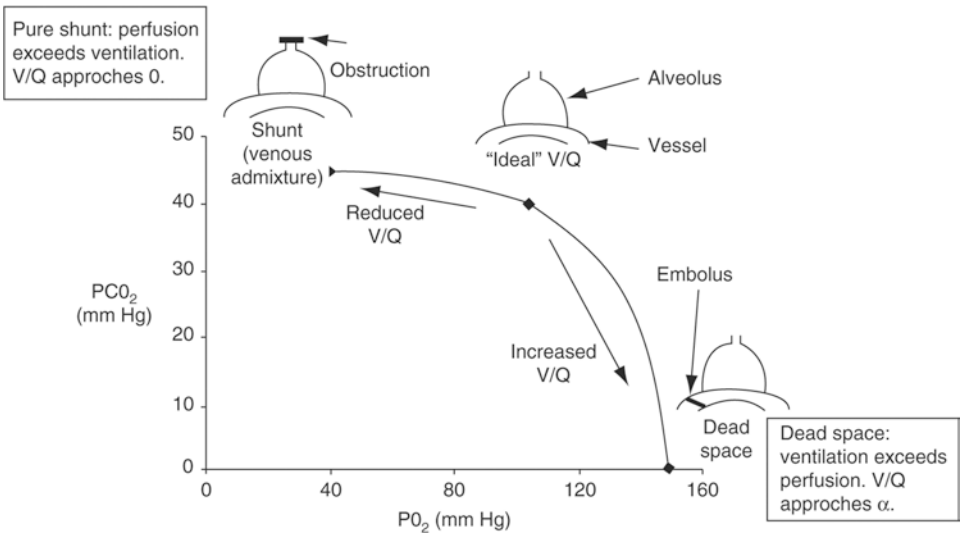

Fig. 11.4 Ventilation-perfusion relationships including extremes: pure shunt and dead space

An important distinction between a true right to left intrapulmonary shunt (IPS) and hypoxemia due to V/Q mismatching (low V/Q ratio but not 0) is the response to 100% FiO_2. There is no increase in PaO_2 with the administration of 100% FiO_2 in a complete IPS, whereas a modest increase in PaO_2 will occur if a low V/Q is the cause of hypoxemia. This relationship is complicated by the possibility of converting low V/Q units to a true IPS due to absorption atelectasis after the administration of 100% FiO_2. Due to the heterogeneous nature of the lung injury associated with ARDS, both IPS and low V/Q units contribute to hypoxemia. However, evidence suggests that IPS is responsible for a larger portion of the hypoxemia. Pathologically, completely atelectatic and fluid-filled alveoli act to produce this IPS. Clinically, this is reflected by little to no improvements in PaO_2 despite the administration of 100% FiO_2 to children with severe PARDS. Therefore, therapies directed at recruitment of alveolar units participating in IPS are more useful in reversing hypoxemia than the administration of high FiO_2 alone.

Normal V/Q relationships in healthy subjects dictate that the majority of ventilation is directed to dependent areas of the lung due to diaphragmatic activity, where fortuitously (by gravitational effects) perfusion is greatest. In the PARDS lung, most of the disease occurs in dependent areas. This leads to poorly aerated dependent sections that continue to be perfused, thus leading to greater V/Q mismatch. This is exacerbated by ventilating subjects in the supine position, where the weight of abdominal contents causes crowding of dependent lung regions. Reduced diaphragmatic activity from sedation and paralysis and dependent atelectasis from edematous lung anteriorly worsen this existing V/Q mismatch by reducing dependent ventilation. Recently, the sponge model has been used to describe why dependent areas tend to have the greater degree of alveolar deaeration. The lung sponge model theory suggests that the increased edema that accumulates down the anterior to posterior axis of the lung leads to superimposed pressure on dependent areas. This superimposed pressure along the gravitational axis causes dependent areas to become deaerated to a greater degree than nondependent counterparts. In this model, the edema is believed to be predominantly in the interstitium causing alveolar collapse by compression, whereas in the air-fluid interface model (alveolar barrier injury), the edema is predominantly in the alveoli. Regardless, in both models, the compromised alveoli are unavailable for gas exchange and FRC is decreased.

Atelectatic and fluid-filled alveoli create low V/Q segments leading to degrees of intrapulmonary shunting and hypoxia.

11.3 Inflammatory Mediators in PARDS

Regardless of the etiology of PARDS, inflammatory mediators are involved in tissue damage as well as lung repair. We will highlight a few inflammatory markers implicated in PARDS.

Pro- and anti-inflammatory mediators are implicated in PARDS pathogenesis.

Tumor necrosis factor-α (TNF-α) and interleukin-1β (IL-1β) are considered the main mediators of early inflammation. Both are released by activated macrophages and lead to an activation of secondary inflammatory mediators including cytokines, reactive oxygen species, and adhesion molecules. Interleukin-6 (IL-6) is produced by macrophages, endothelial cells, and fibroblasts in response to endotoxin, TNF-α, or IL-1β. IL-6 induces pyrexia, and the concentration of this acute-phase protein has been demonstrated to be a predictor of adult ARDS severity. Interleukin-10 (IL-10) serves as an anti-inflammatory cytokine and has been shown to attenuate the production of pro-inflammatory cytokines by alveolar macrophages during ARDS. Patients with ARDS have been shown to have lower concentrations of IL-10 (bronchoalveolar lavage fluid and circulating levels) than those who are at risk for ARDS but do not develop the disease. Transforming growth factor-β (TGF-β) is a pro-inflammatory cytokine that serves as a mediator of tissue fibrosis. The role of TGF-β is likely important in the fibroproliferative phase.

Granulocyte macrophage-colony stimulating factor (GM-CSF) serves a key role in the host defense response in the lung and is necessary for the function of alveolar macrophages. GM-CSF has attracted attention as a therapeutic agent for subjects at risk for ARDS and PARDS. A small randomized clinical trial of GM-CSF infusion in adults showed no improvement in mortality or ventilator-free days. Intercellular adhesion molecule-1 (ICAM-1) is an endothelial surface protein that is upregulated during inflammation. ICAM-1 deficiency impedes neutrophil recruitment. Increased ICAM-1 expression has been demonstrated in a variety of pro-inflammatory conditions and is also a future therapeutic target in ARDS.

11.4 Pathologic Phases of PARDS

Traditionally, three distinct time-dependent histopathological phases of ARDS have been described in adults (Fig. 11.5). While these phases and time course have not been corroborated in PARDS, we present them here as a framework for understanding the progression of the underlying disease process.

11.4.1 Acute Exudative Phase

The initial phase of ARDS typically lasts 1 week and is characterized by:

- Capillary-alveolar barrier injury (damage to type I pneumocytes)
- Development of protein-rich noncardiogenic pulmonary edema
- Surfactant dysfunction and deficiency due to damage to type II pneumocytes
- Neutrophil activation and alveolar infiltration with the initiation of inflammatory cascades
- Pulmonary hypertension
- Beginning of hyaline membrane formation

Distinct time-dependent histopathological phases described in adult ARDS are the acute exudative phase, subacute proliferative phase, and fibrosis with or without recovery.

These events result in pulmonary edema, reduced FRC, and impaired gas diffusion with resultant V/Q mismatching, and intrapulmonary shunting. This leads to profound hypoxemia. It is not uncommon for the patient to have systemic inflammatory response syndrome (SIRS) during this phase, either from the ARDS itself or from the underlying etiological trigger (i.e., sepsis).

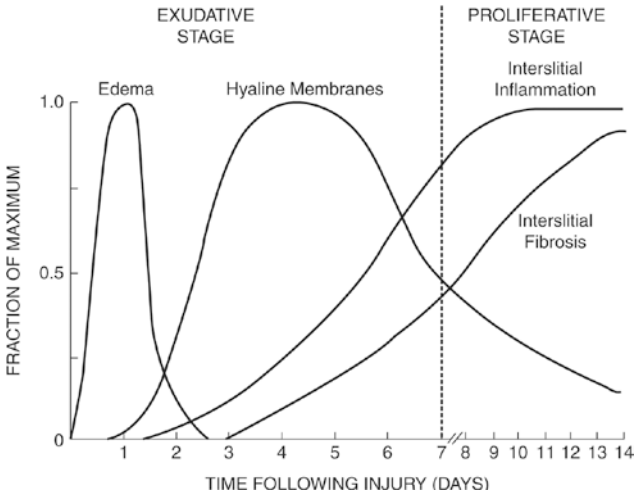

Fig. 11.5 Acute respiratory distress syndrome time course. Fibrotic phase with or without recovery follows the acute exudative and proliferative stages

11.4.2 Subacute Proliferative Phase

The subacute phase begins 7–10 days after insult and is characterized by:

- Fibroblast proliferation
- Ongoing inflammation
- Hyperplasia of type II pneumocytes
- Widening of alveolar septa due to cellular proliferation and organization of hyaline membrane
- Worsening pulmonary hypertension

Modest improvement in oxygenation is seen with the application of PEEP, but ventilation may become impaired due to increasing dead space. Inflammatory mediators indicative of SIRS may decrease during this phase.

11.4.3 Fibrosis With or Without Recovery

From 1 to 3 weeks, the lungs may develop fibrosis and remodeling. It is important to note that not all patients progress through all stages, and some may show resolution in the exudative phase. Also, those progressing to fibrosis may have variable long-term lung function. The long-term sequelae of PARDS remain largely unknown. Adult follow-up studies have shown worsened exercise tolerance and quality of life in ARDS survivors. One retrospective cohort study of survivors of PARDS showed functional status scale score changes consistent with new morbidity in 23% of survivors. More work is needed to better understand the long-term effects of PARDS on children's lives. Biomarkers of fibroproliferation, such as type III procollagen, have received great interest as they may identify a subset of subjects who may benefit from systemic corticosteroids to limit fibrosis.

11.5 Management

Care of the child with PARDS is complex, involving not only mechanical ventilation strategies to address the severe hypoxemia while limiting ventilator-induced lung injury (VILI) but also supportive care with regard to fluid balance, sedation and potential paralysis, treatment of etiologic agent and comorbidities, and modulators of oxygen delivery. We will highlight management strategies as well as consensus recommendations where they exist.

11.5.1 Ventilatory Management: *Maximize PEEP, Minimize VILI*

The main principles of adult ARDS management, extrapolated to PARDS, are limiting damaging distension and opening the lung using PEEP.

Studies have identified a reduction in mortality in adults with ARDS when using a protective lung strategy. This approach advocates for minimizing VILI via restricting tidal volumes to 6 mL/kg for patients and lower for those with excessive plateau pressures (>30 cm H_2O). These strategies have not been validated in PARDS although are commonly adopted and will be discussed with greater detail in the coming sections. A separate but related strategy emphasizes maintenance of FRC using recruitment maneuvers and positive end-expiratory pressures (PEEP), the "open-lung" approach. This approach also emphasizes reduction of VILI, primarily by invocation of the damaging effects of atelectasis rather than by reduction of alveolar stretch per se. As with tidal volume and peak/plateau pressure reduction, these approaches have not been validated in PARDS.

11.5.1.1 Optimizing PEEP

PEEP aids in the recruitment of collapsed alveoli and redistribution of alveolar fluid into the interstitial space. PEEP also decreases the shear forces on the alveoli produced by the repetitive opening and closing of alveoli during mechanical ventilation.

The maintenance of PEEP during mechanical ventilation has several theoretical benefits. PEEP aids in the recruitment of collapsed alveoli and the redistribution of alveolar fluid into the interstitium, thereby improving oxygenation. PEEP leads to the maintenance of functional residual capacity (FRC), thereby decreasing the shear forces on the alveoli that are produced by repetitive opening and closing during mechanical ventilation. Overall, PEEP improves the overall compliance of the lung by increasing and maintaining the FRC to a steeper point on the pressure-volume curve (Fig. 11.6) and homogenizing the distribution of gas in the lung. In a volume mode of ventilation with constant flow characteristics, movement to a more advantageous position on the pressure-volume curve will result in a smaller increase in peak and plateau pressure than the applied increase in PEEP. However, if alveolar overdistention predominates, increases in PEEP will result in an increase in peak and plateau pressures equal to or greater than the applied incremental increase in PEEP. Similarly, in a pressure mode of ventilation, incremental increases in PEEP will result in augmentation of tidal volume as alveolar recruitment occurs (increased compliance). When one reaches the flatter portion of the pressure-volume curve, an incremental increase in PEEP will fail to further increase tidal volume.

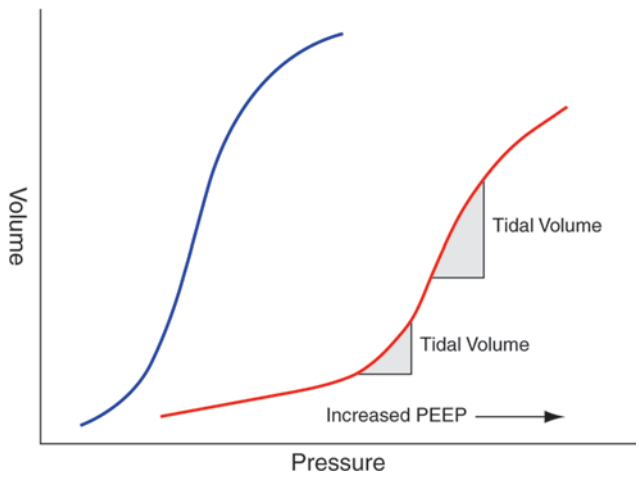

Fig. 11.6 Normal and ARDS pressure-volume curves. The application of PEEP in the noncompliant ARDS lung allows a shift to a more favorable position on the pressure-volume curve

PEEP can have detrimental effects including overdistention of compliant alveoli and the reduction of venous return to the right heart. There are multiple ways to set PEEP. One can identify the lower inflection point of the pressure-volume curve (where collapsed alveoli are opened) using modified super-syringe techniques in modern ventilators (◘ Fig. 11.6). The PEEP level is then initiated above this point to maintain alveolar recruitment. Alternatively, one can incrementally increase PEEP and monitor changes in peak and plateau pressures (when in volume control) or tidal volume (when in pressure control). ARDSNet has set forth a protocolized PEEP/FiO_2 titration strategy for adult ARDS, increasing PEEP to lower FiO_2 requirement. No comparable table exists specifically for PARDS, but the use of the ARDSNet table may be useful in PARDS PEEP titration. A retrospective analysis of multiple PARDS datasets demonstrated an independent association with mortality for patients managed with a PEEP lower than recommended by ARDSNet protocol after controlling for recorded potential confounders. In light of this, it is reasonable to consider ARDSNet guidelines during PEEP titration for PARDS. More work in this area is needed, although it generally appears that PARDS is managed by lower PEEP than would be recommended by adult ARDS guidelines.

The judicious application of PEEP improves the overall compliance of the lung by increasing the FRC to a steeper point of the pressure-volume curve.

It should be noted that in four adult ARDS trials of high versus low PEEP, no survival advantage was seen with higher PEEP. In the most recent trial, which was coupled with aggressive recruitment maneuvers prior to setting high PEEP, the high PEEP group demonstrated higher mortality, although this may have reflected problems with the recruitment and PEEP protocol rather than with high PEEP per se.

11.5.1.2 Minimizing VILI

The application of positive pressure ventilation can produce further inflammatory changes in the lung. To reduce the possibility of worsening VILI, a judicious approach to mechanical ventilation is required. Several strategies can be employed to reduce VILI. The use of PEEP helps to improve oxygenation via maintenance of FRC, decreasing the shear forces on alveoli by preventing repetitive collapse and reopening (atelectrauma). Oxygen toxicity is reduced by limiting FiO_2, usually to a goal of <60%. The optimal use of PEEP allows appropriate weaning of FiO_2. Limitation of volutrauma, lung injury due to overdistension of alveoli, and barotrauma, alveolar injury due to exposure to high pressures, are addressed using small goal tidal volumes and limiting peak and plateau pressures. Permissive hypercapnia to an arterial pH target of 7.25 is often employed to help limit VILI and is usually well tolerated. This rarely may require the addition of sodium bicarbonate or another buffer. The first positive trial in adult ARDS demonstrated the superiority of tidal volumes of 6 mL/kg versus 12 mL/kg, and limiting plateau pressures to 30 cm H_2O rather than 50. The relationship between tidal volumes, pressures, and outcomes is less clear in PARDS, although peak pressures have consistently been associated with poor outcomes. PALICC recommends keeping tidal volumes <8 mL/kg and limiting peak and plateau pressures in the absence of direct trial evidence.

Reduction of tidal volumes and limiting peak and plateau pressures are central to lung-protective ventilation strategies to limit VILI.

11.5.1.3 High-Frequency Oscillatory Ventilation (HFOV)

When considering the mechanical forces contributing to VILI, the use of HFOV in the treatment of ARDS has obvious theoretical advantages. HFOV provides the extreme in the open-lung, low tidal volume approach. Oxygenation is achieved by maintaining lung volume at a sustained mPaw. The mPaw is usually set 4–8 cm H_2O above the mPaw on conventional mechanical ventilation (CMV). Ventilation occurs as small tidal volumes (1–2 mL/kg; sub-dead space)

that are delivered at high frequencies (8–15 Hz or 480–900 breaths/min) around the set mPaw. The major disadvantages of HFOV include the need for heavier sedation, often paralysis, and the reduced pulmonary toilet due to concerns about derecruitment with suctioning.

HFOV and APRV are consistent with the open-lung approaches to maximize alveolar recruitment. Their use should be cautiously considered in PARDS patients failing conventional ventilation.

Two simultaneously published large randomized control trials in adults with moderate to severe ARDS have called the use of HFOV into question. The OSCAR study showed no statistically significant effect on 30-day mortality between HFOV and CMV. The OSCILLATE study was stopped after indication of higher relative risk of hospital mortality in patients receiving HFOV, although this may be related to the specific HFOV protocol used. Large randomized controlled trials of the use of HFOV in modern PARDS are lacking. Current PALICC recommended the consideration of HFOV in patients with moderate-to-severe PARDS when plateau pressures exceed 28 cm H_2O in patients without significant chest wall compliance abnormalities. More data about the efficacy, safety, and optimal management strategies are needed.

11.5.1.4 Airway Pressure Release Ventilation (APRV)

APRV offers several theoretical benefits in the mechanical ventilation of PARDS patients. APRV has often been described as an extreme of inverse ratio ventilation. APRV facilitates oxygenation by sustaining a high pressure (P_{high}) for typically a few seconds (T_{high}). Ventilation occurs with spontaneous breathing during T_{high} as well as during a rapid and brief deflation to a low pressure (P_{low}), often a PEEP of 0 cm H_2O. A brief time (T_{low}) is spent at P_{low} to avoid alveolar derecruitment.

Potential advantages of APRV include the following:

- Oxygenation at lower peak airway pressures for a given tidal volume
- Minimizing overdistension while maximizing recruitment
- Preservation of spontaneous breathing
- Elimination of the need for neuromuscular blockade
- Little to no impact on hemodynamics
- Decreasing ventilator-patient dyssynchrony

Typically, the P_{high} is set at the plateau pressure observed in CMV, and the T_{high} is set at 4–6 s to maintain adequate oxygenation. P_{low} is usually set at 0 cm H_2O. This provides minimal resistance to exhalation during the release time. Use of a higher P_{low} may actually impede expiratory flow. Although often thought as the "PEEP," the P_{low} is not synonymous with PEEP. Instead, PEEP is generated by choosing the correct T_{low}, finding the right T_{low} is crucial in APRV. The optimal time spent at P_{low} should be insufficient to allow full exhalation and allow some intrinsic PEEP, *but also* allow sufficient CO_2 removal during the release. To find this optimal T_{low}, the expiratory flow pattern should be examined. The time it takes for expiratory flow to fall to 50% of the peak expiratory flow best approximates the initial T_{low} setting. Experience using APRV in adults suggests that the most significant benefits are achieved in the spontaneously breathing patient. A more extensive discussion of the mode and necessary adjustments based on gas exchange are found elsewhere in the text.

11.5.2 Improving Oxygen Delivery

A complete discussion of oxygen kinetics is covered in Chap. 2. Key equations regarding oxygen delivery in ARDS can be summarized as:

Oxygen delivery:

$$DO_2 = CaO_2 \times CI \times 10\,dL/L = 550 - 680\,mL/min/m^2$$

$$CaO_2(\text{approximated}) = Hgb \times 1.34\,mL\,O_2/g\,Hgb = 15-17\,mL/dL\,(\text{infant/child}), 16-20\,mL/dL\,(\text{adolescent})\,(\text{ignoring dissolved oxygen})$$

Oxygen consumption:

$$VO_2 = a - vDO_2 \times CI \times 10\,dL/L$$

$$VO_2 = (CaO_2 - CvO_2) \times CI \times 10\,dL/L = 120-200\,mL/min/m^2$$

While optimizing DO_2 and minimizing VO_2 may assist with oxygenation, supraphysiologic oxygen delivery is potentially harmful.

Strategies used to maintain DO_2 include correcting symptomatic anemia, correcting low cardiac output states, and maximizing oxygenation (SaO_2) as described above. Maintaining supranormal DO_2 with liberal use of blood transfusions and inotropes has no role in ARDS therapy and is likely detrimental. Treating fever and pain and preventing catabolism can minimize excessive VO_2. Intubation and mechanical ventilation also play a role for reducing VO_2 as up to 40% of cardiac output can be redirected to the respiratory muscles to maintain minute ventilation in ARDS at the expense of DO_2 to other organs.

11.5.3 Fluid Balance

The effect of fluid overload on lung function in the presence of ARDS is of ongoing interest. Early studies examining the nature of edema formation in the presence of diffuse lung injury demonstrated that the rate of edema formation is proportionate to pulmonary capillary pressure throughout the entire range from normal to elevated pressures. Thus, while in ARDS edema formation occurs in the absence of elevated pulmonary capillary pressures, the edema formation is not *independent* of pulmonary capillary pressure. In cardiogenic pulmonary edema, there is more of a threshold effect such that measurable pulmonary edema does not occur below a PAWP of 16–18. With pulmonary capillary injury, the rate of edema formation occurs at all levels of PAWP and is proportionate to PAWP.

Conservative fluid management with fluid restriction and initiation of diuretics when hemodynamically stable may shorten ventilator duration.

Traditionally, due to the application of high PEEP, patients were volume loaded to help overcome the decreases to venous return that occur with high PEEP. However, this approach neglected the physiology of edema formation as the fluid loading increases pulmonary edema formation. Early studies in intact animal models demonstrated that pulmonary function was improved with diuresis coupled with cardiac output support using inotropes or vasodilators. A multicenter randomized controlled clinical trial of conservative versus liberal fluid strategies in hemodynamically stable (minimal vasopressor/inotrope requirement) adults with ARDS was completed, demonstrating a marked difference in overall fluid balance between the two groups. There was improvement in multiple indices of pulmonary function as well as increased ventilator-free days (days alive and off mechanical ventilation) and fewer total ICU days for the conservative fluid strategy group. The protocol targeted lower CVP and PAWP in the conservative fluid management group with lower thresholds for the use of diuretics and inotropes.

When considering fluid balance, practitioners must balance the risk for pulmonary edema formation with the potentially beneficial effects of preload on oxygen delivery and organ perfusion. There remains a wide variability between fluid resuscitation strategies, the time to initiate vasoactive support to facilitate oxygenation delivery and organ perfusion, and when to use diuretics to achieve

desired fluid balance. Fluid balance should be a consideration during the management of PARDS, but more data is needed to help determine ideal fluid balance management strategy.

11.5.4 Prone Positioning

Prone positioning improves V/Q matching, recruits atelectatic dorsal lung units, and improves drainage of retained secretions.

Adult and initial pediatric data have shown that 65–85% of ARDS patients will have improved oxygenation when placed in the prone position. This improvement may be immediate (within 1 h) or delayed with improvement occurring over 24 h. Mechanisms for improved oxygenation are multifactorial and may include:

- Improved ventilation-perfusion matching. Chest CT scanning of the ARDS lung in adults demonstrates greater disease in dependent portions of the lung. In the supine position, perfusion is greatest in dependent areas, thus leading to greater V/Q mismatching. Prone positioning may transiently increase perfusion to less diseased lung segments.
- Redistribution of tidal volume to atelectatic areas. When placed prone, the patient's recruitment of atelectatic dorsal lung units allows for a more homogeneous distribution of gas throughout the diseased lung. This redistribution is often coincident with lower peak and plateau pressures.
- Improved diaphragmatic excursion by reducing effects of abdominal pressure, but only if the subject is spontaneously breathing.
- Improved postural drainage of secretions.

A randomized control trial of early proning in children with PARDS showed an improvement in oxygenation with the use of proning, but no differences in ventilator-free days or mortality between the prone and supine groups, and the study was stopped early for futility. A study in adults with moderate/severe ARDS (PaO_2/FiO_2 ratios <150) demonstrated significantly improved 28- and 90-day mortality in patients that were proned early in their ARDS course for at least 16 h daily. Prolonged prone positioning is reasonable to trial in moderate and severe PARDS in an attempt to improve oxygenation and V/Q matching, and potentially outcomes.

11.5.5 Corticosteroids

Corticosteroids should be used cautiously in PARDS given the risk of side effects, including immunosuppression, neuromuscular weakness, and re-intubation.

The use of corticosteroids in ARDS has been an active area of research and controversy. The vast majority of data has been derived from adult studies. Adult studies have shown both improved and worsened mortality with the use of methylprednisolone therapy. Due to the differences in timing of initiation, dose, and duration of corticosteroid use, there continues debate about the efficacy in ARDS. A meta-analysis in 2016 of multiple randomized trials demonstrated that patients randomized to receive corticosteroids had more unassisted breathing days. However, the initiation of corticosteroids after 14 days was associated with worse mortality, and all studies of corticosteroids noticed the potential for reinitiation of mechanical ventilation due to neuromuscular weakness. In a small randomized trial of methylprednisolone in PARDS, there were no significant differences in ventilator-free days or mortality. In a retrospective analysis of all steroid exposure in PARDS, steroid exposure >24 h was associated with fewer ventilator-free days, longer duration of ventilation, but no differences in mortality. PALICC recommends against the routine use of corticosteroids in PARDS at this time. Further investigation into the efficacy, dose, duration, and optimal time of initiation of corticosteroids is needed in PARDS.

11.5.6 Inhaled Nitric Oxide

Inhaled nitric oxide improves oxygenation by acting as a selective pulmonary vasodilator. It is unclear if it improves outcomes.

Multiple injuries including microvascular thrombosis, hypoxic vasoconstriction, and underdevelopment of both the pulmonary vascular bed and alveoli in patients with a history of prematurity can lead to elevated pulmonary vascular resistance and pulmonary hypertension in PARDS. The use of high PEEP may also worsen pulmonary hypertension. Inhaled nitric oxide (iNO) is a gaseous vasodilator that is rapidly inactivated by hemoglobin, thus making its vasodilatory actions restricted to the pulmonary vasculature. Theoretically, iNO may help improve V/Q matching. A multicenter randomized controlled trial showed that iNO only transiently improved OI and did not improve 28-day mortality but did reduce duration of mechanical ventilation. A second single-center cohort again showed a decrease in ventilator days in responders to iNO (≥20% improvement in OI or OSI by 6 h after iNO initiation). Again, no change was seen in overall mortality. Use of iNO may be considered in PARDS patients with pulmonary hypertension and those with severe oxygenation abnormalities.

11.5.7 Exogenous Surfactant

Despite initial promise, there is no utility to exogenous surfactant in PARDS. Appropriate delivery of surfactant may have complicated efficacy studies.

The use of exogenous surfactant preparations is standard therapy for neonates with respiratory distress syndrome. Even though endogenous surfactant is both quantitatively decreased and qualitatively dysfunctional, multiple studies examining a variety of surfactant replacements in adult ARDS have all yielded negative results. Initial studies in PARDS showing encouraging results for surfactant replacement were confounded by an imbalance in the number of immunocompromised subjects between treatment arms. A more recent large multicenter randomized trial was stopped early for futility and showed no benefit to oxygenation or mortality with exogenous surfactant, although this may have to do with how surfactant was delivered. The CALIPSO trial focused on the use of surfactant in a subset of PARDS patients with leukemia, lymphoma, or after hematopoietic stem cell transplant and again did not show differences in outcomes between the treatment and placebo group and was stopped early for low enrollment. Thus, as of now, no data support the use of surfactant replacement therapy in PARDS.

11.5.7.1 Neuromuscular Blockade

Neuromuscular blockade improves oxygenation and ventilation by limiting the damaging and insidious effects of ventilator dyssynchrony.

Use of neuromuscular blockade (NMB) during PARDS has potential advantages. The most discussed advantage is limiting patient-ventilator dyssynchrony when sedatives alone are not adequate, thus mitigating double triggering and unintentionally high volumes and pressures contributing to VILI. In addition, NMB facilitates titration to permissive hypercapnia and the use of high-frequency ventilation strategies. Disadvantages include lack of spontaneous breathing contributing to diaphragmatic and respiratory muscle wasting and concerns about contribution of NMB to critical care myopathy and lasting muscle weakness. The ACURASYS trial showed improvement in 90-day mortality without an increase in ICU-associated muscle weakness in adult ARDS subjects (PaO_2/FiO_2 ratios <150) who received 48 h of neuromuscular blockade with cisatracurium early in the course of severe ARDS. No randomized trials of NMB exist specifically for PARDS. It is reasonable to consider NMB early in the course of PARDS as we await a definitive trial in pediatrics.

11.5.8 Extracorporeal Membrane Oxygenation (ECMO)

ECMO should be considered for refractory severe PARDS, especially when ventilator settings and airway pressures are escalating and becoming potentially more damaging.

Children who have progressive respiratory failure despite maximal conventional therapies should be considered for extracorporeal membrane oxygenation (ECMO). In patients that do not have a contraindication for ECMO, OI > 40 is often used as a trigger for initiation, although this varies considerably between institutions. ECMO can be used to both oxygenate and efficiently clear carbon dioxide. Both venoarterial (VA) and veno-venous (VV) ECMO have been used successfully for ARDS, with worldwide experience and comfort with the modality for ARDS increasing after the 2009 H1N1 influenza epidemic. VV-ECMO is often preferred even for patients with cardiovascular dysfunction that is felt to be causally related to the lung injury. In adults, the CESAR trial randomized patients with severe ARDS to referral to ECMO center or continued care. Patients referred to ECMO center showed reduction in mortality or severe disability at 6 months. However, only 75% of those referred to an ECMO center went on ECMO, which leaves open the possibility that ECMO in of itself did not improve outcomes, but the advanced care bundle offered by an ECMO center was the important factor. Recently, a randomized control was halted early due to pre-study futility rules of the primary outcome of mortality at 60 days. Patients were randomized to early VV-ECMO versus conventional therapy, with the opportunity for subjects on conventional therapy to cross over to ECMO. At the time of study termination, the 60-day mortality was 35% for the early ECMO group and 46% in the conventional treatment group, with a relative risk of 60-day mortality of 0.76 [CI 0.55–1.04, $p = 0.09$]. The decision to stop early was heavily criticized. Even with this negative trial, ECMO remains a consideration in severe ARDS. ECMO survival after prolonged mechanical ventilation (particularly > 14 days) has been shown to be poor. For this reason, its use should be considered early in the course of refractory PARDS. No randomized trials exist for ECMO in severe PARDS. PALICC recommends the early consideration of ECMO for severe PARDS.

11.6 Summary

PARDS management has, to date, largely been extrapolated from adult ARDS management, with presumed commonalities in etiology, pathogenesis, and outcomes. However, emerging data suggest that PARDS possesses a distinct epidemiology and outcome profile, with risk factors, etiologies, comorbidities, and outcomes specific to pediatrics. This makes extrapolation of adult ARDS data challenging. Specific studies are needed to advance our understanding of PARDS and explicit comparisons made with adult ARDS. In the interim, a lung-protective approach limiting excessive distending pressures, use of PEEP, and conservative fluid management seem to be reasonable approaches to PARDS, with judicious, thoughtful application of ancillary therapies, carefully weighing risks and benefits in the absence of definitive evidence.

Review Questions

1. Which statement is true regarding the pathophysiology of PARDS?
   A. High V/Q units and intrapulmonary shunting are responsible for the hypoxia.
   B. Lung compliance, defined as $\Delta P/\Delta V$, is reduced in PARDS.
   C. Functional residual capacity is reduced in PARDS due to proteinaceous edema and surfactant dysfunction.

D. The pressure-volume loop is more steep in a child with PARDS than in a healthy child.
E. The thickening of the alveolar-endothelial barrier is a primary cause of diffusion impairment and hypoxia in ARDS.

2. A 4-year-old female was found unresponsive in a pool. During her first day in the PICU, she has required escalation of her mechanical ventilatory support to a PEEP of 12 cm H_2O and an FiO_2 of 70% to maintain saturations of 90%. Her current peak inspiratory pressure is 35 cm H_2O to reach a tidal volume of 6 mL/kg. Which of the following is an accurate description of her pulmonary biomechanics?
   A. High elastance, low compliance, and high functional residual volume
   B. Low compliance, low elastance, and predominately low V/Q mismatched lung units
   C. High compliance, low elastance, and high functional residual volume
   D. Low compliance, high elastance, and predominately low V/Q mismatched lung units
   E. High elastance, low compliance, and high resistance

3. Which of the following is true regarding early therapies in ARDS in light of its physiologic derangements?
   A. Aggressive treatment of hypercarbia may attenuate the ARDS course.
   B. Application of 100% FiO_2 is often sufficient to overcome the hypoxia.
   C. Early use of inotropic agents and diuretics may rapidly reduce ongoing edema formation.
   D. The use of PEEP is to maintain the lungs at a low functional residual volume.
   E. The early and titrated application of a high-PEEP, low-tidal volume strategy can improve oxygenation while limiting ventilator-induced lung injury.

4. Which statement concerning PARDS and mechanical ventilation is true?
   A. High-frequency oscillatory ventilation is recommended for children with refractory hypercarbia despite conventional mechanical ventilation.
   B. High PEEP levels help to increase functional residual volume but worsen V/Q matching.
   C. Prone positioning during mechanical ventilation is used to improve V/Q matching and has improved both oxygenation and mortality in PARDS.
   D. A high-PEEP, high-tidal volume strategy allows for permissive hypercapnia and reduces ventilator-associated lung injury.
   E. A high-PEEP, low-tidal volume strategy is helpful in both improving lung unit recruitment by increasing functional residual volume and limits barotrauma.

5. What are the theoretical benefits of high-frequency oscillatory ventilation in PARDS?
   A. Improved mobilization of airway secretions.
   B. Allows for oxygenation at a set mean airway pressure and ventilation with small tidal volumes at fast rates.
   C. Ventilation is a completely passive process.
   D. Preservation of spontaneous breathing.
   E. Due to the sustained mean airway pressure, the effect on venous return is less than conventional ventilation.

6. Which of the following statements is true regarding adjunctive therapies for ARDS?
   A. Corticosteroids have been shown to improve mortality in PARDS.
   B. ECMO is most effective in patients that have been mechanically ventilated at least 20 days.
   C. Nitric oxide therapy improves oxygenation and reduces ventilator days in PARDS.
   D. Prone positioning may transiently improve oxygenation and has shown improved survival in adult ARDS.
   E. The use of surfactant therapy is proven to benefit patients with lymphoblastic leukemia who develop PARDS.

7. A 3-year-old male develops progressive PARDS after sepsis from an intra-abdominal infection. The patient is on HFOV with a mean airway pressure of 30 cm H_2O, 7 Hz, and an amplitude of 90. The patient is on 75% FiO_2 with saturations of 82%. Arterial blood gas result: pH 7.35, PCO_2 70 mmHg, and PaO_2 40 mmHg
   The most appropriate intervention would be to:
   A. Increase the mean airway pressure to improve oxygenation while making considerations for ECMO
   B. Decrease the hertz to improve ventilation
   C. No changes
   D. Increase the FiO_2 and make no other changes
   E. Increase the mean airway pressure and give surfactant

8. A 22-month-old has progressed to PARDS after pneumonia. He has just been escalated on his ventilator support. He is on pressure-regulated volume control with a tidal volume of 6 mL/kg and a PEEP of 12 cm H_2O and has resulted in a mean airway pressure of 17 cm H_2O. He is on 55% FiO_2. His most recent ABG showed a pH of 7.29, a $PaCO_2$ of 65 mmHg, and a PaO_2 of 50 mmHg. He is on no vasoactives, and he is 1000 mL positive for the last 48 h. Which of the following is most correct?
   A. His oxygenation index is 19. Ventilation should be increased by increasing the tidal volume.
   B. His oxygenation index is 11. He has moderate PARDS, and no changes are needed.
   C. His oxygenation index is 19. He has severe PARDS and should be started on diuretics.
   D. His oxygenation index is 19. The patient has moderate PARDS and should be started on nitric oxide.
   E. His oxygenation index is 11. He has moderate PARDS, and PEEP should be increased to 14 cm H_2O.

Learning Objectives

- Describe the differences between negative and positive pressure ventilation.
- Describe the effects of positive pressure ventilation on the respiratory system.
- Describe the effects of positive pressure ventilation on preload and afterload.
- Describe how the main ventilation characteristics impact oxygenation.
- Describe how the main ventilation characteristics impact ventilation and CO_2 clearance.
- Describe the differences between pressure and volume modes of ventilation.
- Detail the mechanisms of ventilator triggering.
- Detail the different methods of ventilator cycling.
- Describe the methods of delivering assisted breaths.
- Understand how to determine the main ventilator settings.
- Describe the benefit and risk of the patient's spontaneous contribution during mechanical ventilation.
- Describe ventilator strategies to minimize ventilator-induced lung injury and diaphragm dysfunction.
- Detail weaning strategies and extubation readiness assessment.
- Describe the monitoring of mechanical ventilation.

12.1 Introduction

Respiratory failure is one of the main reasons for admission to a pediatric intensive care unit (PICU). About half of the patients admitted to the pediatric intensive care unit (PICU) need a ventilator support. Before the 1930s, respiratory failure was uniformly fatal due to the lack of equipment and techniques for airway management and ventilator support. The use of mechanical support for respiratory failure began with negative pressure ventilation during the poliomyelitis epidemics. Technological progress over time has allowed the widespread use of positive pressure ventilation. This vital support technology has dramatically changed the outcome of pediatric respiratory failure, which now carries a low mortality rate. The performance of ventilators has improved, allowing a better control of delivered ventilation, increased safety, and the development of many ventilation modes. The complexity of the mechanical ventilation options has increased in parallel with the complexity of the PICU population, and the management of ventilator support can sometimes seem overwhelming. In that context, it is essential for the PICU clinicians to understand the functioning and the impact of conventional mechanical ventilation on the critically ill children.

This chapter reviews the main physiological features of respiratory failure and the basic principles of conventional mechanical ventilation to understand the pathophysiological impact of mechanical ventilation. Based on this background, we will describe a logical approach of the initial setup and adjustment of mechanical ventilation in children. The importance of monitoring for mechanically ventilated children will then be described.

12.2 Pulmonary Physiology and Conventional Mechanical Ventilation

12.2.1 Indications for Mechanical Ventilation and Mechanisms of Respiratory Failure

The primary goals of mechanical ventilation are the maintenance of adequate oxygenation and clearance of CO_2 from the body in the amount needed to maintain cellular homeostasis. A diverse group of disease processes, involv-

Table 12.1 Main indications and objectives for airway control and mechanical ventilation

Indications	Main objectives
Respiratory system disorders	
- Pulmonary parenchymal disease	Improvement of hypoxemia and ventilation
- Airway problems	Airway control
- Upper or lower airway obstruction	Ventilation improvement
- Respiratory muscle failure	Ventilation improvement/respiratory unloading
Cardiovascular failure	Respiratory unloading/LV afterload reduction/preload optimization
Alteration in the central control of breathing	
- Deep sedation or analgesia (i.e., postoperative period, trauma)	Control of airway and ventilation
- Altered mental status	Control of airway and ventilation

ing the respiratory, cardiovascular, and central nervous systems, may lead to respiratory failure. The primary indications for endotracheal intubation and mechanical ventilation in the PICU are described in Table 12.1. The objective of the institution of mechanical ventilation varies depending on the disease categories and the respective importance of hypoxemia, hypercarbia, hemodynamic, and neurological status.

12.2.2 Pathophysiology of Hypoxemia and Application to Mechanical Ventilation

The primary cause of hypoxemia in the PICU patients is ventilation-perfusion inequality related to acute lung injury and pulmonary parenchymal disease.

When confronted with the hypoxemic patient, understanding the etiology of hypoxemia is crucial to tailor the management of mechanical ventilation. The primary cause of hypoxemia in the PICU patient is ventilation-perfusion inequality related to acute lung injury and pulmonary parenchymal disease. Both ventilation and perfusion are not uniform in the normal lungs due to pleural pressure gradient and gravity. The ventilation-perfusion (V/Q) ratio is also not homogenous, higher in the apical and lower in the basal regions, leading to a normal global V/Q ratio of about 0.8. In acute pulmonary parenchymal disease, regions with low V/Q ratio generate hypoxemia, when the protective mechanism of hypoxic pulmonary vasoconstriction is overwhelmed.

Other mechanisms can be involved less frequently in hypoxemia: right-to-left shunt, impairment of diffusion capacity, and hypoventilation. Limitation of diffusion capacity is not frequent in acute disease but could occur in complex lung disease. Hypercapnia is usually uncommon in that context in that CO_2 diffuses much faster than oxygen and minute ventilation is normally increased by the hypoxemia-mediated ventilation response. Hypoventilation alone does not produce significant hypoxemia in a healthy lung. However, hypoxemia can occur in case of lung disease or in profound hypoventilation. Another issue that must be considered when caring for hypoxemic patients with ventilation-perfusion mismatch or true shunt is the impact of low mixed venous blood

saturation. Improvement in mixed venous oxygen saturation may also improve arterial oxygen saturation in that context.

In the setting of hypoxemia, the severity of the lung disease may be estimated by the difference between the PaO_2 and the partial pressure of oxygen in the alveoli, the A-a or alveolar-arterial oxygen gradient. The A-a gradient is normally <10 mmHg, and it reflects the integrity of the alveolocapillary membrane and effectiveness of gas exchange. Widened gradient is observed in case of hypoxemia due to V/Q mismatch, diffusion limitation, and shunt, whereas it is normal in case of hypoventilation. Several indices are also used to diagnose and assess the severity of pediatric acute respiratory distress syndrome (PARDS). The oxygenation index (OI = mean airway pressure × FiO_2/PaO_2 × 100) and the ratio of the PaO_2 to FiO_2 (P:F ratio) are both associated with PARDS severity and mortality, and both require an arterial blood gas. In absence of arterial blood gas, the noninvasive oxygenation saturation index (OSI = mean airway pressure × FiO_2/SpO_2 × 100) and SpO_2 to FiO_2 ratio (S:F ratio) can be used as good alternatives of OI and P:F ratio, respectively, provided a SpO_2 of 97% or lower.

Mean airway pressure is the primary determinant of oxygenation, FiO_2 being the second evident determinant. Mean airway pressure can be calculated as the area under the curve of the pressure-time curve. It is therefore mainly determined by the positive end-expiratory pressure (PEEP), the peak inspiratory pressure (PIP), and the inspiratory time. Increasing the mean airway pressure by manipulation of any of these variables will recruit alveoli, improve ventilation-perfusion matching, and decrease intrapulmonary shunting. In addition, increasing mean airway pressure may also result in a significant improvement in respiratory compliance, thereby allowing lower driving pressure (difference between inspiratory and expiratory pressures) to obtain a similar tidal volume, as illustrated in Fig. 12.1.

Mean airway pressure is the primary determinant of oxygenation. It is mainly determined by the positive end-expiratory pressure (PEEP), the peak inspiratory pressure (PIP), and the inspiratory time.

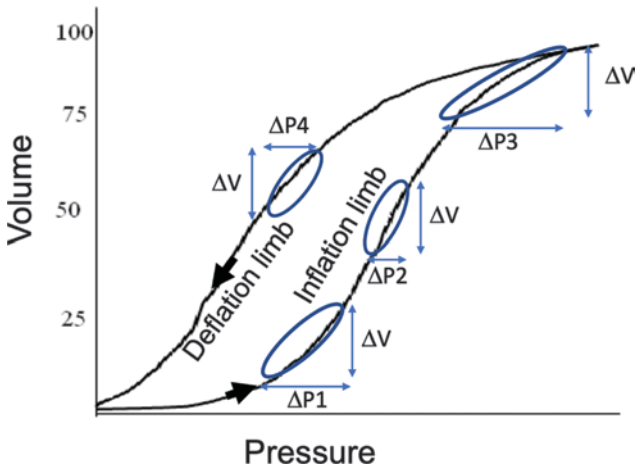

Fig. 12.1 Schematic representation of the respiratory pressure-volume curve. The larger curve represents the entire excursion of the lung volume from a pressure of zero to a maximal pressure. The smaller loops illustrate pressure-volume curves generated with similar and physiologic tidal volumes (ΔV), at different levels of PEEP. The respiratory system compliance (ΔVolume/ΔPressure) can be illustrated as the local slope of the pressure-volume curve. The compliance decreases at each extreme of the ascending limb of the curve, reflecting the overinflation (right extreme, loop 3) and the atelectasis (left extreme, loop 1), as illustrated by the larger ΔPressure observed for similar ΔVolume. The fourth small loop illustrates the interest of ventilating the lung on the deflation limb of the pressure-volume curve, with both a good compliance (relatively small ΔP4) and a large lung aeration, while the level of pressure is smaller than for the loop 1. To go from loop 2 to loop 4 requires a recruitment maneuver

The restoration or preservation of functional residual capacity (FRC) above the closing capacity (CC, the volume at which small airway closure occurs during expiration) is critical in the maintenance of a normal V/Q ratio.

The restoration or maintenance of functional residual capacity (FRC) above the closing capacity (CC, the volume at which small airway closure occurs during expiration) is critical in the maintenance of a normal V/Q ratio. Conditions that decrease FRC below CC (or increase CC above FRC) result in a maldistribution of ventilation-perfusion and adversely affect the mechanics of breathing (► Box 12.1). In conditions associated with a decreased FRC (i.e., pulmonary edema, pneumonitis, PARDS), increasing PEEP is the most logical measure to increase FRC (see below for a full discussion regarding PEEP). In situations associated with increased CC (i.e., bronchiolitis, reactive airway disease), strategies to reduce CC should also be considered (i.e., etiological treatment, bronchodilators, secretions clearance).

Box 12.1 Factors affecting functional residual capacity and closing capacity

Reduced functional residual capacity:

- Acute lung injury/acute respiratory distress syndrome (ARDS)
- Near drowning
- Acute pneumonia
- Pulmonary edema
- Radiation pneumonitis
- Atelectasis
- Supine position
- Abdominal distention
- Obesity

Increased closing capacity:

- Bronchiolitis
- Asthma
- Bronchopulmonary dysplasia
- Smoke inhalation with thermal injury to airway
- Cystic fibrosis
- Tracheomalacia
- Infancy

12.2.3 Pathophysiology of Ventilation Failure (Hypercarbia) and Application to Mechanical Ventilation

The $PaCO_2$ is the result of the equilibrium between CO_2 clearance (by the ventilation) and the body's production of CO_2. In most clinical circumstances, the control of $PaCO_2$ will rely on the control of the minute ventilation, defined as RR times V_T.

One major aim of mechanical ventilation is to provide minute ventilation (respiratory rate [RR] x the tidal volume [V_T]) that is adequate for CO_2 removal. The $PaCO_2$ is the result of the equilibrium between CO_2 clearance (by the ventilation) and the body's production of CO_2 during the energy metabolism. In most clinical circumstances, the control of $PaCO_2$ will rely on the control of the minute ventilation. However, some control of the body's endogenous CO_2 production is possible through the increase in the use of fats versus carbohydrates for nutrition, avoidance of overfeeding, or by control of body temperature. Sedation, prevention of hyperthermia, and even induction of mild hypothermia can also facilitate the control of hypercarbia and limit mechanical ventilation requirements.

Although minute ventilation is defined as RR times V_T, not all of the V_T is involved in effective gas exchanged. That part of V_T that does not participate in gas exchange is referred to as physiologic dead space. Total or physiologic dead space is composed of anatomic dead space (that area of the conducting areas or the trachea and bronchi that do not participate in gas exchange)

and alveolar dead space (those alveoli which are ventilated but not perfused). In the healthy state, the alveolar dead space is minimal so that anatomic and physiologic dead space are approximately the same. Although anatomic dead space, representing approximately 30% of a normal tidal breath or 150 mL in an average-sized adult, does not generally change regardless of the disease process, alveolar dead space may change significantly in patients with pulmonary parenchymal disease, with pulmonary vascular disease, or with changes in cardiac output resulting in alterations in pulmonary perfusion. The latter principle is clearly demonstrated by the abrupt decline in end-tidal CO_2 ($ETCO_2$) that occurs with cardiac arrest, a decrease in cardiac output, or pulmonary embolism. Of note, anatomic dead space tends to augment with younger age.

Dead space ventilation (V_D) refers to ventilation that does not participate in gas exchange. Since the anatomic dead space is relatively constant in patients with healthy lungs, increasing the V_T decreases the ratio of V_D to V_T. In effect, the increased V_T increases alveolar ventilation. It is also the case in most patients with mild to moderate lung disease that alveolar dead space is relatively fixed and that changes in V_T primarily affect alveolar ventilation. Thus, in most cases, a 10% increase in V_T will result in a greater than 10% improvement in effective minute ventilation, such that small increases in V_T are more effective at ventilating than the same proportionate increases in rate. However, in some patients with severe lung disease, ventilation of poorly perfused regions of the lungs (alveolar V_D) can be significant. In this setting, increases in V_T may not decrease V_D/V_T since higher alveolar pressures as a result of larger V_T may result in a further decrease in pulmonary perfusion and increase in alveolar V_D. An estimation of the effect of changes in V_T on V_D/V_T in such clinical scenarios can be provided by estimating V_D/V_T using capnography with $ETCO_2$ measurements. The alveolar dead space fraction (AVDSf) can be estimated using the following equation:

Dead space ventilation (V_D) refers to ventilation that does not participate in gas exchange.

$$\text{AVDSf} = \left(\text{PaCO}_2 - \text{P}_{\text{ET}}\text{CO}_2\right) / \text{PaCO}_2 \quad \left(\text{P}_{\text{ET}}\text{CO}_2 = \text{end} - \text{tidal}\,\text{PCO}_2\right)$$

The alveolar dead space fraction is an important severity marker and is dependently associated with mortality in pediatric acute respiratory distress syndrome.

We can summarize that a change in the metabolic rate with an alteration in CO_2 production, a change in minute ventilation (RR or V_T), or a change in V_D may affect $PaCO_2$. Importantly, ventilation to normocarbia is not necessary and may in fact be harmful, especially in patients with severe lung disease. Current practice includes the use of permissive hypercarbia. The Pediatric Acute Lung Injury Consensus Conference (PALICC) recommended maintaining pH 7.15–7.30 within lung protective strategy in moderate to severe PARDS, except in patients with intracranial hypertension, severe pulmonary hypertension, select congenital heart disease lesions, hemodynamic instability, or significant ventricular dysfunction.

12.2.4 Impact of MV on the Respiratory and the Cardiovascular Systems

Although a lifesaving technology, mechanical ventilation may also have a negative impact on the respiratory system. Ventilation-induced lung injury (VILI) originates from several mechanisms, including volutrauma (the injury caused by alveolar overdistention), atelectrauma (injury due to repeated opening/closure of lung units), barotrauma (consecutive to elevated transpulmonary pressures), and biotrauma (following the release of mediators that can aggravate preexist-

Ventilation-induced lung injury (VILI) originates from several mechanisms, including volutrauma, atelectrauma, barotrauma, and biotrauma.

ing lung injury). A review about VILI incidence and mechanisms is beyond the scope of this chapter. However, it is important to acknowledge that although there is clinical evidence that VILI exists in the pediatric population and that protective lung volume ventilation should be recommended, it remains a field which has been much less studied than in adults. In particular, no large randomized controlled trial assessing the impact of low V_T has been conducted in the PICU. Most components of the ventilation strategy in pediatric patients are therefore based on concepts originating from studies conducted in the adult population. This is particularly important since experimental animal data tends to suggest that the pediatric population may be less sensitive to VILI mechanisms.

Complete assistance by mechanical ventilation, with suppression of the spontaneous respiratory activity, is associated with a rapid diaphragm dysfunction (ventilation-induced diaphragm dysfunction, VIDD).

One goal of mechanical ventilation is to support the respiratory muscles in case of respiration failure, usually associated with a high work of breathing and a risk of diaphragm fatigue. It is, however, clear that complete assistance, with suppression of the spontaneous respiratory activity, is associated with rapid diaphragm dysfunction (ventilation-induced diaphragm dysfunction, VIDD). In adult populations, decreased diaphragm force and atrophy of diaphragm fibers are observed as early as in the first 24 hours and deteriorates further in the absence of spontaneous breathing activity. The dynamic of VIDD in the PICU has been less extensively studied, although diaphragm atrophy has also been reported in infants. The diaphragmatic force is one major factor of extubation success, and maintaining diaphragm function and activity should therefore be an important focus during mechanical ventilation. Importantly, the clinical assessment of the patient breathing activity during mechanical ventilation is not easy. Physiologic studies based on monitoring of esophageal pressure or diaphragm electrical activity have shown that blunted respiratory drive is highly prevalent in the PICU, even at very low levels of support and when the clinical team thought that the patient was actively breathing.

12

Pulmonary vascular resistance is increased when the lung is collapsed and is minimized (optimized) when the lung is inflated to normal functional residual capacity.

The effects of mechanical ventilation on the cardiovascular system are complex and highly dependent on a patient's underlying condition. The basic hemodynamic effects of mechanical ventilation are as follows. During positive pressure ventilation, the output of the right ventricle decreases during inspiration while at the same time, the output of the left ventricle increases. The opposite occurs during a spontaneous or negative pressure breath; right ventricular output transiently increases, and left ventricular output decreases. The effects on left ventricular output are felt to be primarily a consequence of changes in afterload. A positive pressure breath decreases left ventricular transmural pressure, while a negative pressure breath does the opposite, increasing LV transmural pressure. Overall, positive pressure ventilation often results in decreased cardiac output due to decreases in systemic venous return and LV preload and an increase in RV afterload. The effects of positive pressure ventilation on preload are most frequently not wanted, and they may be compensated by increasing intravascular volume through fluid loading. Preload reduction may, however, be a positive effect in patients with fluid overload or congestive heart failure. Patients with normal cardiovascular function can tolerate the effects of positive pressure ventilation with little compromise in the absence of dehydration or intravascular volume depletion. However, the initiation of positive pressure ventilation in the face of hypovolemia, including warm septic shock, can have catastrophic hemodynamic consequences, and one should always be ready to volume load such patients at the time of intubation. Patients with cavo-pulmonary anastomosis who are dependent on passive pulmonary blood flow can be highly sensitive to the application of positive pressure ventilation due to decreased systemic venous return and pulmonary blood flow.

The normal pulmonary vascular bed has low pressure and resistance. Critical illness and especially pulmonary disease can increase pulmonary vascular resistance (PVR) through hypoxic vasoconstriction, acidemia, and the release

of vasoactive mediators. Variables relating to lung inflation may also affect pulmonary vascular resistance through maintenance of normal lung volumes, ventilation-perfusion matching, and minimizing hypoxemia. Pulmonary vascular resistance is increased when the lung is collapsed and is minimized (optimized) when the lung is inflated to normal functional residual (FRC) capacity. The increased PVR at low lung volumes is a result of the combination of hypoxic pulmonary vasoconstriction and some compression of extra-alveolar blood vessels. With lung inflation, the extra-alveolar vessels are held open by adjacent connective tissue. If the lung is inflated much above normal FRC, pulmonary vascular resistance increases as a result of the compression of the alveolar capillary bed within overdistended alveoli. From a purely mechanical perspective, the initiation of positive pressure ventilation with high levels of PEEP can result in decreased cardiac output by virtue of both mechanisms: decrease in systemic venous return and increased pulmonary vascular resistance. These effects are well tolerated in the presence of normal RV function but may be significant in the patient with RV dysfunction or single ventricle with the absence of a right-sided pumping chamber. To the extent that the institution of positive pressure ventilation with therapeutic levels of PEEP can result in the correction of hypoxemia and respiratory acidosis, these beneficial effects on right ventricular performance can counteract the negative mechanical effects. Thus, even in the patient with severe RV dysfunction or Fontan physiology, improving oxygenation and ventilation with the normalization of functional residual capacity can result in decreased PVR and improved cardiac output.

The initiation of positive pressure ventilation with high levels of PEEP can result in decreased cardiac output by virtue of both mechanisms: decrease in systemic venous return and increased pulmonary vascular resistance.

The influence of positive pressure ventilation on the left ventricular performance is multifactorial. As mentioned above, during positive pressure inspiration, LV afterload is affected by intrathoracic pressure acting on the external wall of the LV. The transmission of positive airway pressure to the mediastinum and the external surface of the left ventricle decreases the transmural pressure of the LV, thus decreasing LV afterload. In addition, during the inspiratory phase of a positive pressure breath, LV preload is increased as the positive pressure applied to the lungs aids in emptying the pulmonary veins into the left atrium. The effect of improved LV systolic function during inspiration is most pronounced in patients with LV dysfunction. These patients also benefit from redistribution of limited cardiac output and oxygen delivery by virtue of decreased work of breathing and thus decreased need to provide oxygen for the respiratory muscle work. The proportion of cardiac output which is normally dedicated to the respiratory muscles is small, close to 5%. In case of respiratory failure (including in patients with cardiogenic pulmonary edema), the respiratory muscles consumption increases, and the proportion of cardiac output used by the respiratory system can exceed 30%. Reducing the work of breathing in these patients is therefore essential.

During positive pressure, LV preload is increased, LV afterload is decreased, and RV afterload is increased.

The complex cardiopulmonary dynamics during positive pressure ventilation can be demonstrated at the bedside through the observation of systolic pressure variation in the arterial line waveform occurring during the respiratory cycle.

12.3 Basics of the Ventilator Functioning

12.3.1 Negative Pressure Ventilation

With the poliomyelitis epidemics of the 1930s, negative pressure ventilation was introduced to support patients with neuromuscular weakness leading to acute and chronic respiratory failure. The negative pressure ventilators ("iron lungs") were large tanks into which the patient's entire body was placed (Fig. 12.2). The patient's neck was surrounded by a rubber mat with a small

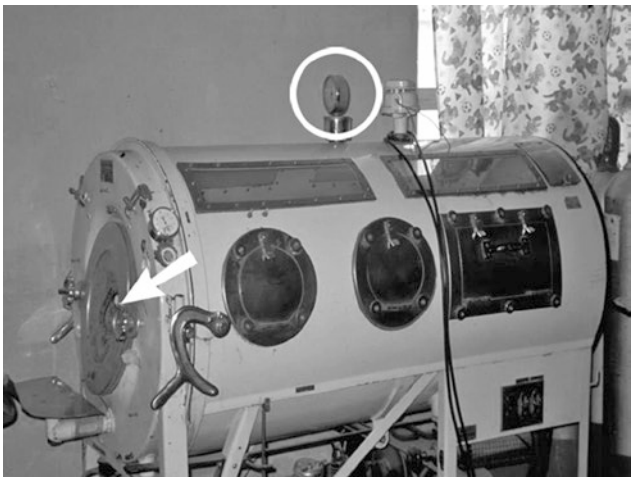

Fig. 12.2 Photograph of a negative pressure ventilator otherwise known as the "iron lung." These devices were used during the poliomyelitis epidemics of the 1930s and 1940s for the treatment of acute and chronic respiratory failure. The rubber sheet with a small opening in the middle (*arrow*) was placed over the patient's head to ensure an airtight seal. The amount of subatmospheric pressure was indicated on the pressure gauge on the top of the tank (*circle*)

opening in the center through which the patient's head protruded. The driving force was a piston located at the bottom of the tank. A downward movement of the piston caused an increase in the volume of the container, creating a negative pressure around the patient's thorax. The negative pressure resulted in the expansion of the chest wall, with air entry through the patient's airway into the lung. Although somewhat effective in patients with respiratory failure related to muscle weakness, there were significant limitations in the amount of negative pressure that could be generated, and as such, these devices were not effective in patients with significant alterations in respiratory compliance or resistance. Additionally, the devices were bulky, restricted access to the patient, and could not be used in patients with airway disease.

Iron lungs hold a place in the medical history, but negative pressure ventilation is still being used and available in the modern era. Large containers have been replaced by cuirass or vests that fit over the patient's thorax and are sealed at the waist and neck. The air within the jacket is intermittently evacuated, thereby creating a negative pressure (compared to the atmosphere). The support can be delivered as a constant negative pressure or with intermittent positive pressure cycles to facilitate exhalation. These devices could be used for home care and found their greatest use in patients with chronic respiratory insufficiency due to neuromuscular weakness but are also sometimes used in acute conditions. Negative pressure ventilation can be used alone or in combination with other type of support, like high-flow nasal cannula or noninvasive ventilation.

The advantages of negative pressure ventilation are that it does not require endotracheal intubation, it can be applied intermittently, it can be used at home without the need for tracheostomy, and it avoids the impact of positive pressure ventilation on cardiovascular system (preload reduction and right afterload increase). This may be particularly interesting in children following cavo-pulmonary anastomoses. In the postoperative setting of these surgeries, positive pressure ventilation can significantly decrease the passive pulmonary blood flow. Although the ideal strategy is to attempt early tracheal extubation, negative pressure ventilation could be an interesting alternative when extubation is not possible.

Negative pressure ventilation also has disadvantages. The delivered support is not synchronized with the patient breathing. In case of abnormal airway with inspiratory resistance, the negative pressure ventilation can exacerbate the respiratory distress. Finally, the fact that no positive pressure is applied in the airway can be perceived as better for the impact on the lung and VILI, but this is not absolutely true. Indeed, the transpulmonary pressure (difference between alveolar pressure and pleural pressure) is the variable that best reflects the lung strain and the risk of VILI. Increasing transpulmonary pressure either by a positive pressure in the alveoli (positive pressure ventilation) or by a negative pressure in the pleura (negative pressure ventilation) can both increase the lung strain and expose to the risk of VILI.

The transpulmonary pressure (difference between alveolar pressure and pleural pressure) is the variable that best reflects the lung strain and the risk of VILI. Increasing transpulmonary pressure either by a positive pressure in the alveoli (positive pressure ventilation) or by a negative pressure in the pleura (negative pressure ventilation) can both increase the lung strain and expose to the risk of VILI.

12.3.2 Positive Pressure Ventilation

As opposed to negative pressure ventilation, during positive pressure ventilation, the inspiratory flow is achieved by the increase in the airway pressure, which generates a pressure gradient from airway to the alveoli. This increases the transpulmonary pressure by increasing the alveolar pressure rather than by decreasing the pleural pressure. Positive pressure ventilation therefore requires an airway interface, mostly endotracheal tube or tracheostomy for conventional ventilation. Noninvasive positive pressure ventilation can also be delivered with a nasal, oronasal, or facial mask, nasal cannula or prongs, or a helmet. In this chapter, we focus on conventional invasive positive pressure ventilation.

When the decision has been made to initiate mechanical ventilation, the clinician will be faced with the following decisions: (a) the mode of ventilation (how the ventilator cycles are determined); (b) the controlled variable (pressure or volume) which will control the tidal breath; (c) the specific ventilator settings, including the magnitude of the controlled variable (inspiratory pressure or tidal volume), the PEEP, the inspiratory time and the ventilator rate, the trigger sensitivity, and the FiO_2; and (d) the alarm settings.

12.3.3 The Different Ventilation Modes

The era of positive pressure ventilation began with controlled mandatory ventilation (CMV) which provided intermittent positive pressure breaths to the patient without the ability to sense the patient's own respiratory efforts and no gas flow in between the ventilator breaths. This provided no means to allow the patient to breath spontaneously, resulting in significant patient-ventilator asynchrony unless deep levels of sedation or neuromuscular blockade were used. CMV was followed by intermittent mandatory ventilation (IMV) which provided a set number of breaths/min provided at a specific interval but also allowed for spontaneous ventilation through the use of a continuous gas flow or a demand valve. Despite the ability to allow spontaneous ventilation, the IMV mode did not synchronize the ventilator breath with the patient's effort, and there was no assistance during the spontaneous breaths. With the development of technology for sensing the patient's respiratory efforts, strict IMV has been replaced by modes such as assist control (AC) and synchronized intermittent mandatory ventilation (SIMV). Both AC and SIMV modes deliver a set number of mandatory ventilator "full" breaths, determined by the set respiratory frequency and the set volume or pressure, synchronized with the patient's effort. If the patient breathes above the set minimal frequency, there will be additional minute ventilation from this spontaneous ventilation.

In SIMV, the additional breaths can be allowed with no added support (SIMV alone) or can be assisted according to pressure support (SIMV-PS) or volume support (SIMV-VS) principle (see below). In assist control, every additional detected breath will lead to a full ventilator breath. The theoretical advantage of AC ventilation is that the patient receives a similar support for each breath. However, if the spontaneous respiratory frequency is excessively high or in case of auto-triggering, the risk of overassistance and of expiratory flow limitation with overdistension may be higher. Of note, those risks also exist in SIMV, and in both modes, it is essential to avoid auto-triggering and limit unnecessary tachypnea. There is also a belief that with SIMV, weaning may be facilitated by the possibility of decreasing either the frequency or the level of support. However, studies in adults rather suggest that this complexity prolongs the weaning duration.

In its earliest forms, triggering was accomplished by detecting a pressure change in the ventilator circuit (usually −1 to −3 cm H_2O). Further refinement of patient effort sensing relies on detection of flow differences between the inspiratory and expiratory limbs of the ventilator circuit (flow triggering). Available now in all new critical care ventilators, flow triggering requires less patient work and is more comfortable than pressure triggering. The trigger setting can be difficult. Setting the threshold too high may lead to failure to sense the patient's spontaneous efforts ("wasted efforts'"). Setting the trigger threshold too low (too sensitive) can lead to auto-cycling of the ventilator due to flow changes caused by cardiac oscillations, turbulence from condensation in the circuit, or a leak around the endotracheal tube. Even with modern ventilators, patient-ventilator synchronization remains a challenge, and mechanically ventilated children spend on average 27% of the time in conflict with their ventilator. An alternative mode of synchronization has been developed with neurally adjusted ventilatory assist (NAVA), in which the ventilator is triggered by the diaphragm electrical activity, a rapid signal of patient's breathing, leading to markedly improved patient-ventilator interactions. NAVA is not considered a conventional ventilation mode and will not be discussed further in this chapter.

12.3.4 The Control Variable: Volume-Controlled Ventilation, Pressure-Controlled Ventilation, and Pressure-Regulated Volume Control

The control variable (pressure or volume) is that parameter which is set to determine the magnitude of the tidal breath.

When volume-controlled ventilation is used, the peak inspiratory pressure (PIP) and plateau pressure (P_{Plat}) should be monitored as changes in PIP or P_{Plat} reflect changes in resistance and compliance of the respiratory system.

With volume-controlled ventilation, a specific V_T is set by the clinician and an inspiratory time is chosen. The flow provided is then integrated based on the tidal volume and inspiratory time. For example, if a V_T of 500 mL with an inspiratory time of 1 s is chosen, 500 mL will be delivered over 1 s using a gas flow of 30 L/min if flow is constant during the entire inspiratory phase (500 mL/1 s = 30 L/min). Commonly, a decelerating flow pattern is used such that the flow is higher in early inspiration and lower toward the end of inspiration. Volume-controlled ventilation may be best used in patients with relatively normal resistance and compliance of the respiratory system. The advantage of volume-controlled ventilation is that a constant V_T is delivered even with changing resistance and compliance. When volume-controlled ventilation is used, the peak inspiratory pressure (PIP) and plateau pressure (P_{Plat}) should be monitored as changes in PIP or P_{Plat} reflect changes in resistance and compliance of the respiratory system. The peak inspiratory pressure (PIP) is strongly influenced by the resistance of the tubing and of the airways. The plateau pressure better reflects the impact of ventilation on the poorly compliant lung.

To measure the plateau pressure, a no-flow end-inspiratory pause (0.2–0.5 s) should be applied to interrupt the flow and allow pressure equilibration in the absence of patient effort. Use of the plateau pressure eliminates the resistance imposed by the ETT and airways and thereby approximates the pressures that occur within the alveoli. Rising pressures require an investigation which should start at the ventilator and work toward the patient including a check for kinking of the circuit or endotracheal tube and obstruction to the endotracheal tube or major airways by mucus, auscultation to rule out mainstem intubation or bronchospasm, and a radiograph to evaluate for deteriorating alveolar disease (i.e., pneumonia, ARDS) or external factors impeding respiratory excursion (i.e., pneumothorax, restrictive diseases of the thorax, abdominal distention) or agitation. Increased resistance of the respiratory system can be suspected when observing a significant difference between peak and plateau pressures. In such cases, increasing inspiratory time decreases the inspiratory flow rate and can be used to decrease the PIP. However, the I:E ratio should be considered when increasing inspiratory times at high ventilator rates or in diseases with high expiratory resistance (asthma) because of the risk of insufficient expiratory time. In setting the ventilator rate, tidal volume, and inspiratory time (or peak flow), one must be aware of the dynamic interplay of these variables. If the peak airway pressure is unacceptably high, the pressure-controlled mode may be chosen, although a decrease in V_T may be a relatively equivalent solution.

Increased resistance of the respiratory system can be suspected when observing a significant difference between peak and plateau pressures.

With pressure-controlled ventilation, a preset pressure above PEEP is delivered over a selected inspiratory time. The inspiratory flow rate will be somewhat dependent upon the airway resistance and respiratory system compliance, achieving high levels initially and decelerating toward zero near the end of inspiration. Most ventilators allow manipulation of inspiratory gas flow rate through selection of the percentage of the inspiratory phase devoted to developing peak airway pressure (how quickly the plateau is achieved). Because inspiratory pressure is the controlled variable, changes in respiratory system mechanics (i.e., compliance and/or resistance) will result in changes in the delivered V_T and minute ventilation. During pressure-controlled ventilation, the delivered V_T is determined by the pressure level above PEEP (sometimes referred to as the delta pressure, ΔP, or the driving pressure), the inspiratory time, loss of V_T from a leak around an uncuffed ETT, and the patient's resistance and compliance. Because there is often flow cessation with pressure equilibration at the end of inspiration in pressure-controlled ventilation, the PIP is usually close to the plateau pressure. But significant differences can occur, especially when the inspiratory time is short or when the resistance of the respiratory system is high. It is usually considered that for a given minute ventilation, the mean airway pressure is higher and the peak pressure is lower in pressure-controlled than in volume-controlled mode, although this remains debated. An additional potential advantage is the decelerating flow pattern, which may help in the recruitment of alveoli with long time constants (pendelluft effect). This advantage must be balanced against the increased shearing forces of the high early inspiratory flow rates. Also, decelerating flow is now also used in most volume-controlled modes.

Given that the PIP is controlled, the risk of barotraumas is assumed to be less than with volume-controlled ventilation. Another potential advantage is that in case of deteriorating compliance, the V_T will automatically decrease for a given delta pressure, applying the principle of a more protective ventilation in the sickest patients. Pressure-controlled ventilation may be particularly beneficial in patients with decreased compliance or alveolar space disease such as pneumonia or ARDS since the higher mean airway pressure may improve oxygenation. On the other hand, the risk of large V_T is higher in pressure-controlled ventilation, as compared to a volume-controlled ventilation set with a low V_T.

During pressure-controlled ventilation, changes in respiratory system mechanics will result in changes in the delivered V_T and minute ventilation.

Pressure-controlled ventilation has also historically been preferentially used in neonates and small infant because of the lack of precision of V_T delivery by older ventilators. A discrepancy of a few mL is a significant issue when the set V_T is 20 mL. Now, critical care ventilators are relatively accurate to very small tidal volumes in neonatal modes.

As with volume-controlled ventilation, inspiratory time is set with pressure-controlled ventilation. Since most pressure modes are time cycled (end inspiration based on the inspiratory time), increasing the inspiratory time will increase the mean airway pressure. Increasing inspiratory time will increase the delivered V_T if inspiratory time is shorter than that required for all lung units to fill and come to pressure equilibration. This situation is different from volume-controlled ventilation where lengthening the inspiratory time may decrease the PIP but does not affect V_T. With pressure-controlled ventilation, the exhaled V_T should be monitored to assess ongoing changes in the compliance of the respiratory system. A decrease in the exhaled V_T should prompt a thorough investigation into its cause, which includes the same steps as outlined above for investigating an increase in PIP during volume-controlled ventilation.

The putative advantage of PRVC is that it combines the advantages of both variable controls: it delivers a relatively fixed V_T (as with volume-controlled) but with the advantageous flow pattern of pressure-controlled ventilation.

Pressure-regulated volume control (PRVC) is an option which combines features of both volume- and pressure-controlled ventilation. The tidal volume is set by the clinician, as with volume-controlled ventilation. However, the pressurization pattern follows the principle of pressure-controlled ventilation, with high early inspiratory flow rates, decelerating flow, and inspiratory pressure relatively constant during a given inspiration (square pressure-time curve). The key difference with pressure-controlled ventilation is that the level of inspiratory pressure is not set, but adjusted breath by breath by the ventilator. The ventilator continuously monitors the delivered inspired V_T and adjusts the next inspiratory pressure accordingly in order to deliver the prescribed title volume. As a safety feature, an internal software algorithm restricts the magnitude of pressure changes so that the patient cannot be markedly overinflated in response to rapid changes in compliance (e.g., tracheal tube kinking). The putative advantage of PRVC is that it combines the advantages of both variable controls: it delivers a relatively fixed V_T (as with volume-controlled) but with the advantageous flow pattern of pressure-controlled ventilation. However, the benefit of this mode has not been demonstrated in the PICU.

From the discussion thus far, it should be apparent that six basic types of ventilation can be considered: AC-pressure-controlled, AC-volume-controlled, SIMV-pressure-controlled, SIMV-volume-controlled, AC-PRVC, and SIMV-PRVC. These are the basic modes of mechanical ventilation used in the pediatric ICU today, and most modern ICU ventilators can provide all of these modes and options. Importantly, the advantages of the different options have not yet been evaluated nor compared in pediatric studies. Clinicians must decide based on the patient condition and the knowledge of the theoretical principle of these different options.

12.3.5 Supported Ventilation

Supported ventilation is defined as a breath that is triggered by the patient, assisted by the ventilator (volume or pressure), and cycled by the patient (the patient determines the inspiratory time). It is used with SIMV ventilation to support spontaneous breaths that occur in between ventilator breaths, or it can be used alone with no set minimal frequency usually as a means of weaning. In that situation, the patient determines the ventilator pattern (i.e., frequency, inspiratory, and expiratory times) by initiating and terminating each breath. Therefore, supported ventilation is used only in patients with an intact

ventilatory drive. The patient provides the work to trigger the breath, and then the remaining work for the breath is shared by the ventilator action and the patient's contribution.

In pressure support ventilation (PSV), once triggered by the patient's effort, the ventilator delivers a rapid and decelerating flow of gas to provide a preset pressure support level. The breath is terminated when inspiratory flow decreases to a percentage (generally 25%) of its peak value. At that point, the exhalation valve opens, and the circuit pressure returns to the expiratory pressure (PEEP). Therefore, the patient retains control of the cycle length and flow characteristics. The V_T is determined by the patient's inspiratory effort, the preset pressure support level, and the respiratory system impedance (resistance and compliance). Traditionally, PSV has been used to compensate for the supposed inspiratory work imposed by the ETT, but this belief has been challenged. Several studies have shown that even minimal levels of pressure support decrease excessively the work of breathing. Even though the internal diameter of pediatric ETTs is small, the flow generated through these tubes are too slow to induce important resistance. The resistance imposed by an ETT is in fact lower than the physiological resistance of the normal turbulent flow through non-intubated pediatric airways. However, PSV may help to compensate for an excessive work of breathing in a patient not yet ready for extubation.

Multiple methods of weaning ventilation with PSV have been used. One approach involves setting the pressure support level high enough to achieve delivery of the typical mechanical tidal breaths (8–10 mL/kg) with no backup SIMV rate and then gradually decrease the pressure support down till extubation criteria are met. Another method involves the combined use of SIMV and PSV in which the pressure support during assisted breaths is set to a minimal level, and the SIMV rate is gradually decreased.

In volume support ventilation (VSV), the supported breaths are triggered and cycled off in a similar way as during PSV. However, the level of pressure assist is not set but regulated by the ventilator to deliver the preset volume, provided that a maximum pressure limit is not exceeded. This mode therefore combines the theoretical benefits of PSV with the capability of providing a guaranteed minimum volume.

12.3.6 How to Set the Control Variable (Tidal Volume or Delta Pressure)

It has become increasingly clear over the last 20–30 years of mechanical ventilation that setting the mechanical ventilator to achieve "normal" values for pH and $PaCO_2$ can cause harm. While this is of utmost importance for nonhomogeneous injured lungs (e.g., ARDS), the principles extend even to those with seemingly healthy lungs. Given the discussion above on dead space ventilation, it may seem more efficient to prioritize increasing V_T to normalize pH, particularly in circumstances where alveolar dead space is increased. However, the use of supraphysiologic V_T (or pressure) has been clearly implicated in the pathogenesis of ventilator-induced lung injury, either further harming an already damaged lung or inducing injury in previously healthy lungs. While there is evidence that pediatric patients (and animals) are less sensitive to high-tidal volume ventilation than adult patients (and animals), we believe that it is still important to stay in or below the resting physiologic range of tidal volume (generally 5–8 ml/kg based on predicted body weight) and consider using lower than this (3–6 ml/kg) for children with more severe impairments in lung compliance.

Setting the mechanical ventilator to achieve "normal" values for pH and $PaCO_2$ can cause harm.

While there is some evidence that pediatric patients (and animals) are less sensitive to high-tidal volume ventilation than adult patients (and animals), it is still important to stay in or below the resting physiologic range of tidal volume (generally 5–8 ml/kg based on predicted body weight) and consider going lower than this (3–6 ml/kg) for children with more severe impairments in lung compliance.

Of course, the tidal volume cannot be decoupled from the ventilator pressures, particularly the delta pressure (peak pressure, PEEP) which is either set (in a pressure control mode) or achieved (in volume set modes). This is because the underlying disease state of the patient alters respiratory system compliance and airway resistance, which in turn affects the pressure-volume relationship. In truth, the mechanisms of injury to the lung are largely dependent on regional transpulmonary pressure gradients and regional tidal volume. The transpulmonary pressure reflects the alveolar pressure minus the pleural pressure (which may be increased if the chest wall compliance is poor), either at end exhalation or end inspiration. We can estimate the alveolar pressure using airway pressure under static conditions (no flow), both at end inspiration (plateau) and end expiration (PEEP). The pleural pressure is more difficult to measure in routine practice but can be estimated with esophageal pressure using a variety of assumptions. However, airway pressure, esophageal pressure, and V_T are estimating what is happening in the respiratory system in general. There may be marked variation in regional pressures and volumes, which ultimately may lead to lung injury.

As a general principle, peak inspiratory pressure is increased under circumstances of impaired lung compliance, impaired chest wall compliance (or increased chest wall elastance), and increased airway resistance. The risk of barotrauma and VILI is most closely tied to the transpulmonary pressure at end inspiration under static conditions, estimated by the plateau pressure minus the pleural (or esophageal) pressure and the transpulmonary driving pressure [(Pplat-P_{Es}plat) – (PEEP-P_{Es}PEEP)]. If the peak pressure is high from increases in airway resistance (such as asthma), then there will be a larger gradient between the peak and plateau pressure as the peak pressure applied during airflow is not all being transmitted to the alveoli. In contrast, if the peak pressure is high from decreased chest wall compliance (such as chest wall edema from fluid resuscitation), the plateau pressure will also be high, but some of that plateau pressure is being dissipated across the chest wall to move it out of the way. As a result, the transpulmonary driving pressure will be lower than the set ventilator driving pressure. These principles are crucial to remember when selecting pressure and volume targets for individual patients as they must be linked to the underlying respiratory system physiology. While pediatric specific evidence is weak, the general consensus is that plateau pressure should be limited to 28 cm H_2O, although there is not clear evidence for this particular target. This can be higher (up to 32 cm H_2O) if there is thought to be significant impairment in chest wall compliance (if a direct estimate of pleural pressure like esophageal manometry is not available). However, the risk of VILI is probably more closely tied to the driving pressure (plateau-PEEP), although there are no clear pediatric specific recommendations regarding optimal limits of this pressure. Adult data has advocated driving pressure targets less than 15 for clinical practice.

While pediatric specific evidence is weak, the general consensus is that plateau pressure should be limited to 28 cm H_2O, although there is not clear evidence for this particular target. This can be higher (up to 32 cm H_2O) if there is thought to be significant impairment in chest wall compliance.

Setting the optimal targets for V_T, inspiratory pressures, and ventilator rate must be individualized for patients but embrace the general principles of limiting these pressures and volumes as much as possible. This implies, particularly for patients with more severe lung disease, that normocarbia is not expected and that pH will be lower than 7.4 during the acute disease. There is no clear standard for the lower limit of "acceptable" pH, and the decisions regarding these limits need to weigh the risks of lung injury against other potential risks of low pH such as hemodynamic status and cerebral and pulmonary blood flow. This will likely mandate heavy sedation and/or muscle relaxation to suppress the patient's respiratory drive. In fact, nearly all of these recommenda-

tions regarding limiting driving, plateau pressure, and V_T are meant for the fully controlled patient. This is because when the patient is breathing spontaneously, the airway pressures underestimate the total pressure generated (sum of patient and ventilator contributions) (see section on spontaneous versus controlled ventilation).

12.3.7 How to Set the Positive End-Expiratory Pressure (PEEP)?

PEEP refers to the positive pressure applied during expiration phase until the initiation of the next breath. PEEP maintains the patency of injured lung units which may collapse during exhalation. Although physiologically accomplishing the same thing, it should be differentiated from CPAP or continuous positive airway pressure, which is the term used during spontaneous ventilation. In normal adults, the functional residual capacity (FRC, the volume at which lung recoil inward is balanced by chest wall recoil outward, obtained when no respiratory effort is ongoing and the glottis is open) and the end expiratory lung volume (EELV, the volume at which the next inspiration begins) are equal and exceed the closing capacity (CC, the lung volume at which airway closure begins to occur). Thus, spontaneously breathing healthy adolescents and adults require little PEEP to prevent atelectasis or de-recruitment. In contrast, newborns and infants younger than 1 year with their highly compliant chest wall will have an FRC that approaches and, in some cases, may be less than CC under passive (i.e., sedated or paralyzed) conditions. Infants, therefore, actively increase and maintain their EELV during spontaneous ventilation using several mechanisms: a rapid respiratory rate with short expiratory times (i.e., there is insufficient time for expiratory flows to reach zero; intrinsic or auto PEEP is present), a braking of the expiratory airflow by the laryngeal muscle contraction during exhalation (which does not occur with a tracheal tube in place) and by the persistence of diaphragm activity during expiration (tonic activity), and increased intercostal muscle tone that stabilizes the chest wall, thereby increasing elastic recoil. This active control leads to the concept of "physiologic PEEP" (typically 3–5 cm H_2O) to avoid airway closure and lung volume de-recruitment with ventilation-perfusion inequalities. Thus, sedated or intubated infants generally require the use of PEEP to overcome the loss of these dynamic compensatory mechanisms. Studies on teens and young adults demonstrated that even patients with apparently normal lungs benefit from the addition of PEEP during prolonged mechanical ventilation.

Infants actively increase and maintain their EELV during spontaneous ventilation using several mechanisms: a rapid respiratory rate with short expiratory times, a braking of the expiratory airflow by the laryngeal muscle contraction during exhalation and by the persistence of diaphragm activity during expiration, and increased intercostal muscle tone that stabilizes the chest wall, thereby increasing elastic recoil. This active control leads to the concept of "physiologic PEEP."

Higher levels of PEEP may be required in patients with alveolar space disease or other pathologic conditions that increase CC and/or decrease FRC, such as conditions associated with poor chest wall compliance (i.e., obesity, fluid overload, restrictive syndrome) or abdominal distention. Change in PEEP is frequently the first method used for regulating mean airway pressure. PEEP increases lung volume at expiration, restoring FRC and preventing the injury associated with the repetitive circle of collapse-opening-recollapse (atelectrauma). The application of PEEP also prevents airway closure during expiration, redistributes pulmonary edema fluid from alveoli to the interstitium, maintains alveolar surfactant activity, and improves ventilation to low V/Q lung units. When applied in the proper amount, PEEP should improve lung compliance so that a given change in pressure results in a greater V_T (Fig. 12.1). This positive impact of PEEP supposes an improvement in

Change in PEEP is frequently the first method used for regulating mean airway pressure.

When applied in the proper amount, PEEP should improve lung compliance.

lung aeration (prevention of lung atelectasis, reopening of non-ventilated area). However, in some patients with very severe parenchymal disease or with heterogeneous disease (complete atelectasis), the PEEP may not be sufficient to reopen the non-aerated area while being sufficient to over-distend the aerated lung segments. In these conditions, PEEP can be counterproductive and be associated with a worsening of lung compliance and of dead space ventilation. Other side effects of excessive PEEP include the depression of cardiovascular function and increase in pulmonary vascular resistance.

Several different methods of determining the optimal PEEP for patients with parenchymal lung disease have been suggested. Lung imaging (i.e., chest X-ray, tomodensitometry, lung ultrasound) can help to evaluate the expansion and aeration of the lung fields. Identification of lower and upper inflection points on the sigmoidal pressure-volume curves has also been used to determine the pressure window between overdistension and atelectasis, but it has been progressively abandoned because of its technical challenge and poor reproducibility. Titration maneuver of PEEP has been described, aiming to determine the opening pressure and the closing pressure, based on the optimal lung compliance. The monitoring of esophageal pressure may also help to determine the PEEP needed to overcome the pleural pressure during expiration, preventing the occurrence of expiratory negative transpulmonary pressure and its risk of lung segment collapse. Finally, FiO_2/PEEP grids are simple tools to guide the PEEP management based solely on the oxygenation requirements. All these methods have been studied primarily in adults, and none of them has been proven superior to simple grids. Evidence in pediatric patients is even more limited. The Pediatric Acute Lung Injury Consensus Conference (PALICC) recommended moderately elevated levels of PEEP (10–15 cm H_2O) in patients with severe PARDS, titrated to the observed oxygenation, markers of oxygen delivery, respiratory system compliance, and hemodynamic response. PEEP levels greater than 15 cm H_2O may be needed for severe PARDS although attention should be paid to limiting the plateau pressure.

Several different methods of determining the optimal PEEP for patients with parenchymal lung disease have been suggested. All these methods have mostly been studied in adults, and none of them has been proven really superior to simple PEEP/FiO_2 grids. Evidence in pediatric patients is even more limited.

The use of PEEP is also discussed in patients with serious airflow obstruction and resulting high intrinsic PEEP. In this condition, the patient's respiratory effort needs to overcome the intrinsic PEEP before inducing a pressure or flow change in the endotracheal tube, leading to marked patient-ventilator asynchrony by triggering delay or wasted efforts. The addition of PEEP in that context can improve ventilator triggering, although application of excessive levels of PEEP may dangerously increase FRC. A logical approach is to use levels of PEEP somewhat below the level of measured auto-PEEP (e.g., 80% of auto-PEEP) to facilitate triggering and to avoid increasing the already markedly elevated FRC.

12.3.8 How to Set the Respiratory Rate and Inspiratory and Expiratory Times?

The rate is commonly set primarily based on the patient's age, the desired $PaCO_2$ level, and the V_T that is delivered. In patients with severe lung injury, higher rates are frequently needed to compensate for lower V_T. In patients with less severe lung injury, higher rates and lower tidal volumes may not always be the most appropriate approach since dead space is relatively constant, causing the ratio of dead space to tidal volume (V_D/V_T) to increase as V_T is decreased. Guidelines for starting ranges of respiratory rates include 12–15 breaths/min for an adolescent, 15–20 breaths/min for an older child (6–10 years of age), 20–30 breaths/min for a toddler, and 30–40 breaths/min for a neonate. Higher rates may be needed in patients with more severe degrees of lung injury, when

hyperventilation is used to treat increased intracranial pressure or pulmonary hypertension or if endogenous CO_2 production is elevated. As previously mentioned, one may be able to limit rate since ventilation to normocapnia is frequently not required in most conditions with the permissive hypercapnia concept.

Depending on the type of ventilation (pressure-controlled or volume-controlled), the effect of changing the inspiratory time has different effects.

The setting of inspiratory time and inspiratory/expiratory ratio (I:E ratio) is frequently overlooked. Depending on the type of ventilation (i.e., pressure-controlled or volume-controlled), the effect of changing the inspiratory time has different effects. With pressure-controlled ventilation, lengthening out the inspiration time will increase the V_T in cases where the inspiratory time is shorter than that required to achieve filling of lung units with the highest time constants. More importantly, the inspiratory time along with PEEP and PIP determines the mean airway pressure. Lengthening the inspiratory time increases the mean airway pressure and will commonly increase oxygenation. Lengthening the inspiratory time can also be used as a therapeutic maneuver to help recruit alveoli with long time constants and help the resolution of atelectasis. With volume-controlled ventilation, change in inspiratory time has little impact on the V_T. Increasing inspiratory time helps to decrease the inspiratory flow rate and thereby reduce the PIP, especially in cases where airway resistance is significant. Depending on the ventilator, the inspiratory time may be set as a fixed time, by adjusting the inspiratory flow rate, as an I:E ratio, or as a percentage of the respiratory cycle. If the I:E ratio or the inspiratory percentage of the respiratory cycle is set, change in respiratory rate affects the actual inspiratory time. Since such changes could result in changes in the peak airway pressure during volume-controlled ventilation or V_T during pressure-controlled ventilation, most ventilator manufacturers have abandoned this practice. If the inspiratory time is fixed, increases in respiratory rate can result in an increase of the I:E ratio and sometimes an inverse of the I:E ratio, especially in cases of auto-triggering or when the patient has a rapid spontaneous ventilation.

During normal spontaneous ventilation, I:E ratio is 1:3 or 1:4. During conventional ventilation with AC, SIMV, or PRVC ventilation, the inspiratory time is preset during the ventilator-programmed breaths as opposed to supported breaths where the patient sets the inspiratory time. In clinical practice, the use of rate and inspiratory time is very variable. Some centers choose to use inspiratory times as low as 0.3–0.5 s for infants and up to 0.7–1 s in adolescents. Other centers commonly used lower rates and longer inspiratory times for all age groups, but it should be kept in mind that non-physiologic long inspiratory times may induce patient-ventilator asynchrony (cycling off delay), which can be uncomfortable.

The underlying disease process should also be considered. Relatively longer inspiratory times can be considered in patients with alveolar space disease and poor compliance to increase mean airway pressure and improve oxygenation. In usual practice, most clinicians restrict the inspiratory time to limit the I:E ratio at 1:1. Reversal of the I:E ratio has been used in the management of patients with severe ARDS in attempts to augment oxygenation and allow weaning of the FiO_2; however, this practice is less frequently used since the PEEP can achieve a similar results on mean airway pressure with more physiological timing. In heterogeneous lungs, prolongation of inspiration facilitates the recruitment of alveoli with long time constants (high resistance and low compliance), encourages collateral ventilation via pores of Kohn and canals of Lambert, reverses atelectasis, and improves matching of ventilation and perfusion. Importantly, the reversal of the I:E ratio may result in inadequate exhalation times, a risk that is exacerbated in case of significant spontaneous ventilation. This may result in air trapping, the stacking of one breath on another (inspira-

tion for the next breath starts before exhalation is completed), thereby resulting in auto-PEEP. An evaluation for the presence of auto-PEEP can be performed by holding the ventilator breath at the end of exhalation. When performing this maneuver, one will observe that the airway pressure will initially be equivalent to the set level of PEEP. However, when the ventilator expiratory valve closes at the end of the expiratory time, the pressure measured in the circuit will then rise above the PEEP (= auto-PEEP) because of the exhalation of the air which was "trapped" within the lung due to the insufficient length of the expiratory phase. Auto-PEEP can also be suspected when looking at the expiratory limb of the flow-time curve on the ventilator. At the end of exhalation prior to the next breath, end expiratory flow that has returned to zero generally indicates a relatively complete exhalation (i.e., absence of significant auto-PEEP).

In patients with bronchospasm and air trapping, a focus on expiratory time is important, favoring prolonged expiration to prevent air trapping. However, a common mistake is to overlook the inspiratory time in these patients with very compliant lungs but very high airflow resistance. Increased airway resistance is an inspiratory as well as an expiratory problem. Shortening inspiratory time may lead to poor distribution of inspiratory volume with failure to involve large areas of lung in gas exchange.

Most ventilators allow the addition of an end-inspiratory pause, which can be set as an absolute time or as a percentage of inspiratory time or cycle time. It can also simply be the result of the flow rate settings. The inspiratory pause holds the inspiratory volume at the end of inspiration without ongoing gas flow. This maneuver also aims to promote the recruitment of alveoli with long time constants which are secondarily filled by the air that had previously reached the alveoli with short time constants (pendelluft effect). During volume-controlled ventilation, the inspiratory pause is associated with a typical decrease on the pressure-time curve, from the peak pressure to a plateau pressure, immediately before the expiratory drop to the PEEP. During pressure-controlled ventilation, this pattern is not observed (squares pressure-time pattern), although this does not imply that the inspiratory pressure is equivalent to a plateau pressure (the flow rate is frequently not zero). To accurately measure the plateau pressure as a reflection of the lung compliance, removing the resistance component with a zero-flow condition is essential. An inspiratory hold should be manually applied (0.5 second) while the patient has no activity (i.e., deep sedation or paralysis), and the resulting pressure at the end of the pause can be recorded as the plateau pressure.

12.3.9 Balancing the Contribution of the Patient to the Ventilation: Benefit/Risk of Spontaneous Breathing

Maintaining spontaneous ventilation with diaphragm contraction in a physiologic range during the course of mechanical ventilation may prevent ventilation-induced diaphragm dysfunction (VIDD).

For the patient with respiratory failure, there is an important balance to attempt to maintain between controlled and spontaneous ventilation. With improvements in noninvasive ventilation as well as modern modes of ventilation to synchronize with the ventilator, increasingly, patients are being maintained with spontaneous ventilation. Maintaining spontaneous ventilation with diaphragm contraction in a physiologic range during the course of mechanical ventilation may prevent ventilation-induced diaphragm dysfunction (VIDD). This is crucial because diaphragm dysfunction is thought to occur in up to 40% of mechanically ventilated patients, results in more difficulty weaning from mechanical ventilation and higher rates of extubation failure, and is associated with higher post-ICU mortality. While there are several risk factors for VIDD which are related to the underlying disease state of the patient and medication choices, higher degrees of controlled ventilation, higher ventilator driv-

ing pressures, and low diaphragm contractile activity are highly implicated in VIDD. Beyond its impact on the respiratory muscles, the patient's contribution to the ventilation also has theoretical advantages for lung recruitment, for the ventilation of lung-dependent zones, for improving the ventilation-perfusion ratio, and for the sedation requirements.

On the other hand, there is increasing evidence to suggest that patients with severe lung injury can exacerbate the lung injury with spontaneous breathing, even when they are not being ventilated (patient self-induced lung injury or SILI). Hence, it may be prudent to interrupt this SILI cycle with fully controlled ventilation with lung protective strategies and sedation and neuromuscular blockade, especially in the sickest patients. Neuromuscular blockade, in particular with cisatracurium, has been shown to decrease mortality in adults with moderate to severe ARDS, with a variety of proposed mechanisms of action including prevention of SILI, relieving patient-ventilator dyssynchrony as a source of VILI, as well as modulating inflammation. These findings have yet to be reproduced in another cohort of adults with ARDS or in children. Thus, the findings should be interpreted with caution.

On the other hand, there is increasing evidence to suggest that patients with severe lung injury can exacerbate the lung injury with spontaneous breathing, even when they are not on a ventilator (patient self-induced lung injury or SILI).

Understanding this balance between controlled and spontaneous ventilation seems particularly important although a matter of debate. There are no data which reliably demonstrate if or when patients cross from "safe" to "unsafe" levels of spontaneous ventilation. It is highly possible that this balance strongly depends on the patient's illness severity. It seems logical to hypothesize that in the sickest patients, the risk of patient self-inflicted lung injury is particularly high, and its prevention should be prioritized, while in patients with less severe pulmonary disease, the benefits of maintaining the spontaneous ventilation may outweigh the risks associated with deep sedation and full ventilation control.

It is difficult to estimate the patient's contribution to mechanical ventilation when they are spontaneously breathing on a mechanical ventilator using only measures of airway pressure and flow. This is because the patient augments the change in airway pressure with a reduction in pleural pressure, resulting in a net larger transpulmonary pressure gradient to achieve the tidal volume. The delivered pressure indicated on the ventilator screen informs on the ventilator action but does not account for the patient contribution, leading to a risk of underestimation of the actual transpulmonary pressure. The use of continuous measures of esophageal pressure, as a reflection of the pleural pressure, can probably help to estimate the net total transpulmonary pressure shared between the patient and the ventilator. The utility of this monitoring is currently under evaluation. More details on esophageal pressure monitoring are provided in the monitoring section below. The patient ventilatory drive can also be estimated using the continuous recording of diaphragm electrical activity (Edi). Using a specific nasogastric tube equipped with an array of microelectrodes, some ventilators can continuously provide the level of Edi. The Edi reflects the patient ventilatory drive (not the mechanical action of the diaphragm) and is closely related to the output of the brain stem respiratory center. Edi monitoring has been primarily developed to control the ventilator, with the mode NAVA (neurally adjusted ventilatory assist). During NAVA, the ventilator support is triggered and proportional to the Edi signal. Beyond NAVA ventilation, the Edi monitoring can also be used to assess the patient ventilatory drive. Edi monitoring has demonstrated that children spend a large proportion of time with no spontaneous activity during conventional ventilation, even when they are thought to be spontaneously breathing by the clinical team.

12.3.10 Weaning the Mechanical Ventilation and Extubation Readiness Test

The course of MV begins with intubation and the provision of ventilator support. As the acute phase of the disease subsides, weaning begins which may take up 50% or more of the total time on assisted ventilation. The end of weaning is defined as the time at which the patient's spontaneous breathing alone can provide effective gas exchange. How this point can best be determined is unclear. At the end of weaning is extubation or the act of removal of the endotracheal tube (ETT). An extensive review on weaning and extubation readiness in pediatric patients was published in 2009. It described that there were many myths, unique practices, little consensus, and less objectivity surrounding these important pediatric critical care activities.

The length of weaning depends on a number of factors, among them fluid status. When total body water increases, lung compliance decreases due to increased lung water, chest wall, and diaphragm edema. In adults with acute respiratory distress syndrome (ARDS), patients managed with a conservative fluid regime had fewer MV days and a quicker return of normal lung function than those receiving a more liberal regime. The importance of fluid balance in children is not as clear although observational data in pediatric acute respiratory distress syndrome (PARDS) is also supportive of a conservative fluid approach. Positive end-expiratory pressure (PEEP) management is another factor that may affect the length of weaning. While institution and escalation of PEEP generally improves oxygenation in PARDS, pediatric practitioners are generally conservative in its application and infrequently change PEEP levels even after oxygenation improves. This may result in failure to recognize that the patient is actually ready for extubation. It is generally recommended that PEEP levels should be physiologic at the time of extubation ($\leq$ 5 cm H20) although extubation from higher PEEP levels may be important to maintain lung recruitment for certain types of patients (e.g., obesity). Sedation further complicates weaning and extubation. Oversedation may depress central respiratory drive, whereas undersedation can leave a child restless which can result in airway trauma from the ETT. Sedation assessment tools have been developed for this purpose which may be helpful to target a particular level of sedation, although implementation of a nurse-driven protocol to achieve these targets does not appear to have a significant impact on weaning times. Differences in diaphragmatic function may relate to longer weaning times in infants and young children. Accessory respiratory muscles are not as developed as in older children. As diaphragmatic dysfunction develops with prolonged MV, the duration of weaning can increase. Steroids may play a role in preventing extubation failure and reintubation by reducing tracheal inflammation associated with tracheal injuries from the ETT, as they do in another cause of subglottic edema in children, croup. Successful randomized controlled trials in both adults and children have started steroids 6–24 hours before extubation, whereas the unsuccessful ones have started the drug under 6 hours before extubation. A Cochrane Review on the role of steroids concludes, "Using corticosteroids to prevent (or treat) stridor after extubation has not proven effective for neonates, children or adults. However, given the consistent trend toward benefit, this intervention does merit further study." Finally, other factors are likely important to the weaning process, but there is a dearth of research in these areas, and they are not further discussed. These include cardiac function, postoperative, neurologic, and nutritional status.

Predictive Indices for Weaning. Several indices have been developed to predict success in weaning and extubation. Although these indices have been vari-

ably used in research, they have not found common use in clinical care, some because of their complexity and others due to lack of proven benefit over clinical judgment in pediatric practice.

Rapid Shallow Breathing Index (RSBI = f / V_T). The RSBI was devised by Yang and Tobin and found to be a good discriminator of weaning success and failure in adults. This test has become more widely used in adult practice and research with varying success. Some investigators have demonstrated that RSBI normalized to actual body weight (f/V_T (ml/kg)) has some predictive ability in pediatrics, although these values are often very low by the time extubation readiness testing occurs, reinforcing the concept that these should be used early in the course of weaning. Both an RSBI <8 or <11 breaths/min/mL/kg body weight have been promoted as good predictors of successful extubation.

Compliance, Respiratory Rate, Oxygenation, Pressure Index (CROP Index) [Dynamic Compliance × (PaO_2/PAO_2) × Maximal Negative Inspiratory Pressure) / Respiratory Rate]. In pediatrics, a CROP Index of >0.15 or >0.1 mL/kg body weight/breaths/min have been recommended as good predictors of successful extubation.

For both RSBI and CROP, as with adults, conflicting studies found that those indices did not reliably predict extubation outcome in children. The RSBI has become moderately popular in adult ICUs. However, since there is a wide range of age groups with different respiratory rates, it may not be a good predictor of extubation success or failure in the pediatric population. Whether age-specific f/V_T ratios would perform better is currently unknown.

Volumetric Capnography. The slope of an expired, single-breath CO2 waveform can be used to calculate the physiologic dead space (V_D/V_T) and a value <0.50 reliably predicted extubation success, whereas a V_D/V_T > 0.65 identified patients at risk for failure. Not all investigators have been able to reproduce this. Volumetric capnography requires an arterial or a capillary blood gas, and the predictive ability may depend on the types of patients studied, degree of parenchymal lung disease, and tidal volume generated.

The slope of an expired, single-breath CO_2 waveform can be used to calculate the physiologic dead space (V_D/V_T) and a value <0.50 reliably predicted extubation success, whereas a V_D/V_T > 0.65 identified patients at risk for failure.

12.3.10.1 Techniques of Weaning

Not all patients require gradual weaning.

Not all patients require gradual weaning. Both adult and pediatric studies have shown that when patients pass a spontaneous breathing test (SBT) and are subjected to an extubation readiness test (ERT), 50–75% of the patients are deemed ready to extubate and will do so successfully. Standardized weaning protocols have been promoted to minimize the time on a ventilator and provide uniform decisions about weaning. The concept of ventilator-free days as an end point is implicitly based on having a low failed extubation rate for any reason other than the original cause of respiratory failure. This standard may be inappropriate in pediatric trials since there is not only a higher rate of failed extubation in this group, but up to 40% of failures may involve upper airway obstruction (UAO). For research purposes, it may be important to define the end of successful weaning in a manner short of extubation. Overall, it is likely that a consistent approach to ventilator weaning will shorten ventilator time and result in better outcomes.

The most common approach to weaning infants and children is gradual reduction of ventilator support. Weaning with synchronized IMV (SIMV) occurs by reducing the ventilator rate. With pressure support ventilation (PSV alone or in combination with SIMV), the inspiratory pressure is initially set to provide the required support and then reduced gradually. As mentioned above, volume support ventilation (VSV) is a special form of PSV that targets a specified minimal tidal volume. Weaning with VSV is somewhat automatic in that the support level required to maintain the set tidal volume is reduced auto-

matically as respiratory mechanics improve. Its disadvantage is it may allow the patient to work harder than desired. Extubation occurs from a low level of ventilator support or after an extubation readiness test (ERT). It appears that it is common practice to extubate infants and children from a low level of ventilator support though there is no rationale for this.

A second school of thought recommends to continuously provide the ventilator support to rest the patient's respiratory muscles and to perform a daily extubation readiness test. MV is discontinued if the test is passed. This approach has been more commonly used to wean adult patients than children.

In a small number of patients, weaning is attempted with alternating periods of complete ventilator support and graded spontaneous breathing with assistance. This "sprinting" is performed on the theory that the respiratory muscles can be slowly trained to sustain complete spontaneous breathing. There is currently little evidence that such an approach is an effective way of training muscles. There are also no data comparing such an approach with more traditional approaches of weaning. A multicenter randomized controlled trial comparing three modes of weaning found that there were no significant differences between having no protocol and weaning by PSV or VSV.

12.3.10.2 Criteria for Readiness for Extubation

Readiness for extubation implies that weaning is completed, and the patient is sufficiently awake with intact airway reflexes, is hemodynamically stable, and has manageable secretions.

Readiness for extubation implies that weaning is completed and the patient is sufficiently awake with intact airway reflexes, is hemodynamically stable, and has manageable secretions. Extubation failure has been variably defined as reintubation within 24–72 hours. Tests commonly used to assess extubation readiness include testing for a leak around the ETT ("leak test") and assessing respiratory muscle strength by measuring negative inspiratory force (NIF).

Cuffed ETTs have been cited as a cause of increased UAO on extubation, but several studies have found no difference in the incidence of failed extubation over all age groups between those intubated with appropriately sized cuffed or uncuffed tubes. The leak test whereby air is heard (without using a stethoscope) to leak around the ETT at low pressure, usually <20–25 cm H_2O, is commonly used to predict UAO after extubation. However, it is neither a sensitive nor specific test. For cuffed ETTs, cuff leak fraction is calculated as (expiratory tidal volume with cuff inflated minus expiratory tidal volume with cuff deflated)/(expiratory tidal volume with cuff inflated). Evaluating uncuffed ETTs, leak percentage is calculated as the fraction (inspiratory tidal volume minus expiratory tidal volume)/(inspiratory tidal volume). In a study of 409 infants and children immediately prior to their extubation, it was found that a cuff leak fraction less than 10% or a leak pressure (with the cuff deflated) greater than 25 cm H_2O was highly associated with risk of UAO following extubation. The presence or absence of a leak was not associated with UAO for uncuffed ETT.

Negative Inspiratory Force (NIF). In the PICU, the test is usually performed quickly at the bedside with an uncalibrated manometer and with both inspiration and exhalation obstructed. The test has not been hitherto standardized nor validated in children. Nonetheless, it is reassuring if a spontaneously breathing patient has a routinely obtained NIF of at least 30 cm H_2O. Similarly, consistently low values (i.e., below 15 cm H_2O), irrespective of technique, are unlikely to be associated with successful weaning to extubation.

12.3.10.3 Impact of Endotracheal Tubes on Weaning and Spontaneous Breathing Trials

No matter how small the ETT, effort of breathing on CPAP of 5 cm H_2O best estimates post-extubation work.

Many clinicians believe that, for an infant or young child, breathing through a small ETT is akin to breathing through a straw, thereby imposing an unacceptable work of breathing. It is therefore a frequent practice to extubate children from levels of 5–10 cm H_2O PSV above PEEP in order to overcome the presumed increased effort of breathing. This notion is contrary to both clinical observation and physiology. In a large prospective trial, the pressure rate product (PRP) was measured in infants and children during preparation for extubation. PRP has been validated as a surrogate for work of breathing and is defined as respiratory rate times peak-to-trough esophageal pressure. The PRP was recorded on PSV and CPAP prior to and after extubation. No matter how small the ETT (down to 3.0 mm ID), effort of breathing on CPAP of 5 cm H_2O best estimated post-extubation work. Furthermore, the PRP on PSV was almost half the level after extubation, significantly underestimating the post-extubation effort of breathing. The reasonable conclusion from this study is that, all things being equal, if a patient cannot breathe comfortably on CPAP alone, there is little chance he or she will do so when extubated.

A further benefit of PRP is that when evaluated along with the maximum NIF, the combination of the former being >500 and the latter ≤30 cm H_2O predicts high reintubation rates of >20%. These values reflect diminished respiratory muscle strength (aPImax) in the face of high effort of breathing (PRP).

12.3.10.4 Assessment of Post-extubation UAO

Upper airway obstruction (UAO) is frequent after endotracheal extubation. Definitive data on risk factors and prevention of pediatric post-extubation UAO have been lacking. More objective measures of post-extubation UAO severity in infants and children may help identify risk factors and elucidate optimal treatment or prevention strategies. Inspiratory flow limitation is relatively specific to extrathoracic UAO, characterized by disproportionately large inspiratory effort relative to flow. The most widely accepted method to measure flow is spirometry, which, for noncooperative spontaneously breathing children, requires a tight-fitting mask over the nose and mouth. This may require sedation and results in changed flow dynamics. Respiratory inductance plethysmography (RIP) is a less invasive alternative to spirometry. With RIP, variations in the self-inductance of a coil (wires around the rib cage (RC) and abdomen (ABD)) are measured as a result of changes in the cross-sectional area of the RC and ABD. The combination of calibrated RIP and esophageal manometry has shown promise for providing both an objective measure of the severity of post-extubation UAO and also some insights into risk factors for UAO. With the addition of a pneumotachygraph on the ETT prior to extubation, RIP flow can be calibrated during 3–5 breaths of airway occlusion during an NIF procedure. This allows the construction of noninvasive flow-pressure loops from the RIP and esophageal pressure measurements (◘ Fig. 12.3).

These loops can be inspected for inspiratory flow limitation after extubation to characterize post-extubation UAO. Patients can be observed as having UAO when inspiratory flow limitation is newly observed after extubation with an increase in PRP (◘ Fig. 12.4, panel A). The reversal of inspiratory flow limitation can also be seen after the child receives a UAO-specific intervention such as racemic epinephrine, heliox, or corticosteroids. UAO can be further classified as subglottic if a jaw thrust maneuver does not reduce PRP by at least 50%.

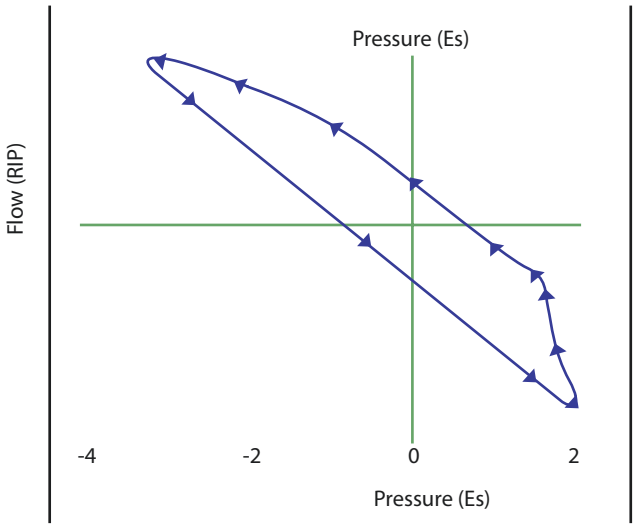

Fig. 12.3 Flow-pressure loop displaying the evolution of flow, obtained from calibrated RIP belts around the thorax and abdomen, and esophageal pressure, obtained using an esophageal balloon catheter

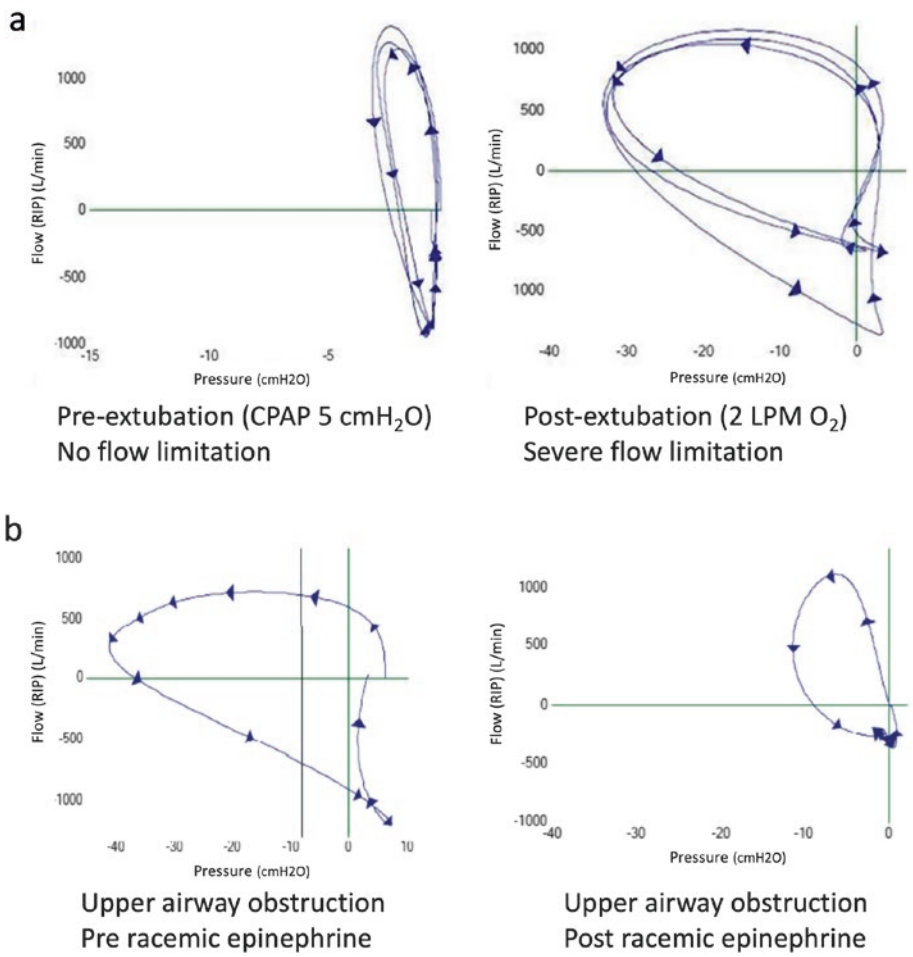

Fig. 12.4 Panel A illustrates the evolution of the flow-pressure loop as recorded in Fig. 12.3 in a 6-month-old infant before (left) and after extubation (right). The right panel shows inspiratory flow limitation after extubation due to upper airway obstruction, as denoted by the flattened flow-pressure limb above the X-axis and large negative change in esophageal pressure. The pressure rate product also increased tenfold. Panel B illustrates the evolution of inspiratory flow limitation in an infant with UAO before (left) and after racemic epinephrine (right). The narrowing of the loops illustrates the improvement in UAO

12.3.11 Role of Automation and Clinical Decision Support System

While the basic principles of lung protective ventilation have been embraced by pediatric intensive care physicians, there is still great variability in ventilator management.

While the basic principles of *lung protective ventilation* have been embraced by pediatric intensive care physicians, there is still great variability in ventilator management. Most critical care practitioners believe they are being lung protective, but it is likely that consistent, replicable decisions are not made to minimize ventilator support across the duration of mechanical ventilation for patients with lung injury. Since respiratory support is required in the majority of children in the PICU and because complications may occur with its use, it is essential to develop strategies to improve patient outcome and reduce medical errors related to mechanical ventilation. The observed variation in clinical practice is likely due in part to clinicians' low adherence to guidelines, and this is compounded because many facets of caring for a mechanically ventilated patient in the PICU lack high levels of evidence or evidence is conflicting. There is good evidence, however, that clinical decision-making with a protocol decreases practice variation between clinicians, standardizes patient care, and improves research and patient outcomes. Replicable ventilator management decisions should help decrease practice variability and directly shorten the length of mechanical ventilation for children in pediatric ICUs. A Cochrane systematic review assessing the impact of automated versus nonautomated weaning for critically ill adults and children identified 21 trials, and the meta-analysis suggested a reduction in ventilation duration and ICU length of stay, although a great heterogeneity was observed, and only two trials were conducted in pediatric ICU.

Decision support tools, both paper and electronic, have been demonstrated to improve medical care, reduce errors, and improve patient outcomes. However, paper-based protocols are dependent on caregiver availability and are often written in broad terms so they remain dependent on clinician judgment and local context for interpretation and therefore are difficult to transfer from one PICU or NICU to another intensive care unit. Paper-based tools can be difficult to follow accurately, leading to low adherence rates. Computer decision support (CDS) tools like computer-based protocols are an automated method to reduce medical errors. Such tools aim to ensure replicable, evidence-based clinician decisions for equivalent patient states and to improve protocol compliance. The tools can generate explicit recommendations that can be carried out with little inter-clinician variability while still remaining responsive to the patient's unique situation. The tools can assist clinicians by standardizing descriptors and procedures, by consistently performing calculations, by incorporating complex rules with patient data, and by capturing data relevant to decision-making. Computer-based protocols can contain more extensive detail than textual guidelines or paper-based flow diagrams while at the same time protecting the user from complexity and information overload.

Decision support tools vary in terms of how dynamic they are, the degree of specificity of their recommendations, and the level of integration into workflow. One end of the spectrum includes general guidelines that consist of a set of broad, static recommendations. At the other end of the spectrum are computerized protocols, which function as a set of standardized orders, with detailed explicit instructions based on dynamic patient-specific parameters, available at the point of care. The latter type of protocol has been called an "explicit computerized protocol" (ECP). A few ventilators have incorporated closed-loop algorithms to automatically adjust the ventilator settings depending on the patient condition and trajectory. These specific modes have been mostly developed for the weaning phase of the ventilation (e.g., SmartCare

system), and more recent tools aim to manage the complete ventilation process from the acute to the weaning phase (e.g., Intellivent system).

The systems need to be fed with clinical information and ventilator data. The first parameter to be defined is a surrogate of the child's lung volume. Actual body weight is not accurate enough as children may be malnourished or obese. The PALICC guidelines recommend using predicted body weight. Height is a better alternative in most cases except when neuromuscular weakness or spinal deformity is present. In such circumstances, ulna length is an excellent surrogate. Ventilator input data may include set ventilator parameters and measured ventilator parameters (i.e., spontaneous respiratory rate, expiratory tidal volume and air leak around the endotracheal tube, dynamic compliance, resistance). CO_2 removal is assessed intermittently by arterial or capillary PCO_2 on blood gas, continuously with end-tidal CO_2 ($PETCO_2$) and transcutaneous PCO_2 and also indirectly by spontaneous respiratory rate and tidal volume in some assist modes when respiratory control is functioning properly. Oxygenation can be assessed intermittently by PaO_2 on blood gases and continuously by SpO_2. For real-time adjustment of ventilation, ECPs are currently using SpO_2 and end-tidal CO_2 in addition to respiratory rate and tidal volume or predicting PaO_2/FiO_2 ratio from SpO_2/FiO_2 ratio and pH from a previous arterial to end-tidal CO_2 difference utilizing the Henderson-Hasselbalch equation.

Barriers to protocol use are considerable including lack of awareness, lack of familiarity with the protocol, lack of agreement, lack of efficacy, lack of known improved outcome, and lack of ability to overcome the inertia of previous practice. There are also external barriers: protocol-related barriers (i.e., not easy to use, not convenient, cumbersome, confusing) and environment-related barriers (e.g., new resources or facilities not accessible). To ensure acceptance, users must feel that they can count on the system to be available whenever they need it. The amount of downtime needed for data backup, troubleshooting, and upgrading should be minimal. The response time must be fast, data integrity must be maintained, and data redundancy must be minimized. It is also important to assess the amount of training necessary for users to feel comfortable with the system. The ventilator market itself is also a barrier to the implementation of ECPs. There are numerous companies, and the competition between them results in difficulties implementing the same ECP in different ventilators.

12.3.12 Monitoring of the Mechanical Ventilation

12.3.12.1 Blood Gas

Noninvasive SpO_2-based oxygenation saturation index (OSI) (mean airway pressure x FiO_2/SpO_2 x 100) is an adequate surrogate marker for the ABG-based oxygenation index OI (mean airway pressure x FiO_2/PaO_2 x 100), as long as SpO_2 is between 80% and 97%.

While arterial blood gas (ABG) and capillary blood gas (CBG) measurements are the standards for supportive management in pediatric intensive care units, frequent use of SpO_2 (and end-tidal CO_2) requires incorporating noninvasive technologies into decision-making and scoring systems. Given the challenges to placing arterial catheters in small children in daily care, practitioners frequently make decisions for children based on oxygen saturations obtained from pulse oximetry. Pulse oximeters are developed to perform optimally in a range of oxyhemoglobin saturation from 70% to 100%. It is not always clear how well pulse oximeters perform when the majority of observations are in infants and children in a hypoxemic range. Nonetheless, in practice, pulse oximetry in the low range is now routinely used for clinical decision-making for children with cyanotic congenital heart disease.

ABG-based measures of hypoxemia such as PaO_2/FiO_2 (PF) ratio have been used in ICU severity of illness scores as diagnostic criteria for acute respiratory distress syndrome (ARDS) and for scoring of lung injury. It is now well demonstrated that noninvasive SpO_2-based oxygenation saturation index OSI (mean

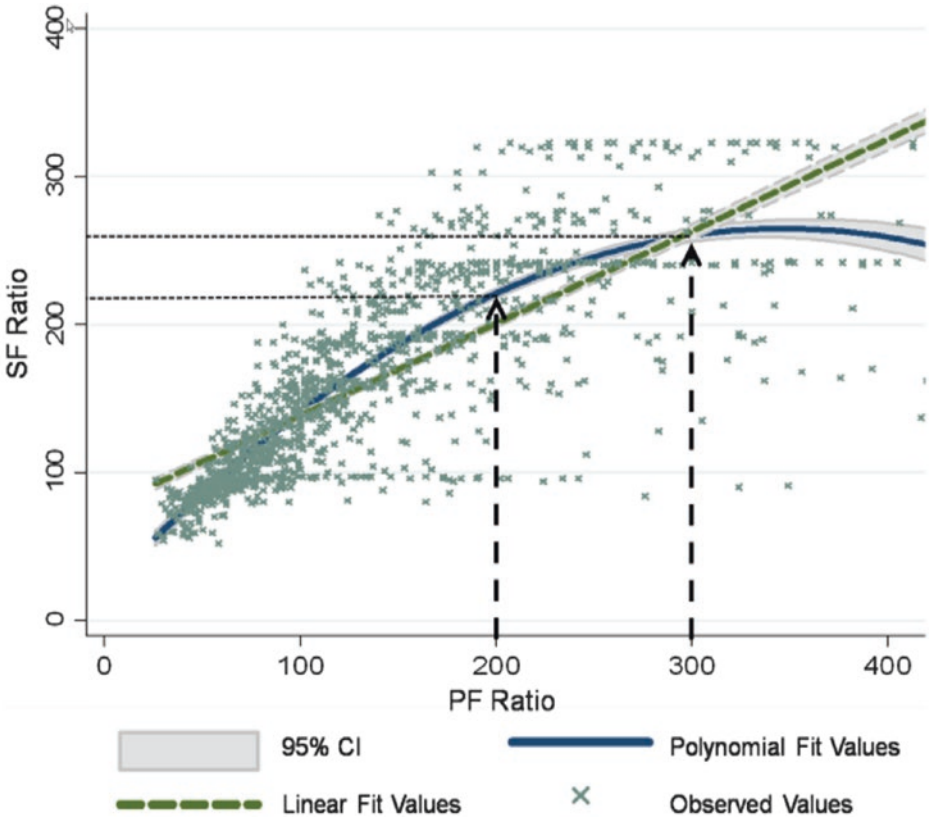

Fig. 12.5 Association between the PaO_2/FiO_2 (PF) ratio and the SpO_2/FiO_2 (SF) ratio in a cohort of children with hypoxemic respiratory failure and a SpO_2 between 80% and 97%

airway pressure × FiO_2/SpO_2 × 100) is an adequate surrogate marker for the ABG-based oxygenation index OI (mean airway pressure × FiO_2/PaO_2 × 100), as long as SpO_2 is between 80% and 97%. Similarly, the S/F ratios of 264 and 221 correspond well with the P/F ratio cutoff values of 300 and 200, respectively (Fig. 12.5). While it is clear that there is considerable scatter of SpO_2 values corresponding to a PaO_2 value, the accuracy of these measurements can be improved if targets of SpO_2 are consistently between 88% and 95%.

The most widely used noninvasive sensor to estimate adequacy of ventilation is end-tidal carbon dioxide pressure ($PETCO_2$). However, the relationship between $PETCO_2$ and $PaCO_2$ changes as a function of alveolar dead space. Additionally, estimating pH from $PETCO_2$ is confounded by changing metabolic acidosis with illness frequently compounded by the use of diuretics. Nonetheless, incorporating noninvasive measures of intrapulmonary shunt, noninvasive continuously available values from the ventilator and previously known values for pH and PCO_2 from an ABG or CBG, allows accurate pH prediction for up to 12 hours in a relatively stable patient, as illustrated in Fig. 12.6. The advantage of continuous pH projection is that it permits more frequent (lung protective) ventilator changes than from intermittent blood gases. Similarly, a model has been developed to continuously estimate the $PaCO_2$ based on the $PETCO_2$, mean airway pressure, FiO2, and the capnographic index (KPIv) derived from volumetric capnography, using the following equation:

$$\text{Predicted } PaCO_2\,(\text{mmHg}) = 0.859 + 0.827 \times PETCO_2\,(\text{mmHg}) + 0.310 \times MAP\,(\text{cm}\,H_2O) + 0.081 \times FiO_2\,(\%) + 0.529 \times \text{KPIv}$$

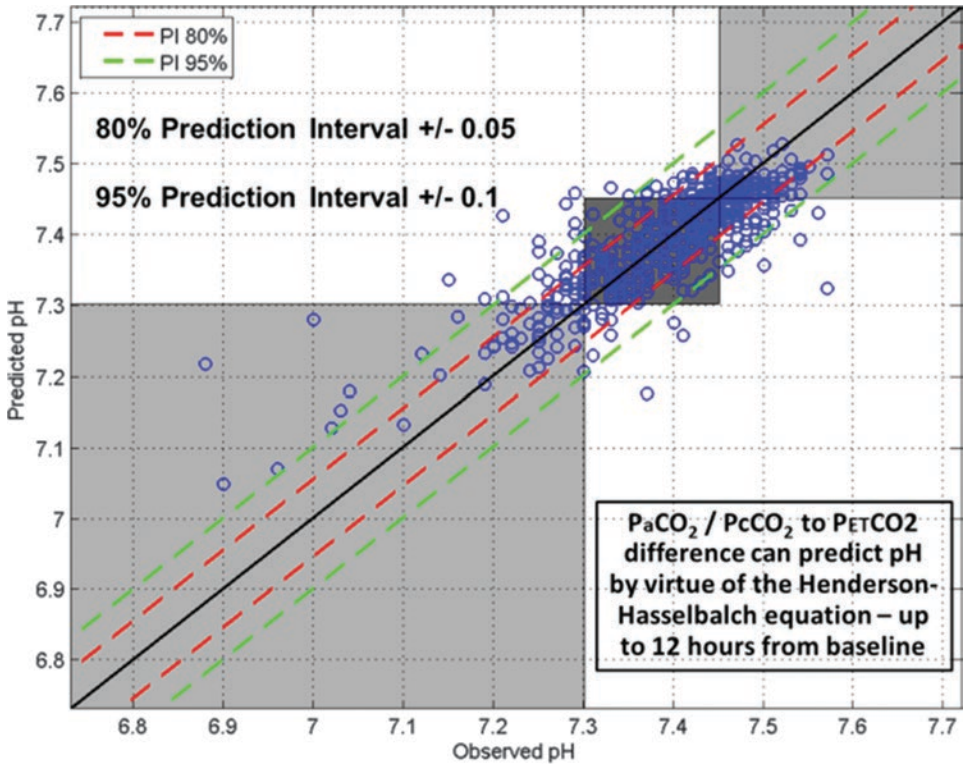

Fig. 12.6 pH prediction utilizing the Henderson-Hasselbalch equation, based on the previous pH and the PCO_2-$PETCO_2$ difference

12

This model is shown to achieve a predicted $PaCO_2$ correct at ±5 mm Hg in 95% of measurements.

12.3.12.2 Capnography

Capnography describes the continuous display of carbon dioxide partial pressure in the expired breath ($PETCO_2$). Capnography is noninvasive, accurate, easy to do, and relatively inexpensive and has been studied extensively. Capnography can be measured with the mainstream technique (i.e., sensor placed in line between the proximal end of ETT and ventilator circuit Y-piece) or with the sidestream technique (exhaled gases are aspirated from near the proximal end of the endotracheal tube and analyzed at a sensor nearby). There are two distinct types of capnography. Conventional, time-based capnography allows only qualitative and semiquantitative measurements. Volumetric (volume-based) capnography has emerged as the preferred method to assess the quality and quantity of ventilation. Volumetric capnography combines the measurement of exhaled CO_2 with continuous flow (and hence volume) measurement to provide a continuous measure and visual display of the quantity of CO_2 eliminated and how it relates to expired breath volume. These measurements can be used to estimate anatomic and physiologic dead spaces and ventilation effectiveness, while with both methods, pattern recognition of displayed waveforms can be used to identify pathophysiological problems, as detailed in Fig. 12.7. In the figure, the area X represents the actual volume of CO_2 exhaled at one breath. Adding all single breaths at 1 minute gives the total elimination of CO_2 per minute ($V'CO_2$). Area Y represents the amount of CO_2 that is not eliminated due to alveolar dead space. The latter is increased in cases of lung overdistention, pulmonary embolism, pulmonary hypertension, and decreased cardiac output. It decreases when these conditions are ameliorated. An elevation of the baseline during Phase I indicates rebreathing of

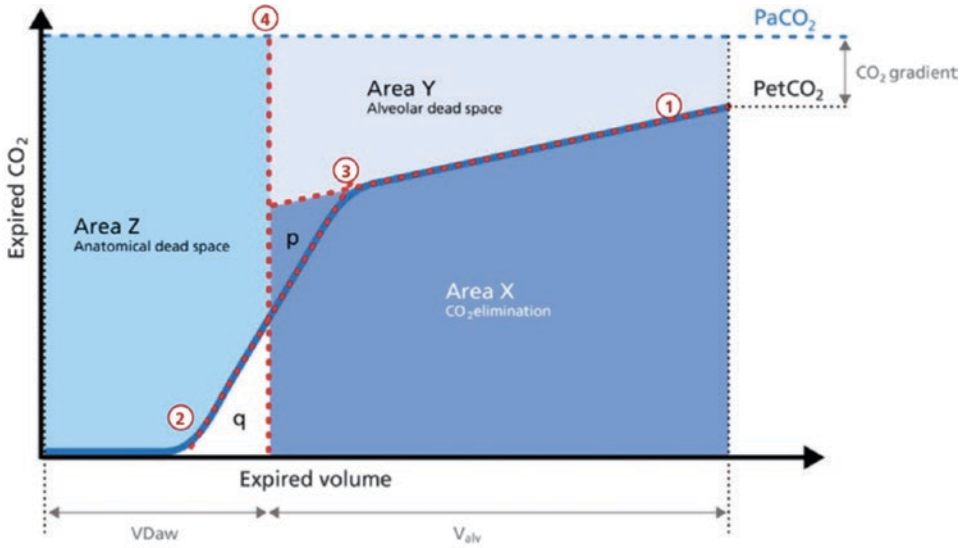

Fig. 12.7 Volumetric capnography typical tracing and identification of the different slopes and corresponding physiological variables, where (1) signifies the slope of Phase III, (2) signifies slope of Phase II, (3) the intersection of lines 1 and 2 define the limit between Phases II and III, and (4) a perpendicular line is projected onto the X-axis, and its position is adjusted until the areas p and q on both sides become equal

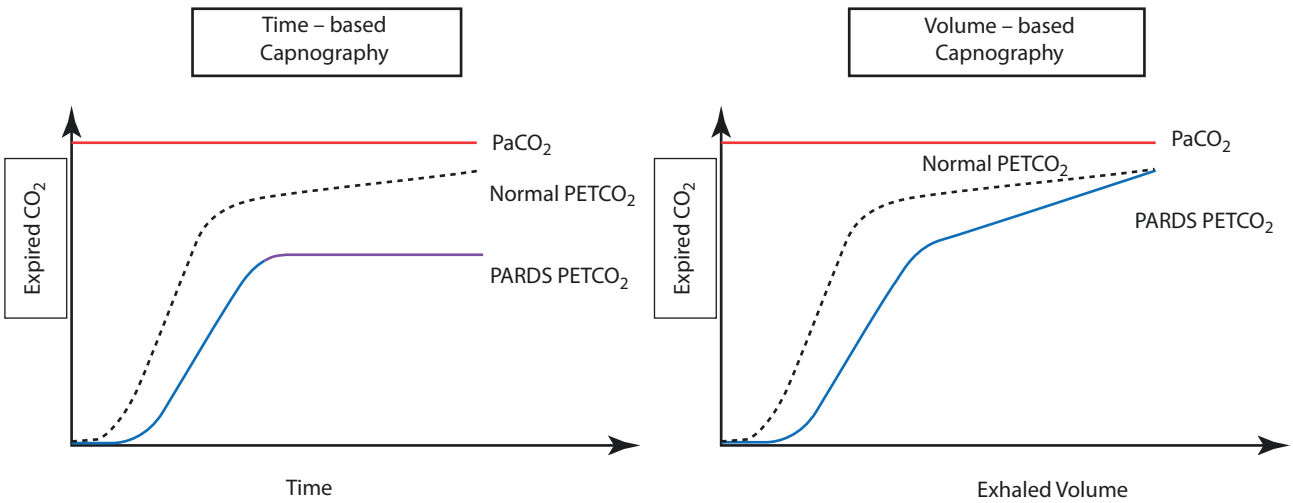

Fig. 12.8 Schematic representation of time-based capnography (left panel) and volumetric capnography (right panel) in patients with pediatric acute respiratory distress syndrome (PARDS)

CO_2, which may be due to mechanical problems with the ventilator, the need for recalibration of the CO_2 sensor, or incomplete reversal of neuromuscular blockade while breathing spontaneously.

In pediatric ARDS, the ventilation-perfusion ratio is disturbed, and both types of capnography have been associated with mortality prediction, particularly when added to oxygenation metrics. Using time-based capnography, the alveolar dead space will be increased, but the slope of Phase III is usually almost flat. More distinct changes are shown by the volumetric capnography curve. Here, Phase I may be larger due to increased anatomic dead space caused by PEEP. The slope of Phase II is decreased due to lung perfusion abnormalities, and the slope of Phase III is increased due to lung heterogeneity (Fig. 12.8).

Capnography can be used to estimate anatomic and physiologic dead spaces and ventilation effectiveness.

12.3.13 Pleural Pressure Monitoring

The pleural pressure estimate may be useful for setting the PEEP, setting the delta pressure, and estimating patient effort and degree of spontaneous ventilation.

As mentioned above (sections on setting inspiratory pressure and PEEP), an estimate of pleural pressure has many theoretical implications during mechanical ventilation. Unfortunately, pleural pressure cannot be measured in routine clinical practice, so the most common surrogate relies upon an esophageal pressure. In general, the esophageal pressure is measured in the lower 2/3 of the esophagus and presents a global estimate of the pleural pressure in the thorax. In truth, regional pressure may be considerably different since during normal physiologic conditions, the pleural pressure differs from apex to base of the lung or from ventral to dorsal regions when the patient is lying supine. The pleural pressure estimate may be useful for setting the PEEP, setting the delta pressure, and estimating patient effort and degree of spontaneous ventilation. It may also be useful to quantify patient-ventilator asynchrony and measure intrinsic PEEP and a variety of other applications.

During fully controlled ventilation (i.e., no spontaneous effort), the pleural pressure is used to estimate transpulmonary pressure at end expiration (to set PEEP) and at end inspiration (to set tidal volume or delta pressure). At end expiration, when there is no airflow (expiratory hold), the pressure in the pleural space gives an estimate of the pressure being exerted by the chest wall. Under normal conditions (not mechanical ventilation), the pleural pressure is slightly more negative than the alveolar pressure (i.e., −3 to −5 with alveolar pressure = 0). This results in a slightly positive transpulmonary pressure (Palv-Ppl of +3 to +5) at end expiration, which promotes the alveoli staying open, above the critical closing capacity. If the pleural pressure is increased (i.e., obesity, chest wall edema), then the transpulmonary pressure at end exhalation will become negative, without applying PEEP. This may promote alveolar collapse and can exacerbate atelectrauma as a mechanism of lung injury, particularly for patients with ARDS. Hence, an area of active investigation is to determine whether using esophageal manometry (generally with esophageal balloon catheters) as an estimate of pleural pressure can be used to select optimal PEEP levels in patients with ARDS. A Phase II study has shown some promise in this approach for adults with ARDS compared to the ARDSnet low PEEP/FiO_2 grid. A larger Phase III study recently studied the titration of PEEP with esophageal pressure compared to the ARDSnet high PEEP/FiO_2 grid, in adults with severe ARDS. In this study, there was no difference. While this approach likely has applicability in pediatrics, there are additional limitations with the accuracy of esophageal balloon catheters in small children, which would be important to overcome before widespread use.

The esophageal pressure can be used at end inspiration (during an inspiratory hold) to estimate the transpulmonary driving pressure and transpulmonary pressure at plateau. These variables may be crucially important when considering VILI from barotrauma. This is because under conditions of significant chest wall restriction, much of the inspiratory pressure is dissipated across the chest wall. Having a more precise estimate of the transpulmonary pressure may allow for slightly higher plateau and driving pressures to be applied, in circumstances where the chest wall compliance is poor. This remains an active area of investigation, with limited current evidence to suggest a particular target for this transpulmonary pressure. Similar issues with the accuracy of balloon catheters in pediatrics need to be overcome before this approach can be considered for widespread use in children.

Applications related to selection of PEEP and driving pressure using esophageal pressure are highly sensitive to the accuracy of the balloon catheter because an accurate assessment of the actual pleural pressure is needed to set the airway pressure. In contrast, applications related to effort or work of

breathing are more robust in pediatrics using esophageal manometry because they simply use the change in esophageal pressure rather than the absolute value for applications. Classically, esophageal manometry has been combined with measures of tidal volume, airway pressure, and flow to measure work of breathing. This work of breathing is characterized by the force needed (i.e., change in pressure, both airway and esophageal) over a distance (i.e., the tidal volume). This work is shared between the patient and the ventilator, with an algorithm used to divide the contribution coming from the patient with what is coming from the ventilator, based on the Campbell diagram. This has advantages of understanding the overall stress on the respiratory system (in this case, shared between patient and ventilator). However, oftentimes, the patient's effort while on mechanical ventilation is the more important clinical variable to consider when adjusting the ventilator settings. This is frequently estimated with the pressure time product (PTP), given by the area under the esophageal pressure tracing during inspiration times the respiratory rate, where inspiration is typically defined using spirometry to characterize when airflow crosses zero. Therefore, this requires the use of an additional sensor (other than esophageal manometry) to estimate patient effort of breathing. To overcome this limitation, some investigators use the pressure rate product (PRP), which is defined as the peak-to-trough change in esophageal pressure during a breath multiplied by the respiratory rate. This is simpler to calculate and does not require an additional sensor. While these metrics generally provide similar results under conditions of increased respiratory load, the circumstances of when to use one versus the other remains an area of investigation.

12.3.14 Chest Radiography

A chest radiography is generally obtained after tracheal intubation and, in most situations of clinical deterioration, to detect complications or the displacement of tubes and catheters. It is also required to establish the diagnosis of PARDS, even if its interpretation is difficult with large interobserver variability. The optimal frequency of radiograph control in mechanically ventilated children is not established. Some studies conducted in adult ICUs suggest that an on-demand strategy can safely replace the routine daily radiograph strategy. It is not certain if this approach may be completely transposable to children with acute respiratory failure, in whom half of routine chest X-rays are followed by an intervention. However, routine radiography could probably be avoided when the risk of intervention is low, in particular when the number of devices is low, and in stable and older children.

12.3.15 Diaphragm Ultrasound

In recent years, diaphragm ultrasound has become an increasingly utilized modality in research and clinical practice to quantify patient effort of breathing as well as identify architectural changes in the diaphragm which may signify ventilator-induced diaphragm dysfunction. There are a variety of approaches which advocate slightly different methods for the orientation of the ultrasound probe and methods for measurement. The general concept is to measure the diaphragm in the zone of apposition, where it is running near vertically along the chest wall. Serial measurement of the diaphragm thickness during exhalation can be used to identify atrophy of the muscle throughout the course of ventilation and is thought to be an indirect surrogate for VIDD. Further investigation is needed to see if these architectural

Very low diaphragm thickening fractions have been described as common during controlled ventilation and may be implicated in thinning of the diaphragm during MV. In contrast, very high thickening fractions may be present when work of breathing is high and has been associated with hypertrophy of the diaphragm muscle, which also may have implications on overall diaphragm function.

changes truly correspond to direct measures of respiratory muscle strength (such as airway or esophageal pressures during airway occlusion (i.e., aPiMax or ePiMax). In addition, similar measurement of the diaphragm thickness and how this varies during inspiration compared to exhalation can be used to estimate a thickening fraction (or diaphragm contractile activity). Very low thickening fractions have been described as common during controlled ventilation and may be implicated in thinning of the diaphragm during MV. In contrast, very high thickening fractions may be present when work of breathing is high and has been associated with hypertrophy of the diaphragm muscle, which also may have implications on overall diaphragm function. As of now, these tools fit largely in the research domain in pediatric mechanical ventilation.

12.3.16 Diaphragm Electrical Activity Monitoring

The monitoring of electrical activity of the diaphragm (Edi) is a new, minimally invasive, bedside technology that was primarily developed for ventilation mode NAVA. In addition to its role in NAVA ventilation, this technology provides the clinician with previously unavailable and essential information on diaphragm activity. The Edi signal is acquired using a specific nasogastric catheter equipped with multiple microelectrodes, connected to a specific ventilator, in which a signal processing algorithm allows the detection of the diaphragm position and the construction of an optimal Edi signal not affected by the diaphragm movement. The Edi is a rapid electrical signal, which closely reflects the output of the phrenic nerves. The quantification of the Edi allows easy detection of overassistance or oversedation with absent ventilator drive. This situation occurs frequently during conventional ventilation. Approximately one-third of children had no or very low diaphragm activity in a recent study. Increased inspiratory Edi levels can also suggest insufficient support, while a strong tonic activity may reflect the patient's efforts to increase lung volume. Edi monitoring also allows the detection and quantification of patient-ventilator asynchrony, which occurs during more than a quarter of the time during pediatric conventional ventilation.

Importantly, Edi reflects the ventilatory drive (i.e., patient "demand"). When correlated to the resultant mechanical action (e.g., the inspiratory force generated by the diaphragm contraction, with no ventilator support), one can obtain an index of the neuromechanical efficiency (NME) of the diaphragm.

$$\text{NME} = \text{negative inspiratory pressure} / \text{inspiratory Edi}$$

The quantification of the Edi allows to easily detect situations of overassistance or oversedation with absent ventilatory drive, insufficient support with high drive, and asynchrony.

The combination of Edi with esophageal pressure monitoring provides an estimate of respiratory neuromechanical efficiency.

This index has been shown as an interesting predictor of extubation failure in adults, but pediatric studies are lacking. ◘ Figure 12.9 provides an illustrative example of the evolution of the neuromechanical efficiency in an infant with a neuromuscular disorder. Further studies are warranted to demonstrate the impact of this monitoring on important clinical outcomes.

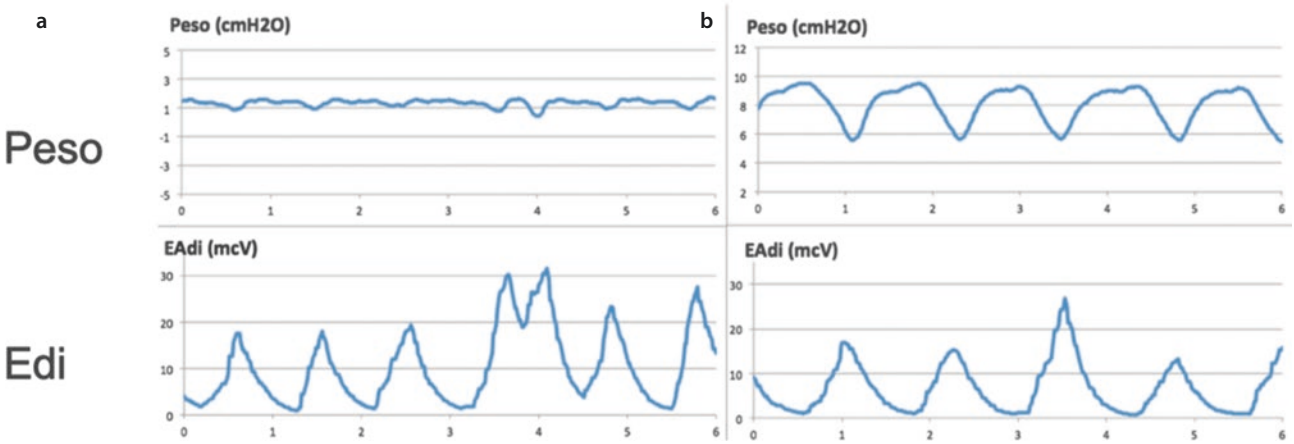

Fig. 12.9 Illustration of the neuromechanical efficiency assessed using diaphragm electrical activity (Edi) and esophageal pressure (Peso) monitoring in an infant with congenital myotonic dystrophy. Panel A illustrates this infant at 3 weeks post-term, with low esophageal pressure swings and relatively high Edi, reflecting a poor neuromechanical efficiency. Panel B shows the same infant 3 weeks later, after a respiratory weaning in NAVA ventilation. Peso swings were larger for relatively similar Edi, suggesting an improved efficiency of the diaphragm

12.4 Summary

The ability to implement and provide mechanical support to children with respiratory failure may be the single most important maneuver ever added to the ICU armamentarium. Although this technology started with the introduction of endotracheal intubation in the operating room, the more recent advances have focused on the design and function of modern mechanical ventilators which can deliver complex ventilator modes and allow precise adjustments. However, a large part of the management of pediatric mechanical ventilation is not based on strong evidence, more of which is needed. In that context, it is essential for the PICU care physician to understand the functioning and the impact of mechanical ventilation, as well as the main pathophysiological concepts leading to ventilator-induced lung injury and diaphragm dysfunction. Future studies are necessary to better understand how to best titrate the ventilation to each patient-specific condition and needs and to guide the development of future ventilators which will probably include automatic assessment and adjustment of the ventilation provided.

Review Questions

1. A 14-year-old, 50 kg male develops post-obstructive pulmonary edema following a near-hanging. He develops profound hypoxia and requires endotracheal intubation and mechanical ventilation at the referring institution. He arrives ventilated in a volume control mode. His settings are FiO_2 80%, rate 16, tidal volume 400 mL, inspiratory time 1 s, and PEEP 10 cm H_20. The PIP is measured at 34 cm H_20. He is lightly sedated but appears agitated. An arterial blood gas reveals pH 7.58, $PaCO_2$ 21 mmHg, and PaO_2 98 mmHg. The following is the most likely cause of the hypocarbia:
   A. High spontaneous rate causing excessive minute ventilation
   B. High ventilator rate causing excessive minute ventilation
   C. Large tidal volume causing excessive minute ventilation
   D. Large tidal volume causing excessive PIP
   E. Short inspiratory time allowing prolonged expiration

2. Which of the following is most correct regarding the inspiratory time in mechanical ventilation?
   A. Altering the inspiratory time in pressure-controlled ventilation can affect minute ventilation but does not affect mean airway pressure.
   B. An inspiratory pause added at end expiration does not add to the total inspiratory time.
   C. Lengthening the inspiratory time in volume-controlled ventilation can decrease the inspiratory flow and thus PIP.
   D. Longer inspiratory times help recruit alveoli with short time constants.
   E. Pressure support ventilation requires the inspiratory time be preset depending on the degree of airflow resistance or noncompliance.

3. A 9-year-old, 30 kg girl with severe influenza infection develops ARDS and progressive hypoxia. Current ventilator settings are SIMV-volume, FiO_2 100%, rate 16, tidal volume 200 mL, inspiratory time 1.4 s, and PEEP 10 cm H_2O. The PIP is measured at 40 cm H_2O, and the plateau pressure is 34 cm H_2O. Arterial blood gas reveals pH 7.28, $PaCO_2$ 51 mmHg, and PaO_2 48 mmHg. Appropriate application of PEEP is best demonstrated by:
   A. Improved oxygenation with decreased PIP
   B. Improved oxygenation with increased PIP
   C. Improved oxygenation with decreased plateau pressure
   D. Pressure volume curve demonstrating a decrease in delta volume with no change in delta pressure
   E. Pressure volume curve demonstrating an increase in delta volume with increased delta pressure

4. Pressure support ventilation is a mode that is:
   A. Patient triggered (flow or pressure), flow limited, and pressure cycled
   B. Patient triggered (flow or pressure), pressure limited, and flow cycled
   C. Patient triggered (flow or pressure), time limited, and time cycled
   D. Patient triggered (flow or pressure), volume limited, and flow cycled
   E. Time triggered, pressure limited, and flow cycled

5. A 16-year-old with chronic renal disease and long-standing hypertension presents with respiratory distress and hypertensive crisis. Admission vital signs are temperature 38.7, heart rate 108, respiratory rate 44, blood pressure 189/102, and oxygen saturation of 88% while breathing 100% FiO_2. He appears mottled with cool extremities and poor pulses. His chest radiograph shows bilateral patchy infiltrates and cardiomegaly. He rapidly progresses to respiratory failure and requires endotracheal intubation and positive pressure ventilation. Thirty minutes after intubation, his vitals are heart rate 90, ventilator rate 12, spontaneous rate 20, blood pressure 159/92, and oxygen saturation of 98% while on 60% FiO_2. He has improved color and has easily palpable pulses. He is comfortable with intermittent benzodiazepine sedation. Arterial lactate has declined to 3.5 mMol/L from 5.7 at admission. The most likely explanation for his hemodynamic improvement is:
   A. Improved oxygenation due to the application of positive pressure
   B. Positive pressure reducing afterload to the right heart
   C. Positive pressure reducing afterload to the left heart
   D. Positive pressure reducing preload to the left heart
   E. Positive pressure reducing preload to the volume overloaded right heart

6. A 2-year-old, 12 kg female develops respiratory failure due to pneumococcal pneumonia and right empyema. She undergoes video-assisted thoracoscopic surgery and has a patent draining right chest tube. She is ventilated with SIMV-volume, FiO_2 40%, rate 16, tidal volume 90 mL, inspiratory time 1.2 s, and PEEP 6 cm H_2O. The PIP is measured at 24 cm H_2O, and the plateau pressure is 20 cm H_2O. Her oxygen saturation is 98%, and she appears comfortable on a low-dose midazolam infusion and intermittent morphine. She develops acute hypoxia with oxygen saturation falling to 81%. Her lung exam is significant for equal but diminished breath sounds and no wheezing. The PIP is measured at 34 cm H_2O, and the plateau pressure is 23 cm H_2O. Her perfusion is adequate, and she is progressively agitated. The most appropriate initial intervention would be:
   A. Increase FiO_2 to 100% and administer a bronchodilator
   B. Increase FiO_2 to 100% and administer a neuromuscular blocker
   C. Increase FiO_2 to 100% and increase PEEP to 10 cm H_20
   D. Increase FiO_2 to 100% and reduce the tidal volume to 6 ml/kg
   E. Increase FiO_2 to 100% and suction the endotracheal tube

7. The optimal ventilator circuit has:
   A. Low resistance, high compliance, and nebulizer system for humidification
   B. Low resistance, high compliance, no servo-controlled heated wire system, but a rainout trap
   C. Low resistance, low compliance, and extra spacers between the Y-piece and the patient for easy patient positioning
   D. Low resistance, low compliance, and nebulizer system for humidification
   E. Low resistance, low compliance, and servo-controlled heated wire humidification system

8. Which of the following maneuvers will not increase the mean airway pressure?
   A. Adding an inspiratory pause
   B. Increasing the inspiratory time
   C. Increasing the PIP
   D. Increasing the PEEP
   E. Increasing the minute ventilation by increasing the respiratory rate at fixed I:E ratio

Learning Objectives

- Describe the patient population appropriate for consideration in the use of noninvasive mechanical ventilation.
- Understand the advantages and disadvantages of noninvasive mechanical ventilation.
- Describe the indications for use of high-frequency oscillatory ventilation (HFOV).
- Describe the "open-lung" concept.
- Understand the advantages and disadvantages of HFOV.
- Describe the mechanics of airway pressure-release ventilation (APRV).
- Describe the mechanics of high-frequency percussive ventilation (HFPV).
- Understand the population and unique needs of long-term ventilation patients.

13.1 Introduction

The evolution of care within the PICU has resulted in a population of patients surviving illnesses that previously were fatal. Mechanical ventilation is one of the major supportive therapeutic modalities used in pediatric critical care that have helped to achieve this result. Enhanced survival has led to the development of PICU survivors with residual lung disease in part secondary to the techniques used to ventilate them. The more complicated nature of mechanical pulmonary support, the desire to improve ventilator-patient synchrony, enhance patient comfort, and ease weaning from support; and the desire to minimize pulmonary trauma and to try to improve patient outcome have resulted in the introduction of many nonconventional modes of ventilation. Additionally, the desire to achieve these stated goals has also sparked an examination of less invasive forms of mechanical ventilation. Unfortunately, many of these modes of support were included into ventilators without sufficient dissemination of information regarding their use for respiratory failure. Few randomized controlled studies have been applied to these ventilation modes. This has resulted in a disparity in the variety of options available at the bedside and the knowledge to apply these modes to the pediatric population.

This chapter aims to narrow the gap between technological advancement and bedside application.

13.2 Noninvasive Ventilation

Noninvasive ventilation was one of the earliest modes of support for hypoventilatory conditions such as the polio epidemics of the mid-1900s. As the historical need for support transitioned from acute muscle pump dysfunction to one of acute pulmonary parenchymal disease, so did the transition from noninvasive to invasive support. Additionally, the development of medical devices that could deliver invasive ventilation was a prerequisite for this transition to occur. As a consequence, the use of noninvasive pulmonary support waned until the mid-1980s when a renaissance of sorts occurred in its application for treatment of acute respiratory failure. Several distinct physiologic advantages of noninvasive ventilation as well as disadvantages of invasive ventilation have fueled the reemergence of this modality.

13.3 Negative Pressure Ventilation

Negative pressure ventilation (NPV) can be defined as the application of subatmospheric pressure onto the thorax during inspiration. Historically, the initial use of noninvasive ventilation involved variations of negative pressure devices such as the iron lung. A recent FDA-approved device, the Hayek RTX oscillator is a ventilator which delivers NPV via a plastic cuirass or "turtle shell." This device has the ability to provide negative continuous pressure to the chest, similar to CPAP. It also can be set in control mode to deliver biphasic pressure, a negative pressure to augment inspiration and positive pressure to augment exhalation. Additionally, it can provide rapid alternating (oscillating) positive and negative pressures to the chest as physiotherapy to aid in secretion clearance.

NPV devices consist of two components: a ***chamber*** in which the thorax is exposed to the subatmospheric pressure and a ***pump***, which creates the pressure. All chambers used for NPV require a distance of several centimeters between the anterior chest wall and the surface of the chamber. This distance allows for anterior movement of the thorax during inspiration. The separation of the chamber and chest wall is inherent in the iron lung and cuirass ventilators.

Most pumps used for NPV are pressure-cycled and have controls for setting peak negative pressure and frequency. The ability to adjust respiratory cycle times is especially useful in younger children with their inherent need for higher breath frequency and shorter inspiratory times. Volume-cycled pumps are also available but are rarely used owing to their inability to compensate for air leaks that are commonplace with these devices.

In the PICU, the use of NPV has historically been limited to the iron lung due to its efficiency at creating a greater tidal volume per amount of negative pressure generated. The amount of tidal volume generated is related to the surface area of the thorax and abdomen over which the negative pressure is applied; therefore, the iron lung is the most efficient and the cuirass the least. Previously, the use of a cuirass was limited to the support of children with neuromuscular weakness and minimal parenchymal lung disease. Acute respiratory failure, on the other hand, was treated with the iron lung-type chamber if NPV is to be employed. However, the Hayek device has shown promise in studies for use with acute respiratory failure. In this form of ventilation, active exhalation leads to an enhanced minute ventilation and thus the ability to adequately ventilate children with parenchymal disease.

Three modes of NPV are available to accomplish the desired ventilatory goals. The most common of these modes is ***cyclical NPV*** in which the pump creates a set negative pressure to assist with thoracic expansion during inhalation. Cessation of the negative pressure and a return to atmospheric pressure upon the thorax allow for passive exhalation due to the elastic recoil of the anterior chest wall and lungs. ***Negativelpositive pressure ventilation*** uses a combination of negative inspiratory pressure and positive expiratory pressure. While infrequently used, this mode is thought to eliminate the increased functional residual capacity that exists with cuirass-type chambers. The third mode of NPV is ***continuous negative pressure*** in which a constant subatmospheric pressure exists throughout the respiratory cycle. The *negative end-expiratory pressure* (NEEP), which is present, allows for maintenance of end-expiratory volumes analogous to the positive end-expiratory pressures (PEEP) used in positive pressure ventilation. However, the negative hemodynamic consequences associated with PEEP, such as reduced venous return and depressed cardiac output, are avoided with the use of NEEP. Enhanced afterload applied

Continuous negative pressure ventilation should be cautiously applied and supported by the use of fluids and/or vasoactive infusions in children with decreased cardiac function.

upon the heart with NPV through diminished transthoracic pressures has a negligible but present effect on cardiac output. The afterload effect may be exacerbated in children with markedly depressed left ventricular function, and therefore, continuous negative pressure ventilation should be cautiously applied and assisted by the use of fluids and/or pressors in this subset of patients. Spontaneous respirations can occur throughout the NEEP period with the addition, if so desired, of cyclic increased negative pressure "breaths" imposed at a periodic predetermined rate. In children, who tend to have a greater propensity toward atelectasis related to smaller respiratory bronchioles and greater thoracic elastic recoil, the use of continuous negative pressure ventilation has become increasingly popular.

Physiologic consequences of NPV in addition to the cardiac effects noted earlier include enhancement of renal function most likely related to the augmented cardiac output. Studies have revealed that NPV results in increased free water clearance and urine volume without changes noted in urinary excretion of sodium, potassium, serum renin activity, serum aldosterone, atrial natriuretic peptide, and vasopressin levels. Less desirable side effects include the loss of coordinated upper airway reflexes frequently resulting in upper airway obstruction/apnea during sleep. Additionally, lower esophageal sphincter dysfunction has been associated with NPV resulting in increased gastroesophageal reflux disease.

Advantages of NPV include the lack of need for an artificial airway and the skilled personnel required to insert the airway. Furthermore, the complications associated with the insertion and maintenance of these airways is also avoided. Disadvantages of NPV include (1) limited access to the patient for assessment and therapeutic interventions, (2) lack of familiarity of caregivers with the use of this modality, (3) the need for skilled personnel to maintain the airway or insert an artificial airway emergently if needed due to patient deterioration, and (4) the lack of a direct conduit for assistance in removing secretions.

Historically, NPV has been used in the neonatal population to treat respiratory distress syndrome. Its use has fallen out of favor in deference to the use of positive pressure ventilation. Recently, a single-center 3-year experience using the Hayek device in pediatric acute respiratory failure was published. In this retrospective review, the authors concluded that in their population with a mean age of 15.5 months, 70% of the patients treated with NPV required no additional escalation of care. The most common diagnosis in this group was bronchiolitis. The authors noted that NPV failed primarily in patients with upper airway obstruction and also resulted in more frequent use of continuous sedation and delay in the initialization of enteral nutrition. Interestingly, they also reported a 28% decrease in the annual percentage of PICU intubations after NPV introduction when compared to the previous 3-year period.

Negative pressure ventilation (NPV) may be superior to positive pressure ventilation in children with single ventricle cardiac physiology who have undergone the Fontan procedure or have severe right ventricular restrictive physiology such as in the tetralogy of Fallot (TOF). NPV may improve pulmonary blood flow and cardiac output secondary to enhanced venous return and reduced pulmonary vascular resistance when compared to positive pressure ventilation.

Additionally, NPV has been used in children with single ventricle physiology who have undergone the Fontan procedure or have severe right ventricular restrictive physiology such as in the tetralogy of Fallot (TOF). The deleterious effects on venous return and the diminished diastolic pulmonary arterial flow associated with intermittent positive pressure ventilation (IPV) are poorly tolerated in these children. The low cardiac output state and widened arteriovenous oxygen content difference associated with these physiologic changes is reversed with the use of NPV. An early study in the 1990s demonstrated increases in pulmonary blood flow of between 40% and 80% in patients with TOF and between 42% and 52% in Fontan patients when switching from IPPV to NPV in the postoperative period. These values reversed to their previous levels when IPPV was reintroduced. In addition to the enhancement of venous return associated with NPV, another possible mechanism for this improvement includes the

reduction of elevated pulmonary vascular resistance which occurs with positive pressure inflation of the lungs beyond functional residual capacity.

In summary, NPV for acute respiratory failure and postoperative assistance with Fontan or restrictive right ventricular physiology is a viable and potentially very helpful modality for use in children. The ability to avoid ventilator-induced lung disease and endotracheal intubation and improve cardiac output warrants a more extensive reevaluation of its use in children with acute respiratory failure.

13.4 Noninvasive Positive Pressure Ventilation

Noninvasive positive pressure ventilation (NPPV) refers to the cyclical application of positive pressure ventilation without the need for an artificial invasive airway. By virtue of its effectiveness and convenience, NPPV delivered by an interface via the nose or mouth has become the preferred method of noninvasive ventilation. Traditional use for chronic ventilation needs in children with chest wall deformities, neuromuscular weakness, and central hypoventilation has recently been expanded to its use for acute hypoxic respiratory failure (HRF) and postoperative patients and to facilitate extubation in difficult-to-wean patients.

The reduction in the complications associated with invasive ventilation such as direct airway trauma, the preservation of the upper airway defense mechanisms, and the maintenance of upper airway function and comfort are some of the major reasons for the use of NPPV.

There are many compelling reasons for using noninvasive ventilation. The reduction of the complications associated with invasive ventilation such as direct airway trauma, preservation of the upper airway defense mechanisms, as well as maintenance of upper airway function and comfort are major considerations for the preferential use of NPPV. Dental, laryngeal, and tracheal injuries occur frequently. Nosocomial pneumonias facilitated by the provision of direct access to the lower airways by the endotracheal tube are well documented. The inability to eat and communicate because of the endotracheal tube contributes to the patient's anxiety and discomfort and frequently leads to the need for increased sedation and analgesia to improve ventilator-patient synchrony. By avoiding these complications, NPPV may reduce morbidity, assist with the weaning process, decrease ICU and hospital length of stay, as well as reduce overall costs and enhance patient comfort.

The mechanism by which NPPV assists ventilation is the same as for invasive PPV; supra-atmospheric pressure is applied intermittently via the airways, increasing transpulmonary pressure and inflating the lungs. Exhalation is achieved by passive lung recoil. Additionally, positive end-expiratory pressure (PEEP) and inspiratory pressure support can assist ventilation by lowering transdiaphragmatic pressure, respiratory muscle pressure-time index, and the diaphragmatic electromyographic activity. The ventilation achieved from a preset inspiratory pressure (IPAP) varies based on the mechanical characteristics of the respiratory system. These characteristics include the total thoracic compliance and resistance as well as auto-PEEP, respiratory rate, and mask leakage. An additional important characteristic of NPPV is its ability to assist spontaneous respirations. This function is initiated by either a flow or pressure trigger. In the weak or sedated child, inspiratory effort may be insufficient to activate this function and may need to be overcome by imposing a higher mandatory rate to essentially impose a controlled mode of ventilation. The expiratory trigger can either be a function of time or a reduction in inspiratory flow. In the case of expiratory flow trigger, care must be observed in children with large air leaks as a result of ill-fitting masks. In such situations, the lack of

inspiratory flow reduction can result in prolongation of inspiration by the machine beyond the child's inspiratory effort and therefore impede exhalation. Frequently, NPPV results in reductions in respiratory rate and accessory muscle use and increases in tidal volume and minute ventilation. Furthermore, enhanced oxygenation as a result of improved ventilation-perfusion matching, as well as enhanced left ventricular function, due to the afterload-reducing effects of increased intrathoracic pressure, may break the vicious cycle of worsening respiratory muscle function and gas exchange in children with acute HRF.

NPPV may result in enhanced oxygenation as a result of improved ventilation-perfusion matching as well as enhanced left ventricular function.

The lack of a direct conduit to the lower airway will inhibit direct removal of secretions. Alternative secretion management tools such as insufflation-exsufflation and high-frequency chest wall oscillation are important to assist with secretion removal and prevention of atelectasis. NPPV requires cooperation on the part of the patient to maximize its effects when treating HRF. Deep sedation and paralysis will result in less than optimal oxygenation and ventilation and therefore is difficult to use in the uncooperative or unconscious child.

Complications associated with NPPV include aspiration, gastric distension and perforation, nasal bridge irritation and ulcerations, pneumomediastinum and pneumothorax, exacerbations of gastroesophageal reflux disease, enhanced anxiety, and irritation of the eyes.

Complications associated with NPPV include aspiration, gastric distension and perforation, nasal bridge irritation and ulcerations, pneumomediastinum, and pneumothorax. Additionally, exacerbation of gastroesophageal reflux disease, enhanced anxiety, and eye irritations are not infrequently reported adverse effects.

Experience with NPPV in children is limited but growing in the treatment of acute respiratory failure (ARF). Extensive use of NPPV exists in the neonatal and adult literature for the treatment of ARF secondary to neonatal RDS, COPD, pulmonary edema, pneumonia, and ARDS.

Early reports describe a small number of patients in which NPPV was used to assist with extubation and avoid reintubation. A retrospective report published in 1995 described the successful use of NPPV in children with various causes of HRF for both avoidance of intubation or reintubation. In this report, 9 of 10 children were able to avoid intubation, and 16 of 18 children were able to remain extubated with the assistance of NPPV. Shortly thereafter, a prospective study of 34 patients with 35 episodes of acute respiratory failure and hemodynamic stability reported that avoidance of intubation was accomplished in 91% of HRF episodes.

Use of NPPV in status asthmaticus has been reported in a number of studies. A review of status asthmaticus with hypoxemia reported that 19 of 26 patients were able to avoid intubation when using a nasal interface. Another report described 5 children with status asthmaticus who used NPPV for a mean duration of 33 hours and resulted in significant improvement in respiratory rate and modified Pulmonary Index Score. A subsequent study prospectively assessed the use of NPPV in 20 children with lower airway obstruction. Results of this study included a reduction in Clinical Asthma Score as a result of reduction in respiratory rate, accessory muscle use, and dyspnea when compared to standard therapy. Only one patient in this study required mechanical ventilation; however, the authors admitted that the incidence of intubation for asthma at baseline within their institution was quite low and therefore was not a useful outcome variable.

NPPV may therefore be beneficial in a variety of acute disorders resulting in HRF. In addition to avoiding the use of endotracheal intubation and its associated complications, other potential benefits such as reduction in length of stay, diminished use of sedatives, improved patient comfort, and reduction of PICU costs will need to be evaluated in a large prospectively randomized study.

13.5 High-Frequency Oscillatory Ventilation

Since the early 1990s, the importance of opening the lung and keeping it open has been described and accepted. Emphasis has been placed on the benefit of small-pressure amplitudes to prevent lung damage due to shearing forces and minimize surfactant loss. Related concepts included the benefits of intrinsic PEEP due to shortened expiratory times which contributes to the maintenance of airway recruitment of noncompliant lung units while allowing ventilation to occur at markedly lower amplitudes than what is used in conventional ventilation. High-frequency oscillatory ventilation (HFOV) applies these concepts to their fullest extent. HFOV preserves end-expiratory lung volumes and minimizes cyclic stretch while avoiding overdistension at end inspiration by using tidal volumes, which approach or are smaller than the anatomic dead space. The use of high mean airway pressures (P_{aw}) results in the recruitment and maintenance of lung units. Superimposed upon this P_{aw} are sinusoidal pressure oscillations at a frequency of 3–15 Hz.

Mechanisms of gas transport in HFOV have been elucidated through experimental animal work. CO_2 elimination is a function of the frequency and the square of the tidal volume ($VCO_2 = f \times Vt^2$). Tidal volume correlates with the amplitude of oscillation (Δ P) and is inversely related to frequency (Hz). Recruitment of alveoli is related to the P_{aw} and the inspiratory to expiratory time ratio (I:E). Direct bulk airflow can account for only proximal alveolar units and the major airways. Asymmetry of the gas flow profile during different phases of the ventilator cycle (parabolic in one phase and square in the other phase) results in a flow of gas in one direction through the center of the airway and in the other direction along the periphery. Augmented dispersion is a concept of gas dispersion first described in 1953 by Geoffrey Taylor. This theory states that gas dispersion results from the interaction along the profile of high-velocity gas flow and the radial diffusion of gases in motion. Therefore, net transport of gases occurs beyond the bulk flow front. Interregional gas mixing occurs due to asymmetry of alveolar time constants. In this concept, units with short-time constants fill and empty rapidly. At the end of exhalation, the fast units are empty and ready to fill, whereas the slow units are still emptying. Consequently, gas moves from the slow units to the fast units. During inspiration, the opposite occurs with gas moving from the fast units to the slow units. This movement has been named pendelluft movement. Pendelluft may play a larger role in lung disease with heterogeneous injury. Finally, as in conventional ventilation, molecular diffusion results from random motion of gas molecules resulting in gas transport across the alveolar membrane. Additionally, in HFOV, a diffusion gradient is generated from the mouth (high O_2) to the alveolus as O_2 is transported into the pulmonary circulation (low O_2). Likewise, a similar gradient in the opposite direction assists with CO_2 elimination (◘ Fig. 13.1).

Carbon dioxide (CO_2) elimination is a function of the frequency (f) and the square of the tidal volume (Vt): [$VCO_2 = f \times (Vt)^2$] in HFOV. The tidal volume correlates with the amplitude of the oscillation (ΔP) and is inversely related to the frequency (Hz).

Several mechanisms have now been described that contribute to gas exchange in HFOV including bulk convection, asymmetric velocity profiles, Taylor dispersion and turbulence, pendelluft, molecular diffusion, and collateral ventilation.

When initiating HFOV, optimization of PaO_2 occurs in a linear fashion as lung volume is increased up to a point when alveolar overdistension occurs. This open lung strategy may be accomplished by initially setting P_{aw} 4–5 cm H_2O above the P_{aw} used during conventional ventilation. This is done to maintain airway recruitment and to counteract the known attenuation of P_{aw} by the endotracheal tube. P_{aw} does not equate with alveolar pressure both due to this attenuation and because exhalation in HFOV is active which results in some airway collapse and the generation of a pressure gradient between proximal and distal airways. Additionally, pressure oscillations are less dampened in atelectatic lungs, thereby exposing the conducting airways to higher and poten-

When initiating HFOV, the mean airway pressure (P_{aw}) is set at 4–5 cm H_2O above the P_{aw} used during conventional ventilation. This increment is utilized to maintain airway recruitment and to counteract the attenuation of P_{aw} by the endotracheal tube.

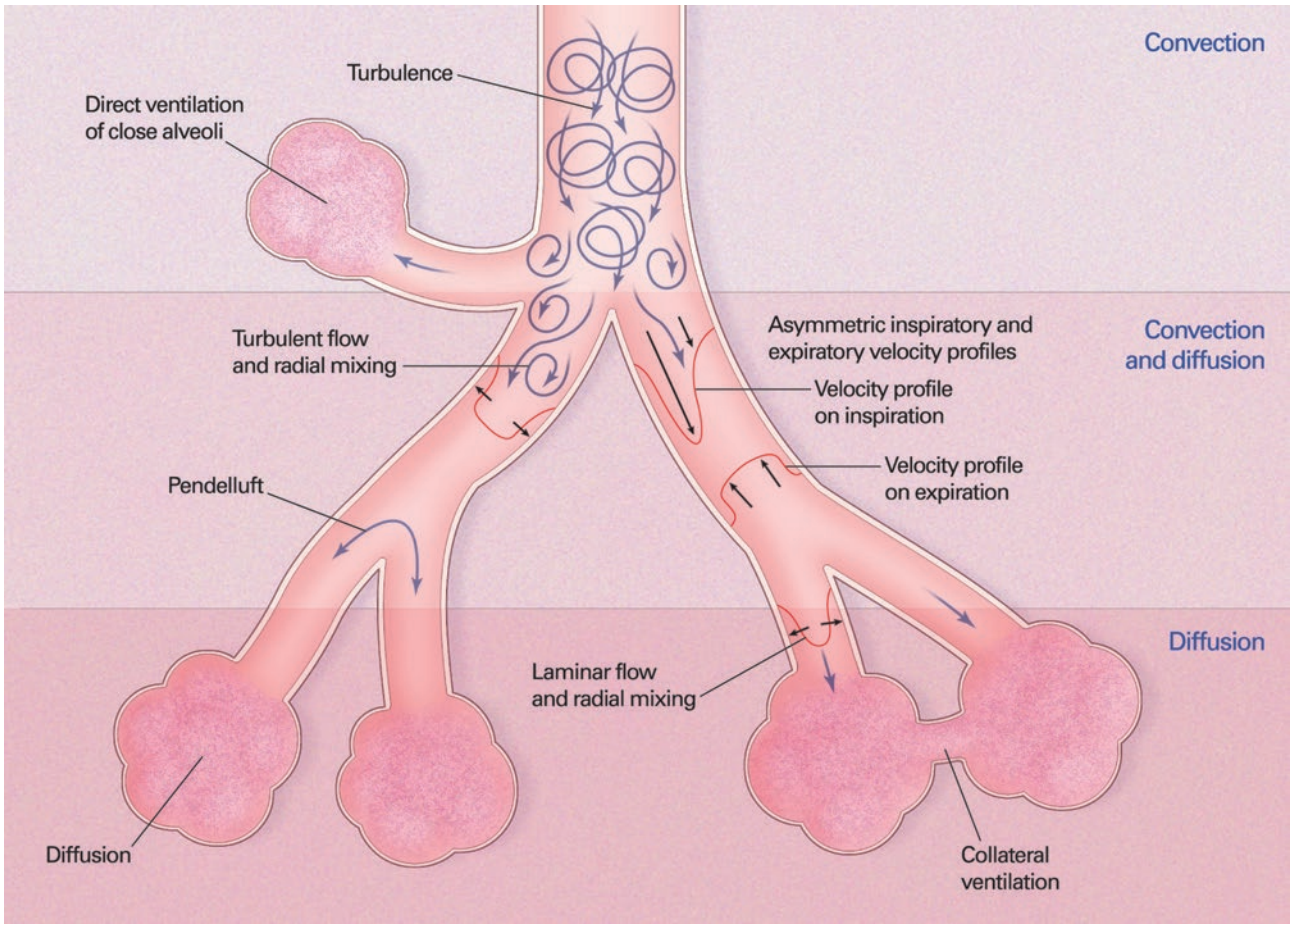

Fig. 13.1 Schematic of gas exchange during high-frequency oscillatory ventilation. (Slutsky 2002)

Hypoxemia is treated by adjusting the P_{aw} upward in small increments (1–2 cm H_2O).

Historically, the HFO frequency is set based on the age and size of the patient with higher levels (12–15 Hz) used in infants, moderate levels (8–12 Hz) in young children, and low levels (3–8 Hz) in older children and adolescents. Newer approaches take into consideration the disease characteristics of lung compliance and airway resistance.

tially injurious pressure swings. Additional elevations of Paw above the initial 4–5 cm initially applied may be required to adequately recruit otherwise unexpanded lung units. In addition to the elevation of Paw, recruitment maneuvers such as sustained dynamic inflation episodes or stepwise pressure increases over 5–6 minutes may be useful.

In practice, the initial 4–5 cm H_2O P_{aw} pressure increase over conventional ventilation should be followed with additional small increments (1–2 cm H_2O) in P_{aw} to a point when oxygenation does not improve with a fixed FiO_2. As airways are recruited, a concomitant decrease in amplitude (ΔP) may be noted as a function of improving compliance, approximating total lung compliance (TLC). Subsequently, P_{aw} may be weaned to a point when oxygenation begins to deteriorate, consistent with derecruitment. Additionally, amplitude may again increase consistent with derecruitment.

Historically, it has been recommended setting the frequency (f) based on the patient's age and observation of chest wiggle adjusted to achieve adequate vibrations to the abdominal or groin level. Higher levels (12–15 Hz) are used in infants, moderate levels (8–12 Hz) in young children, and low levels (3–8 Hz) in older children and adolescents. However, an approach to improvements in ventilation should also be determined by lung characteristics and the disease process. With decreased compliance due to atelectasis, there is a significant increase in ΔP peak-to-trough transmission in the distal airways and alveoli. Conversely, increased resistance of the lung results in decreased peak-to-trough transmission distally in the airway and alveoli. Therefore, in diseases such as ARDS, it

may be wise to use the highest possible f since it determines the rate of oscillations and directly influences Vt. Because f is inversely proportional to Vt, a higher f results in a smaller Vt. Therefore, using a higher f makes it easier to avoid dynamic hyperinflation and possible lung injury. An additional method to prevent overdistension is achieved by keeping the diaphragm between the eighth and tenth posterior ribs on an anteroposterior chest X-ray. Consequently, once optimal f is chosen, the ΔP is titrated, in 2–3 cm H_2O increments to achieve optimal CO_2 elimination. In patients with increased airways resistance, a lower f, in theory, may be beneficial to allow for adequate delivery of a larger Vt to the distal airways. As in lung diseases with poor compliance, the ΔP is titrated to achieve adequate CO_2 elimination. Additional ways to treat hypercarbia include decreasing the frequency in 0.5–1 Hz increments, or partially deflating the endotracheal tube cuff, if present.

In patients with air leak, after initial airway recruitment, P_{aw} may be lowered in small increments until a point is reached at which the air leak is eliminated. In such cases, optimization of oxygenation is likely to require FiO_2 ≥60%, and acceptance of higher levels of CO_2 will likely be necessary. Alternatively, similar results may be achieved with higher frequencies and shorter inspiratory times.

Weaning a patient from HFOV can be considered when clinical improvement allows progressive diminishment of P_{aw} while maintaining FiO_2 of ≤60%. While neonatal literature reports the successful liberation of infants directly from HFOV, this is not able to be accomplished in older children. This is due to the difficulty of allowing children to spontaneously breathe while on HFOV. While spontaneous breathing during HFOV may result in improved oxygenation and ventilation, it is only feasible for small children owing to their smaller airflow demands. The larger child's airflow demands exceed the maximal possible bias flow delivered by the oscillator, therefore leading to increased work of breathing. Because of this, older and larger children will require deep sedation and probable neuromuscular blockade in order to prevent spontaneous breathing. Therefore, transition from HFOV is usually to a form of conventional ventilation. Consideration of this transition generally may occur when P_{aw} ≤20 cm H_2O and the FiO_2 remains ≤60%. As noted earlier, due to attenuation of P_{aw} by the endotracheal tube, the P_{aw} of conventional ventilation can frequently be significantly lower than was present on HFOV prior to the transition.

Few good studies have been performed to compare HFOV with conventional ventilation in pediatric patients with HRF. Recently, two randomized adult trials (OSCILLATE and OSCAR) have been published and reported poorer mortality outcomes for HFOV compared to conventional ventilation in the treatment of HRF. Subsequently, a retrospective multicenter pediatric study, utilizing propensity score matching, compared HFOV and conventional ventilation in the treatment of HRF in children. The study noted that HFOV had significantly worse outcomes in terms of length of mechanical ventilation, ICU length of stay, and mortality. The study was criticized for many reasons including its retrospective design, its inclusion criteria, and its statistical approach in multiple editorials and letters to the editor. To date, there have been no prospective randomized trials of comparing HFOV and conventional ventilation in HRF. Thus, we are left with numerous case reports using HFOV as rescue therapy for patients with HRF who failed conventional ventilation. The reports have contributed little to the knowledge base as to its suitability as primary therapy but have expanded the experience and familiarity with its use for pediatric practitioners. Only one multicenter randomized crossover study has been reported in children with HRF and/or

During HFOV, the lungs should be inflated such that the diaphragm lies between the eighth and tenth posterior ribs on an anteroposterior chest radiograph.

Hypercarbia is treated by increasing the amplitude in 2–3 cm H_2O increments, decreasing the frequency in increments of 0.5–1 Hz, or partially deflating the endotracheal tube cuff.

air leak. In this study, 70 patients were randomized to either conventional ventilation using a limited pressure strategy or HFOV. Results of this study found no difference in survival or duration of mechanical ventilation. However, significantly fewer patients in the HFOV arm of the study required mechanical ventilation at 30 days after entry. Additional post hoc analysis revealed that those patients that crossed over to the HFOV study arm did not benefit as well as those patients placed on HFOV primarily. This reinforces the generally held belief that in order to be successful, alternative modes of ventilatory support must be invoked before irreversible lung injury has occurred. More recently, a retrospective analysis has been performed in patients with HRF who were initially managed with conventional mechanical ventilation strategies and subsequently transitioned to HFOV. Significant improved outcomes were obtained in patients transitioned to HFOV prior to 24 hours after initiation of mechanical ventilation. In patients evenly matched for Oxygen Index and risk of mortality, a 59% survival was achieved in patients transitioned to HFOV in the early group and 13% in those who were placed on HFOV beyond 24 hours.

In conclusion, HFOV remains an option in the treatment of HRF. Experience with HFOV has proven its safety in the PICU although its efficacy remains in question. Larger studies as well as earlier implementation during HRF may elucidate further benefits. Additionally, improved methods at determining optimal alveolar expansion may better enable optimization of HFOV settings perhaps leading to better outcomes.

13.6 High-Frequency Percussive Ventilation

High-frequency percussive ventilation (HFPV) is a form of high-frequency ventilation, which delivers subphysiologic volumes at rapid rates via the volume-diffusive respirator (VDR).

The subtidal volume impulses are superimposed on a conventional pressure-controlled, time-cycled ventilator (CV) usually set at a rate of 10–15 breaths per minute.

Numerous case reports have documented the successful use of HFPV to improve oxygenation and ventilation in the neonatal and pediatric population for acute respiratory failure, ARDS, and inhalational injury.

High-frequency percussive ventilation (HFPV) is a form of HFV, which delivers subphysiologic volumes at rapid rates via the volume-diffusive respirator (VDR). The VDR is a pneumatically powered time-cycled, pressure-limited ventilator with inspiratory and expiratory oscillation. The VDR has a phasitron (Venturi mechanism) positioned in the proximal airway, which delivers timed impulses of subtidal volumes of respiratory gases at a frequency of 200–900 beats/min. The subtidal volume impulses are superimposed on a conventional pressure-controlled cycle ventilator (CV) usually set at a rate of 10–15 breaths/min. Physiologically, the stepwise inflation of the lungs diffuses O_2 distally into the airway while also mechanically mixing returning alveolar CO_2 entering the peripheral airways. On inspiration, a diaphragm connected to the phasitron fills with gas and pushes it forward, blocking the expiratory ports, and the jet delivers short percussive pulsations. Due to the high-pressure gradient at the start of inspiration between the mouth and alveolus, a large amount of air is entrained. As the gradient drops during inspiration, air entrainment and total flow decrease, but the jet pulsations continue. During this period, oscillatory equilibrium occurs at which time no further alveolar inflation occurs, and percussive mixing of intrapulmonary gases takes place. When the time limit is reached, the CV cycles off; however, the phasitron continues to fire. PEEP is maintained by a set flow as the expiratory limb opens and expiration takes place passively until reaching a preset baseline pressure. The endotracheal tube cuff, if present, is partially deflated to assist with mobilization of secretions, which occurs from the continuous application of percussive forces. Additional benefits of cuff deflation include enhanced elimination of CO_2 and avoiding the generation of dangerous intra-alveolar pressures.

Numerous case reports have documented successful use of HFPV to improve oxygenation and ventilation in the neonatal and pediatric population for both acute respiratory failure/ARDS and inhalational injury. Additionally, there have been two prospective randomized controlled studies in the use of HFPV for pediatric burn patients. One study randomized 43 patients to CV or HFPV following inhalational injury. HFPV was found to provide adequate ventilation at significantly reduced PIPs (30 vs. 43 cm H_2O) as well as a trend toward lower rates of pneumonia and mortality rates. A subsequent prospective study randomized 64 children to HFPV and low-volume (6–8 ml/kg) pressure-controlled ventilation. This study demonstrated enhanced oxygenation and ventilation with lower PIPs (30 vs. 39 cm H_2O) but again revealed no difference in pneumonia, ARDS, sepsis, or mortality.

Two prospective, randomized, controlled studies of the use of HFPV for pediatric burn patients found HFPV to provide adequate oxygenation and ventilation at significantly reduced peak inspiratory pressures than conventional ventilation.

One small (31 patients) single-center, observational study of pediatric ARF described the effectiveness of HFPV in patients who failed conventional ventilation. The authors concluded that significant improvements in oxygenation index, oxygen saturation index, PaO_2/FiO_2, and oxygen saturations were present as early as 12 hours and persisted through 48 hours after transition. Additionally, significant reductions in $PaCO_2$ were present within 6 hours and persisted through 48 hours after transition. Furthermore, these improvements in gas exchange were achieved with reduced peak inflating pressures throughout the study period. Most importantly, the authors reported that 84% of the transitioned patients survived to hospital discharge.

Although no studies have been reported in children, several adult reports have indicated possible benefits in HFPV in patients with head injury associated with increased intracranial pressure (ICP) in the presence of ARDS. These studies have demonstrated significant improvement in oxygenation, ventilation, and lowering of ICP when compared to CV.

HFPV may provide an alternative to CV in the treatment of ARF and inhalational injuries. HFPV may improve oxygenation and ventilation as well as improve mobilization of airway secretions and debris while lowering inspiratory pressures and potentially reducing risk of barotraumas.

13.7 Airway Pressure-Release Ventilation

Airway pressure-release ventilation (APRV) is a time-triggered, pressure-limited, and time-cycled mode of ventilation specifically intended for patients with a sustained spontaneous respiratory effort. Although in theory APRV can also accomplish complete ventilation in patients without spontaneous respiratory effort, it is rarely applied this way in pediatric patients. APRV is reported to reduce the discomfort associated with pressure-controlled ventilation and provides the advantages of pressure limitation.

Airway pressure-release ventilation (APRV) is a time-triggered, pressure-limited, and time-cycled mode of ventilation specifically intended for patients with a sustained spontaneous respiratory effort.

APRV consists of a high-flow continuous positive airway pressure (CPAP) around which patients can spontaneously breath. Additionally, there are regular, intermittent "breaths" accomplished by opening of the expiratory valve resulting in an abrupt, brief lowering of circuit pressure that allows outflow of gas from the lungs (release volume). This results in alveolar ventilation and removal of CO_2. APRV can be thought of as two levels of CPAP ventilation with the majority of the time spent at the higher level of CPAP. Unlike CPAP, APRV can improve both oxygenation and ventilation through this combination of elevated P_{aw}, timed releases, and spontaneous efforts.

In addition to FiO_2, the settings applied in APRV revolve around establishing the high- and low-pressure levels, as well as time intervals for which each of these pressure levels exist. These settings are designated as pressure high (P_{high}),

pressure low (P_{low}), time high (T_{high}), and time low (T_{low}). The conventional application of these settings includes a P_{high} equivalent to the plateau pressure during conventional ventilation, in the 20–35 cm H_20 range. A T_{high} in the 4–10 seconds range with P_{low} established between 0 and 4 cm H_2O, and T_{low} between 0.2 and 0.8 seconds. With such long inspiratory times and diminished expiratory times, APRV, without spontaneous respiratory effort, could be described as an extreme version of inverse ratio ventilation. Increases in oxygenation are established through manipulation of mean P_{aw} as described by the equation:

$$\frac{\left(P_{high} \times T_{high}\right) + \left(P_{low} \times T_{low}\right)}{\left(T_{high} + T_{low}\right)}$$

Tidal (release) volume is established by the amount of difference in the two pressures and can vary based on the thoracic compliance, resistance, and the T_{low}. As alveoli recruitment occurs, the "release" volumes progressively increase.

Tidal (release) volume is established by the amount of difference in the two pressures and can vary based on the thoracic compliance and resistance, as well as the T_{low}. As alveoli recruitment occurs, the "release" volumes progressively increase.

The use of recruitment maneuvers has been shown to improve gas exchange and compliance, although these effects appear to be nonsustained, requiring repeated application. Alternatively, APRV may be viewed as a nearly continuous recruitment maneuver, where the P_{high} creates a stabilized "open lung" while at the same time facilitating spontaneous breathing.

APRV additionally augments oxygenation and ventilation in low-compliance pulmonary diseases by reducing shunting caused by diminished FRC from collapsed alveoli. The recruitment of alveoli through the use of prolonged plateau pressures allows collateral ventilation through the pores of Kohn, the canals of Lambert, and the channels of Martin to assist in the expansion of lung units with long time constants or decreased compliance. The efficiency of collateral ventilation is enhanced with decreased ventilator frequency, thus establishing APRV as an optimal choice to enhance alveolar recruitment through these pathways.

Ventilation may be enhanced by increasing the frequency of depressurization cycles, reducing impedance to expiratory flow by reducing P_{low}, lengthening the duration of depressurization (T_{low}), or treating bronchospasm.

The allowance of unrestricted, spontaneous breathing throughout the respiratory cycle improves patient comfort, eliminates patient-ventilator dyssynchrony, and theoretically diminishes the need for sedation and paralysis. Thorough engagement of the diaphragm by spontaneous breathing has been shown to distribute ventilation in a different pattern than mechanical or assisted breaths. Whereas mechanical breaths preferentially ventilate poorly perfused, well-aerated, nondependent lung units, spontaneous breaths tend to ventilate well-perfused, underaerated, dependent alveoli. This results in enhanced ventilation-perfusion matching and diminished dead space ventilation. An additional benefit of spontaneous ventilation is achieved by decreasing intrathoracic pressures, thus enhancing venous return and cardiac index.

Oxygenation is improved by increasing the level of P_{high} (recruiting alveoli with higher opening pressures), increasing the T_{high} (enhancing collateral circulation and recruitment of lung units having high resistance), increasing the P_{low} (preventing derecruitment), or shortening the T_{low} of the release breath (increasing intrinsic PEEP).

The clinician determines the frequency, magnitude, and length of the depressurization cycles in response to the patient's ventilation needs. Increasing the frequency of depressurization cycles enhances ventilation. Reducing impedance to expiratory flow by reducing P_{low}, lengthening the duration of depressurization (T_{low}), or treating bronchospasm also increases release volumes and improves ventilation. Conversely, systemic oxygenation improves by increases in P_{aw}, increasing the level of P_{high} (recruiting alveoli with higher opening pressures), increasing the T_{high} (enhancing collateral circulation and recruiting lung units having high resistance), increasing the P_{low} (prevent derecruitment), or shortening the T_{low} of the release breath (increase intrinsic PEEP). Usual practice for setting T_{low} involves adjusting the time such that expiratory flow during the release phase reaches 50–75% of its peak value (i.e., expiratory flow and exhalation are not complete).

Data on clinical outcomes in pediatric patients using APRV are limited to case series and a single small crossover design study. More recently, a retrospective, single-center moderately large (104 patient) study reported on the use of either HFOV or APRV in pediatric patients failing conventional ventilation. This study reported a mortality rate of 39% in this patient population, consistent with the rate found in NCV use for respiratory failure in other studies. Interestingly, this study noted that survival was associated with a nearly doubling of oxygenation after 24 hours compared to oxygenation improvements in non-survivors.

Therefore, routine use of APRV in ALI cannot be advocated on the basis of clinical information available today. However, the potential benefits of reduced peak inspiratory pressures, enhanced oxygenation and ventilation, reduced neuromuscular blockade and sedation, as well as improved hemodynamics warrant consideration for its use in patients with deteriorating clinical conditions with conventional mechanical ventilation. As discussed earlier in this chapter, larger studies as well as earlier implementation during HRF may elucidate further benefits. APRV is an alternative consideration in the spontaneously breathing patient who requires mechanical ventilation support yet experiences significant discomfort or potentially dangerous pressures with conventional ventilation. APRV may be combined with pressure support, tracheal gas insufflation, or prone positioning to further support the patient's respiratory efforts and has been used in the setting of ARDS in both adult and pediatric patients.

APRV may be considered an alternative for the spontaneously breathing patient who requires mechanical ventilation support requiring potentially toxic pressures or experiencing significant discomfort with conventional ventilation.

13.8 Long-Term Mechanical Ventilation

Patients requiring prolonged mechanical ventilation are rapidly increasing in number. Improved ICU care has resulted in many patients surviving acute respiratory failure to require prolonged mechanical ventilation during convalescence. Also, mechanical ventilation is increasingly used as a therapeutic option for patients with symptomatic chronic hypoventilation, with an increased effort to predict nocturnal hypoventilation to initiate ventilation earlier. Unfortunately, there are no comprehensive databases or national registry of home ventilator patients—therefore, the precise number of home ventilator patients is unknown.

A 2011 review of the Kids Inpatient Database produced by the Agency for Healthcare Research and Quality for the years 2000–2006 found that there were an estimated 7812 discharges associated with long-term mechanical ventilation (LTMV). Compared to discharges for children with complex chronic conditions (CCCs), LTMV had significantly higher mortality, longer lengths of stay, higher mean charges, more emergency department admissions, and more discharges to long-term care. From 2000 to 2006, there was a 55% increase in the number of LTMV discharges and a concurrent 70% increase in hospital charges. The majority of LTMV discharges occurred in children under 4 years of age with approximately 50% of the charges attributed to children <1 year old. To my knowledge, no comprehensive review has been compiled regarding pediatric LTMV in the ensuing decade.

A nationwide review of pediatric inpatient discharges showed that compared with discharges for other children with complex chronic conditions, long-term ventilated patients had significantly higher mortality, longer lengths of stay, higher mean charges, more emergency department admissions, and more discharges to long-term care.

Mechanical ventilation in the home is not a new idea. Patients with poliomyelitis benefited from home mechanical ventilation by iron lung during the years before the 1950s. With the development of positive pressure ventilators, home use of these devices with tracheostomies emerged as a viable technology. In 1977, the LP3 portable volume ventilator was approved by the FDA for use outside the hospital. The initial target population for home mechanical ventilation was ventilator-dependent pediatric patients. This effort was led by Dr. Allen Goldberg, who learned of this approach in France and returned to Children's Hospital of Pennsylvania to begin the first home ventilator program there.

The population of children receiving long-term mechanical ventilation outside of the acute care setting has grown dramatically over the last two decades but with no comprehensive review of their numbers, characteristics, and outcomes.

An important reimbursement milestone occurred in 1981 with Katie Beckett, an infant with viral encephalitis that left her ventilator-dependent in a pediatric ICU in Iowa. Officials from Medicaid, the government health insurance plan for the needy, initially claimed that it could only pay for her care in the pediatric ICU. At the behest of her family (and others), the Medicaid waiver program (sometimes referred to as the "Katie Beckett waiver") was passed. This program allowed parents like the Becketts, who made too much money to qualify for Medicaid, to be covered for their child with extreme medical costs, even though their child lived at home instead of in an institution. Technology, expertise, and funding were now available to support ventilator-dependent patients outside of the hospital.

Ideally, the preferred location for long-term mechanical ventilation is in the home because costs are reduced, quality of life is enhanced, and integration into the community is maximized. For the pediatric ventilator patient, the advantages of home ventilation also include being reunited with parents and family, which greatly enhances normal development and relationships. Home mechanical ventilation also reduces exposure to hospital-borne infections and frees hospital ICU beds for other acutely ill patients.

The indications for mechanical ventilatory support in the home are increasing as technology and infrastructure support improve. However, the levels of support and the goals of support can differ substantially, depending upon a number of factors. For example, some conditions may require support only at night and/or intermittently during waking hours. Other conditions, however, require high levels of support 24 h/d. Disease trajectory can also affect goals and planning. For example, a slowly improving process (e.g., premature infants recovering from chronic lung disease of infancy) may warrant plans for weaning the support. On the other hand, progressive respiratory failure (e.g., adolescents with Duchenne muscular dystrophy) will need the incorporation of plans for future palliative care.

In light of this growing population, the pediatric intensivist's exposure to this patient population has also grown exponentially. While encountering these patients with acute illnesses is common, the care of these patients is not dissimilar to other PICU patients with CCCs. Depending on the particular PICU in which the practitioner practices, one may also require involvement in the decision-making, home caregiver training, and the delineation of home medical equipment in the patient readying for their initial discharge to home. This preparation can entail a lengthy process lasting for weeks to months. When caring for such a patient, one of the most challenging aspects the pediatric intensivist will encounter is changing their own mindset. As opposed to the acutely ill PICU patient, LTMV patients preparing for discharge by definition are clinically stable and do not require frequent laboratory testing or radiologic examination. Likewise, every perturbation in oxygen saturation, O_2 requirement, or episode of agitation does not necessarily require specific and aggressive intervention. Additionally, the comprehensive care required by the children will require the intensivist to address areas of care not frequently encountered in caring for typical PICU patients. Areas to address include long-term weaning goals, preparation for emergency situations at home, determination of environment of care (home, long-term care facility, foster care), activities of daily living, mobility, communication, as well as psychosocial concerns for both the patient and their family. As the training and exposure of most pediatric intensivists is somewhat limited in this patient population, it would behoove the intensivist to avail themselves of the expertise of pediatric pulmonologists, rehabilitation professionals (occupational, physical, and speech therapists), and social workers to assist them in developing the comprehensive outpatient care plan that these complex patients require.

13.9 Conclusion

Nonconventional modes of mechanical ventilation have no prospective large randomized clinical studies establishing their efficacy in the use for pediatric patients with acute respiratory failure. The use of these modes of ventilation is best reserved for clinical failures of conventional ventilation and in those patients who may benefit from avoidance of the negative consequences of such ventilation. Outcome studies and multicenter randomized trials of various forms of nonconventional ventilation would be helpful in establishing proper boundaries for use of these modes in pediatric patients.

Review Questions

1. Negative pressure ventilation is MOST likely to benefit which of the following causes of respiratory failure?
   A. Acute pulmonary edema
   B. Bronchiolitis
   C. Increased intracranial pressure
   D. Left-sided myocardial dysfunction
   E. Neuromuscular disease with minimal parenchymal lung disease

2. Noninvasive positive pressure ventilation is most likely to be beneficial in which of the following patients?
   A. Cooperative 7-year-old with status asthmaticus
   B. Fourteen-year-old with traumatic brain injury and facial trauma
   C. Two-year-old with pneumonitis following lye ingestion
   D. Anxious 8-month-old with abdominal distention and gastroesophageal reflux-induced bradydysrhythmias
   E. Obtunded 14-year-old with suspected encephalitis.

3. A 5-year-old with acute hypoxemic respiratory failure is being supported with high-frequency oscillatory ventilation requiring 100% oxygen. His most recent arterial blood gas reveals a pH of 7.38, a $PaCO_2$ of 52 mm Hg, a PaO_2 of 47 mm Hg, and an oxygen saturation of 81%. Chest radiograph reveals no evidence of a pneumothorax and lung expansion to the eighth rib posteriorly. The most appropriate ventilator adjustment would be to:
   A. Adjust the I:E ratio
   B. Increase the amplitude by 2 cm H_2O
   C. Increase the frequency by 2 Hz
   D. Increase the mean airway pressure by 2 cm H_2O
   E. Partially deflate the endotracheal tube cuff

4. In comparison to conventional ventilation, the use of high-frequency percussive ventilation in pediatric patients with inhalational injury has been found to be associated with:
   A. Decreased lengths of mechanical ventilation
   B. Decreased mortality
   C. Decreased peak inspiratory pressures
   D. Increased incidence of pneumonia
   E. Lower PaO_2/FiO_2 ratios

5. A 12-year-old male with acute respiratory distress syndrome is being supported with airway pressure-release ventilation requiring 100% oxygen. His most recent arterial blood gas reveals a pH of 7.37, a $PaCO_2$ of 53 mm Hg, a PaO_2 of 49 mm Hg, and an oxygen saturation of 83%. Which of the following interventions would be MOST likely to improve his oxygenation?
   A. Administering a dose of neuromuscular blockade
   B. Decreasing the P_{low}
   C. Decreasing the T_{high}
   D. Increasing the P_{high}
   E. Increasing the T_{low}

6. Care of children receiving long-term mechanical ventilation, when compared to other children with complex chronic conditions, has been demonstrated to involve which of the following?
   A. Shorter length of stay since then they can be discharged while on a ventilator
   B. Increased mortality
   C. Lower average costs
   D. Fewer emergency department visits
   E. Greater likelihood of discharge to home care

7. Which of the following represents the most beneficial effect of utilizing airway pressure-release ventilation (APRV) for the treatment of severe acute respiratory distress syndrome requiring mechanical ventilatory support with potentially toxic pressures?
   A. APRV allows for the preservation of spontaneous ventilation.
   B. APRV enhances the removal of CO_2 via collateral ventilation.
   C. APRV is associated with a lower incidence of nosocomial infections.
   D. APRV maintains favorable hemodynamics.
   E. APRV maintains the recruitment of collapsed alveoli.

Learning Objectives

Cardiac Physiology and Function

- State the importance of cardiac histology and anatomy as it relates to the normal cardiac cycle.
- Describe the relationship between chemical and cellular events in the myocardium and the normal cardiac cycle.
- Describe how pathologic states can alter the normal chemical and cellular events in the heart. Understand how these chemical and cellular changes affect the overall function of the heart and cardiac output.
- Summarize the components of cardiac output and the physiologic response to low cardiac output states at different ages.
- Summarize the cardiovascular response to alterations in intravascular pressure and volume.
- Discuss afterload physiology and the effect of changes in afterload on cardiac function.

Cardiopulmonary Interactions

- Describe the relationship between the function of the pulmonary and cardiovascular systems under normal conditions.
- Describe how pathologic cardiovascular and pulmonary states alter cardiopulmonary interactions.
- Discuss how positive and negative pressure ventilation affect cardiovascular physiology in the presence of normal and altered cardiovascular function.
- Explain the relationship between pulmonary and cardiovascular function in patients with single ventricle physiology/Fontan.

14.1 Introduction

In critical care, nothing is for free; the art of critical care is using a strong knowledge of physiology to optimize interventions to balance their effects between the heart and lungs.

The cardiovascular system is responsible for providing adequate blood flow to meet the metabolic demands of the body and its organs. The principles governing blood flow and pressure in the vascular system are referred to as hemodynamics. The most significant function of the cardiovascular system is the delivery of oxygen to meet the demand for cellular oxygen consumption. Although increases in oxygen delivery can occur over time through an increase in hemoglobin concentration, during an acute illness, the primary physiologic response to an increase in oxygen demand is an increase in cardiac output. If cardiac output is not sufficient to meet the metabolic needs of the body as a whole, a redistribution of regional blood flow and constriction of venous capacitance vessels must occur to maintain adequate oxygen delivery to vital organs. If the redistribution of blood flow is insufficient to meet the metabolic demands of a specific organ, organ dysfunction will begin to develop. The cardiovascular system of an otherwise healthy child with acute illness will typically perform this function well, but in the critically ill child, the physiologic response to increasing oxygen demand may be inadequate and unable to meet the metabolic needs of the body. Caring for the child with critical illness often requires interventions by the intensivist to balance oxygen and nutrient delivery with oxygen consumption and waste removal. In some cases, therapeutic interventions to support one system, such as positive pressure mechanical ventilation to support breathing, will have both beneficial and undesirable effects on the cardiovascular system. When caring for the critically ill child, it is essential to have a fundamental understanding of normal cardiac physiology, cardiopulmonary interactions, and how critical illness and therapeutic interventions can alter cardiovascular function. This chapter reviews the physiology and function of the heart and how critical illness alters cardiovascular

physiology. In addition, the unique interactions that occur between the heart and lungs will be discussed in both the healthy and ill child, including the unique cardiopulmonary interactions in a child with single ventricle anatomy.

14.2 Cardiac Physiology and Function

14.2.1 Cardiac Structure and Cycle

Cardiac myocytes begin rapidly proliferating early in fetal life; during the perinatal period, proliferation stops. During the perinatal period of human development, cardiac myocytes undergo a second round of DNA synthesis and nuclear mitosis without cytokinesis. This leaves the majority of cardiac myocytes binucleated. Adult cardiac myocytes do not reenter the cell cycle when exposed to growth signals. Thus, the only means for cardiac mass enlargement is through an increase in cell size or hypertrophy. The failure of adult cardiac myocytes to reenter the cell cycle significantly limits their potential for self-renewal or repair after injury such as a myocardial infarction. An intensive field of research is whether other progenitor or stem cells can be signaled to differentiate into cardiac myocytes in order for repair to occur after significant injuries.

The heart is the pump to the vascular system. The left ventricle has an ellipsoid shape with the long axis directed from apex to base. The left ventricle's shape is the ideal geometry to pump blood into the higher pressure systemic vascular system. The efficient function of this pump is dependent on the integrity and coordination of the anatomic components of the four-chambered heart through the cardiac cycle as illustrated in ◘ Fig. 14.1. The cardiac cycle is divided into ventricular contraction (systole) and ventricular relaxation (diastole). Throughout the cardiac cycle, oxygen-depleted blood returns to the right atrium while oxygen-rich blood returns to the left atrium. The returning blood results in a pressure rise in the atria and venous system referred to as the *v* wave. Once ventricular pressure falls below the atrial pressure during diastole, the right-sided three-leaflet tricuspid valve and left-sided two-leaflet mitral valve (atrioventricular or AV valves) open, and blood enters the respective ventricles; atrial pressure begins to fall as the ventricles rapidly fill. Toward the end of diastole, atrial contraction (seen as the *a* wave on atrial pressure monitoring) occurs propelling an additional volume of blood into the ventricles while producing a rise in atrial and venous pressure. Because there are no valves between the venous system and the atria, the right atrial waves can also be seen in the venous system. Under normal conditions, atrial contraction contributes less than 20% of ventricular filling but can have a more significant contribution when diastolic filling time decreases as heart rate rises or when ventricular walls are stiff and thickened, which is most often due to hypertrophy.

Dysrhythmias disrupt the cardiac cycle resulting in uncoordinated anatomic and contraction function. For example, a venous "cannon" *a* wave can be appreciated when atrial contraction occurs against a closed AV valve due to dyssynchrony between the atrium and ventricles.

After atrial contraction, filling is complete, and the ventricle contains an end-diastolic volume (EDV) of blood with a resultant end-diastolic pressure (EDP). Clinically, the EDV represents the patient's intravascular volume status or preload and impacts the contractile nature of the myocardium illustrated by Starling's law (◘ Fig. 14.2). The QRS complex marks the beginning of ventricular depolarization/contraction and the start of systole. As ventricular contraction proceeds, pressure in the ventricles exceeds that of the atria, closing the AV valves and producing the first heart sound, S_1 (◘ Fig. 14.1). AV valves are anchored to the ventricles via chordae tendineae and papillary muscles that prevent valvular inversion into the atria. Competency of the AV and outflow tract valves allows ventricular isovolemic contraction to occur. The bowing of

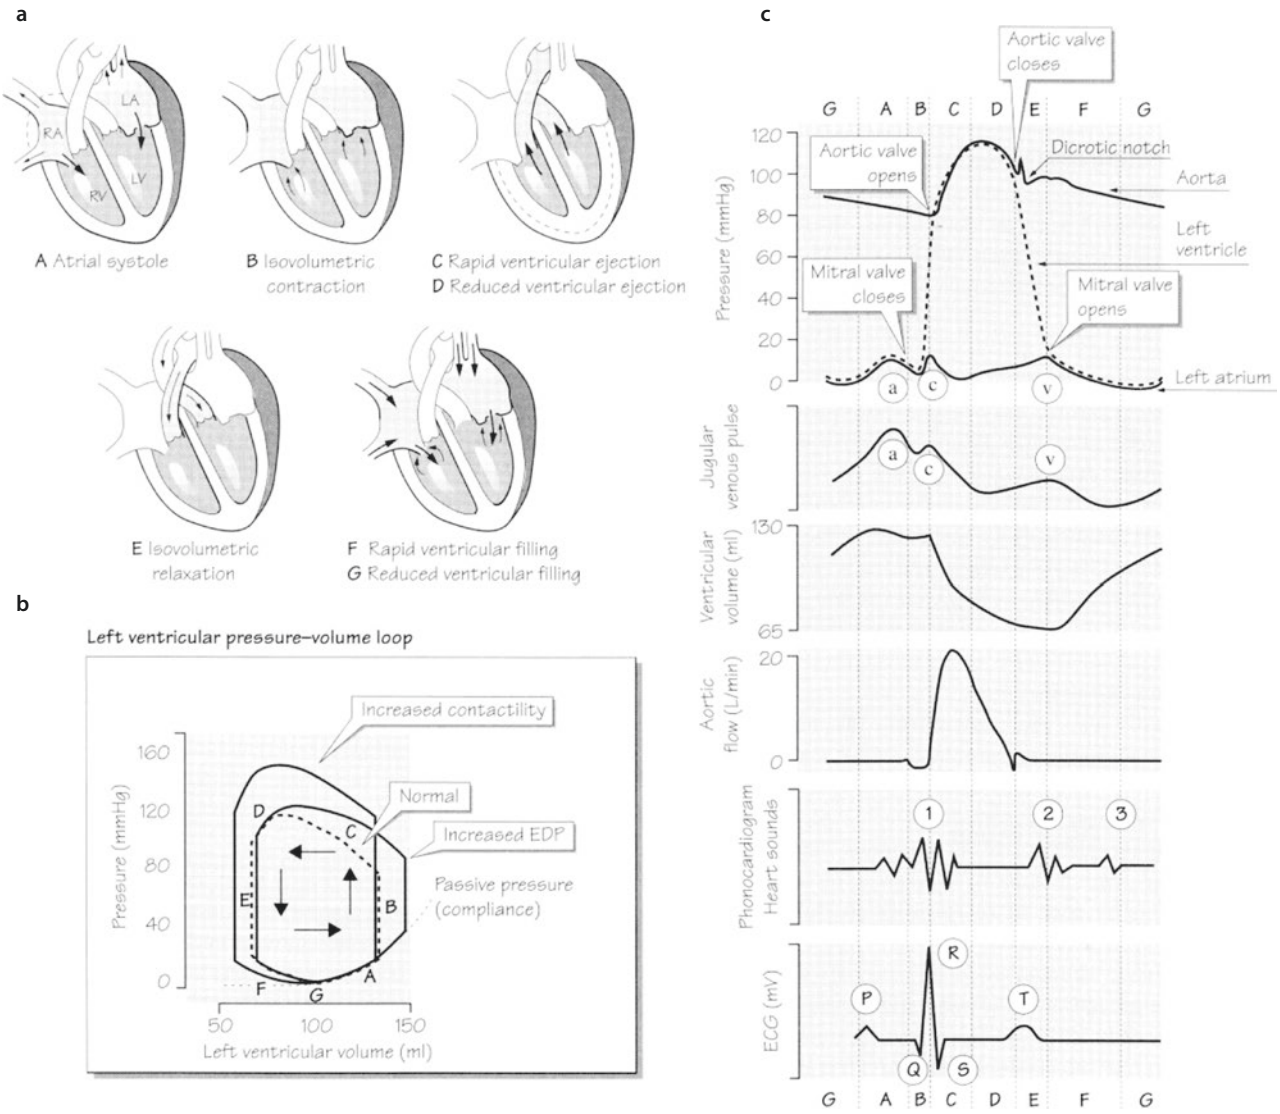

Fig. 14.1 Elements of a complete cardiac cycle: anatomic sequence **a**; left ventricular pressure-volume loop **b**; time-correlated left atrial, left ventricular, aortic, and venous pressures; ventricular volume; aortic flow; heart sounds; and electrocardiogram, through the cardiac cycle **c**. (From Aaronson et al. (2004))

the AV valves from the pressure generated during ventricular contraction results in an atrial and venous *c* pressure wave. When pressure in the ventricles exceeds the diastolic pressure in the aorta and pulmonary artery, the outflow valves are forced open and blood is ejected. Once ventricular contraction stops and repolarization begins, marked by the appearance of the electrical T-wave, pressure in the ventricle falls below that of the aorta and pulmonary artery, closing the aortic and pulmonary valves, producing the aortic A_2 and pulmonary P_2 components of the second heart sound (S_2). With closure of the aortic valve, pressure in the aorta briefly increases resulting in the aortic dicrotic notch pressure wave. The volume of blood ejected during one heartbeat is the stroke volume (SV); the ejection fraction is the proportion of EDV blood ejected, or SV/EDV, and is often used to estimate heart function. Once the outflow valves close, diastole begins again. The ventricles enter into isovolemic relaxation while the atria continue filling. The right atrium fills with caval

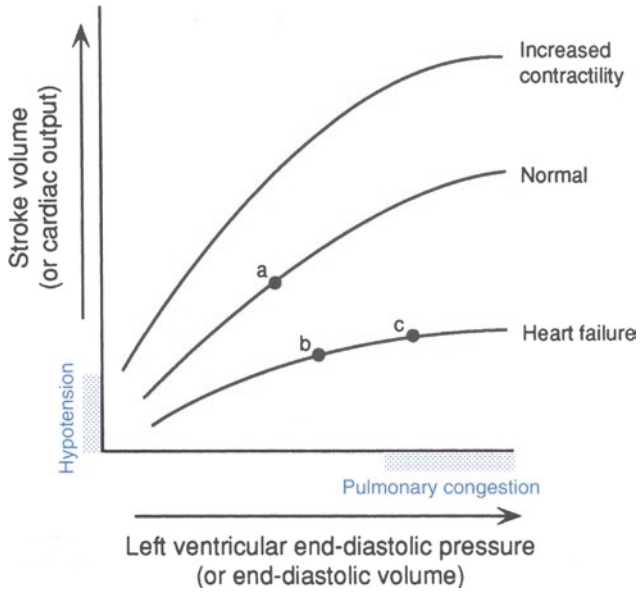

Fig. 14.2 Frank-Starling curves. Left ventricular (LV) performance curves relate preload, measured as LV end-diastolic volume (EDV) or pressure (EDP), to cardiac performance, measured as ventricular stroke volume or cardiac output. On the curve of a normal individual (*middle line*), cardiac performance continuously increases as a function of preload. States of increased contractility (e.g., norepinephrine infusion) are characterized by an augmented stroke volume at any level of preload (*upper line*). Conversely, decreased LV contractility (commonly associated with heart failure) is characterized by a curve that is shifted downward (*lower line*)

venous blood while the left atrium fills with pulmonary venous return. The *v* central venous pressure wave is produced during atrial venous filling against the closed AV valves. When atrial pressure exceeds ventricular pressure, the AV valves open and ventricular filling begins (Fig. 14.1).

The cardiac cycle also impacts oxygen delivery to the myocardium via the right and left coronary arteries originating from the aortic root. Blood flow (Q) into the coronaries is proportional to aortic diastolic pressure and inversely related to resistance (Q = P/R). During systole, small coronary branches are compressed by the contracting myocardium increasing resistance and limiting flow, leaving the majority of coronary blood flow to occur during diastole. Coronary blood flow is therefore affected by changes in aortic diastolic pressure and diastolic filling time. The majority of coronary venous blood returns to the heart via the coronary sinus into the right atrium. The coronary perfusion gradient across the myocardium can be thought of as the difference between the aortic diastolic pressure and the right atrial pressure or EDP of the left ventricle, whichever is higher.

Myocardial perfusion gradient between the aortic diastolic pressure and the right atrial or left ventricle end-diastolic pressure (LVEDP) becomes an important factor when respectively treating patients with high atrial pressures, such as patients with Fontan physiology or patients with reduced cardiac pumping function that leads to an elevated LVEDP.

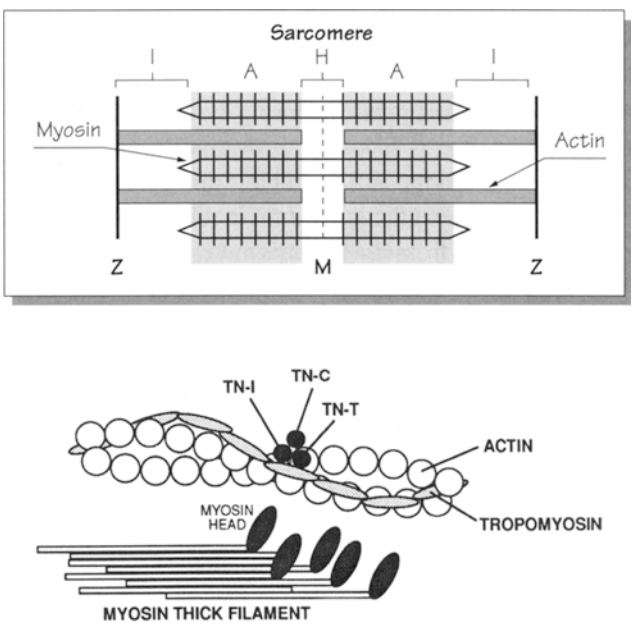
The heart resides in the pericardial sac that is made up of a fibrous outer layer and an inner serosal layer. The serosal layer lines the external surface of the heart muscle forming the visceral pericardium and then folds back onto itself to line the outer fibrous layer forming the parietal pericardium. The space between the visceral and parietal pericardium contains a small amount of fluid to reduce friction between the layers generated during the cardiac cycle. Restrictive disease affecting the pericardium or excess pericardial fluid can adversely affect cardiac filling and function during various portions of the cardiac cycle. Furthermore, the parietal pericardium attaches to the diaphragm. Thus, in settings with a flattened diaphragm, such as severe asthma or bronchiolitis or excessive positive pressure ventilation, the heart is compressed impairing venous filling.

The "heart" image on chest X-ray should always be referred to as a cardiac shadow or silhouette. The concept of a cardiac shadow allows for including pericardial pathology in the differential diagnosis of an enlarged silhouette.

14.2.2 Myocardial Contraction: Cellular Components

The cardiac cycle is dependent on sequences of myocardial contraction and relaxation. The cardiac myocyte is a highly specialized cell that contains substructures that enable this ongoing contraction-relaxation cycle.

Surrounded by sarcoplasmic reticulum, cytoplasm, and mitochondria are bundles (fibrils) that comprise the contractile apparatus. Fibrils are made up of individual sarcomeres that contain the basic myofibrillar contractile units: actin, tropomyosin, troponin, and thick myosin filaments. Actin is the thin filament attached to the sarcomere at the Z-line which interdigitates between the myosin components (◘ Fig. 14.3). The muscle flexes when the myosin heads attach to and "pull" on the actin filaments in an ATP-dependent process, sliding the components past each other. Tropomyosin resides between the grooves of the actin filaments. Troponin is a three-subunit regulator protein consisting of troponin T (TN-T) that acts to attach actin and tropomyosin filaments, troponin C (TN-C) that acts as a calcium binding site, and troponin I (TN-I) that acts to inhibit the ATPase responsible for the actin-myosin interaction. Under the influence of calcium, troponin functions as the "on-off" switch for myocardial cell contraction. An increase in cytosolic calcium concentration enables the interaction of cardiac myosin and actin filaments, whereas a decrease in cytosolic calcium concentration inhibits actin-myosin interaction. During relaxation, actin-myosin binding is inhibited by troponin I and tropomyosin. When intracellular calcium levels rise, calcium is available to bind to TN-C. Calcium binding to TN-C blocks TN-I's inhibitory effect on tropomyosin, thus allowing tropomyosin and troponin to undergo conformational changes that are conducive to actin-myosin cross bridging. Contraction continues until intracellular calcium levels are reduced by calcium uptake into the sarcoplasmic reticulum, freeing TN-C of calcium with subsequent inhibition of the actin-myosin interaction and relaxation of the myocardial muscle (◘ Fig. 14.3). A number of protein regulators in the myofilament regulate the interaction of actin and myosin. Mutations of one of these protein regulators, cardiac myosin-binding protein C, are responsible for the disease hypertrophic cardiomyopathy.



◘ **Fig. 14.3** Muscle element structures and interaction: (*Top*) sarcomere unit; A band (A), H zone (H), I band (I), M line (M), and Z disc (Z). (*Bottom*) Schematic diagram of the main contractile proteins of the myocyte, actin, and myosin. Tropomyosin and troponin (components TN-I, TN-C, and TN-T) are regulatory proteins

The electrical activity of the heart initiates the cardiac cycle. At the cellular level, "excitation-contraction" coupling relates depolarization of the heart to cellular calcium flux and the cellular contraction-relaxation sequence (◘ Fig. 14.4). The intracellular membranous sarcoplasmic reticulum (SR) is largely responsible for both the increase in cytoplasmic calcium concentrations required for contraction and the removal of calcium allowing for relaxation. During phase two of cellular depolarization, calcium enters the cell via L-type voltage-gated calcium channels within the cell membrane (sarcolemma); however, the rise in calcium concentration is not great enough to trigger muscle contraction. Instead, the initial cellular increase in calcium triggers a larger release of calcium stored in the SR via ryanodine receptors – "calcium-induced calcium release." With the large increase in intracellular calcium, calcium binds to the TN-C subunit of troponin, changing the configuration of tropomyosin and allowing the actin and myosin elements to initiate contraction. Contraction will continue as long as there is calcium available to bind TN-C and ATP to fuel the process. As the cell electrically repolarizes, the cell membrane calcium channels close. Calcium is actively sequestered back into the SR via an ATPase-dependent pump; calcium is also extruded from the cell by a sodium-calcium exchanger and to some degree by an active calcium ATPase-dependent pump residing in the cell membrane. Once calcium is no longer available to bind to TN-C, tropomyosin again inhibits the interaction of actin and myosin, reestablishing relaxation and diastole.

Given the importance of calcium ions in myocardial contraction and relaxation, it is not surprising that most inotropic agents, both positively and negatively affecting the heart, mediate their effects via impacting calcium flux within the cardiac cell. G protein-coupled receptors often mediate the effects of different cardiac inotropes through activation of a second messenger system that affects calcium ion flux. Infusions of calcium salts can act as a potent inotrope, particularly in neonates due to the dependence of the neonatal heart on transcellular calcium flux. Specifics regarding various clinical inotropes are discussed in ▶ Chap. 17, Cardiovascular Drug Therapy. Plasma-ionized calcium concentrations have a direct effect on myocardial contraction; low ionized calcium concentrations have a negative inotropic effect, while raising plasma-ionized calcium concentrations positively influences contraction but can also increase afterload by stimulating vascular smooth muscle contraction. Acidosis exerts a direct negative inotropic effect in general, but acidosis stimulates endogenous sympathetic nervous system activity that can counteract this effect. Acidosis also has the property of increasing plasma-ionized calcium concentrations, shifting the equilibrium between protein-bound calcium and free calcium, which potentially increases inotropic activity. Critically ill patients may present with both acidosis and ionized hypocalcemia as part of their illness. Furthermore, infusions of albumin or blood products can transiently lower ionized calcium concentration due to calcium binding with albumin or citrate, respectively. Therefore, it is important that clinicians identify and correct low ionized calcium concentrations prior to or in concert with attempting pharmacologic correction of acidosis.

Correction of acidosis is often best left to the patient as the clinicians address the cause. A mild to moderate acidotic environment can be beneficial, allowing for a higher ionized calcium concentration and ease of unloading oxygen to tissue from hemoglobin (left shift of oxyhemoglobin dissociation curve).

14.2.3 Cardiac Pump Function

Cardiac output (CO) is the measure of blood volume per unit time delivered to the body and is the product of stroke volume (volume of blood pumped per heartbeat in milliliters) and heart rate (beats per minute). Stroke volume is determined by the following: *preload*, the amount of blood in the heart affecting myocardial fiber stretch prior to contraction; *afterload*, the forces opposing the ejection of blood from the ventricles; *contractility*, the strength of myocar-

Heart rate is a valuable marker for cardiovascular integrity in newborns and young children. Stroke volume is largely fixed in neonates, which results in the need to increase heart rate to increase CO in this population.

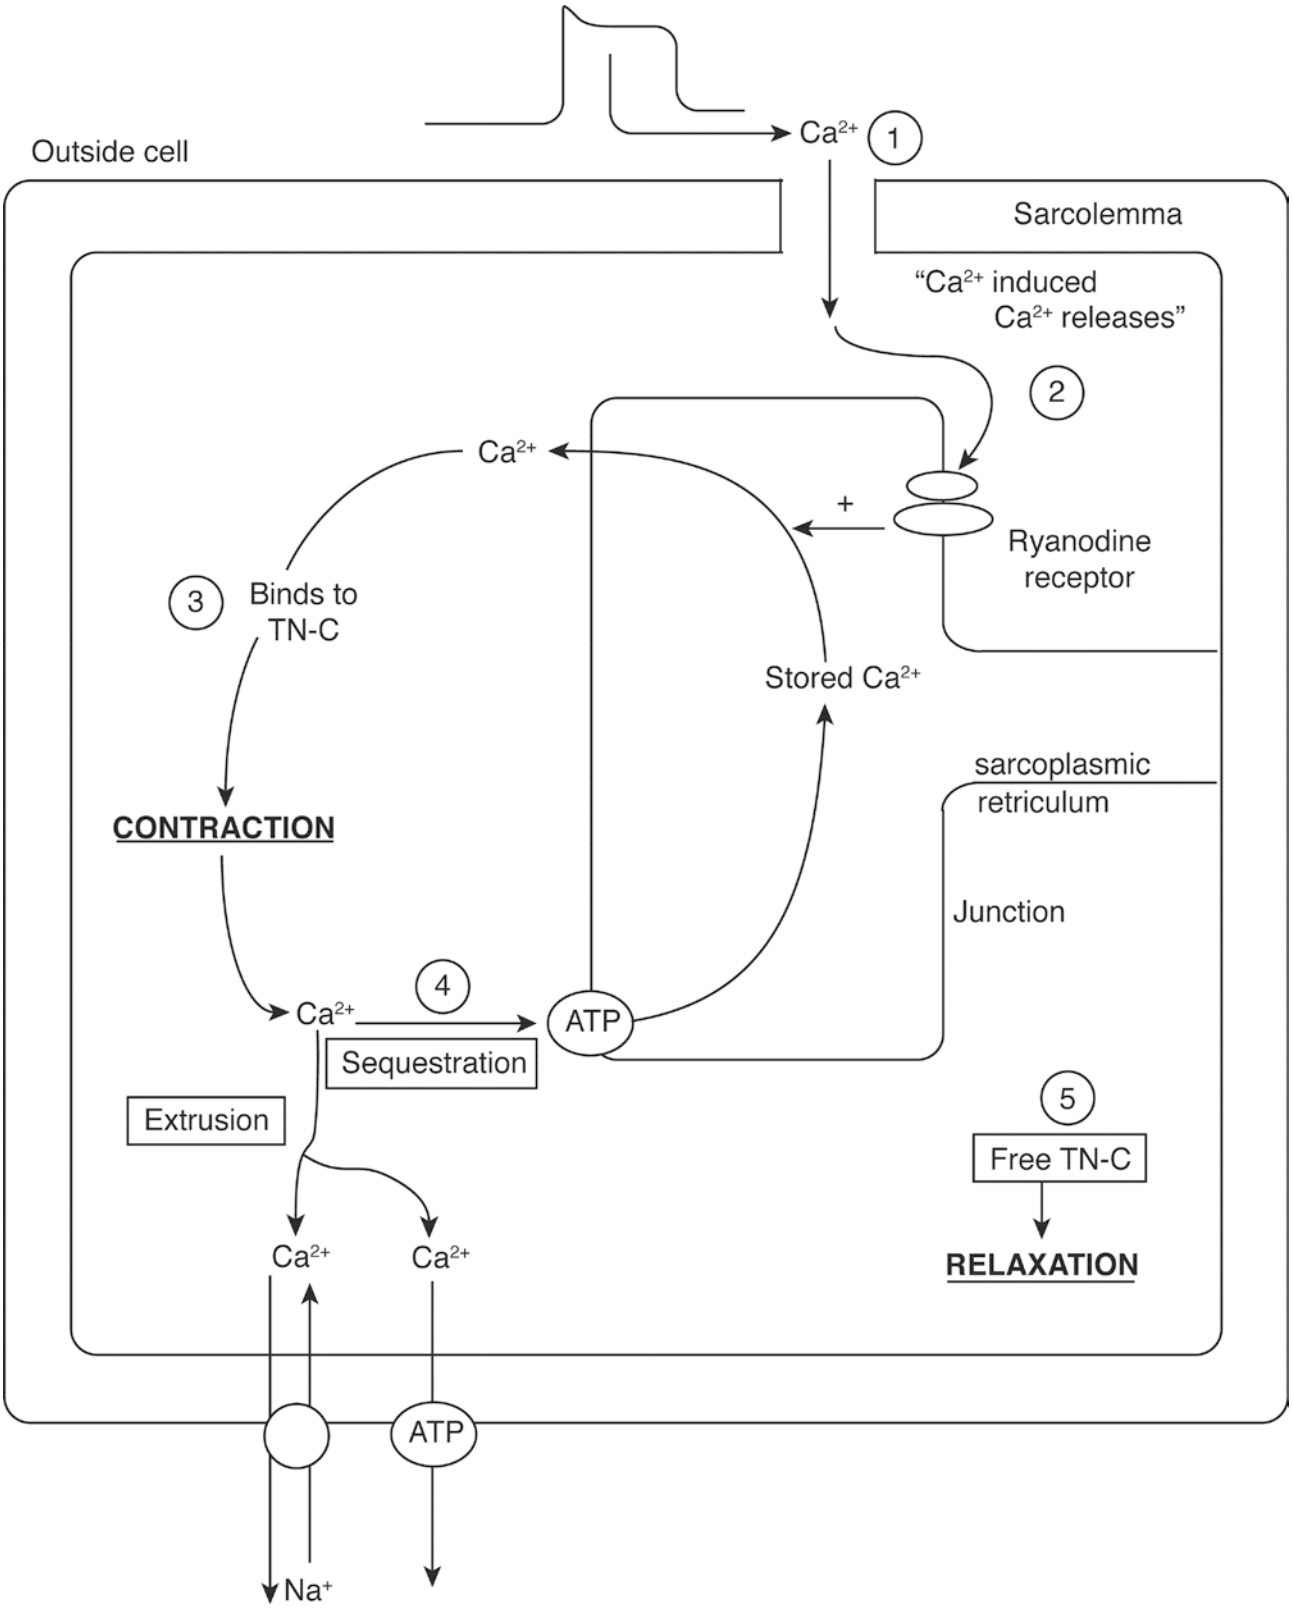


Fig. 14.4 Cellular cardiac cycle: (1) Myocardial depolarization opens L-type calcium channels in the sarcolemma allowing calcium to enter the cell. (2) Rising calcium concentrations trigger an even greater release of calcium from calcium stores within the cell via ryanodine receptors on the sarcoplasmic reticulum (SR) – "calcium-induced calcium release." (3) Calcium concentrations are now high enough to bind to troponin, allowing actin and myosin to interact and muscle contraction to occur. (4) Cellular repolarization triggers sequestration of calcium back into the SR and extrusion of calcium out of the cell, lowering intracellular calcium concentrations. (5) Falling intracellular calcium concentrations free tropomyosin to once again inhibit actin and myosin interaction leading to myocardial relaxation

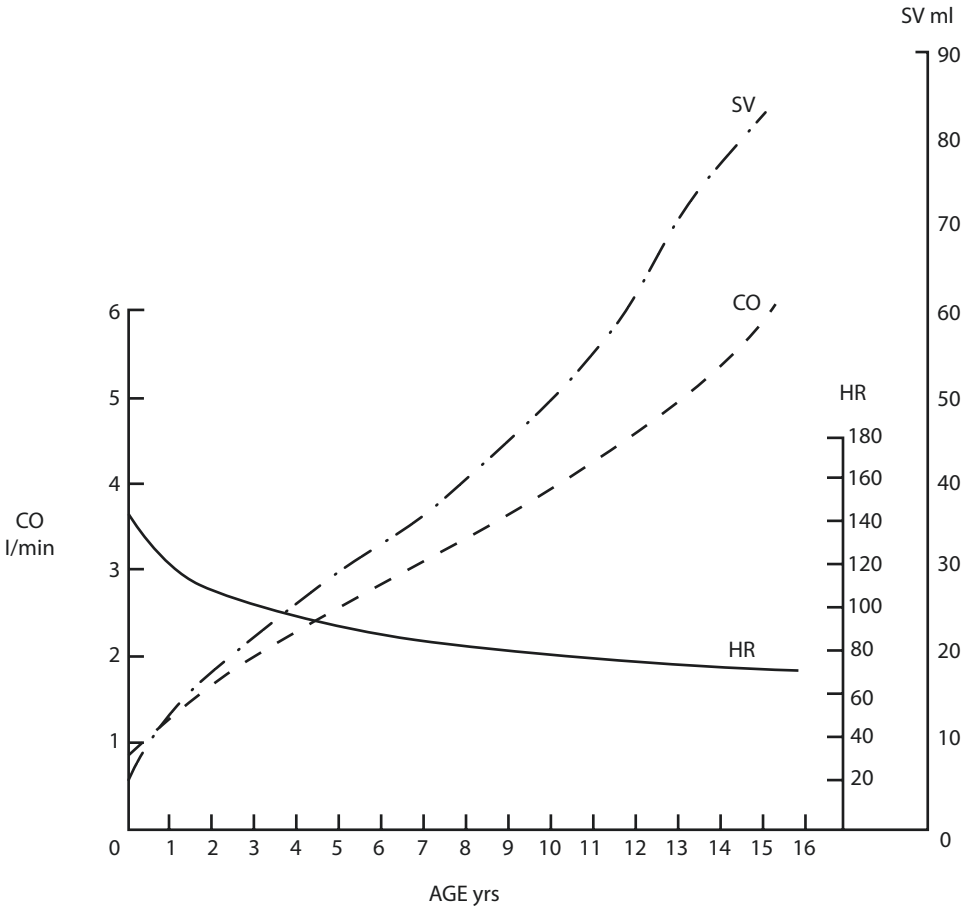

Fig. 14.5 Changes in cardiac output (*CO*), stroke volume (*SV*), and heart rate (*HR*) with age

dial contraction independent of preload and afterload; and *lusitropy*, the rate of myocardial relaxation. As the body grows, cardiac output must increase to keep up with the body's increased absolute metabolic activity. The relative effect of stroke volume and heart rate as determinants of cardiac output shifts with advancing age; stroke volume increases with age accounting for most of the absolute increase in cardiac output as an individual gets older while heart rate decreases (Fig. 14.5). The cardiac index (CI) is a measure of an individual's cardiac output (CO) adjusting for their size or body surface area (BSA); CI = CO/BSA. A normal CI is in the range of 2.5–4 L/min/m^2. Note that although absolute stroke volume and cardiac output increase with age, the stroke volume index and cardiac index decrease in older children and adults compared with infants and young children.

14.2.4 Stroke Volume: Preload

Otto Frank in the late 1800s and E. H. Starling in the early 1900s both noted that stroke volume increased as the pre-contraction cardiac muscle fiber length was increased. Muscle fibers exposed to a "load" prior to, or "pre," contraction lengthen and allow for an increased number of actin-myosin interactions during contraction, generating a stronger force. The stretching of the cardiac muscle is equated with end-diastolic ventricular volume; the greater the end-diastolic volume, the greater the stretch and resultant increase in ejected stroke volume during systole. The relationship between stroke volume and end-diastolic volume is known as the Frank-Starling ventricular function curve (Fig. 14.2).

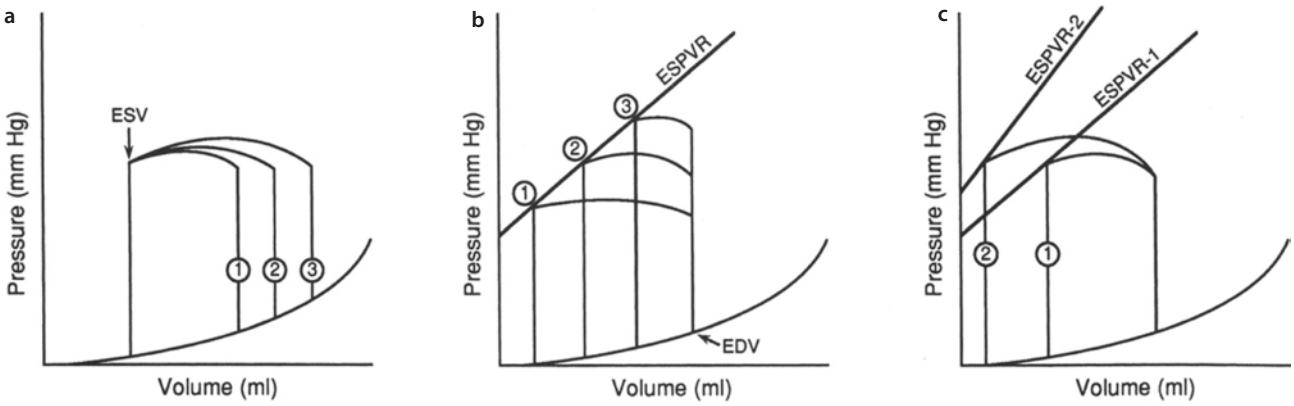

Fig. 14.6 The effect of varying preload, afterload, and contractility on the pressure-volume loop. **a** When arterial pressure (afterload) and contractility are held constant, sequential increases (*lines 1*, *2*, *3*) in preload (measured in this case as end-diastolic volume (*EDV*)) are associated with loops that have progressively higher stroke volumes but a constant end-systolic volume (*ESV*). **b** When preload (*EDV*) and contractility are held constant, sequential increases (*points 1*, *2*, *3*) in afterload (which increases arterial pressure) are associated with loops that have progressively lower stroke volumes and higher end-systolic volumes. There is a nearly linear relationship between the afterload and the ESV, termed the end-systolic pressure-volume relation (*ESPVR*); the slope of this curve defines the contractile state of the heart. **c** A positive inotropic intervention shifts the end-systolic pressure-volume relation upward and leftward from ESPVR-1 to ESPVR-2, resulting in loop 2, which has a larger stroke volume and smaller end-systolic volume than the original loop 1. (From Lilly (2003))

End-diastolic pressure is often used as equivalent to end-diastolic volume because it is easier to measure but can be misleading under a number of situations, such as when the compliance of the ventricle is poor, venous compliance is increased, or when the cardiovascular system is exposed to increased intrathoracic pressure. The effects of increasing preload on stroke volume while holding afterload and contractility constant can also be depicted in a pressure-volume loop diagram (Fig. 14.6a). As end-diastolic volume is increased, the heart ejects larger stroke volumes, always returning to the same end-systolic starting volume. The opposite effect on stroke volume is observed when preload is decreased and explains the decrease in stroke volume in conditions associated with hypovolemia or increased vascular capacitance where preload is reduced.

14

14.2.5 Stroke Volume: Afterload

Afterload is the force the ventricle has to overcome to eject blood into the systemic or pulmonary systems. From a cellular perspective, afterload is the sum of the forces against which cardiac fibers must shorten during systole. Factors affecting afterload include vascular pressure, vascular resistance, intrapleural pressure, and blood viscosity; clinically, afterload is often related to the systemic or pulmonary vascular resistance. As afterload is increased, muscle shortening and the velocity of contraction decreases, resulting in less blood ejected during each cardiac cycle when preload and contractility are held constant. The effects of increasing afterload on stroke volume are shown in Fig. 14.6b; as afterload is increased, end-systolic pressure rises along with end-systolic volume, resulting in a smaller stroke volume. Clinically, contractility and preload are not constant. Thus, as afterload (typically resistance) increases in a patient with normal cardiac function, stroke volume is often maintained by a normally functioning ventricle, but at the cost of arterial hypertension (SV α P/R).

The systemic aortic blood pressure and pulmonary artery pressure are often used as references for left and right ventricular afterload, respectively.

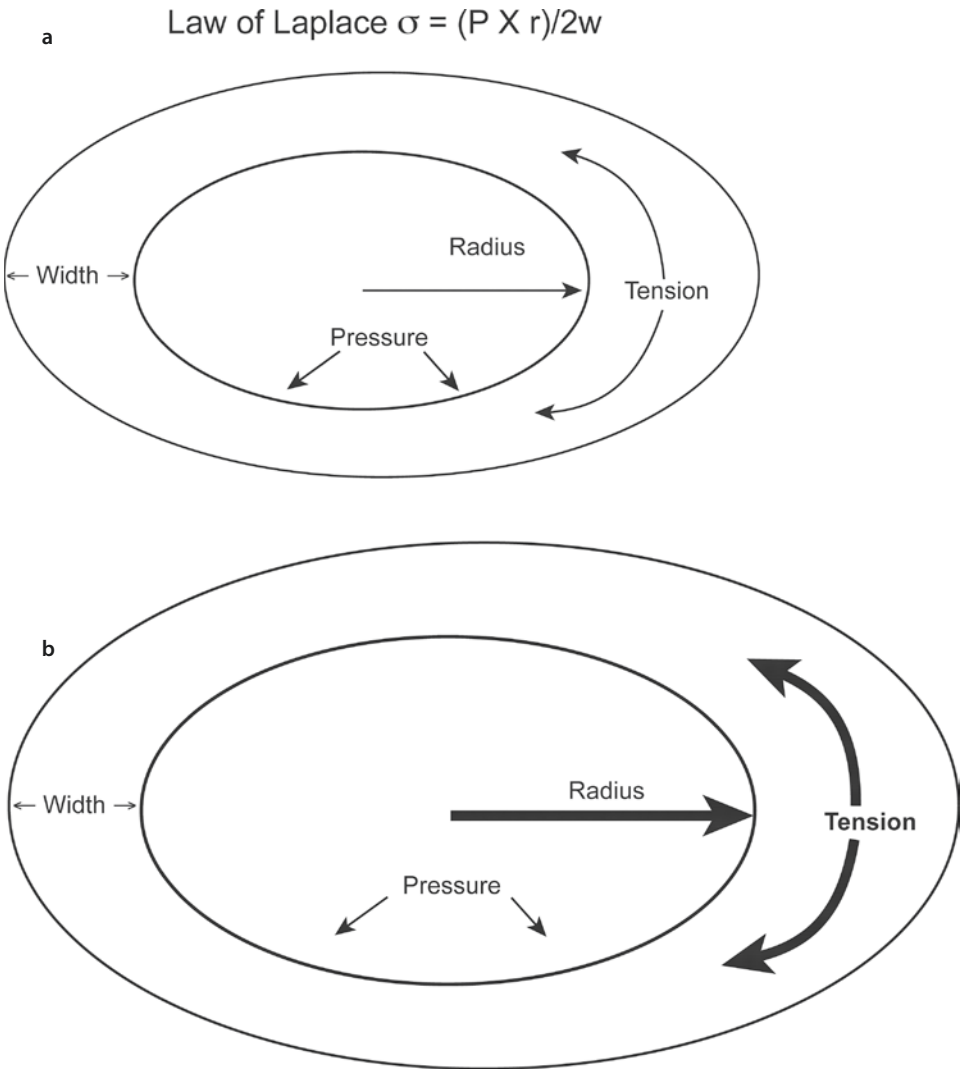

Fig. 14.7 Law of Laplace: T = (P × r)/2w, where *T* is wall stress or tension, *P* is pressure, *r* is radius, and *w* is wall thickness. **a** Normal left ventricular radius. **b** Effect of increasing ventricular radius on wall tension (afterload)

However, using pressures as an indicator of afterload can be misleading. Pressure is directly proportional to both flow (Q), or think of it as cardiac output, and resistance (R): P = QR. In the case of compensated shock, cardiac output may be decreased while resistance has increased by a similar amount, leading to a significant increase in afterload but little change in systemic pressure. The clinical signs indicating a compensated shock state tell the clinician more about the afterload on the heart than the blood pressure alone.

Afterload can also be expressed as ventricular wall tension during contraction, estimated using the law of Laplace for a sphere: T = (P × r)/2w, where T is wall stress or tension, P is ventricular transmural pressure, r is ventricular radius, and w is ventricular wall thickness (Fig. 14.7). Although the ventricle is not a perfect sphere and the law of Laplace is only an estimate of wall stress, the formula allows for a greater understanding of clinical cardiac conditions. According to Laplace's law, increasing the radius of the ventricle increases the wall tension needed to balance a given transmural ventricular pressure. As a result, increasing the forces (afterload) that resist ventricular wall shortening should lead to a decrease in stroke volume. Despite the effect of increasing radius on afterload, in the healthy heart, SV may actually increase because the positive effects of increasing fiber length (preload) are greater than the negative effects of increasing ventricular radius.

Healthy hearts are relatively preload dependent and afterload independent. Failing hearts tend to be relatively afterload dependent and preload independent. Thus, as afterload increases in the healthy heart, CO is maintained and blood pressure increases, whereas in the failing heart, blood pressure is maintained and CO falls as afterload increases.

In contrast, this relationship is altered in the failing myocardium when the ventricle is pathologically dilated (as in congestive heart failure or dilated cardiomyopathy). The myocardial fibers may be unable to generate enough force to overcome the effects of increasing ventricular radius (increased afterload), which leads to a progressive decline in ventricular performance despite adequate (or more than adequate) preload. Various causes of heart failure lead to ventricular dilatation, increasing the ventricular radius and increasing wall stress resulting in greater energy expenditure per stroke volume. Clinically, the use of diuretics (decrease ventricular radius and thus indirectly decrease afterload) and vasodilators (decrease systemic vascular resistance and thus directly decreasing afterload) are the mainstay in the treatment of the failing dilated myocardium. Conversely, ventricular hypertrophy can occur secondary to chronic increases in afterload such as with long-term hypertension; the increase in wall thickness leads to a decrease in wall stress but unfortunately can adversely affect ventricular compliance and end-diastolic relaxation and ultimately decrease stroke volume.

14.2.6 Stroke Volume: Contractility

Myocardial contractility relates to the ability of muscle to generate force and is independent of preload and afterload. As discussed earlier, the inotropic state of the myocardium is dependent on cellular calcium flux. The independence from preload is noted in the Frank-Starling curve; for a given EDV, SV increases as contractility increases, which may reflect the effect of positive inotropic agents (see ▶ Chap. 17, Cardiovascular Drug Therapy) or endogenous hormonal catecholamine influences such as epinephrine. The curve is depressed in a negative inotropic environment such as in congestive heart failure. The effects of increasing contractility on stroke volume can also be demonstrated in the pressure-volume loop diagram (◘ Fig. 14.6c).

14.2.7 Stroke Volume: Lusitropy

Lusitropy refers to the rate of myocardial relaxation. Myocardial relaxation is not simply a passive process of elastic recoil of the muscle fibers but rather an active process involving the movement of calcium ions across membranes. Cardiac lusitropy is influenced by a number of factors including the thickness of the ventricular wall, ventricular wall composition (healthy muscle vs. pathologic fibrosis or amyloid), elastic recoil, sympathetic stimulation, loading conditions, and mechanical interaction with the pericardium. In the healthy myocardium, relaxation is load dependent. An increase in systolic pressure slows the myocardial relaxation rate. An increase in heart rate shortens the duration of the cardiac myocyte action potential and accelerates myocardial relaxation. A negative change in lusitropy typically results in reduced diastolic distensibility in most cases. Diastolic dysfunction can lead to or exacerbate preexisting heart failure in three ways: increasing cardiac filling pressures, reducing cardiac output at rest due to reduced stroke volume, and limiting the augmentation of cardiac output during exertion. Diastolic dysfunction can lead to pulmonary edema secondary to left atrial hypertension from elevated cardiac filling pressures and endocardial ischemia due to impaired coronary perfusion.

14.3 Cardiopulmonary Interactions

Caring for critically ill children requires a thorough knowledge of heart-lung interactions, how critical illness can alter these interactions, and finally how therapeutic interventions in the intensive care unit can affect cardiopulmonary function.

Cardiopulmonary interactions in the healthy patient with normal function of the heart and lungs are subtle and typically go unrecognized. Examples of these interactions include normal variations in systolic blood pressure and heart rate during spontaneous respiration. Even the use of positive pressure ventilation (PPV) and exaggerated spontaneous respiratory efforts do not typically cause cardiovascular compromise in the patient with normal cardiac and pulmonary function. However, the use of PPV for respiratory failure may impair cardiovascular system function. It is important to emphasize that mean airway pressure, which directly influences mean intrathoracic pressure, is the key variable affecting cardiopulmonary interactions during PPV. Other phasic changes in airway pressure have generally minor effects. Decreased cardiac output is a recognized consequence of increased mean airway pressure resulting from the use of positive end-expiratory pressure (PEEP) during the treatment for respiratory failure and during recruitment maneuvers. Extremely negative pleural pressures, as seen during airway obstruction and asthma exacerbations, may also compromise cardiac output. Conversely, the use of PPV can improve cardiac output in patients with left ventricular dysfunction, whereas weaning from PPV can improve cardiac output in patients with right heart failure.

The physical approximation of the heart and lungs within the thoracic cavity, the placement of the pulmonary vasculature in series with the cardiac ventricles, and the extrathoracic systemic vascular bed provide the basis for heart-lung interactions (◘ Fig. 14.8). As a result of this unique physical layout, changes in intrathoracic pressure or lung volume may have opposite effects on the right (RV) and left ventricle (LV).

14.3.1 Neural Regulation of Cardiopulmonary Interactions

Increase in pulmonary blood flow during inspiration improves ventilation/perfusion matching.

The importance of neural mediation between heart and lung function is well recognized. One subtle cardiopulmonary interaction in the healthy individual is the rhythmic change in heart rate during the respiratory cycle. The increase in heart rate during inhalation and decrease in heart rate during exhalation, known as respiratory sinus arrhythmia, are controlled by input from the brain stem through the vagus nerve. Evidence exists that even this seemingly minor cardiopulmonary interaction has a physiologic role in improving cardiorespiratory function by matching perfusion with ventilation. The transient increase in alveolar ventilation during inspiration is matched by an increase in venous return, heart rate, and pulmonary blood flow. This matching of ventilation and perfusion decreases dead space ventilation and intrapulmonary shunting, thus improving gas exchange. Respiratory sinus arrhythmia is a simple yet physiologically significant example of cardiorespiratory interactions that occur during spontaneous respiration. Respiration also affects autonomic regulation of vascular tone. For example, apnea results in decreased heart rate and increased systemic vascular resistance due to vagal and sympathetic influences. This "diving reflex" serves to maintain perfusion to the brain and heart while decreasing myocardial oxygen consumption.

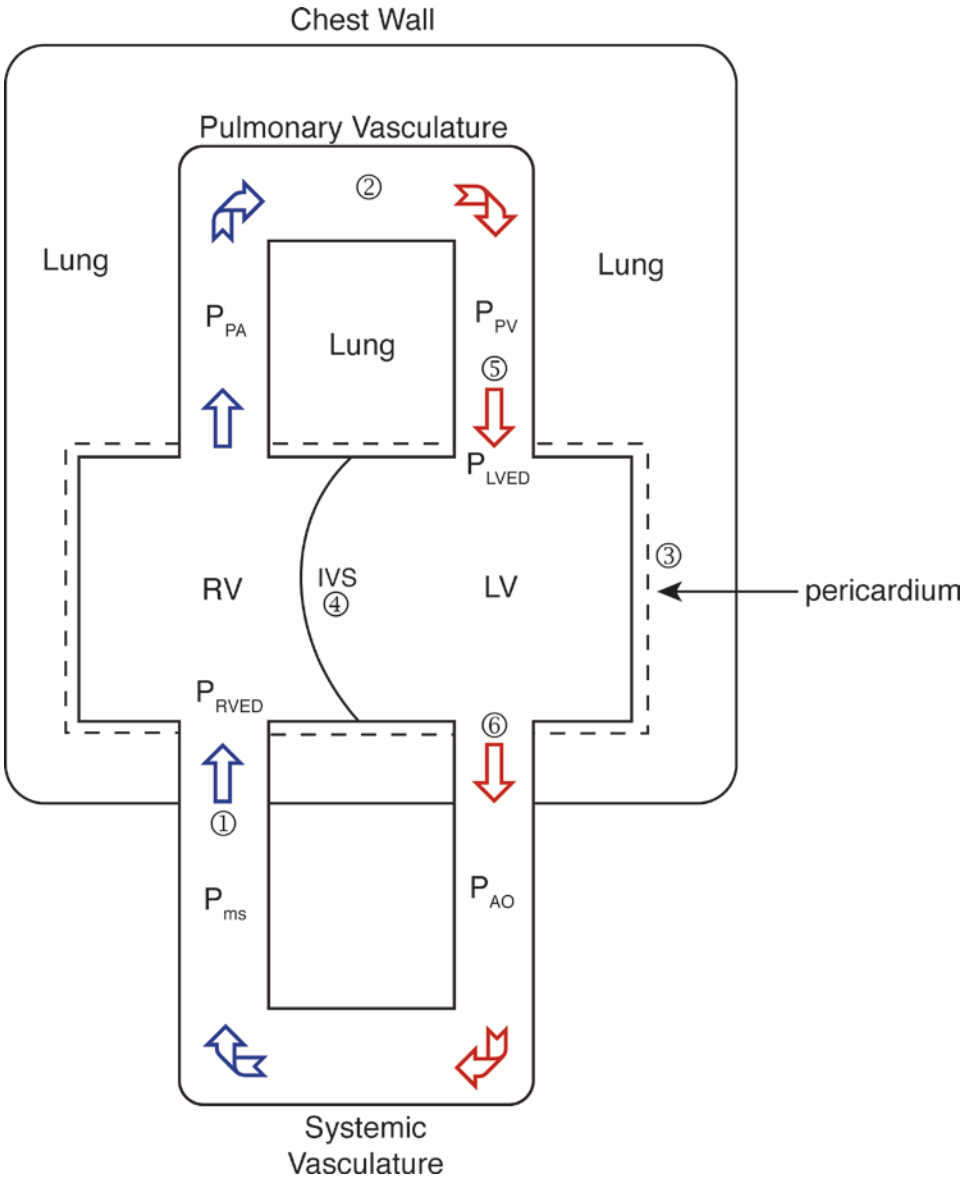

Fig. 14.8 Schematic figure showing the relationship between cardiovascular and pulmonary structures that affect cardiopulmonary interactions. The important relationships include those between (*1*) the mean systemic venous pressure (P_{ms}) and right ventricular end-diastolic pressure (P_{RVED}), (2) lung volume and pulmonary vascular resistance, (3) the cardiac fossa restricted by the pericardium and lungs, (4) the interventricular septum (*IVS*) shared by the right (*RV*) and left ventricle (*LV*), (5) the effect of intrathoracic pressure (*ITP*) and lung volumes on pulmonary venous capacitance and LV filling, (6) and the effect of ITP on LV afterload. 14

14.3.2 Intrathoracic Pressure Changes During Respiration

Fundamental to understanding cardiopulmonary interactions are the pressure and volume changes that occur in the various intrathoracic compartments during respiration. It is primarily the transmural wall pressure and lung volume surrounding the heart and pulmonary vasculature that are ultimately responsible for alterations in cardiac function during respiration. Spontaneous respiration produces negative (subatmospheric) intrapleural pressures, whereas mechanical ventilation transmits positive pressure to the airways and thorax.

The intrathoracic pressures that are generated with respiration are distributed unequally throughout the airways and thorax due to gravitational forces, regional differences in elastic properties of the lung, and the fibrous structure of the pericardium. Gravitational forces on the lung and mediastinal structures create a pressure gradient within the esophagus and the pleural space that is

position dependent. During spontaneous respiration and PPV in the upright position, the pressure in the pleural space at the apex of the lung is less than at the base of the lung. In addition, regional differences in pleural pressure independent of gravitational forces exist and are likely due to regional differences in elastic properties of the lung and chest wall. However, the use of high positive airway pressures abolishes the gravitational gradient and reduces regional differences in pleural pressure.

Transmission of intrathoracic pressures to the pericardial space is variable due to regional elastic properties in the lung and pericardium, gravitational forces, intravascular volume, and changes in lung compliance.

Ultimately, the forces acting on the external muscular wall of the heart and vasculature are those that are most relevant to the clinician considering heart-lung interactions, but they are also the most difficult to measure. Correlation between pressures measured in the airway, esophagus, pleural space, and pericardial space can vary significantly. Elastic properties of the lung and fibrous pericardium likely contribute to the pressure difference within these spaces. Although the qualitative changes in pressure measured at different locations within the thorax during respiration correlate with respect to the positive or negative direction of the change, the quantity of pressure change within the various intrathoracic spaces can be quite variable. Pressures generated in the airway or pleural spaces are attenuated prior to reaching the pericardial space. Epicardial pressures are also influenced by intravascular blood volume as well as surrounding extrapericardial pressures. Intravascular volume loading increases pericardial surface pressure and decreases the influence of respiration on pericardial pressure. Esophageal and pleural pressures tend to underestimate the pressures within the pericardial space when ventricular volumes are increased. Therefore, using a surrogate pressure, such as esophageal or airway, for pericardial pressures to calculate vascular transmural wall pressure is potentially inaccurate.

Changes in thoracic wall and lung compliance also alter the transmission of intrathoracic pressures to the external cardiac surface. In respiratory failure requiring mechanical ventilation, transpulmonary pressure increases as compliance of the respiratory system decreases and airway pressures generated by PPV are attenuated before they reach cardiovascular structures. To maintain lung volumes for adequate gas exchange, however, higher airway pressures may be required, resulting in elevated pleural and pericardial pressures that may contribute to hemodynamic compromise.

14.3.3 The Effect of Respiration on Cardiac Function

Spontaneous respiration with negative (subatmospheric) pressure ventilation may improve cardiac output in children with RV dysfunction.

Depending on the underlying cardiac and hemodynamic condition of the patient, cardiac function can be affected in a positive or negative manner during respiration. During spontaneous inspiration with subatmospheric intrathoracic pressures, RV output increases due to increased venous return, whereas LV output decreases due to dilation of intrapulmonary veins. Therefore, spontaneous breathing with negative pressure ventilation may improve cardiac output in children with RV dysfunction. Conversely, during the inspiratory phase of PPV, RV output decreases and LV output initially increases. Although PPV has favorable effects on LV afterload, using high levels of PPV has been associated with a decrease in LV stroke volume and cardiac output. The mechanisms responsible for the decrease in cardiac output during PPV include a decrease in systemic venous return, an increase in RV afterload, decrease in LV preload, and a decrease in ventricular contractility.

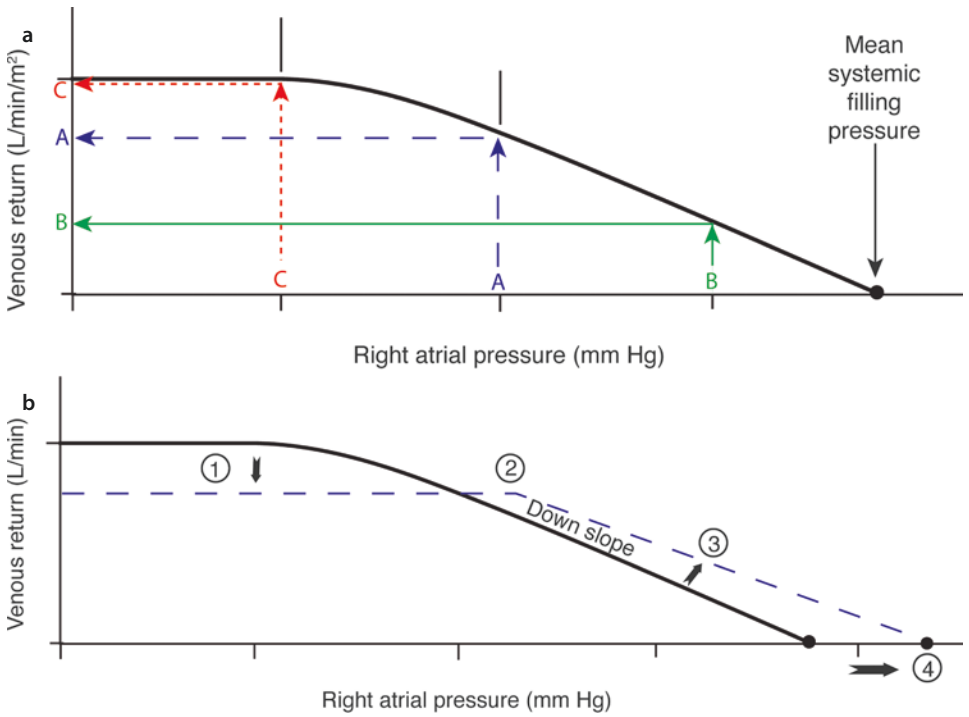
14.3.4 Right Ventricular Preload/Systemic Venous Return

Spontaneous respiration increases venous return by decreasing P_{RA} and increasing the pressure gradient between the systemic veins and the right atrium.

Venous return is limited by collapse of extrathoracic blood vessels when P_{RA} is less than 0 mm Hg.

PPV decreases venous return by increasing P_{RA} and reducing the pressure gradient between systemic veins and the right atrium.

The influence that respiration has on venous blood returning to the heart is arguably the most important clinical effect of breathing on cardiac output. Although transient differences between venous return to the right heart and output from the left heart can occur, in steady-state conditions, LV output must be equal to venous return. Since Guyton performed his studies on venous return in dogs and applied his findings to humans, many investigators have studied the effect of respiration on venous return to the heart. Respiratory changes in intrathoracic pressure primarily alter venous return by changing right atrial pressure (P_{RA}) and shifting the intercept of P_{RA} on the venous return curve (◘ Fig. 14.9a). Subatmospheric intrathoracic pressures generated during spontaneous respiration decrease P_{RA} and increase the pressure gradient between systemic veins and the right atrium, resulting in an increased systemic venous return and thus pulmonary blood flow. Collapse of extrathoracic blood vessels limits the effect of subatmospheric intrathoracic pressure on venous return, which becomes maximum when right atrial pressure is below 0 mm Hg. Decreasing right atrial pressure below the upper inflection point on the venous return curve will not increase venous return but may have deleterious effects on cardiac function by increasing LV afterload (discussed below). The clinical importance of the plateau in venous return is recognizing that weaning from PPV (invasive or noninvasive) and transitioning to spontaneous (negative) pressure ventilation (NPV) may increase cardiac output but is limited by the



◘ **Fig. 14.9** **a** Effect of changing right atrial pressure (P_{RA}) on venous return. Baseline P_{RA} and venous return are represented by A. As P_{RA} increases from A to B, the intercept on the venous return curve shifts and results in lower venous return. Venous return is zero when P_{RA} equals mean systemic filling pressure. During spontaneous inspiration with an obstructed airway (Muller maneuver), P_{RA} decreases from A to C, and the intercept on the venous return curve shifts left and increases venous return. The effect of decreasing P_{RA} on venous return is limited by the plateau on the venous return curve, caused by collapse of the extrathoracic blood vessels. **b** The effect of positive end-expiratory pressure (PEEP) on the venous return curve. The application of PEEP in an animal model affected the venous return curve by (1) decreasing the maximum venous return (plateau), (2) shifting the inflection point of the venous return curve to the right, (3) altering the slope of the curve (1/resistance), and (4) increasing the zero flow intercept of the curve. These changes in the venous return curve help maintain venous return at higher right atrial pressures during PPV. (From Fessler et al. (1992))

collapse of extrathoracic blood vessels. Transmission of airway pressure to the right atrium during PPV decreases the pressure gradient between the "upstream" systemic venous vasculature and "downstream" right atrium, resulting in decreased venous return. This effect increases with increasing airway pressure until the right atrial pressure is equal to the mean systemic filling pressure (the pressure of the entire systemic circulation if blood flow were to be transiently stopped), at which point the absence of a pressure gradient prevents venous blood from returning to the heart.

Evidence suggests the effect of positive airway pressure on venous return is more complex than that described above. In an animal model, PEEP did not simply increase right atrial pressure and shift the intercept of the curve to the right; instead, it altered almost every aspect of the venous return curve (Fig. 14.9b). The effect of raising right atrial pressure during PPV is offset to some degree by an increase in upstream venous pressure and an alteration in the resistance to venous return, which helped maintain venous return to the right heart. This observation has been made by others and is attributed to the effects of respiration on vascular tone and splanchnic blood flow.

The influence of respiration on the systemic vasculature and the splanchnic vascular bed in particular is important to the discussion of venous return. Due to the large capacitance of the splanchnic vascular bed, its contribution to venous return is significant. During respiration, downward movement of the diaphragm into the closed abdomen increases intra-abdominal pressure and alters blood flow from both splanchnic and nonsplanchnic blood vessels through the IVC. The ultimate effect of respiration on IVC blood flow is determined by the patient's intravascular volume status and can be described using a model of vascular compartment "zones" analogous to the pulmonary vascular zones (Fig. 14.10). By isolating flow from splanchnic and nonsplanchnic sources of venous blood, animal studies have demonstrated how intravascular volume status affects the venous blood return through the IVC during diaphragm contraction. In hypervolemic animals with abdominal vascular zone

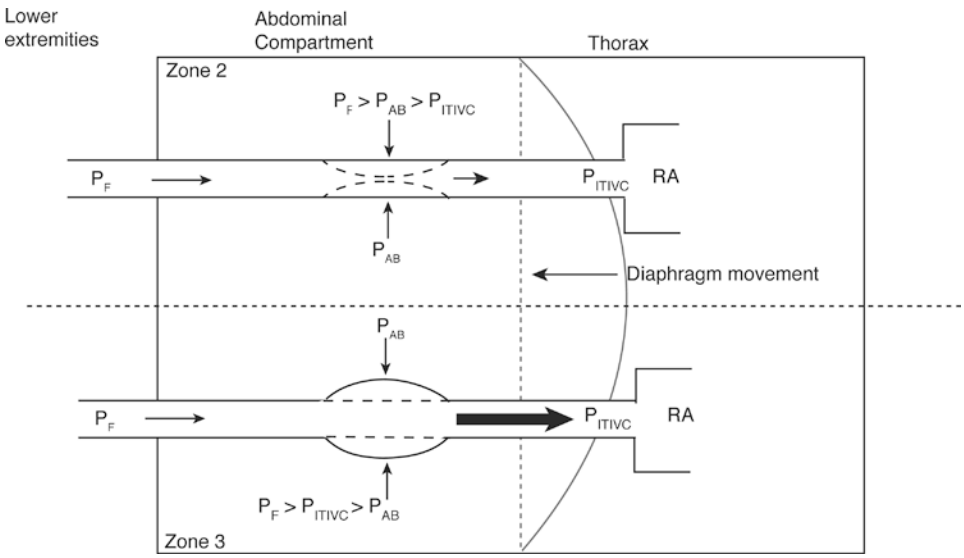


Fig. 14.10 The effect of respiration on inferior vena caval (IVC) blood flow using the vascular compartment zone model. In the upper panel modeling a Zone 2 condition (hypovolemic state), an increase in abdominal pressure during diaphragm descent increases splanchnic blood flow but creates a resistor and inhibits nonsplanchnic blood flow from the lower extremities. In the lower panel modeling Zone 3 conditions (hypervolemic state), an increase in abdominal pressure increases splanchnic blood flow. The increase in abdominal pressure does not create resistance to nonsplanchnic blood flow. *RA* right atrium, P_{AB} abdominal compartment pressure, P_F femoral venous pressure, P_{ITIVC} intrathoracic inferior vena cava pressure

III conditions, total IVC blood flow increased throughout contraction of the diaphragm due to an increase in splanchnic blood flow through the IVC. In hypovolemic animals with abdominal zone II conditions, IVC blood flow followed a biphasic pattern: initially increased with diaphragmatic contraction but subsequently decreased. The source of the initial increase in blood flow originates from splanchnic vessels. The later decrease in blood flow was caused by resistance to infrahepatic, nonsplanchnic blood flow. These studies provide convincing evidence that extrathoracic blood volume is an important component of cardiopulmonary interactions and serve to remind us that these interactions may be more correctly termed cardiovascular-pulmonary in nature. The importance of intravascular volume status during PPV is clear from studies using intravascular volume expansion during PPV, which have demonstrated that decreased cardiac output during PPV can be compensated for by intravascular volume infusion.

The healthy patient with adequate cardiopulmonary function and circulating blood volume will tolerate the effects of PPV on venous return with little or no compromise in cardiac output, likely through increased venous vascular tone, which decreases venous capacitance. However, there are circumstances (e.g., hypovolemic, septic, or hemorrhagic shock) when patients may not tolerate PPV, especially if high mean airway pressures are used in conjunction with hypovolemic states. In some circumstances, the reduction in cardiac output caused by PPV can be improved with intravascular volume expansion, which restores the pressure gradient between the systemic veins (i.e., the mean systemic filling pressure) and the right atrium. Although the amount of volume required to restore the pressure gradient is based on the patient's intravascular status and the mean airway pressure, clinical experience shows that 3–5 ml/kg is generally required. Subsequent boluses might be considered based on the patient's pathophysiology and physiologic response to the initial fluid challenge. In patients with cavopulmonary shunt physiology who are dependent on passive venous blood flow for pulmonary circulation, the use of any PPV may decrease cardiac output by decreasing systemic venous return. Therefore, patients with poor RV diastolic function or Fontan physiology may benefit from early weaning from PPV.

14.3.5 Right Ventricular Afterload

Both low and increased lung volumes contribute to increased pulmonary vascular resistance and RV afterload.

Since the RV and the pulmonary circulation, to which the RV delivers blood are both intrathoracic structures, they are affected by intrathoracic pressure changes in a similar manner. Therefore, the pressure difference between the internal and external ventricular wall, or transmural wall pressure, that directly affects LV afterload during respiration (discussed later) is not the primary respiratory determinant of RV afterload. Instead, the respiratory parameter most influential in determining RV afterload is lung volume.

During normal spontaneous respiration, the pulmonary vascular bed is a system with low pressure and resistance. Critical illness can increase pulmonary vascular resistance (PVR) through hypoxic vasoconstriction and the production of chemical mediators. In addition, mechanical forces may increase pulmonary vascular resistance through changes in lung volume. Optimizing lung volumes, matching ventilation with perfusion, reducing hypoxia and hypercapnia, and avoiding mechanical shear forces in the lung will minimize PVR and thus RV afterload. The mechanical effects of lung inflation during PPV can influence pulmonary vascular resistance via chemical mediators even after the cessation of lung stretch. The effect of active pulmonary vasocon-

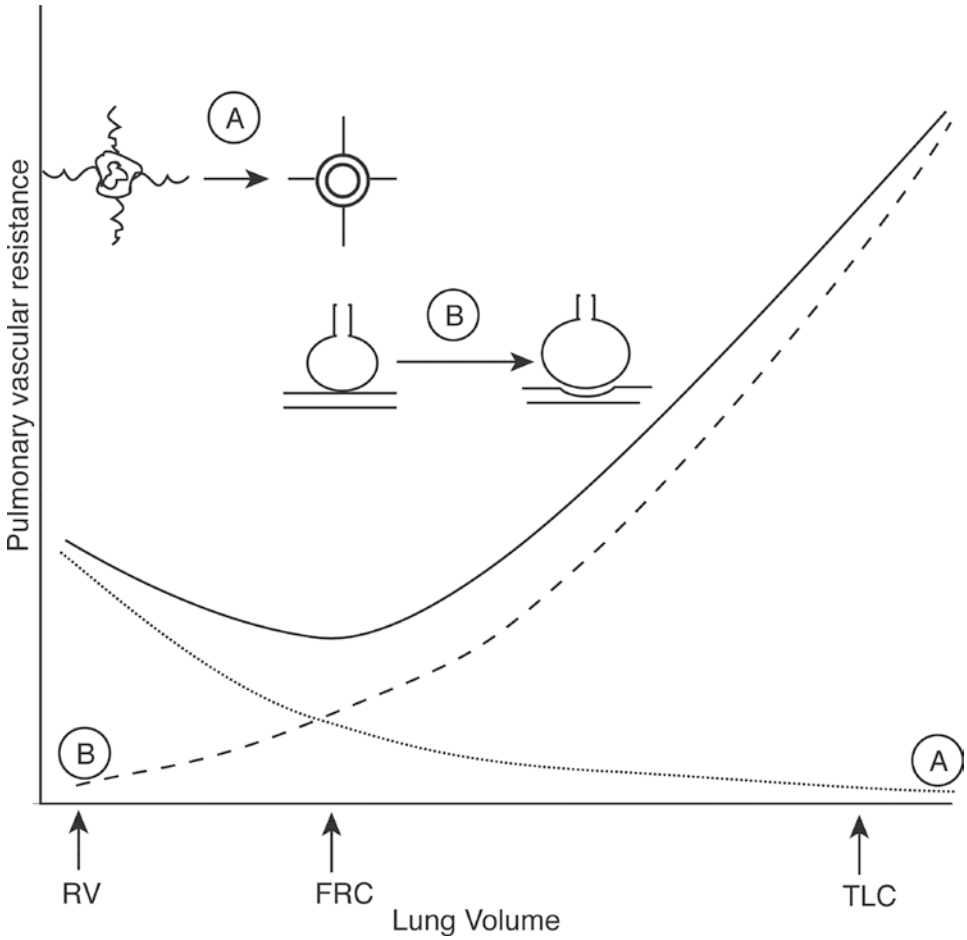

Fig. 14.11 Effect of lung volume on pulmonary vascular resistance. The effect of increasing lung volume on extra-alveolar vessels is shown in *inset and curve A* (••••). As lung volume increases, the extra-alveolar vessels are opened by mechanical forces and, in combination with the reversal of hypoxic vasoconstriction, reduce pulmonary vascular resistance. The effect of lung volume on alveolar capillaries is shown in *inset and curve B* (– – – –). As lung volume further increases, alveolar vessels are compressed and vascular resistance increases. The *solid line* combines the two vascular compartments and shows that deviations in lung volume either above or below *FRC* increase pulmonary vascular resistance and right ventricular afterload. *RV* residual volume, *FRC* functional residual capacity, *TLC* total lung capacity

striction from hypoxia, acidosis, and other chemical mediators is important to consider when discussing RV afterload. These mediators should be considered in cardiopulmonary interactions and are discussed in more detail elsewhere in this textbook. In the remainder of this section, we will review the mechanical forces that contribute to PVR and its effect on RV afterload.

Studies performed in isolated animal lungs provide the basis for our understanding of the relationship between PVR and lung volume. The relationship between lung volumes and PVR has been studied during inflation of the lungs from a collapsed state to full inflation. These studies identified several salient features of the relationship between lung volumes and PVR: (1) a slight decrease in PVR occurs as lungs are inflated from a collapsed state to a moderately inflated state, and (2) a significant increase in PVR occurs at high levels of lung inflation (Fig. 14.11).

The relationship between lung volume and PVR is present during both positive and negative pressure ventilations. The effect of lung volume on PVR is best understood if the pulmonary vascular bed is separated into two compartments: extra-alveolar vessels and vessels physically associated with alveoli. PVR is slightly increased when the lung is totally collapsed and decreases to its lowest point when the lung is inflated to functional residual capacity. The increased PVR noted at low lung volumes is attributed to a combination of hypoxic pulmonary vasoconstriction and collapse of extra-alveolar blood vessels. As the lung is inflated, the extra-alveolar vessels are held open by connective tissue that supports the vessel wall. Evidence for this phenomenon was found on microscopic examination of pulmonary vessel casts at various stages

PVR is lowest at lung volumes around FRC. PVR increases at low lung volumes due to hypoxic vasoconstriction and collapse of extra-alveolar vessels. PVR increases at high lung volumes due to alveolar distension that compresses alveolar capillaries.

of lung inflation, which demonstrated contortions and grooves in extra-alveolar small pulmonary vessels when the lung is collapsed. As lung volumes are increased above FRC, pulmonary vascular resistance increases as a result of the compression by distended alveoli of the alveolar capillary bed and decreased capillary blood volume.

PPV may be associated with an increased RV afterload in several clinical situations. The use of PEEP in patients with acute respiratory failure is associated with a decrease in right ventricular output. At low levels of PEEP, the decrease in RV output is a result of a decrease in systemic venous return, while at higher levels of PEEP, increased pulmonary vascular resistance also contributes to decreased RV output. Studies have shown that the effect of PEEP on RV function is dependent on the baseline function of the RV. Patients with baseline normal RV function did not have deterioration of RV function with the use of high levels of PEEP, while patients with RV dysfunction at baseline experienced a significant decline in RV function with the use of PEEP.

Typical tidal volume changes that occur around FRC with spontaneous respiration have minimal effect on PVR.

Typical tidal volume changes that occur around FRC with spontaneous respiration have minimal effect on PVR. The increase in PVR associated with atelectasis or moderate hyperinflation is unlikely to cause a clinically significant decrease in RV function or output in patients with normal RV function, while the patient with RV dysfunction may benefit from optimizing lung volume. Clinical experience in patients after Fontan procedures shows that even in the absence of the active RV pump, cardiac output can be maintained by optimizing lung volume and minimizing PVR. Therefore, optimizing lung volume to restore functional residual capacity will decrease PVR and improve RV output in patients with any of the following: RV dysfunction, cavopulmonary shunts, or neuromuscular disease or respiratory muscle fatigue associated with atelectasis or lung overdistension. Although optimizing lung volume around functional residual capacity remains an important goal in patients with large intracardiac shunts or single ventricle physiology, unnecessary use of supplemental oxygen and hyperventilation should be avoided as further reduction of PVR may be associated with increased pulmonary blood flow at the expense of systemic output.

14.3.6 Left Ventricular Preload/Pulmonary Venous Return

Respiration may alter LV preload as a result of changes in RV output, pulmonary vascular capacitance, compression of the cardiac fossa, and ventricular interdependence (Fig. 14.12). There is evidence to suggest that all of these mechanisms may contribute to decreasing LV preload under different baseline conditions. Because the RV and LV are in series, at steady state, left ventricular preload is ultimately dependent on the output of the RV. Therefore, any of the respiratory conditions discussed in the previous sections that decrease RV output will subsequently decrease LV preload and cardiac output.

LV preload may be altered by changes in pulmonary vascular capacitance. During spontaneous inspiration, subatmospheric intrathoracic pressures increase the capacitance of the intrathoracic vascular bed and result in a transient decrease in LV filling. The effect of PPV on pulmonary blood volume is dependent upon the intravascular volume status of the patient and is similar to the effect of respiration on the abdominal vascular compartment discussed previously (Fig. 14.10). When pulmonary artery and left atrial pressures exceed alveolar pressures (hypervolemic zone III conditions), then lung inflation with PPV leads to a transient increase in pulmonary venous return, a phenomenon known as thoracic pump augmentation. When alveolar pressures are greater than left atrial pressures during lung inflation (hypovolemic zone II

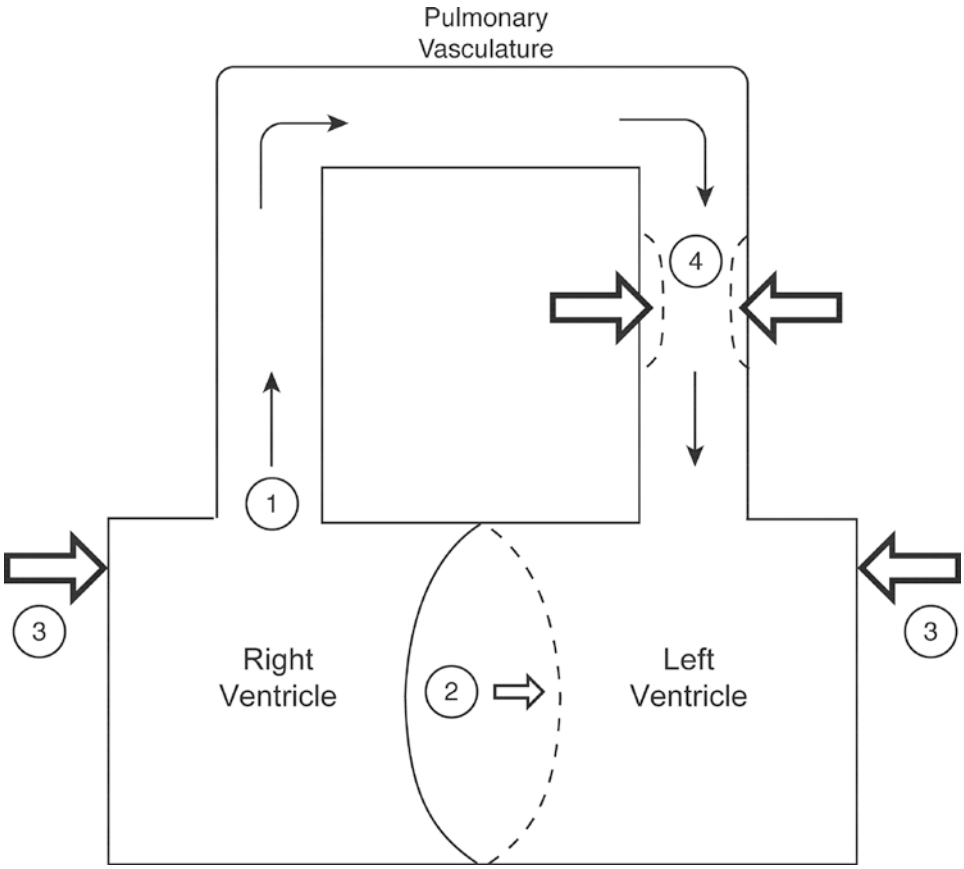

Fig. 14.12 Mechanisms by which left ventricle filling (preload) may decrease during respiration
1. Decrease in right ventricle (RV) output
2. Leftward deviation of the interventricular septum due to increased RV volumes (as a result of increased systemic venous return, increased RV afterload, and/or decreased RV contractility)
3. Compression of the cardiac fossa secondary to increased lung volumes
4. Decreased pulmonary venous return in hypovolemic states (zone 2 vascular compartment conditions) when transpulmonary pressures increase. In zone 3 conditions (hypervolemia) pulmonary venous return may increase as transpulmonary pressures are increased (Refer to Fig. 14.3)

An increase in venous return or RV afterload during respiration may transiently displace the interventricular septum into the LV, decreasing LV compliance and preload.

conditions), pulmonary venous return decreases. The importance of having adequate intravascular volume for LV preload is supported in both animal and human studies utilizing PPV during LV failure. Clinically, LV output during PPV is improved in patients with LV dysfunction associated with an increase in pulmonary blood volume (zone III conditions). Conversely, the use of PPV when LV filling pressures are normal or low can result in a decrease in cardiac output.

A salient feature of cardiopulmonary interactions is that the right and left ventricles share a septal wall and a space within the semirigid pericardium. Therefore, the combined volumes of the cardiac chambers cannot exceed the total volume of the pericardial space, a concept referred to as ventricular interdependence. When PPV results in increased RV afterload, RV diastolic volume increases and LV filling is reduced as a leftward shift of the interventricular septum occurs. An increase in venous return associated with subatmospheric intrathoracic pressure during spontaneous inspiration may also result in leftward deviation of the interventricular septum resulting in decreased LV compliance and diastolic volume. Clinically relevant situations in which this may occur include asthma and upper airway obstruction, where the combination of high lung volumes (increasing PVR and RV afterload) and increased venous return due to marked fall in intrathoracic pressure combines to decrease LV compliance, thus contributing to the pulsus paradoxus observed in severe asthma exacerbations. Reduced LV compliance is further enhanced by the compression of the cardiac fossa by the hyperinflated lungs and cardiac compression by the parietal pericardium, which is attached to the diaphragm and is pulled tight as the diaphragm is flattened. The use of PEEP greater than 15 cm H_2O in patients with acute respiratory distress syndrome has been asso-

ciated with a leftward shift of the interventricular septum due to an increase in RV afterload. In addition, similar to the effects from the hyperinflated lungs in an asthmatic patient, the use of PEEP can compress and limit the total volume of the cardiac fossa, resulting in smaller LV end-diastolic volumes and higher filling pressures. However, both of these effects of positive pressure are dependent on lung compliance; less compliant lungs limit transmission of pressure to the cardiovascular structures.

14.3.7 Left Ventricular Afterload

The influence of respiration on LV afterload occurs through changes in intrathoracic pressure acting on the external wall of the LV. The changes in intrapericardial pressures during respiration alter the transmural wall pressure of the LV, thus contributing to alterations in LV afterload. If the downstream aortic pressure and ventricular wall dimensions remain constant, the changes in external cardiac pressure during respiration may become the predominant factor in altering LV afterload. As described in more detail below, LV afterload is increased by negative pressure ventilation and decreased by positive pressure ventilation.

14.3.8 Negative Pressure Ventilation

Spontaneous respiration with airway obstruction increases LV afterload during inspiration by increasing transmural ventricular wall pressure.

The generation of negative pleural pressures during spontaneous breathing increases left ventricular afterload, which may decrease LV stroke volume and cardiac output (◘ Fig. 14.13a). From a mechanical standpoint, negative pleural pressures oppose the inward displacement of the ventricular wall during systole by generating a greater pressure gradient for the left ventricle to overcome. The spontaneously breathing asthmatic patient provides an example of how pleural pressure affects LV afterload. If normal left ventricular systolic pressure is 90 mm Hg and pleural pressure is 0 mm Hg, then the gradient that the LV must overcome to eject is 90 mm Hg. The asthmatic patient may generate significant negative (subatmospheric) pleural pressure during inspiration, which the LV must overcome in addition to the systolic pressure, that is, the asthmatic generating −20 mm Hg pleural pressure creates a pressure gradient that must be overcome by the contracting LV of 110 mm Hg, and hence, afterload is increased. The decrease in LV stroke volume with negative intrathoracic pressure is independent of changes in LV preload, lung volume, RV output, and RV volume, providing evidence that increased LV afterload is a significant contributor to decreased LV output during spontaneous breathing in conditions such as severe asthma. Cardiac output is usually maintained in the person with normal cardiac function, even with extremely negative intrathoracic pressures generated with airway obstruction. However, hypovolemia coupled with extreme negative intrathoracic pressure may result in a significant decrease in LV output, a common scenario in severe asthma. Similarly, while the normally functioning LV may be able to compensate for an increase in afterload during spontaneous breathing, the inability of the failing LV to overcome this increase in afterload may become clinically relevant. Pulmonary edema described with extreme negative pleural pressures in upper airway obstruction from laryngospasm, croup, and epiglottitis is explained by increased pulmonary blood volume as a result of increased LV afterload combined with increased venous return, which contributes in turn to higher capillary hydrostatic pressure, transcapillary fluid movement, and pulmonary edema. As noted previously, an increase in LV afterload contributes to the development of pulsus paradoxus during asthma and airway obstruction.

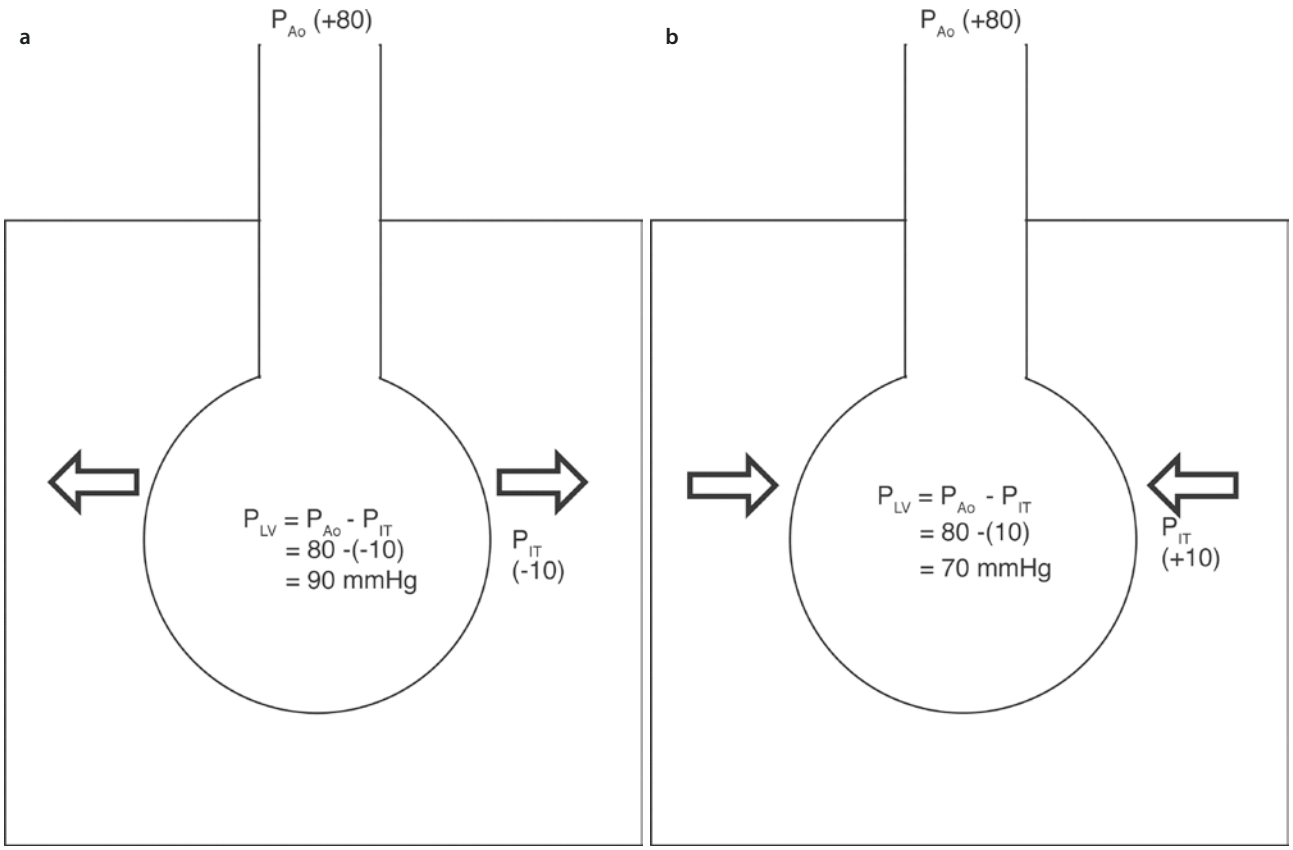

Fig. 14.13 **a** Left ventricular (LV) afterload during spontaneous respiration. LV afterload is proportional to the transmural LV wall pressure (difference between the arterial pressure (P_{AO}) acting on the internal ventricular wall and the intrathoracic pressure (P_{IT}) acting on the external surface of the ventricular wall) during systole. The total pressure or afterload the LV must overcome (P_{LV}) is the difference between P_{AO} and P_{IT}. **b** LV afterload during positive pressure ventilation. The increase in the surrounding intrathoracic pressures create an inward force exerted against the LV wall that reduces transmural left ventricular wall pressure, thus reducing LV afterload

14.3.9 Positive Pressure Ventilation

PPV has the opposite effect on LV systolic function by lowering the transmural wall pressure and decreasing LV afterload, resulting in improved LV function and cardiac output, assuming the patient has an adequate intravascular volume (Fig. 14.13b). As described previously during the inspiratory phase of a positive pressure breath, LV preload is increased secondary to augmented emptying of the pulmonary veins into the left atrium. The effect of improved LV systolic function during inspiration is most pronounced in patients with LV dysfunction. PPV also improves the economics of oxygen delivery and consumption in patients with decreased cardiac output. In the presence of congestive heart failure with its attendant decreased lung compliance and increased work of breathing, PPV reduces work of breathing and the demands on the heart to deliver oxygen to meet the metabolic needs of the respiratory muscles. Additionally, the use of CPAP in patients with asthma has been shown to decrease the work of breathing, heart rate, and LV afterload.

PPV decreases LV afterload by decreasing transmural ventricular wall pressure.

The importance of PPV effects in patients with LV dysfunction has been demonstrated in several clinical studies. Continuous positive airway pressure and PPV have been shown to increase stroke volume in adult patients with LV dysfunction and reduce mitral regurgitation in adult patients with heart failure and LV systolic dysfunction. The failure to pass spontaneous breathing trials and wean from mechanical ventilation is associated with significant LV dys-

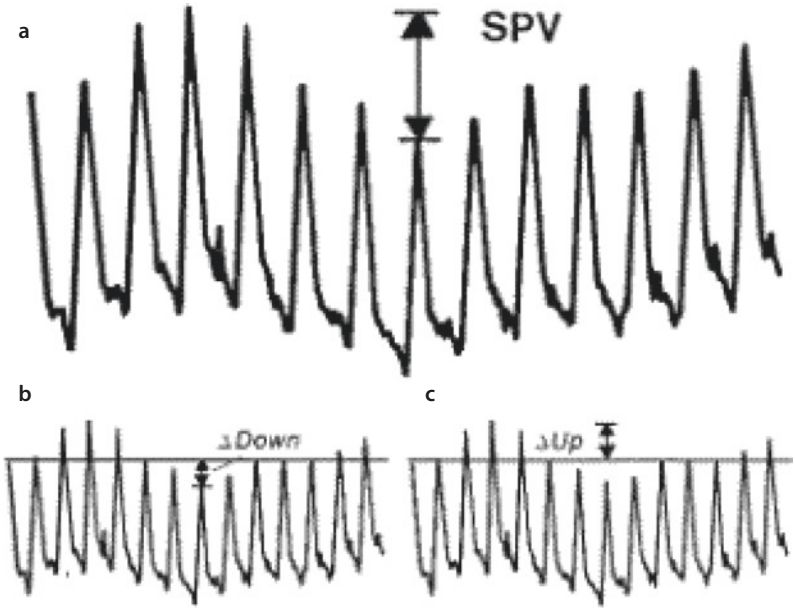

Fig. 14.14 Arterial blood pressure tracing demonstrating systolic pressure variation (*SPV*) during positive pressure ventilation. *Δ down* is the decrease in systolic pressure during early expiration. *Δ up* is the increase in systolic pressure during inspiration. The reference line is the systolic pressure during a short period of apnea at resting lung volume and is the baseline pressure from which Δ up and Δ down are calculated. (From Preisman et al. (1997))

function, manifested by the inability to increase cardiac output and meet the oxygen demands of respiratory muscles. For these reasons, the use of noninvasive PPV is a clinically relevant therapy to consider in any child with LV failure and respiratory distress.

Understanding the complex cardiopulmonary dynamics during positive pressure ventilation has led to the appreciation of systolic pressure variation. This term refers to the arterial pressure waveform changes that occur during positive pressure mechanical ventilation. The hemodynamic principles are similar to those in pulsus paradoxus, but instead of a fall in pressure during spontaneous negative pressure breathing, there is a transient rise in systolic pressure during the inspiratory phase of positive pressure breathing. This has led some to refer to this phenomenon as "*reverse pulsus paradoxus*"; however, *systolic pressure variation* (SPV) is the more correct term (Fig. 14.14).

A single positive pressure breath normally affects the arterial pressure in a biphasic manner. The initial response of a positive pressure breath is to "squeeze" pulmonary vascular blood into the LA (recall the opposite "pooling" of blood occurs with spontaneous negative pressure inspiration), augmenting LV preload leading to a rise in systolic pressure. In addition, positive intrathoracic pressure reduces the afterload on the LV further augmenting this early rise in arterial pressure. This is referred to as the Δ up component of SPV. Following this Δ up during early inspiration, a fall in systolic pressure occurs secondary to decreased systemic venous return and increased RV afterload during the positive pressure breath, which continues into the early expiratory phase. The transient reduction in RV preload and stroke volume impairs LV preload resulting in a smaller LV stroke volume and a brief reduction in arterial pressure that occurs later in the expiratory phase of the positive pressure breath (Δ down). Many studies have showed that SPV in mechanically ventilated patients can be quantified by a variety of methods and can be used to assess intravascular volume and assess fluid responsiveness (see ► Chaps. 16 and 34).

Clinically, an increase in SPV (>10 mm Hg) has been seen early in the setting of hypovolemia. This is due to an exaggerated Δ down component. Several studies observed an increase in the SPV occurring prior to a fall in arterial pressure and may be as predictive of hypovolemia as a low PAWP (<10 mm Hg). An increase in the SPV due to a greater fall in the Δ down component can also occur due to high airway pressures alone secondary to decreased venous return.

An increased SPV can also be seen when the Δ up component is increased rather than an exaggerated fall in the Δ down component. During a positive pressure breath, the Δ up component reflects a transient augmentation in the left ventricular stroke volume by increased LV preload and decreased LV afterload. This effect is increased in the setting of LV dysfunction. Therefore, a patient in CHF may have an increased SPV due to improved myocardial performance (augmented Δ up component) as a result of increased preload and decreased afterload while on positive pressure ventilation.

14.3.10 Effect of PPV on Contractility

The negative effects of PPV on myocardial contractility has been attributed to one of two mechanisms: (1) alterations in coronary artery perfusion leading to inadequate oxygen delivery to the myocardium and (2) the presence of myocardial depressant factors produced during PPV.

Myocardial contractility may be compromised by compression of coronary arteries during PPV.

In addition to decreased RV preload and increased afterload, the reduction in RV output at levels of PEEP around 20 cm H_2O may be due to a decrease in RV contractility. The effect of PEEP on RV function is more significant when RV function is depressed at baseline or when coronary artery blood flow is compromised prior to the use of PPV. The use of PEEP in adults after cardiopulmonary bypass is associated with decreased RV function, but only in a subset of patients with already established right coronary artery stenosis, a condition uncommon in children. When such predisposing conditions are present, addressing adequate right ventricular coronary perfusion becomes a priority. Interventions aimed at increasing coronary blood flow, such as increasing diastolic blood pressure or reducing PEEP and mean airway pressure, should be considered. A limited number of animal studies support compression of coronary arteries as a potential mechanism for decreased cardiac contractility during PPV. In isolated animal hearts, an increase in pressure on the external surface of the heart decreased coronary artery blood flow and produced myocardial ischemia, providing indirect evidence that PPV may contribute to a decrease in myocardial contractility by compromising coronary blood flow.

Compared to the mechanical effects on cardiac function during PPV, the release of circulating factors that depress myocardial function is probably not of major importance in cardiopulmonary interactions. Although some investigators have found evidence of decreased LV contractility during PPV, most studies have not demonstrated a detrimental effect on LV contractility in animals or humans during the use of PPV or PEEP. Animal studies provide conflicting results on the role neural reflexes and circulating chemical mediators (such as prostaglandins or cytokines) play in decreasing myocardial function during mechanical ventilation. Separating the effect of mechanical forces on the heart during PPV from the effect that circulating mediators may have on myocardial contractility is difficult, especially in the intact cardiopulmonary system. In summary, the primary effects of PPV on cardiac function appear to be the mechanical influences on preload and afterload, while the effect of PPV on myocardial contractility appears to play a lesser role.

14.3.11 Cardiac Effects on Respiratory Function

The ability to maintain an adequate cardiac output to meet the metabolic demands of respiratory muscles is the major effect of cardiac function on respiratory function.

One of the most important effects the heart has on pulmonary function is the adequate delivery of oxygen to meet the metabolic demands of respiratory muscles. When cardiac output is insufficient to meet the respiratory muscle oxygen requirement, respiratory failure occurs. Although patients with normal cardiovascular function can meet the increase in metabolic requirements of the respiratory muscles during illness, the patient with decreased cardiac function may be unable to meet respiratory muscle oxygen demand and is at high risk for respiratory muscle failure. This has been demonstrated in an experimental model of obstructive shock due to tamponade. Canine subjects that were artificially ventilated survived the period of poor cardiac output while all of the canines that were allowed to spontaneously breathe during cardiogenic shock died secondary to respiratory failure. No changes occurred in the mechanical properties of the respiratory system, and death was due to impairment of respiratory muscle contraction. These findings emphasize the importance of interventions that improve cardiac output, decrease the work of breathing, or both during cardiopulmonary dysfunction that reestablishes the balance between oxygen delivery and consumption. Therefore, PPV can be beneficial in patients with poor LV function and respiratory failure by reducing the work of breathing, decreasing oxygen consumption of the respiratory muscles, and reducing LV afterload.

Alterations in cardiac output can affect gas exchange in the lung by changing ventilation and perfusion matching.

Another important cardiac effect on lung function relates to the matching of ventilation and perfusion in the lung. When cardiac output is decreased, there is an increase in the area of lung that is ventilated but not well perfused (West Zone 1; see ◘ Fig. 14.15). The application of PPV in this circumstance may increase dead space ventilation by increasing alveolar pressures and decreasing venous return. An extreme example of this physiology is a patient in cardiopulmonary arrest with adequate ventilation but poor pulmonary blood flow. In this example and others with poor cardiac output, increasing cardiac output improves matching of ventilation with perfusion and gas exchange (Zones 2 and 3).

The existence of an intrapulmonary shunt significantly affects the gas exchange function, which can also be affected by changes in cardiac output. Patients with pulmonary shunts with low cardiac output, and therefore low venous blood oxygen saturation, also have decreased oxygen saturation of blood returning to the left atrium. Systemic arterial oxygen saturation can be improved by increasing cardiac output and thus systemic venous oxygen saturation (see ◘ Fig. 14.16).

Acute lung injury is often inhomogeneous so that alveoli have varying levels of compliance; therefore, PPV with high levels of PEEP may worsen gas exchange by overdistending compliant alveoli and compressing their associated alveolar capillaries. Blood is then shunted to capillaries associated with noncompliant alveoli that are not participating in gas exchange. When this occurs in conjunction with a decrease in cardiac output, the effect is to increase dead space ventilation and physiologic shunting, resulting in ineffective gas exchange. High airway pressures or PEEP may also contribute to poor arterial oxygenation if this results in over-distension of the lung volume by increasing pulmonary vascular resistance and increasing right to left shunts through an existing patent foramen ovale, atrial septal defect, or ventricular septal defect. Lung volume, not pressure, is the most important contributor of pulmonary vascular resistance as noted in the previous section on RV afterload.

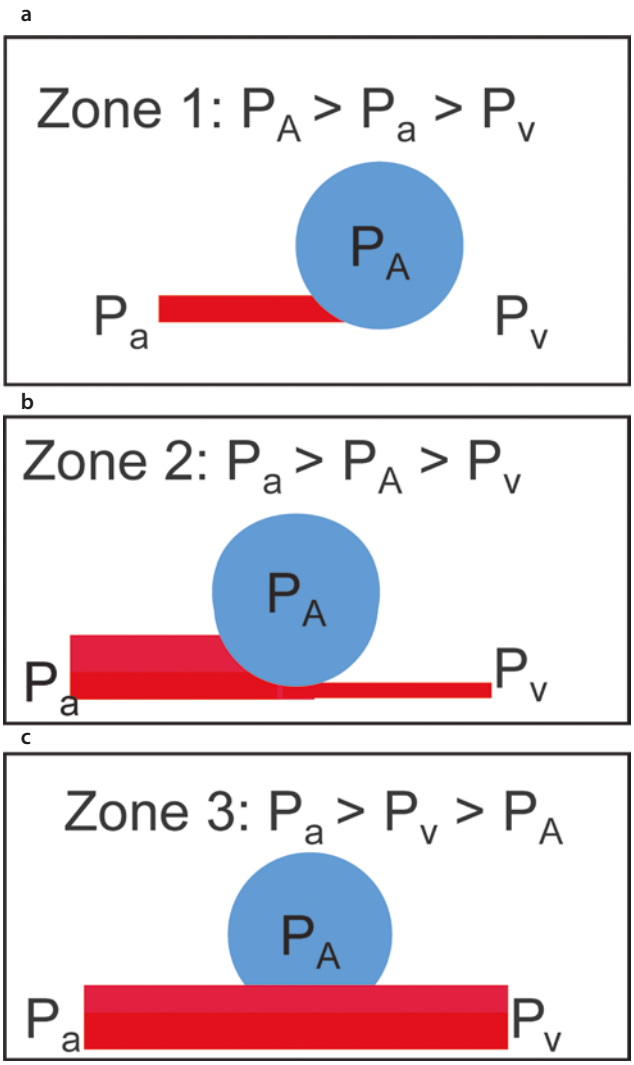

Fig. 14.15 Decreased right ventricle (RV) output may increase *Zone 1* (area of dead space ventilation) in the lung **a** as fewer alveoli are associated with capillary blood flow associated with increased intra-alveolar pressure. Increasing RV output increases the *Zones 2 and 3* conditions of the lung **b**, **c**, increasing the number of alveoli participating in gas exchange. *PA* alveolar pressure, *Pa* pulmonary artery pressure, *Pv* pulmonary vein pressure

In children with congenital heart disease, alterations in pulmonary blood flow and pulmonary artery pressure have been shown to effect lung mechanics. Increases in pulmonary blood flow associated with increased pulmonary artery pressures result in decreased lung compliance and increased airway resistance. The changes in lung mechanics that occur with pulmonary artery hypertension may have several etiologies including displaced lung volume by an enlarged heart and/or increased pulmonary blood volume, increased interstitial lung fluid, mechanical compression of the smaller airways or alveoli, and bronchoconstriction. There is some evidence that airway muscle hypertrophy and bronchoconstriction play a significant role in changing lung mechanics during pulmonary artery hypertension. The existence of smooth muscle hypertrophy in both pulmonary vasculature and respiratory airways may be explained by the action of local mediators that stimulate smooth muscle hypertrophy in both airways and vascular beds.

Pulmonary hypertension and increased pulmonary blood flow result in increased transcapillary fluid movement into interstitial tissues, which contribute to a decrease in pulmonary compliance and increase in airway resistance.

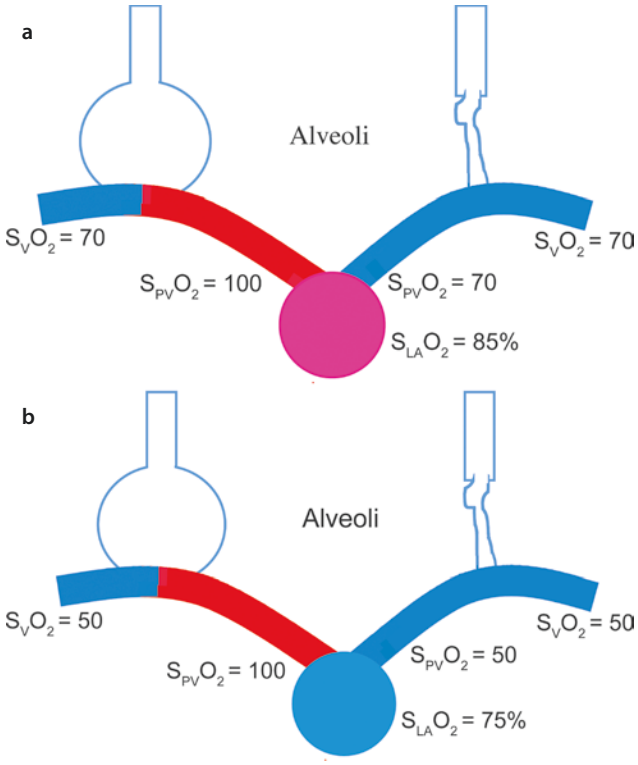

Fig. 14.16 **a** The effect of a 50% pulmonary shunt on left atrial oxyhemoglobin saturation ($S_{LA}O_2$) when cardiac output is normal. **b** With the same shunt, a decrease in venous oxygen saturation (S_VO_2) associated with poor cardiac output results in lower $S_{LA}O_2$. Increasing cardiac output **a** improves arterial hemoglobin oxygen saturations in patients with pulmonary shunts. $S_{PV}O_2$ pulmonary venous oxyhemoglobin saturation

14.3.12 Cardiopulmonary Interactions in Patients with Fontan Physiology

A clear understanding of cardiopulmonary interactions is crucial to managing children with Fontan physiology. Following the Fontan procedure, pulmonary blood flow is completely passive and dependent on complex cardiopulmonary interactions that affect the pressure gradient between the systemic venous system and the systemic ventricle's atrium. Sufficient preload, minimal PVR (i.e., afterload), low systemic ventricular end-diastolic pressure, and adequate systemic ventricular function are all key determinants of passive pulmonary blood flow and hence cardiac output. However, adequate pulmonary blood flow is mainly dependent on low PVR, which is highly sensitive to changes in intrathoracic pressure, lung volumes, and ventilation. Although PPV decreases afterload and increases cardiac output in a failing LV in an otherwise normally structured heart, a substantial decrease of systemic ventricular afterload without preload reserve in the patient with Fontan physiology will not increase cardiac output. Instead, the use of any PPV may decrease cardiac output in the patient with Fontan physiology by increasing lung volumes and PVR and decreasing systemic venous return secondary to increased intrathoracic pressure. Clinical experience in patients after Fontan procedure shows that even in the absence of the active RV pump, cardiac output can be maintained by optimizing lung volume, minimizing PVR, and avoiding positive intrathoracic

pressure. Therefore, patients with Fontan physiology often benefit from early weaning from PPV, extubation, and spontaneous breathing.

However, when weaning from PPV cannot be achieved secondary to acute lung injury or hemidiaphragmatic paralysis, patients with Fontan physiology benefit from ventilatory strategies that optimize lung volumes around FRC and by minimizing peak, positive end-expiratory, and mean airway pressures. Use of other unconventional ventilation modalities may also be considered when conventional mechanical ventilation fails to improve gas exchange and maintain cardiac output in patients with severe lung disease and Fontan physiology. For example, high-frequency jet ventilation may be effective in reducing mean airway pressure and increasing cardiac output. Similarly, the use of high-frequency oscillation ventilation (HFOV) in patients after Fontan operation had no significant effect on cardiac output or PVR. This latter finding may be explained by the importance of optimizing lung volumes to reduce PVR and the difference in airway and pleural pressures in the poorly compliant lung. Negative pressure ventilation (NPV) has also been used to manage the low cardiac output state in Fontan patients with significant lung injury. Although augmentation of venous return by NPV is ultimately limited by collapse of the extrathoracic blood vessels, the high baseline intravascular volume status and venous pressures in Fontan patients makes this phenomenon less likely when NPV is utilized in these patients. However, the use of alternative modes of mechanical ventilation has not gained widespread use in the management of Fontan patients due to the recognized advantages of early extubation to spontaneous breathing.

In summary, after Fontan operation, consideration should be given toward optimizing lung volumes, minimizing airway pressure, addressing pleural space pathology, maintaining adequate intravascular volume and preload, and proceeding toward spontaneous negative pressure breathing as soon as it is feasible.

Fontan physiology is analogous to a waterfall where the systemic and AV valves intermittently form locks regulating flow, allowing blood to flow downstream to lower pressure environments until the single ventricle pumps it back upstream.

14.4 Summary of Cardiopulmonary Interactions

Factors important in cardiopulmonary interactions include understanding the changes in intrathoracic pressure and lung volume during spontaneous versus positive pressure respiration, the effects of intravascular volume status, and the baseline function of the heart and lungs. In many situations, the baseline condition of the patient, including the intravascular volume status and myocardial function, will determine the ultimate clinical effect, if any, that the cardiac and respiratory systems may have on each other. Anticipation of heart-lung interactions during support of the critically ill child promotes early recognition of alterations in cardiopulmonary function and prevents deleterious effects of therapy (◘ Fig. 14.17).

2. Leftward deviation of the interventricular septum due to increased RV volumes (as a result of increased systemic venous return, increased RV afterload, and/or decreased RV contractility)

3. Compression of the cardiac fossa secondary to increased lung volumes

4. Decreased pulmonary venous return in hypovolemic states (Zone 2 vascular compartment conditions) when transpulmonary pressures increase. In Zone 3 conditions (hypervolemia), pulmonary venous return may increase as transpulmonary pressures are increased (refer to ◘ Fig. 14.10)

Review Questions

1. A 6-month-old infant undergoes a VSD repair due to heart failure symptoms and failed medical management, including poor growth velocity. The postoperative course is complicated by third-degree heart block with a ventricular escape rhythm. Which finding is most likely to be noted on a CVP tracing of this patient?
   A. Giant V waves
   B. Change in the slope of the y descent
   C. V wave with an increased amplitude compared to the A wave
   D. Cannon A waves
   E. Loss of the C pressure wave

2. During what phase of the cardiac cycle is aortic pressure the highest?
   A. Ventricular filling
   B. Ventricular ejection
   C. Atrial systole
   D. Isovolemic relaxation
   E. Isovolemic contraction

3. While evaluating an 11-month-old, 10 kg infant with tachycardia (180 beats per minute) and poor perfusion, the critical care physician notes that the heart rate decreases momentarily to 170 beats per minute, and the pulses became stronger after compressing the liver of the infant. Which of the following physiological changes most likely explains the response?
   A. The compression on the liver produced a sudden increase in the systemic vascular resistance, and the increased afterload resulted in the stronger pulses and decreased heart rate.
   B. The compression on the liver produced a sudden vagal response clinically manifested by the decreased heart rate.
   C. The compression on the liver produced a temporary increase in contractility with a resultant increase in cardiac output (stroke volume) and a slowing of the heart rate.

D. The compression on the liver reduced venous return to the heart, thereby decreasing preload resulting in clinical deterioration manifested by the decreased heart rate.
E. The compression on the liver transiently increased preload with a resultant increase in cardiac output (stroke volume) and a reflexive slowing of the heart rate.

4. A 2-month-old infant presents with renal failure secondary to an obstructive uropathy. The infant is tachypneic and noted to have a metabolic acidosis with a blood pH of 7.20. Sodium bicarbonate (1 mEq/kg) is administered intravenously in an attempt to improve the blood pH. Shortly thereafter, the infant's perfusion is clinically noted to decline. Which of the following is the best potential explanation for the change in hemodynamics?
   A. Despite bicarbonate therapy, the blood pH remained sufficiently low to negatively affect the myocardium.
   B. The increase in the blood pH further reduced the low plasma-ionized calcium concentration, negatively affecting myocardial contractility.
   C. The increase in the blood pH led to direct systemic vasodilatation resulting in hemodynamic compromise.
   D. The rapid rise in sodium concentration resulted in a negative inotropic effect on the heart.
   E. The respiratory rate increased further after the bicarbonate therapy resulting in further energy expenditure and cardiovascular compromise.

5. A previously healthy 10-year-old child develops ARDS after sustaining abdominal and lower extremity trauma in a motor vehicle collision. She received crystalloid fluid resuscitation and multiple blood product transfusions to achieve hemodynamic stability. She requires a positive end-expiratory pressure (PEEP) of 15 cm H_2O to maintain acceptable arterial oxygenation but develops poor cardiac output with this ventilator strategy. Which of the following is the most likely primary cause of her decreased cardiac output?
   A. A decrease in left ventricular contractility due to myocardial depressant factors
   B. A decrease in left ventricular filling due to interventricular septal shift into the left ventricle
   C. A decrease in systemic venous return secondary to increased mean airway pressure
   D. An increase in left ventricular afterload due to increased transmural wall pressure
   E. An increase in right ventricular afterload secondary to lung overdistension

6. Which of the following is a contributing factor in the clinical presentation of pulsus paradoxus?
   A. A decrease in left ventricular afterload
   B. A decrease in pulmonary vascular resistance
   C. An increase in myocardial contractility
   D. An increase in right ventricular volume
   E. A rightward shift of the interventricular septum

7. A 3-year-old male with a known cardiomyopathy and decreased left ventricular function is admitted to the pediatric intensive care unit with a presumed viral laryngotracheobronchitis. In addition to reducing the work of breathing, tracheal intubation and the use of positive pressure ventilation will benefit cardiac function in this child in which of the following ways?
   A. A decrease in left ventricular afterload
   B. A decrease in right ventricular afterload
   C. A decrease in systemic venous return
   D. An increase in cardiac contractility
   E. An increase in systemic venous return

8. A 12-year-old male with a severe asthmatic exacerbation has worsening respiratory distress that is now accompanied by poor perfusion, worsening tachycardia (190 beats per minute), and hypotension (83/56 mm Hg). The physiologic explanations for the hypotension include relative hypovolemia secondary to increased insensible water losses and decreased intake, hypoxemia-induced myocardial dysfunction, and
   A. Decreased right ventricular afterload
   B. Decreased systemic vascular resistance
   C. Increased left ventricular afterload
   D. Increased partial pressure of carbon dioxide
   E. Untoward effect of steroid therapy

9. A 12-year-old male with a severe asthmatic exacerbation has now developed compromised perfusion with significant tachycardia (185 beats per minute) and hypotension (82/42 mm Hg). An appropriate initial hemodynamic intervention in this child would be to:
   A. Administer a crystalloid fluid bolus (10 mL/kg) to augment preload
   B. Initiate a low-dose epinephrine infusion (0.05 mcg/kg/min) to augment contractility
   C. Initiate an infusion of milrinone (0.5 mcg/kg/min) to augment contractility and foster ventricular relaxation
   D. Initiate an infusion of sodium nitroprusside (1 mcg/kg/min) to decrease systemic afterload
   E. Initiate inhaled nitric oxide (20 ppm) to decrease pulmonary vascular resistance

10. Which of the following statements regarding cardiovascular-pulmonary interactions is *false*?
   A. An increase in systemic venous return or in right ventricular afterload during respiration may displace the interventricular septum into the left ventricle and decrease left ventricular compliance and preload.
   B. Extremes in lung volumes (both low and high) can result in elevations in pulmonary vascular resistance.
   C. Adequate intravascular volume is important for both RV and LV output when initiating positive pressure ventilation.
   D. Negative intrathoracic pressure generated during spontaneous breathing increases the pressure gradient from the systemic veins to the right atrium.
   E. Negative intrathoracic pressure generated during spontaneous breathing has no effect on extrathoracic large veins.

Learning Objectives

- Describe the relative proportions of blood flow and oxygen consumption in the pulmonary, cardiac, renal, splanchnic, and cutaneous circulations.
- Describe the mechanisms that change regional blood flow in response to stress and pathological conditions.
- Summarize the role of the microcirculation in determining regional blood flow.
- Describe the unique characteristics of the coronary, cerebral, pulmonary, splanchnic, and renal vasculature.
- Describe the importance of local regulation of blood flow and mechanisms for achieving local control, including autoregulation of flow to major organ systems.
- Describe differences in oxygen extraction ratio in different organs, including the high oxygen extraction in the heart and the brain and relatively low extraction in the kidney.
- Describe the mechanisms of hypoxic pulmonary vasoconstriction.
- Review causes of increased and decreased pulmonary vascular tone.
- Review the importance of control of cerebral vascular tone in specific conditions.
- Understand the mechanisms and effects of control of cutaneous vascular tone.

15.1 Regulation of Blood Flow and Oxygen Consumption at the Major Tissue Beds

The major role of the circulatory system is to supply all the tissue beds with oxygen and nutrients and remove the end products of metabolism. During critical illness or injury, the circulatory system must adjust flow to organs and tissues to assure adequate flow to vital organs (i.e., the heart and the brain). The uninterrupted flow of oxygen and nutrients is necessary to sustain viability and function of the many specialized tissues. Since energy is needed for any function in the human body and it can be provided only by nutrients and oxygen, it is only logical that through the billions of years of evolution, all the tissues developed regulatory mechanisms that couple their function and energy consumption with substrate delivery by the circulatory system.

The vascular system components each play a role in the distribution and control of blood flow. *Large arteries* are responsible for distribution of blood flow and contribute very little to vascular resistance and blood flow regulation under normal conditions. Large arteries have sympathetic innervation, but increased smooth muscle tone in these vessels does little to change resistance; instead, it makes the artery stiffer (i.e., less compliant).

Small arteries range from 0.2 to 1.0 mm in diameter and provide vascular resistance that helps determine blood flow distribution. The small arteries typically distribute blood within an organ.

Arterioles are 0.01–0.2 mm (10–200 μm) and provide pressure and flow regulation by altering their resistance. Both small arteries and arterioles are typically highly innervated by autonomic nerves (especially from the sympathetic nervous system (SNS)). Together, these are the resistance vessels. Note that increased vascular tone not only reduces flow to the area of distribution, but it also decreases capillary hydrostatic pressure, which favors interstitial fluid absorption. It is important to recognize that SNS distribution to the vas-

cular beds is not uniform. For example, autonomic innervation in the splanchnic, skin, and skeletal muscle vascular beds is more extensive, which can selectively redirect blood flow from those beds when flow to more critical vascular beds must be preserved.

Capillaries are 6–10 μm, venules are 10–200 μm, and veins are 0.2–5 mm (200–5000 μm). Venules and veins are often innervated and help regulate blood flow and distribution. In most vascular beds, postcapillary resistance only contributes ~15% to the overall vascular resistance, but this is higher (~30%) in the pulmonary circulation and may be higher in pathological conditions.

About 70–75% of blood volume is in the venous vasculature. Thus, the veins serve as a capacitance reserve system; increased SNS activity reduces venous compliance considerably, which helps increase venous return by reducing the size of the vascular tank. Increased venous tone also increases venous pressure in extrathoracic veins creating a pressure gradient with the right atrium favoring venous return. Of note, the parasympathetic nervous system does not directly innervate arteries or veins (with a few exceptions) but can modulate SNS activity.

All the different tissue beds can autoregulate the amount of blood flow they receive to meet their needs. Although many individual differences exist, there are major similarities. The *myogenic response* describes the mechanism by which vessels respond to an increase in transmural pressure or stretch by constricting, thereby restoring blood flow to baseline levels. This is mediated by opening of mechanosensitive cation channels, principally Na^+, which depolarizes the cell membrane, thus activating voltage-gated Ca^{2+} channels that increase intracellular calcium concentration, which leads to smooth muscle contraction. Conversely, a fall in transmural pressure reduces vascular tone.

Tissue hypoxia (i.e., low partial pressure of oxygen in the tissues) leads to vasodilation in the local tissue arteriolar structures, which increases the flow of oxygenated blood into the territory. That is true for all tissues except the pulmonary circulation where tissue hypoxia leads to pulmonary arterial vasoconstriction. The reason for that difference is discussed in detail in the pulmonary circulation section.

15

Tissue hypoxia is a potent regulator of regional blood flow.

Tissue hypoxia causes vasodilation in all vascular beds except in the pulmonary circulation.

Note that tissue *hypoxia* is not the same as *hypoxemia* (i.e., low *blood* partial pressure of oxygen). There are four major causes of tissue hypoxia: (1) ischemic hypoxia (i.e., inadequate blood flow); (2) anemic hypoxia where there is inadequate oxygen carrying capacity, such as seen with aplastic crisis in sickle cell disease; (3) hypoxemic hypoxia as seen in a patient with severe acute respiratory distress syndrome; and (4) histotoxic hypoxia, such as seen with carbon monoxide or cyanide poisoning, but also seen in some patients with sepsis who have an impaired ability to utilize oxygen. Not infrequently, tissue hypoxia results from a combination of more than one of these factors. Understanding the underlying cause(s) of tissue hypoxia helps direct therapy to reverse this condition.

There are four major causes of tissue hypoxia: (1) inadequate blood flow (ischemic hypoxia), (2) low oxygen carrying capacity (anemic hypoxia), (3) low arterial oxygen saturation (hypoxemic hypoxia), and (4) impaired ability to metabolize oxygen (histotoxic hypoxia). One or more of these factors may occur in a patient.

Metabolism produces byproducts (e.g., CO_2, adenosine, protons, and 2,3-diphosphoglycerate); accumulation of these byproducts influences the arteriolar tone leading to vasodilation and increased blood flow. High levels of tissue CO_2 significantly increase cerebral and striate muscle blood flow, and adenosine dilates maximally the coronary arteries.

The myogenic response is a major mechanism that autoregulates regional blood flow.

Besides direct activation of vascular smooth muscle cells (VSMC) by norepinephrine released from sympathetic nerves, important actions on vascular tone are mediated by hormonally acting epinephrine released from the adrenal

gland. Although norepinephrine is also released from the adrenal gland (~20% of total catecholamine released), the latter normally does not act as a circulating hormone on adrenergic receptors. The actions at adrenergic receptors are determined by whether they are innervated or hormonal receptors (see ▶ Chap. 20, "Vasoactive Agents"). Sympathetic nerves terminate at α_1- and $ß_1$-adrenoceptors, whereas the hormonal effects of epinephrine are mediated through action at α_2- and $ß_2$-adrenoceptors. Differential actions in organs are mediated in large part by the density of different adrenoceptor types and the extent of tissue innervation by sympathetic nerves in the tissue beds. For example, there is a high density of $ß_2$-adrenoceptors in skeletal muscle vascular beds; thus, when epinephrine is released from the adrenal gland, it selectively increases blood flow to the skeletal muscles to address the energy needs to either run or fight a predator. Under the same stress, activation of SNS nerves in the skin, renal, and splanchnic circulation reduces blood flow to those organs and constricts capacitance veins increasing venous return.

15.1.1 Local Hormonal/Nervous System Factors Affecting Vascular Tone

Although the dynamic balance between sympathetic and parasympathetic nervous system outputs plays an important role in regulating blood flow, it is important to recognize that these autonomic systems interact with a complex array of factors that also influences vascular tone, especially during a critical illness. These additional factors explain much of the variation in clinical action observed when exogenous vasoactive drugs are infused to adjust blood flow and pressure (see ▶ Chap. 20, "Vasoactive Agents").

A wide range of local or systemic mediators either stimulate vasoconstriction or vasodilation, as summarized in ◘ Table 15.1. Besides direct action on VSMC or endothelial receptors, some mediators modulate sympathetic nervous system activity. For example, angiotensin is not only a direct vasoconstrictor, but it also acts at presynaptic angiotensin receptors to increase norepinephrine release from sympathetic nerves.

Since most mediators work through receptor systems, it is also important to recognize that receptors are dynamic structures on the cell surface that are actively regulated in terms of their density, surface presentation, and activity. For example, tonic stimulation of a receptor by an agonist typically leads to downregulation of the receptor. Conversely, blocking the receptor (e.g., with a ß-adrenoceptor blocker) increases receptor density on the cell surface.

To add to the complexity of VSMC tone regulation, receptors activate various internal signaling systems, such as G-proteins that either stimulate or inhibit various enzyme systems in the cell, leading to an increase or decrease in secondary message systems, such as cGMP, cAMP, inositol triphosphate, and diacylglycerol. These messengers then act at various enzyme systems that ultimately regulate cytoplasmic calcium concentration. These enzyme systems are also regulated, most often by the addition or removal of phosphate.

Besides acting directly on VSMC, a number of mediators exert their action by stimulating or inhibiting endothelial nitric oxide (NO) production. Thus, injury to the endothelium, which may occur during sepsis, trauma, etc., may impair the ability of local endothelium to produce NO, leading to increased vascular tone, as well as predisposing to activation of the clotting system.

Table 15.1 Summary of the actions of mediators on vascular smooth muscle tone

Mediator	Reduce vascular tone	Increase vascular tone
Norepinephrine	N/A	Acts at α_1- and α_2-adrenoceptors
Epinephrine	Acts at $ß_2$-adrenoceptors	Acts at α_1- and α_2-adrenoceptors
Angiotensin II		VSMC receptor; also acts on presynaptic receptors to increase NE release from sympathetic nerves
Vasopressin	Oxytocin receptors in pulmonary vascular bed	V_1 VSMC receptor
Endothelin (ET-1)	Action at ET_B on endothelial cells stimulates local NO production	Through ET_A and ET_B receptors on VSMC
Histamine	VSMC and endothelial receptors in systemic vascular bed	VSMC receptor in pulmonary circulation, especially in pulmonary venules
ANP and BNP	VSMC receptors	
Bradykinin	VSMC receptors	
NO	Intracellular activation in VSMC of cGMP production	
PGE_1 and PGI_2	VSMC receptors and endothelial receptors (the latter increase NO)	
Thromboxane (TXA_2)		VSMC receptors
$PGF_{2\alpha}$ and PGE_2	VSMC in pulmonary circulation	
Adenosine	Acts on endothelial receptors to increase NO release	
EDHF	Released by endothelium and hyperpolarizes VSMC	
Tissue hypoxia	Hypoxia-inducible factor (HIF) production and unclear mechanisms to reduce VSMC tone in systemic circulation	Acts at oxygen-associated K^+ channel in pulmonary VSMC
Increased tissue CO_2	Reduces tone in VSMC in systemic circulation	Increases tone in VSMC in pulmonary circulation by unclear mechanism
K^+	Increased tissue K^+ activates K^+-dependent K^+ channels, which hyperpolarizes VSMC	

VSMC vascular smooth muscle cells, *ET_A and ET_B* are endothelin A and B receptors, *NO* nitric oxide, *ANP and BNP* atrial and B-type natriuretic peptide, *EDHF* endothelium-derived hyperpolarizing factor

In summary, it should be clear that simple explanations of changes in blood flow due to changes in SNS activity, for example, are unlikely to fully explain what happens during critical illness when the VSMC receives conflicting "messages" from various mediators. More details on the role of various mediators on blood flow in specific regional vascular beds are provided in the following sections.

Detailed review of all the mediators noted in Table 15.1 is beyond the scope of this chapter. The following section reviews several important mediators and mechanisms that control VSMC tone.

Endothelium-Derived Vasoactive Factors

- *Nitric oxide*: Nitric oxide (NO) diffuses from the endothelium and potently relaxes the overlying VSMC resulting in vasodilation. In some arterial territories, NO also produces vasodilation through the activation of potassium channels resulting in cell hyperpolarization. Nitric oxide is produced in endothelial cells by NO synthase from L-arginine, where it then diffuses into smooth muscle cells and activates soluble guanylate cyclase, which increases the intracellular concentration of cGMP. Increased cGMP, through several intermediate steps, relaxes VSMC tone. Several pieces of evidence suggest that endothelial NO synthase (NOS) activity plays an important role in arterial basal tone. Inhibitors of NOS decrease intracellular cGMP concentrations producing vasoconstriction. Injury to the endothelium also increases tone in the overlying vessel.

  The concentration of NOS is also controlled by up- or downregulation of its gene expression. Shear stress, cGMP, transforming growth factor β1, atherosclerosis, cirrhosis, and pregnancy upregulate the gene, while LDL cholesterol (oxidized), hypoxia, TNFα, and heart failure downregulate the gene.
- *Prostacyclin*: Prostacyclin is a product of arachidonic acid synthesized by the cyclooxygenase enzymes, COX1 and 2. Prostacyclin produced in endothelial cells causes significant vasodilation by acting at VSMC receptors to increase intracellular cAMP, activation of potassium channels, and possibly by increased NO production; it also is a potent inhibitor of platelet aggregation.
- *Endothelium-derived hyperpolarizing factor (EDHF)*: In addition to NO and prostacyclin, the endothelium relaxes smooth muscle by releasing EDHF, which is thought to be a soluble transferable factor that causes smooth muscle cell hyperpolarization inhibiting smooth muscle contraction. The impact of EDHF on vasodilation and arterial tone is inversely related to the size of the artery; thus, EDHF has a greater effect than NO in smaller arteries. Inhibition of NO and prostacyclin does not eliminate the action of EDHF, indicating that it is some yet to be determined factor. Hyperpolarization of the cell membrane by EDHF is mediated by activation of ATP-sensitive and calcium-dependent potassium channels. Some data suggest that it may be different factors in different tissues, with data supporting hydrogen peroxide, sulfur dioxide, and potassium ions as mediators.
- *Endothelin*: Endothelin is one of the few vasoconstricting endothelial-derived mediators. It is produced as three isopeptides (ET-1 to ET-3) originating from larger propeptides. The propeptides are transformed to active endothelin by endothelin-converting enzymes. Different endothelin isopeptides are produced in different tissues. For example, only ET-1 is normally produced by cerebral endothelium. Endothelin production can be upregulated by thrombin, transforming growth factor β1, hemoglobin, and TNFα and can be downregulated by NO and cGMP.

Local mediators and the autonomic nervous system play a significant role in blood flow regulation.

Local mediators do not work in isolation—the net effect on VSMC tone reflects the balance between vasoconstrictor and vasodilator signals, which are also affected by changes in receptor density, presentation, activity, and changes in post-receptor activity.

Endothelial injury reduces the action of some mediators that depend on stimulating NO production.

NO causes vasodilation by activation of VSMC soluble guanylate cyclase, which increases intracellular cGMP.

Prostacyclin causes vasodilation by acting through a VSMC receptor to increase intracellular cAMP, which activates potassium channels, and by increasing endothelial NO production through action at an endothelial receptor.

EDHF is more important than NO for vasodilation of smaller arteries. EDHF has not been fully characterized yet and may represent more than one mediator, depending on the vascular bed.

Endothelin is a potent endothelial-derived vasoconstricting mediator. There are two endothelin receptors on vascular smooth muscle: ET_A and ET_B; the latter receptor is also on vascular endothelial cells where endothelin binding stimulates increased NO production.

To complicate the understanding of its physiologic effects, endothelin can bind to two different vascular receptors, ET_A and ET_B. In vascular smooth muscle, these receptors are coupled to Gq-protein; receptor activation increases inositol triphosphate (IP3), which increases the release of Ca^{2+} from the sarcoplasmic reticulum. Increased intracellular Ca^{2+} concentration causes vasoconstriction. ET_B receptors on vascular *endothelial* cells respond to endothelin by increasing NO production. Studies show that low doses of ET-1 cause vasodilation through endothelial ET_B receptor activation; higher concentrations result in vasoconstriction through activation of VSMC ET_A receptors. The action of endothelin varies based on the vascular bed. For example, ET_A and ET_B receptor blockade does not alter basal cerebral artery tone, suggesting that endothelin has no role in the tonic regulation of the cerebral VSMC, whereas endothelin receptor inhibitors are effective in the management of pulmonary hypertension.

15.2 Potassium Channels

Activation and opening of potassium channels allow potassium to flow out of the cell down its concentration gradient, which removes positively charged ions from within the cell causing hyperpolarization of the VSMC membrane → closure of voltage-dependent Ca^+ channels → decreased intracellular Ca^+ concentration → smooth muscle relaxation. The resting VSMC membrane potential has been measured in vitro to range from −40 to −70 mV in different vascular beds. Minimal changes in the resting potential lead to significant changes in smooth muscle tone and arterial resistance. There are four main potassium channels that have been identified as part of the regulatory mechanism of regional blood flow:

- *ATP-sensitive potassium channels* (K_{ATP}) are regulated by intracellular concentrations of ATP. Decreased ATP concentration causes dissociation of ATP from the channel, which results in channel opening. Several mediators cause hyperpolarization of the arterial smooth muscle membrane through this mechanism: adenosine, cAMP, opioids, calcitonin gene-related peptide, vasoactive intestinal peptide, and EDHF are only some of the identified mediators. Nitric oxide does not act through activation of ATP-sensitive potassium channels.

  ATP-sensitive potassium channels also have been implicated in vasodilation induced by hypoxia, acidosis, and hypotension where ATP production is compromised. The effect of these channels in the regulation of basal arterial tone is less clear and demonstrably less crucial.
- *Calcium-dependent potassium channels* (K_{ca+}) are activated by increased intracellular calcium ion concentrations. Their activity increases with membrane depolarization. As with the K_{ATP} channels, many mediators have been implicated in the activation of K_{ca+} channels. Isoproterenol and cAMP increase their activity. cAMP-mediated K_{ca+} channel activation is thought to play a significant role in basal vascular tone regulation. Activation of the same channels by NO and cGMP may play a significant role in the microcirculation.
- *Voltage-dependent potassium channels*, also called delayed rectifier potassium channels, open when membrane depolarization occurs. Their role is generation of an outward current that leads to repolarization. They seem to be part of the control system regulating vascular tone. Their exact role in regulating the circulation in different vascular beds is currently unclear.

- *Inward-rectifier potassium channels* open with membrane hyperpolarization, and it is believed that they play a role in maintenance of basal tone and membrane resting potential. The role of these channels needs to be further investigated, but it was recently shown that elevations of extracellular potassium activate the channels and lead to vascular relaxation. The role of the inward-rectifier potassium channels may be more important than initially thought; for example, they may play a significant role in neurovascular coupling. Specifically, when neurons are activated and depolarized, slight increases in extracellular potassium concentrations may, through the inward-rectifier potassium channels, cause direct smooth muscle relaxation and hence cerebral arteriole vasodilation, which helps match blood flow to increased neuron metabolic activity.

Activation of ATP-sensitive potassium channels causes hyperpolarization of the VSMC membrane → closure of voltage-dependent Ca^+ channels → decreased intracellular Ca^+ concentration → smooth muscle relaxation.

There are four types of K^+ channels that play a role in VSMC tone: (1) ATP-sensitive potassium channels, (2) calcium-dependent potassium channels (3), voltage-dependent potassium channels, and (4) inward-rectifier potassium channels.

15.3 Temperature Regulation of Blood Flow

Since the human body can only function within a narrow range of core temperatures, blood flow and vascular tone are also influenced by temperature. Metabolic expenditure is inversely related to body temperature within the normal physiologic temperature range. When the body needs to increase its core temperature, significant peripheral vasoconstriction is seen in all tissues in contact with ambient colder temperature in order to limit further heat loss. Blood flow is shifted to the core of the body away from the skin to reduce radiant and convective heat loss and maintain internal vital organ temperature for normal function.

Temperature plays a significant role in blood flow regulation either directly by reducing or increasing heat loss through the cutaneous vascular bed or indirectly by altering the metabolic rate.

15.4 Blood Flow and Oxygen Consumption

Although clinicians think about blood flow in terms of L/min/m^2 for cardiac index (CI), organ blood flow is often expressed in units of mL/min/100 g of tissue. To put organ blood flow into context with the overall cardiac output, it is helpful to recognize that weight-based cardiac output changes markedly across the pediatric age range compared with the relatively stable blood flow measured per body surface area (i.e., neonate CI is 4–5.5 L/min/m^2 vs adults at 2.5–4 L/min/m^2). When expressing this flow per 100 g, however, the overall cardiac output is ~24 mL/min/100 g in a neonate, falling to ~14.7 mL/min/100 g in a 6–7-year-old and to ~8.7 mL/min/100 g in a 70 kg adult.

Note that since skeletal muscle represents 45% of body mass, the maximal blood flow in skeletal muscle represents a huge increase in cardiac output due to increased oxygen demand. Similarly, the skin has the potential of becoming an important source of increased blood flow since it represents 7.5% of body weight and can increase flow over 18-fold from baseline.

Many organs receive blood flow well in excess of their metabolic demand, whereas other organ beds extract a larger than normal fraction of delivered oxygen. Overall oxygen extraction is normally approximately 25% of the delivered oxygen; this can be remembered if you recall that one of the four oxygen molecules bound to hemoglobin is normally consumed in the microcirculation. Oxygen extraction is measured as the arteriovenous O_2 content difference (mL O_2/100 mL of blood). The values for organs are seen in Table 15.2. As noted, the heart has high oxygen extraction at baseline, whereas other organs, such as skeletal muscle or the splanchnic circulation, can maintain adequate tissue oxygen by extracting a greater percentage of the delivered oxygen when blood flow is low. On average, about ~5 mL O_2/100 mL of blood is extracted (22–30% across most organs).

Table 15.2 Resting and maximal blood flow in various organs and normal oxygen extraction across adult organ beds ($AVDO_2$). The proportion of blood flow as a percentage of cardiac output is presented for adults; brain blood flow in infants will be a higher percentage of cardiac output. Flow is measured in mL/100 g/min

Organ	Resting blood flow (mL/100 g/min)	Maximal blood flow (mL/100 g/min)	Magnitude of increase from resting to maximal	Percentage of resting cardiac output	$AVDO_2$ mL of O_2 per 100 mL blood (O_2ER)
Brain	54	140	2.6-fold	14	6 (31%)
Heart	70	390	5.5-fold	4.5	11 (57%)
Liver/splanchnic[a]	98	250	2.55-fold	25	5 (26%)
Kidney	310	390	1.25-fold	20	1.5 (7.8%)
Muscle	4	18	4.5-fold	21	5 (26%)
Skin	8	150	18.75-fold	7.5	2 (10%)

$AVDO_2$ is the arteriovenous oxygen content difference (mL O_2/100 mL of blood) and O_2ER (oxygen extraction ratio) is the percentage of oxygen extracted from arterial blood assuming a hemoglobin concentration of 14 g/dL, 100% arterial oxygen saturation, and PaO_2 of 100 mm Hg

[a]Liver/splanchnic flow represents hepatic artery and portal venous blood flow to the liver; the latter represents most of the splanchnic blood flow

15.5 Mechanisms of Regional Blood Flow Regulation during Stress and Pathological Conditions

When thinking about blood flow and its organ system regulation, it may help to consider how a municipal water system delivers water. The water tower creates the driving pressure, similar to the heart's pumping function. When someone opens a faucet, water flows through that faucet based on the pressure head. If too many faucets are open at the same time, as may be seen with sepsis, then the pressure and flow at each faucet in the water system falls. Furthermore, if the water tower is depleted of water, pressure and flow will fall. Similarly, if the capacitance venous system relaxes excessively, the blood return to the heart falls and thus less blood flow and pressure is generated.

The same basic principles (oxygen delivery, local and systemic mediators, and autonomic nervous system) that regulate blood flow during usual physiologic conditions apply during stress.

The driving pressure generated by the heart and the vascular tone in organs determine regional blood flow. If too many vascular beds are dilated, the pressure and flow throughout the circulatory system will fall.

During stress, whether from a critical illness or running a marathon, metabolic demand increases and the autoregulatory mechanisms of blood flow and oxygen delivery act to increase blood flow where it is most needed. The human stress response evolved to help survive threats from predators. Thus, the autonomic stress response is designed to assure that there is adequate blood flow to skeletal muscles to fight or run. Sympathetic nervous system (SNS) activation leads to epinephrine release from the adrenal gland, which acts preferentially at the hormonal β_2-adrenoceptors that are prominent in the skeletal muscle bed. It also acts at cardiac β_1- and β_2-adrenoceptors to increase contractility and heart rate, which increases cardiac output. SNS activation also increases the action at innervated α_1-adrenergic receptors, which are more highly concentrated in the splanchnic, renal, and cutaneous circulations; this helps redirect blood flow from those organs while preserving blood flow to the brain and heart, which have little response to α-adrenergic stimuli.

In addition to autonomic system activation, a host of other mediators are active during stress states, depending on the nature and type of stress. In addition to regulation of regional blood flow by SNS activation and release of various mediators, there are local mechanisms that help maintain blood flow. These local mechanisms vary depending on the organ involved, as detailed in subsequent regional circulation discussions below.

In different pathological states (e.g., cardiogenic or hypovolemic shock, hypertension, diabetes, sepsis), malfunction of different regulatory mechanisms (e.g., endothelial dysfunction with decreased NO production and/or vasodilatory sensitivity) causes impaired oxygen delivery and blood flow to the tissues. The analysis of circulatory regulation during specific pathological states is beyond the scope of this chapter. These mechanisms are discussed in other chapters addressing specific pathological states.

15.5.1 Hemodynamic Coherence and the Microcirculation

In the management of critical illness, attention is often focused on restoring mean arterial pressure (MAP), filling pressures such as the central venous pressure (CVP), and cardiac index (CI). The assumption is that achieving these macrocirculatory endpoints will restore regional organ perfusion. Recent studies using methods to study the microcirculation, however, show that this is not always the case. The term "hemodynamic coherence" was introduced in 2015 to describe this association between the macro- and microcirculations.

For hemodynamic coherence to function properly, the compensatory mechanisms at the macro- and microcirculatory levels should match oxygen delivery to the normally heterogeneous tissue metabolic demand. Thus, activation of the SNS, renin-angiotensin-aldosterone system, local biochemical control mechanisms, and signaling molecules should match oxygen demand to oxygen delivery. Unfortunately, during critical illness or injury, activation of the inflammatory and coagulation system often disrupts or obstructs microvessels with platelets and/or fibrinogen. There also may be localized over- or underproduction of NO, and the membrane receptor and post-receptor signaling pathways may be altered depending on the competitive signals received by endothelial and vascular smooth muscle cells.

Based on studies of the microcirculation in various animal models and during critical illness, four types of microcirculatory alterations are thought to underlie the loss of hemodynamic coherence. These alterations are typically associated with a reduced functional capillary density and thereby the loss of the capacity of the microcirculation to deliver oxygen to the tissues.

1. *Heterogeneity in microcirculatory perfusion* with obstructed capillaries next to perfused capillaries. Sometimes, there are shunts in the microcirculation that allow blood flow to bypass capillaries. This type of disturbance is often seen in sepsis, but also was observed in children on ECMO. The degree of capillary heterogeneity was associated with increased morbidity and mortality. Note that this circulatory abnormality results in reduced oxygen extraction, as seen in patients with sepsis. Thus, reduced oxygen extraction and consumption in tissue beds and organs may not be because cells are unable to extract oxygen; instead, some cells within the microvascular bed receive oxygen well in excess of their metabolic demand while other cells are ischemic.
2. *Hemodilution* reduces oxygen carrying capacity at the capillary level and may increase diffusion distance between capillaries containing red blood

Hemodynamic coherence describes the relationship between the macro- and microcirculations. In critical illness, this relation may be disrupted so that microcirculation may be impaired despite restoration of macrocirculatory parameters. Four types of microcirculatory alteration are thought to underlie the loss of hemodynamic coherence: (1) heterogeneity in microcirculatory perfusion, (2) hemodilution, (3) vasoconstriction/tamponade, and (4) tissue edema, which increases diffusion distance from capillaries.

cells (RBCs) and tissue cells. This abnormality is most often seen in patients undergoing cardiopulmonary bypass with hemodilution.

3. *Vasoconstriction/tamponade*: vasoconstriction reduces RBC flow, *or* increased venous pressure increases hydrostatic pressure impeding (tamponade) microcirculatory flow. The latter may be induced by increased venous vascular resistance or excessive fluid resuscitation. If fluid resuscitation increases venous pressure, this may adversely affect the microcirculation. Studies of microcirculatory flow observed that vasopressors may improve systemic blood pressure, but excess microcirculatory vasoconstriction can impair tissue blood flow. Of note, hyperoxia may be a cause of this type of flow restriction where increased oxygen tension in the blood delivered to tissues is sensed locally as adequate blood flow leading to local vasoconstriction, which may compromise flow to at-risk microcirculation.
4. *Tissue edema increasing diffusion distance*. If capillary permeability is increased, any increase in capillary hydrostatic pressure leads to more interstitial fluid, which may overwhelm the lymphatic system, especially if the right atrial pressure is increased or the inflammatory response has obstructed lymphatic drainage. This mechanism may partly explain the worse outcome observed in the liberal fluid resuscitation group in the randomized trial of conservative versus liberal fluid resuscitation in African children. Microcirculation studies in adults with malaria show that giving fluid to improve cardiac output did not improve microvascular obstruction and instead promoted tissue edema in the lungs and kidney.

Ideally, clinicians will be able to resuscitate patients by assuring adequate perfusion to the microcirculation, but readily available and noninvasive bedside tools to reliably monitor microvascular blood flow and metabolic balance in the tissues are not yet available. Clinicians may suspect ongoing abnormalities in microcirculatory flow when the patient has restoration of macrocirculatory goals, but there are ongoing acidosis, lactate production (or slow lactate clearance), and evidence of worsening organ dysfunction.

15.6 Coronary Circulation

15.6.1 Anatomy, Histology, and Physiology

Humans have two coronary arteries. The right coronary artery supplies the posterior descending artery in ~70% of the population, which represents a right dominant circulation.

The human heart is supplied by two main coronary arteries. The left coronary artery gives rise to two major branches, the left anterior descending and the left circumflex artery. The left coronary artery mainly supplies the left atrium and the anterior, septal, and lateral walls of the left ventricle. The right coronary artery mainly supplies the right atrium and the right ventricle as well as the posterior septal and inferior left ventricular territories in 85% of the population. By convention, the artery that supplies the posterior third of the interventricular septum—the posterior descending artery—determines the coronary dominance. In ~70% of the population, the right coronary supplies the posterior descending coronary artery; in ~10%, this artery is supplied from the left circumflex, and in ~20% of the population, it is provided by both coronary arteries (Fig. 15.1).

The heart is a highly aerobic organ that needs continuous inflow of oxidation substrates to generate ATP, as it cannot tolerate anaerobic metabolism for prolonged periods. The baseline oxygen consumption of the myocardium (MVO_2) is high compared to most other organs; it ranges from 8 to 15 mL/min/100 g compared with lower basal oxygen consumption in other organs as

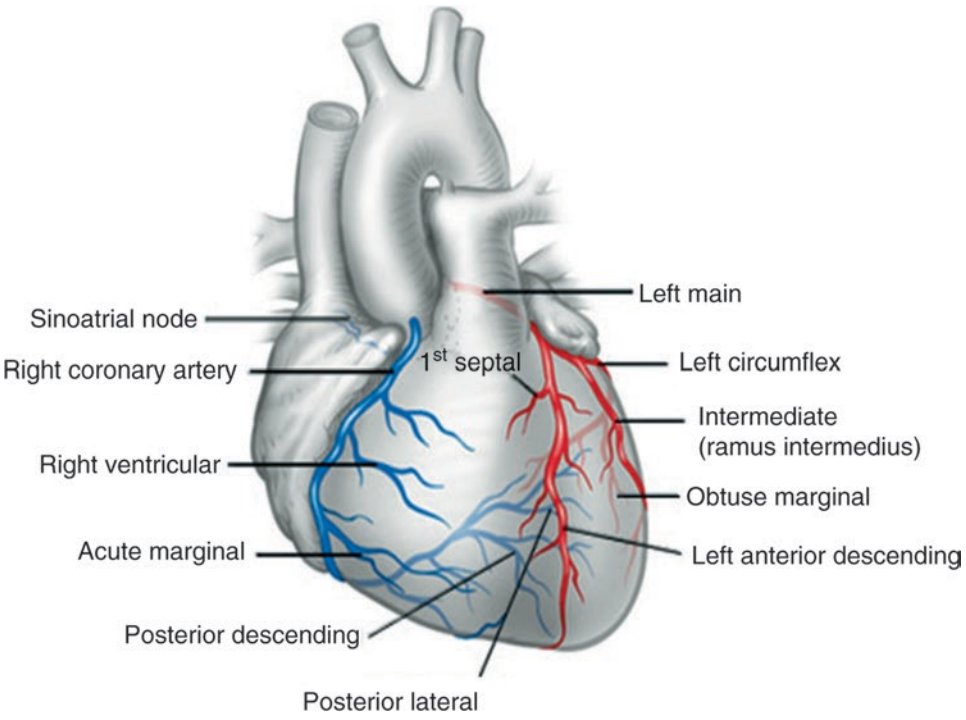

Fig. 15.1 Typical anatomy of the coronary arteries in a human heart. A right dominant circulation is shown: the posterior descending coronary artery (PDCA) is provided by the right coronary artery, which occurs in ~70% of the population. In ~10% of the population, the PDCA is provided by the left circumflex artery (left dominant system), and in ~20%, both coronary arteries (codominant system) supply the PDCA

Table 15.3 O_2 consumption in various adult organ systems

Organ system and state	O_2 consumption (mL O_2/min/100 g)
Resting heart	8
Arrested heart	1.5
Heart during heavy exercise	70
Brain	3
Kidney	5
Skin	0.2
Resting muscle	1
Contracting muscle	50

The table demonstrates the wide range in O_2 consumption in the heart and skeletal muscle based on metabolic demand

summarized in Table 15.3. In the arrested heart, MVO_2 immediately decreases to ~10% of normal metabolism (~1.5 mL/min/100 g). That is true for the fibrillating heart as well, where there is no organized contractile function and no wall stress. Conversely, MVO_2 and thus coronary blood flow can increase ~9-fold during heavy exercise.

Energy consumption of the myocardium is determined by the following factors: myocardial wall stress, heart rate, and myocardial contractility. Direct measurement of myocardial wall stress or MVO_2 is difficult but can be estimated by the pressure-rate product, which is the systolic blood pressure times the heart rate. Clinical studies show that the pressure-rate product is closely related to MVO_2 and myocardial wall tension. For the heart to meet its energy requirements, the coronary blood flow must be capable of rapid adjustments.

Basal oxygen consumption varies widely across organ systems and may need to increase up to 50-fold with increased metabolic demand

15.6.2 Local Regulation of Coronary Blood Flow

The normally beating heart is perfused via coronary blood flow mainly during diastole (Fig. 15.2). The elastic properties of the aorta, which acts as a reservoir, allow for a constant relatively uniform coronary blood flow throughout diastole. Coronary perfusion pressure (CPP) is defined as the diastolic blood pressure minus right atrial pressure, since most coronary blood drains into the coronary sinus located in the right atrium. Thus, during cardiopulmonary resuscitation (CPR), cardiac perfusion occurs mainly during the decompression phase of chest compression when the diastolic aortic pressure is higher than the right atrial pressure creating a positive CPP gradient.

Unlike flow through the left coronary artery, right coronary artery blood flow also occurs during systole because RV intracavitary pressure and wall stress is significantly lower than aortic blood pressure throughout the entire cardiac cycle, unless severe right ventricular hypertrophy exists due to pulmonary hypertension or pulmonary stenosis (Fig. 15.2).

Coronary perfusion of the left ventricle occurs mainly during diastole; the driving force for coronary blood flow is determined by the coronary perfusion pressure, which equals diastolic blood pressure minus right atrial pressure.

The major coronary arteries are conductance vessels and do not cause a pressure drop throughout their course to the epicardium (unless a blockage exists). The size of the epicardial coronary arteries ranges from 0.3 to 6 mm in caliber. Coronary circulation resistance is generated from the arterioles (resistance vessels) with diameters ranging from 10 to 200 μm. The resistance vessels give rise to an enormous number of capillaries that form a very dense network of approximately 3000–3500 capillaries per square millimeter, which maximizes the capillary to myocardial cell ratio and couples the supply of oxygen to demand. If the myocardium hypertrophies, the density of the capillary network decreases. One of the most remarkable physiologic properties of the coronary microcirculation is its recruiting capability. Under normal conditions, many capillaries are closed by increased tone of the precapillary sphincter. When myocardial oxygen demand increases, relaxation of the precapillary sphincter drops the resistance and increases the capillary density and thus blood flow per 100 g of myocardial tissue, which allows the heart to achieve the

Epicardial coronary vessels are conductance vessels that do not cause a significant pressure decrease even during maximal blood flow. Arterioles with diameters of 10–200 μm are the resistance vessels.

Capillary recruitment is a very efficient mechanism to improve oxygen delivery to the myocardial tissue when there is increased metabolic demand or when flow is impeded by epicardial vessel obstruction.

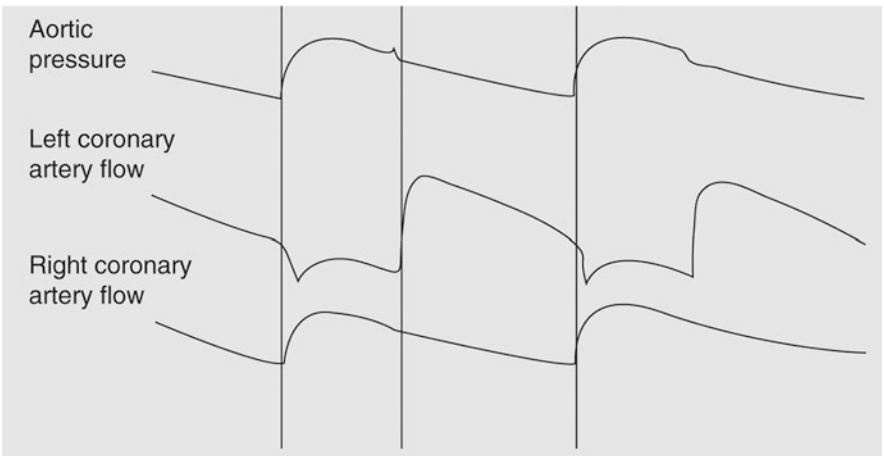

Fig. 15.2 During systole and diastole, blood supplied by the coronary vessels is exposed to changing myocardial pressures. During isovolumic contraction of the left ventricle (preejection), myocardial tissue compression causes flow in vessels supplied by the left coronary artery to fall to zero or even become retrograde. With the onset of diastole, removal of the compression results in a large inflow into these vessels early in diastole. Flow parallels diastolic aortic pressure during the remainder of the cycle. *In the normal right ventricle, flow occurs during systole because systolic myocardial pressures in the wall of the right ventricle do not exceed aortic pressure*. The flow profile in the right ventricle closely resembles the pressure profile in the aorta

wide range of oxygen delivery to meet changing metabolic demand as noted in ◘ Tables 15.2 and 15.3.

The coronary circulation resistance is regulated mainly by the small arterioles with a diameter below 30 μm. Myogenic regulation by smooth muscle control occurs at intermediate arteries with diameters between 30 and 60 μm. Larger arteries are the site of flow-mediated dilation. When the small arterioles dilate, vascular resistance decreases and coronary blood flow increases. This downstream drop in pressure causes the larger vessels' smooth muscle to relax in order to avoid collapse, further decreasing resistance. The increased flow at the largest epicardial vessels causes an increase in shear stress, which induces epicardial vessel relaxation.

Coronary circulation resistance is mainly determined by the smallest arterioles with diameter <60 μm. Arteriolar dilation increases shear stress of the epicardial arteries, which induces dilation of the conductance vessels.

15.6.3 Specific Determinants of Coronary Blood Flow

15.6.3.1 Transmural Distribution of Coronary Blood Flow

Subendocardial tissue experiences greater pressure than the epicardium during systole so that local blood flow occasionally ceases during systole. During diastole, the ratio of endocardial to epicardial flow is about 1.5:1 but averages for the entire cardiac cycle to about 1.25:1. During resting conditions, the endocardium's energy requirements are approximately 20% higher than the epicardium so that the increased subendocardial blood flow matches the increased metabolic demand.

Endocardial muscle has higher oxygen demand and therefore receives ~25% more blood flow during the cardiac cycle compared with the epicardial myocardium. Endocardial blood flow may cease during systole, so diastolic endocardial blood flow is ~50% higher than epicardial flow.

The subendocardial tissue is more vulnerable to ischemia for the aforementioned reasons. A total decrease of regional coronary blood flow by 40% due to an epicardial coronary stenosis causes the normal ratio of endocardial to epicardial blood flow of 1.25 to drop to 0.4. This flow redistribution from the endocardium to epicardium is exaggerated during exercise, tachycardia, stress, or by the use of potent arteriolar vasodilators such as adenosine or dipyridamole. This phenomenon has been called coronary steal. Elevated left ventricular diastolic pressures and left ventricular hypertrophy further decrease the perfusion ratio between the endocardium and the epicardium. An increase in mean aortic pressure can improve endocardial perfusion and bring the ratio closer to normal. This is because the endocardial arterioles are maximally dilated and, therefore, flow is mainly pressure dependent. Reducing myocardial oxygen consumption by β-adrenoceptor inhibition, which decreases metabolic demand, helps restore the balance between coronary blood flow and oxygen consumption. If a nonselective β-blocker is used, the inhibition of peripheral vascular β_2-adrenoceptors increases systemic vascular resistance and thus diastolic blood pressure, which improves CPP, but increases afterload and thus ventricular wall stress.

When an epicardial arterial stenosis exists, the endocardial vessels within the distribution territory are maximally dilated, and therefore blood flow is mainly dependent on diastolic arterial pressure.

15.6.3.2 Metabolic Regulation of Coronary Blood Flow

Coronary blood flow regulation is very closely related to the metabolic need of the myocardium, which is the main regulator of local blood flow. Since there are limited glycogen reserves to support anaerobic ATP production, the heart requires a continuous supply of oxygen to generate ATP aerobically to meet its substantial metabolic demand. Any increase in cardiac metabolic requirements leads to a near instantaneous decrease in coronary resistance. Arterial occlusion for even 1 second leads to a reactive increase of coronary blood flow, called *reactive hyperemia.* Many agents and mediators have been implicated in this phenomenon, but the specific mechanism(s) remains uncertain. Adenosine, ATP, and nitric oxide (NO) have been studied extensively as mediators of reactive hyperemia.

Adenosine, ATP, and nitric oxide are considered important flow regulation mediators.

Cardiac muscle uses fatty acids (~60–70%) and carbohydrates (~30–40%) for energy.

Oxygen extraction is maximal, and the coronary sinus oxyhemoglobin saturation is ~30% at rest.

The major cardiac metabolic substrates for energy are fatty acids (60–70% of energy production) and carbohydrates (glucose, lactate, and ketones; ~30–40%). To meet its high metabolic demand, the heart extracts 65–70% of the delivered oxygen unlike other organs that extract only 20–30% of delivered oxygen. Thus, the coronary sinus venous oxyhemoglobin saturation is ~30% at rest. The heart is able to extract oxygen even at low arterial partial pressure of oxygen.

Adenosine and ATP are powerful coronary dilators that are considered important mediators of local metabolic regulation. Adenosine and ATP concentrations increase at times of an imbalance in the supply-to-demand ratio for oxygen; the rise in the interstitial concentration of adenosine parallels the increase in coronary blood flow. Although adenosine meets most of the criteria for a metabolic regulator of coronary blood flow, inhibition of the adenosine receptor does not always reduce the magnitude of the hyperemia in response to metabolic stimuli in animals or humans. Thus, adenosine is not the only mediator responsible for this phenomenon.

Nitric oxide (NO) is also a mediator of coronary blood flow regulation. Adenosine acts through endothelial receptors to stimulate NO production, which also increases in response to tissue hypoxia and flow-mediated increased endothelial shear stress. NO inhibition decreases the magnitude of coronary vascular relaxation in response to metabolic stress. NO is mainly responsible for the late sustained phase of reactive hyperemia.

A host of other mediators have been implicated in local vascular tone control including vasodilator (prostacyclin) and vasoconstrictor (thromboxane) prostaglandins, natriuretic peptides, bradykinin, endothelin, angiotensin II, and histamine. As noted previously, these mediators create the potential for complex effects on local vessel tone, but metabolic factors are likely the predominant determinants of myocardial blood flow. Inhibition of adenosine, nitric oxide, and K^+ channels together completely blocks the increase of coronary blood flow during exercise in dogs. Since NO is derived from the endothelium, an intact endothelium is important; endothelial injury and dysfunction reduces NO production and often leads to increased local vascular tone, which increases the risk of ischemia.

15

Since myocardial oxygen demand is the main determinant of coronary blood flow, it is helpful to recognize differences in oxygen demand related to the different types of work that the ventricle performs. In the heart, work is related to the volume of blood pumped and the pressure that needs to be generated to perform the pumping function (i.e., volume × pressure). Left ventricular stroke work index (LVSWI) is defined as SI × (MAP-LAP) × 0.0136 g-m/m^2, where SI is the stroke index (mL/beat/m^2), MAP is the mean arterial pressure, LAP is the left atrial pressure (which may be estimated by the pulmonary artery occlusion pressure), and the factor converts the parameter into the units noted.

For a given degree of ventricular work, the myocardial oxygen demand is significantly lower when the ventricle is performing volume rather than pressure work. This difference in oxygen demand is used clinically to improve cardiac output in patients with reduced ventricular pumping function by lowering vascular resistance.

Note that LVSWI increases when either or both SI or the MAP-LAP component increases. However, the oxygen demand for a given degree of ventricular work is *not* constant. If the patient's systemic vascular resistance increases, oxygen consumption increases much more than if the SVR decreases and SI increases to achieve the same level of LVSWI. Thus, the metabolic demand of the heart is lower when it is doing volume rather than pressure work. This is observed clinically in an infant who tolerates a large ventricular septal defect where the right ventricle can pump three to four times the amount of blood pumped by the left ventricle compared with the infant with pulmonic stenosis where the increased pressure work results in heart failure. The ventricle prefers to do volume work pumping into a low vascular resistance system rather than pressure work trying to pump into a vascular system with high resistance or pumping across a fixed obstruction.

15.6.4 Adrenergic Control of Coronary Blood Flow

For the heart to maintain a sustained increase in coronary blood flow during prolonged periods (e.g., exercise), there is a need for positive feedback mechanisms that can alter the hemodynamics in a way that promotes coronary blood flow. Local metabolic control is inadequate to explain the phenomenon, and all the substances (e.g., NO, adenosine, and K^+_{ATP} channels) that have been tested alone or in combination could not account for the changes observed during exercise. However, during rest, NO and K^+_{ATP} channels contribute significantly to the maintenance of vascular tone.

NO, adenosine, and K^+_{ATP} channels contribute to the maintenance of coronary vascular tone during rest but cannot account for all the changes seen during exercise.

Both sympathetic and parasympathetic nerves enervate the coronary arteries, suggesting that they can regulate coronary blood flow. Activation of β_2-adrenoceptors increases flow, whereas activation of α_1-adrenoceptors causes vasoconstriction. These actions, however, can be overcome based on changes in metabolic demand. For example, coronary vasoconstriction is not observed when high doses of epinephrine are given during cardiac arrest. In addition, critical illness may alter the response to sympathetic stimulation; for example, adults with septic shock have increased coronary blood flow despite vasodilated sepsis with low diastolic blood pressures.

When the sympathetic nervous system is activated during exercise or illness-related stress, contractility, heart rate, and cardiac output increase. Systolic blood pressure rises, but often diastolic blood pressure falls due to increased blood flow to skeletal muscles mediated by reduced systemic vascular resistance. These physiologic changes increase myocardial metabolic demand and thus coronary blood flow, which is achieved through the effects of local metabolic mediators causing coronary vasodilation. In experimental models, it is difficult to isolate the local metabolic effects from the adrenergic effects.

15.6.4.1 α-Adrenergic Effects on Coronary Blood Flow

Direct α-adrenergic activation with simultaneous β-adrenergic blockade decreases coronary blood flow that can be reversed with α-adrenergic blockers. In addition, at a given level of oxygen consumption, α-adrenergic blockade causes higher coronary blood flow and lower coronary arterial resistance.

In the systemic circulation, excessive α-adrenergic-mediated vasoconstriction increases systemic vascular resistance, which increases afterload on the ventricle. Increased diastolic pressure increases the compressive forces especially on the subendocardial tissues, which can result in subendocardial ischemia. In addition, as noted above, increased afterload increases myocardial oxygen demand more than doing volume work. Thus, even though direct α-adrenergic stimulation is expected to cause coronary vasoconstriction, the increased myocardial metabolic demand by the increased systemic afterload typically increases coronary blood flow, although the flow increase may be limited by the effects of increased α-adrenergic activity on the coronary circulation.

15.6.4.2 β-Adrenergic Effects on Coronary Blood Flow

Activation of β_2-adrenoceptors causes direct coronary vasodilation. Experimentally, the effect is very difficult to separate from metabolic vasodilation due to locally produced mediators.

β_2-adrenoceptor activation causes coronary vasodilation and increased blood flow.

The effects of β-adrenoceptor stimulation on heart rate and cardiac contractility further augment coronary blood flow due to increased metabolic demand. In summary, the effects of adrenergic stimulation on the coronary circulation is determined by both direct actions on the coronary vessels and indirect effects mediated by changes in heart rate, contractility, and afterload.

15.6.5 Coronary Blood Flow during CPR

During cardiac arrest (asystole or ventricular fibrillation (VF)), coronary flow ceases when the mean aortic pressure equals the mean central venous pressure. Usually that occurs after 3–5 min. During the electrical phase of VF cardiac arrest (the first 4–5 min), biphasic or monophasic shocks have a high success rate. In the circulatory phase of VF arrest (5–10 min), effective CPR to supply the heart with the energy needed for the reinstitution of an organized rhythm is required prior to successful shocks.

During CPR, coronary perfusion occurs during the decompression phase, and a CPP of at least 15 mm Hg is needed for successful resuscitation.

During chest compression, both the aortic pressure and the right atrial pressure increase; indeed, since the right atrium is located just below the sternum, often the right atrial pressure exceeds aortic pressure during active compression. During the decompression phase, the right atrial pressure falls faster and lower than the aortic pressure, creating the pressure gradient that perfuses the heart with oxygenated blood. The inability to achieve a CPP above 15 mm Hg during CPR is a poor prognostic factor for a successful outcome.

15.6.6 Effects of Acidosis, Hypocapnia, and Hypercapnia on Coronary Blood Flow

Coronary arteries vasodilate during systemic acidosis accompanied by a decreased response to vasoactive medications. The vasodilation occurs predominantly due to the inability of the regulatory vascular mechanism to distinguish between local and systemic acidosis. Interestingly, when myocardial blood flow was measured in humans during hypo- and hypercapnic conditions, there was an increase in blood flow only during hypercapnia, but no changes were observed during hypocapnia. Respiratory acidosis has complex effects; in intact (i.e., non-anesthetized) animals, an acute respiratory acidosis is a potent stimulus for sympathetic nervous system activation with increased epinephrine concentrations resulting in increased myocardial oxygen demand. This will increase coronary blood flow *independent* of any direct effect of pCO_2 on coronary vessels.

Acidosis causes a decrease in the response of the coronary arteries to vasoconstrictors. Hypercapnia but not hypocapnia alters coronary blood flow, likely due to systemic activation of the SNS.

The normally high degree of oxygen extraction by the heart and low coronary sinus pO_2 are also accompanied by an increased pCO_2 in coronary blood. At baseline, myocardial tissue pCO_2 is increased and rapidly rises during ischemia. During severe ischemia or cardiac arrest, intramyocardial pCO_2 rises rapidly above 100 mm Hg with an accompanying fall in pH; tissue pCO_2 in excess of 300 mm Hg was documented in animal arrest models. Giving sodium bicarbonate in this setting simply generated higher myocardial tissue pCO_2 levels without improving myocardial tissue pH, illustrating the ineffectiveness of attempting to correct myocardial tissue acidosis by giving sodium bicarbonate.

Hypercapnia has important systemic effects mediated by activation of the SNS that increases myocardial oxygen demand and likely overcomes its direct effects on coronary vascular tone.

Giving bicarbonate to correct acidosis during cardiac arrest likely worsens tissue acidosis by increasing local pCO_2 production, which lowers rather than improves pH.

15.7 Cerebral Circulation

15.7.1 Anatomy and Histology

The human brain is a metabolically active organ that receives ~25% of the cardiac output via the carotid and vertebral arteries. The circle of Willis helps ensure that in the case of unilateral traumatic injury or occlusion of one carotid

or vertebral artery, both hemispheres and the brainstem can maintain blood flow. The circle of Willis gives rise to six main arteries that travel superficially over the brain across the subarachnoid space. From these main arteries, superficial arteries penetrate into the brain parenchyma and branch into arterioles. As the arteries become smaller, the smooth muscle cell layer becomes thinner until it disappears at the capillary level. The Virchow-Robin space surrounds the penetrating arteries; that space disappears as the arterioles penetrate deeper into the cerebral tissue. On the outer side of the Virchow-Robin space, there is the *glia limitans* membrane formed by astrocytes. The capillary density is not uniform in the brain and depends on the location and metabolic activity of the area. The capillary consists of an endothelial cell layer, pericytes, and the capillary basal lamina. The foot projections of the astrocytes are attached on the lamina. The cerebral capillaries are unique since they are not fenestrated and instead have tight junctions forming the blood-brain barrier (BBB).

Endothelial cells play a crucial role in regulating vascular tone by releasing vasoactive mediators such as NO, free radicals, prostacyclin, and endothelin. Pericytes have contractile properties and participate in the control of capillary size.

The brain receives ~25% of the cardiac output. The circle of Willis provides additional security for brain perfusion. Even with total occlusion or trauma of one carotid artery, blood supply to the brain is not significantly jeopardized.

15.7.2 Cerebral Circulation Autoregulation

The normal human brain can maintain a reasonably constant cerebral blood flow (CBF) over a large range of cerebral perfusion pressures (CePP; MAP minus intracranial pressure (ICP)). The normal autoregulatory range for CePP in adults is 50–150 mm Hg (or MAP of 60–160 mm Hg, assuming ICP is 10 mm Hg); a similar range was found in infants and young children. Constant CBF is achieved by altering the vascular resistance (Fig. 15.3). There are four proposed mechanisms for cerebral autoregulation: (1) myogenic, the intrinsic ability of vessels to dilate or constrict in response to changes in transmural wall pressure; (2) neurogenic, mediated by innervation of cerebral vessels; (3) metabolic, likely the main mechanism where changes in tissue pO_2, pCO_2, adenosine, and other mediators affect vascular tone; and (4) endothelial, production of either vasodilating (e.g., NO, prostacyclin) or vasoconstricting (e.g., endothelin) mediators to alter vascular tone.

Due to the functional and anatomical proximity and interrelation of cerebral arteries with neurons and glial cells, the term "neurovascular unit" is used to describe the unity of this structure (Fig. 15.4).

The superficial cerebral arteries penetrate into the parenchyma and give rise to arterioles. The smooth muscle layer progressively becomes thinner until it disappears at the capillary level.

The capillaries are unique since they are not fenestrated and instead have tight junctions forming the blood-brain barrier.

The brain can maintain a reasonably constant cerebral blood flow over a wide range of cerebral perfusion pressures (50–150 mm Hg in adults), by altering the vascular resistance. There are four proposed mechanisms for cerebral autoregulation: (1) myogenic, (2) neurogenic, (3) metabolic (likely the main mechanism), and (4) endothelial.

Neurovascular unit describes the functional unity of arterioles, neurons, and glial cells.

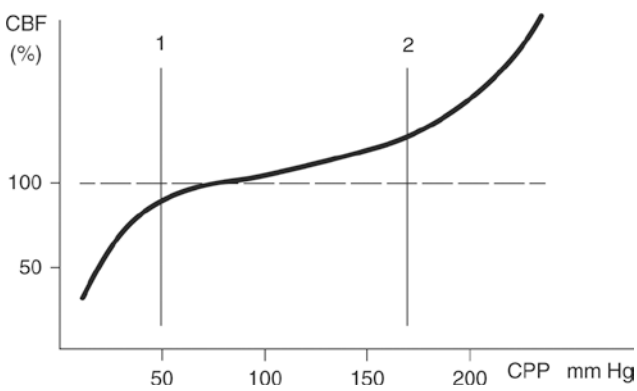

Fig. 15.3 Dependence of total cerebral blood flow (CBF) on cerebral perfusion pressure (CPP). 1 and 2 are the lower and upper limits of cerebral autoregulation, respectively

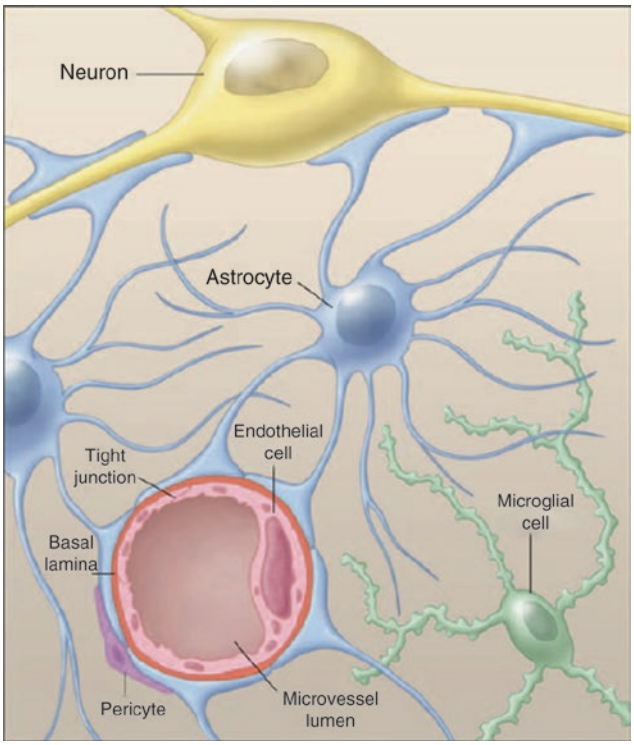

Fig. 15.4 Diagram depicting the neurovascular interface including neurons, astrocytes, microglial cells, and cerebral microvessels. Together with the basal lamina matrix, astrocytic end feet, and pericytes, endothelial cells build the blood-brain barrier

The blood-brain barrier is absent at the choroid plexus.

The restrictive BBB likely blunts the response of CBF to systemic humoral stimuli. With brain injury, the BBB may be disrupted and circulating mediators may then act on neuronal receptors changing metabolic demand and thus blood flow. In the choroid plexus, the BBB is absent so that the effects of systemic stimuli can be observed (e.g., vasopressin causes significant local vasoconstriction).

15

15.7.3 Hypoxia and Carbon Dioxide–Related Cerebral Autoregulation

Hypoxemia leading to tissue hypoxia and hypercapnia are two potent stimuli causing vasodilation, which increases CBF. The mechanism of hypercapnia-induced vasodilation is by alteration of tissue pH rather than sensing the absolute pCO_2 value. This has important clinical implications: acute changes in pCO_2 produce rapid changes in cerebral vascular tone, but as renal mechanisms restore the arterial and extracellular pH toward normal by increasing or decreasing the bicarbonate concentration, the initial cerebral vascular effect following a change in pCO_2 is lost over time.

CBF increases significantly with acute hypercapnia, which causes hyperemia. The effect lasts a few hours until the cerebral extracellular pH is corrected by the kidney.

Acute changes in $PaCO_2$ values between 20 and 80 mm Hg change CBF by 1–2 mL/100 g/min for each 1 mm Hg change in $PaCO_2$. The change in CBF is related to the normocapnic CBF; when blood flow is increased, the relative response to hypocapnia is increased. Cerebral blood volume changes to $PaCO_2$ are similar to changes in CBF, but the relative change is less marked. During hypotension, the flow autoregulation response to changes in $PaCO_2$ is lost, whereas untreated hypertension does not affect the response of the cerebral circulation to changes in $PaCO_2$. Hypothermia reduces metabolic demand; thus, normocapnic CBF and the CBF response to changes in $PaCO_2$ are reduced.

During profound hypotension, pCO_2-related autoregulation is lost. Hypothermia reduces metabolic demand and thus CBF and the response to pCO_2 changes.

When ICP is increased, acute hyperventilation can reduce ICP and improve CePP as long as the hyperventilation does not adversely affect systemic venous return. Unfortunately, there is accumulating evidence that therapeutic hyperventilation with hypocapnic goals is harmful, which is likely due to the adverse effects of increased intrathoracic pressure on cardiac output combined with the loss of the pCO_2 effect on CBF over time, as noted above. Thus, current recommendations are to reserve hyperventilation for the transient treatment of acutely increased ICP that cannot be controlled by other methods.

Hypocapnia-induced cerebral vasoconstriction produces short-term effects which are lost as the kidney restores the pH toward normal. Thus, hypocapnia is used for short-term control of ICP until other control methods can be implemented.

15.7.4 Flow-Mediated Regulation

Large cerebral arteries play a significant role in CBF regulation. The tone of the larger arteries determines the perfusion pressure of the microvasculature. This is necessary to protect the thin-layered arterioles from exposure to high pressures, which could lead to their rupture and destruction. Whenever there is large vessel regulation of the tissue circulation, the phenomenon of a vascular "steal" can occur. To avoid vascular steal, the cerebral circulation has another regulatory mechanism: when one region becomes vasodilated in response to increased blood flow needs, the larger upstream arteries dilate to reduce the perfusion pressure and limit stealing blood from the other regions. Flow-mediated vasodilation has been debated as a control mechanism in other vascular beds, but it is of paramount significance in the cerebral circulation.

Flow-mediated vasodilation of the large arteries as a response to microcirculatory vasodilation reduces the risk of vascular steal from other brain territories.

15.7.5 Cerebral Blood Flow with Brain Injury

With traumatic, inflammatory, or ischemic injury, cerebral autoregulation, especially in the area of injury, may be lost so that changes in CePP produce passive changes in CBF. Unfortunately, there are no readily available methods to assess the effects of manipulating CePP on CBF and tissue oxygenation. Some information is available from the use of near-infrared spectroscopy or the use of brain tissue oxygen sensors. As expected from animal studies, sometimes increasing the CePP improves tissue oxygenation without worsening ICP, and in other patients, increasing CePP exacerbates ICP and worsens tissue oxygenation.

Recent data from experimental animals with traumatic brain injury (TBI) suggest that the responses to increasing CePP may vary due to age or gender differences and the agent used to restore CePP (e.g., comparing dopamine to norepinephrine infusion). Male pigs were found to have more disruption of autoregulation compared with females following TBI. In addition, norepinephrine infusion improved CBF in female animals after TBI but not in males, but norepinephrine improved CBF in both genders of neonatal animals with TBI. This complexity may explain some of the variation in response to treatments to improve cerebral blood flow.

CBF autoregulation may be disrupted after ischemic, inflammatory, or traumatic brain injury.

The best method to improve CePP without worsening ICP is difficult to predict with variation in response observed based on gender and age in experimental animals.

15.8 Pulmonary Circulation

15.8.1 Anatomy, Histology, and Physiology

The lungs have a unique double arterial supply originating from the pulmonary and bronchial arteries. There is also a double venous system consisting of the pulmonary and azygos veins. Pulmonary arteries follow the airway bifurcations for multiple generations (17 branching orders) all the way to the level of respiratory bronchioles. Multiple, additional small branches bifurcate inde-

The lungs have dual arterial supply from the pulmonary and bronchial system.

There are 17 branching orders for the pulmonary arteries.

pendently from the airways and penetrate into the lung parenchyma. At the level of the respiratory unit, the pulmonary precapillary arterioles divide into small capillaries (first-order branches) that flood the alveolar wall and allow for the maximum blood gas exchange surface. The draining vessels from the acini form venules and veins located in the interlobular and interlobar septa. The oxygenated blood drains via the four pulmonary veins into the left atrium.

There are five normal histological types of pulmonary arteries:

(i) Elastic arteries (branch orders 17–13). They consist of adventitial, muscular, and intimal layers. The muscular layer is bounded by internal and external elastic laminae with three or more layers within the muscle layer. The medial thickness is only 1–2% of the external diameter, providing a low resistance to flow.

(ii) Muscular arteries (branch orders 13–3). These smaller vascular structures have a thicker muscle layer relative to their external diameter (2–5%), and there is no internal elastic lamina. Pulmonary arteries and arterioles normally have much less smooth muscle compared with similarly sized systemic arteries.

(iii) Partially muscular arteries (branch orders 5–3). Most 50–100 μm arterioles have a spiral arrangement of smooth muscle fibers, and the surrounding muscle coat is incomplete. Again, the limited muscular coat makes them much more easily distensible and compressible compared with systemic arterioles.

(iv) Nonmuscular arteries (branch orders 5 to 1). They have no elastic laminae. The muscle cells are replaced by a pericyte whose basement membrane fuses with that of the endothelial cell lining.

(v) Supernumerary arteries. These are small relatively thin-walled arteries which branch acutely from the parent vessel starting from the orders of 11–12. About 3 supernumeraries take off between each bifurcation. They have a sphincter at their beginning to provide a pressure "step down" from the larger arteries to the smaller arterioles that are supplied by them. They provide a shortcut for blood supplying the alveoli adjacent to the conduit arteries and bronchi.

There are five histological types of pulmonary arteries: elastic, muscular, partially muscular, nonmuscular, and supernumerary.

The thin walls and relatively small amount of smooth muscle in pulmonary vessels compared with systemic arteries and arterioles of equivalent size have important physiologic consequences. The pulmonary vessels have much lower resistance to blood flow compared with systemic vessels. They are also more distensible and compressible than systemic vessels, which affects pulmonary blood flow under conditions commonly seen in the PICU, such as positive pressure ventilation; changes in alveolar and intrapleural pressure can affect pulmonary vascular resistance (PVR).

The thinned wall arterial vessels in the pulmonary circulation have low resistance to flow and are more easily distended or compressed compared with similar-sized systemic arteries and arterioles.

The normal histologic appearance may be modified by conditions that stimulate arterial muscular hypertrophy and growth, such as high shear states associated with large left-to-right intracardiac shunts. These changes may lead to elevated pulmonary vascular resistance (PVR), increased reactivity to stimuli such as hypoxia and hypercarbia, and eventually fixed pulmonary hypertension.

Increased muscularization of the pulmonary vasculature may be caused by high flow and/or pressure resulting in increased vascular reactivity and increased pulmonary vascular resistance.

The pulmonary capillary network has been described as a channel system where each channel is as long as it is wide and has been pictured as a sheet of blood (one red cell thick) with intervening tissue "posts." This vascular network also has been likened to an underground parking garage. The floor to roof height (capillary width) increases about 3% per cm H_2O rise in capillary pressure and decreases as the lung expands. The capillaries densely surround the ~300 million alveoli in the "mature" lung. The huge number of alveoli results in a potential surface area for gas exchange that is estimated to be between 50 and 100 m^2 in the adult.

The capillary network can be envisioned as an underground parking garage or as a sheet of blood with intervening tissue "posts."

The bronchial arteries arise from the aorta or intercostal arteries and supply the bronchial tree, visceral pleura, lymph nodes, and the walls of larger pulmonary arteries and veins with nutrients. About 2% of the left ventricular output is delivered to the bronchial arterial circulation. Some of the bronchial venous drainage enters the azygos and hemiazygos system, but about 70% supplies the intrapulmonary bronchi and drains into the pulmonary veins, creating a small right to left physiological shunt (approximately 1%). When the bronchial circulation increases significantly in pathological states (e.g., bronchiectasis, congenital cyanotic cardiac malformations), the effect of the desaturated bronchial venous blood on the systemic circulation is magnified and can complicate the clinical picture of those patients. In some cases, the bronchial circulation can increase to 30% of total cardiac output in severe bronchiectasis. Most bronchial arterial supply to the bronchioles forms anastomoses at the capillary level with the pulmonary circulation, but there are also bronchopulmonary anastomoses. In the setting of high left atrial pressures, as in congestive heart failure and mitral stenosis, bronchial flow is diverted from the smaller bronchi and bronchioles to the carinal and major bronchial vessels, increasing the drainage into the right atrium and therefore decreasing the right to left shunt.

Most bronchial arteries anastomose with the pulmonary veins and drain into the left atrium, causing a ~1% anatomic right to left shunt.

15.8.2 Normal Pulmonary Pressures

Systolic pulmonary artery pressure varies between 18 and 25 mm Hg and diastolic pulmonary artery pressure ranges between 6 and 10 mm Hg with a mean pulmonary artery pressure (MPAP) between 10 and 16 mm Hg. There is a significant alteration of the normal physiological values in higher altitudes with lower barometric pressures. A MPAP >25 mm Hg at rest and >30 mm Hg with exercise is considered abnormal and qualifies as pulmonary hypertension.

The mean pulmonary vein pressure is identical to the left atrial pressure (LAP); in the absence of mitral stenosis, LAP is close to the left ventricular end-diastolic pressure of 6–10 mm Hg. The driving pressure (i.e., MPAP – LAP) for the entire cardiac output through the lungs is normally <10 mm Hg, which is <10% of the systemic driving pressure. This is possible because of the extremely low pulmonary vascular resistance, which is approximately one-tenth the systemic vascular resistance. This low resistance permits the use of Glenn shunts and the Fontan repair to achieve pulmonary blood flow in the absence of a pumping ventricle.

The normal mean pulmonary artery pressure is 10–16 mm Hg.

A mean pulmonary artery pressure >25 mm Hg at rest and >30 mm Hg with exercise are criterial for pulmonary hypertension.

15.8.3 Pulmonary Vascular Resistance

Pulmonary vascular resistance (PVR) cannot be measured directly, but is estimated based on Poiseuille's law, which states that for a Newtonian fluid flowing steadily through a nondistensible tube, $P_1 - P_2 = Q * R$, where P_1 and P_2 are the pressures (mm Hg) at the beginning and end of the tube, Q is flow in L/min, and R is resistance. For the pulmonary circulation, the equation is PVR = (MPAP – LAP)/Q. This formula only provides an approximation of the PVR since blood is not a Newtonian fluid, flow is pulsatile rather than continuous, and the "tube" is a distensible set of vessels. The result of this formula results in Wood Units. Multiplying the calculated Wood Units by 79.9 (often rounded to 80) gives the result in metric system units: dynes-s × cm^{-5} units. The normal PVR range in healthy children and adults is 1–3 Wood Units or 80–240 dynes-s × cm^{-5}.

The distribution of PVR differs from that in the systemic circulation where ~70% of SVR is due to the systemic arteries and arterioles. In the pulmonary circulation, ~33% of PVR is due to arteries/arterioles, ~33% is at the capillary level, and, ~33% is due to the pulmonary venous system. These differences

Pulmonary vascular resistance is less than 10% of the systemic vascular resistance, about 1–3 Wood Units or 80–240 dynes-s × cm^{-5}.

have clinical implications; for example, administration of furosemide in patients with pulmonary edema often produces clinical improvement more rapidly than any change in urine output. Data suggests that bolus furosemide stimulates PGE_1 production, which relaxes the postcapillary venules and thus rapidly reduces pulmonary capillary hydrostatic pressure.

The relatively small amount of vascular smooth muscle in the pulmonary arterioles, the low intravascular pressures, and the high distensibility (and compressibility) of the pulmonary circulation lead to extravascular factors having a much greater effect on PVR compared with the systemic circulation. Gravity, body position, lung volume, alveolar and intrapleural pressures, intraventricular pressures, and changes in RV output can all have a significant effect on PVR *without* any alteration of pulmonary arteriole vascular tone.

During exercise or other stresses that increase cardiac output, there is only a small increase in pulmonary artery pressure because of flow-induced distension of compliant vessels and arterial/capillary recruitment of regions of the lungs that were not being perfused at rest.

The high compliance of the pulmonary arterial tree and the ability to recruit unused arterial beds during increased circulating volume is a natural defense mechanism against pulmonary hypertension. At rest, not all of the pulmonary capillaries are perfused, especially those in nondependent lung areas. It is estimated that at rest half to up to two-thirds of pulmonary capillaries are not perfused. During exercise, there is only a small increase in the pulmonary arterial pressure despite increasing cardiac output up to five times normal. This is possible because of the recruitment of pulmonary arterial beds and capillaries that leads to a significant decrease of the pulmonary vascular resistance. In addition, increased flow and a small increase in pulmonary vascular pressure distend perfused arterioles and capillaries, reducing PVR. This reduction in PVR does not require neural or hormonal effects since it can be demonstrated in an isolated pump-perfused ventilated lung. In addition, with exercise there is a small rise in left atrial pressure due to increased blood flow, which leads to distention of the pulmonary venous system with a further decrease in pulmonary resistance (recall that PVR = (MPAP-LAP)/Q).

15.8.4 Hypoxic Pulmonary Vasoconstriction

Unlike the response to hypoxia in the systemic circulation, which is characterized by smooth muscle relaxation and increased localized blood flow, tissue hypoxia *reduces* flow in the pulmonary circulation. This is thought to be a protective mechanism to match pulmonary blood flow at the microcirculatory level to areas of the lung that are being effectively ventilated by restricting flow to areas of the lung that are poorly ventilated. The mechanism of hypoxic pulmonary vasoconstriction is not completely understood. It occurs locally only in the area where there is alveolar hypoxia. Connection to the central nervous system is not required since increased PVR is observed in an isolated lung ventilated with a hypoxic gas mixture perfused using a constant flow pump.

Direct action of alveolar hypoxia on the small pulmonary arteries that are surrounded by the alveoli is mediated by the fall in tissue oxygen tension, which inhibits specific K^+ channels that depolarize the VSMC membrane with subsequent opening of calcium channels that cause smooth muscle constriction.

Systemic arterioles respond to tissue hypoxia with vasodilation.

Although the pO_2 within the pulmonary arteriole is determined by the oxygen saturation of the mixed venous blood entering the pulmonary artery, the small arterioles are surrounded by alveoli, so that the tissue pO_2 on the *outside* of the arteriole falls when the alveolar pO_2 (P_AO_2) decreases. This is consistent with recent data that suggests that tissue hypoxia acts *directly* on the pulmonary vasculature to produce hypoxic pulmonary vasoconstriction. During normoxia, a redox mediator, hydrogen peroxide (H_2O_2), maintains voltage-gated O_2-sensitive K^+ channels in an oxidized *open* state. Hypoxic withdrawal of reactive oxygen species inhibits K^+ channels, thereby depolarizing pulmonary artery smooth muscle cells. This depolarization activates voltage-gated Ca^{2+} channels, enhancing Ca^{2+} influx and promoting vasoconstriction. The role of O_2-sensitive K^+ channels is conserved in most specialized O_2-sensitive tissues, including the ductus arteriosus and carotid body. The unique occurrence of

hypoxic vasoconstriction in the pulmonary circulation relates to the co-localization of an O_2-sensor and O_2-sensitive K^+ channels in resistance pulmonary arteries.

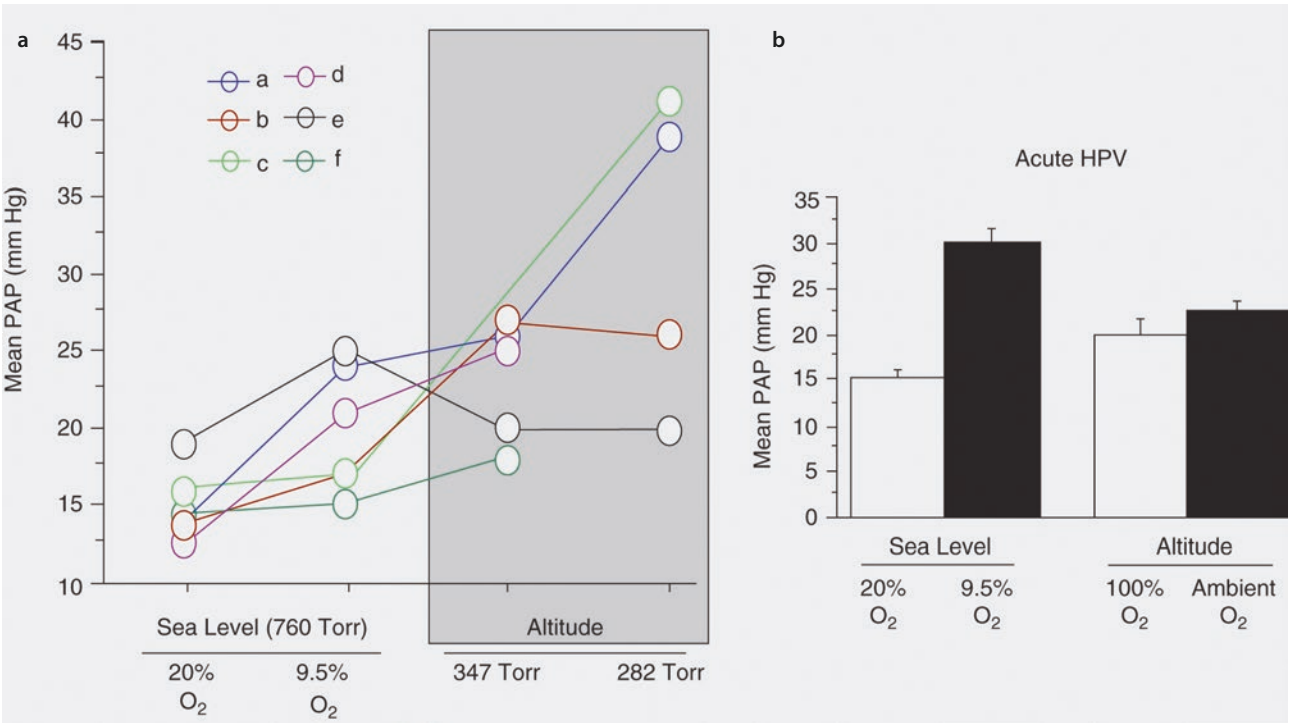
Although this response may optimize ventilation-perfusion matching when ventilation inequalities exist among different areas of the respiratory system, in some circumstances, this response can harm the patient. For example, at high altitude when barometric pressure and thus the partial pressure of inspired oxygen are low, the generalized alveolar hypoxia increases pulmonary vascular resistance and pulmonary artery pressure, which increases right ventricular workload and pressure. Similarly, in a patient who developed increased muscularization of their pulmonary arterioles with an elevated PVR (e.g., a postsurgical child who had a large right to left shunt), an obstruction in their endotracheal tube leads to a rapid fall in their P_AO_2 and thus an increased PVR that may lead to rapid clinical deterioration. With continued exposure to a hypoxic environment, the acute hypoxic pulmonary vasoconstriction response is diminished (◘ Fig. 15.5).

Hypoxic pulmonary vasoconstriction (HPV) is not a beneficial response in the presence of hypoxia affecting the whole lung (e.g., high altitude or endotracheal tube obstruction in a patient following surgical repair of a large right to left shunt).

The increase in pulmonary vascular resistance in response to decreased P_AO_2 is mainly caused by constriction of arterial vessels <500 μm. The effect of this vasoconstriction on the upstream, more compliant elastic vessels is an increase in their transmural pressure and thus their diameter. That is why measuring the right pulmonary artery diameter is used as a marker of pulmonary hypertension. Currently, it is generally accepted that all hypoxic vasoconstriction occurs upstream from the capillary bed and the site of fluid filtration.

Small arteries <500 μm are predominately responsible for hypoxic pulmonary vasoconstriction, and by distending the compliant elastic larger arteries, pulmonary hypertension may be recognized on the CXR.

Pulmonary vasoconstrictors such as catecholamines, histamine, prostaglandins, serotonin, and endothelin increase the potency of the hypoxic constricting response. Vasodilators such as bradykinin, adenosine, prostacyclin, and nitric oxide decrease the potency of the response.



◘ **Fig. 15.5** Dissociation of acute hypoxic pulmonary vasoconstriction from the hemodynamic response to chronic hypoxia. Volunteers in operation Everest were exposed to hypoxia in an altitude simulator. (**a**) The hemodynamic response to prolonged hypoxia in individual volunteers (a through f) was not predicted by their initial HPV response, suggesting a mechanistic dissociation between hypoxic pulmonary vasoconstriction and chronic hypoxic pulmonary hypertension. (**b**) Acute hypoxic pulmonary vasoconstriction is suppressed with chronic hypoxia (From Michelakis et al. (2004))

The larger the region of the lung that is hypoxic, the less pronounced is the blood flow diversion.

Hypercapnia augments and hypocapnia decreases the response to alveolar hypoxia. The larger the size of the hypoxic lung region, the less pronounced is the flow diversion. For example, if one lung is made hypoxic, about 50% of the blood flow to that lung is diverted, but when only 10% of the total lung is hypoxic, about 80% of the blood flow to that region is diverted. Animals that have adapted to high altitudes have no hypoxic pulmonary vasoconstrictive response. Finally, it is believed that there are genotypic and phenotypic differences among humans that account for why some are more prone to high altitude sickness and pulmonary edema than others.

15.8.5 Pulmonary Vascular Tone and Clinical Implications

The balance of circulating and local vasoconstricting and vasodilating factors is critical for the maintenance of the low basal pulmonary artery tone and resistance.

The pulmonary vascular bed is innervated and is continuously exposed to circulating vasoactive substances, which could affect PVR and blood flow. Maintenance of low PVR is of vital importance for humans, and there are multiple mechanisms to protect against the development of high pulmonary artery pressure.

15.8.6 Pulmonary Vasoconstrictors

G-protein-coupled receptors (Gs-vasodilation and Gq-vasoconstriction) are part of many pathways that control the basal vascular tone.

Most vasoconstrictor mediators have little effect in normal pulmonary vasculature, but they may cause or contribute to increased PVR in patients with preexisting pulmonary hypertension.

Multiple circulating vasoconstrictors have been identified (e.g., angiotensin II, ET-1, serotonin, norepinephrine, histamine, urotensin II, leukotrienes, and thromboxane), but they appear to have limited effect on normal PVR since the administration of specific receptor antagonists of these vasoconstrictors does *not* cause any further relaxation of the normal pulmonary circulation. These substances are believed to act on receptors that belong to the seven transmembrane families of G-protein-coupled receptors. Activation of these receptors activates phospholipase C leading to activation of protein kinase C, which through several steps increases intracellular Ca^+ concentration that results in smooth muscle contraction. Although these mediators are likely not important in patients with normal pulmonary vasculature, several of them have been implicated as a cause of pulmonary artery smooth muscle hypertrophy and vasoconstriction, and they may play a role in chronic pulmonary hypertension.

15.8.7 Pulmonary Vasodilators

Multiple endogenous substances (e.g., atrial and B-type natriuretic peptide, NO, prostacyclin, prostaglandin E_2, acetylcholine, bradykinin, epinephrine, substance P, vasoactive intestinal peptide) can dilate the pulmonary arteries and lower PVR when the muscular tone is increased either by a constrictor or by hypoxia. Studies using "knock-out" animals demonstrated that each one of these agents separately makes a minimal contribution to the maintenance of the low PVR.

Elevation of vascular smooth muscle intracellular cGMP or cAMP concentration causes vasodilation.

Pulmonary vasodilators act mainly through elevation of VSMC intracellular concentrations of cAMP or cGMP. Some agonists bind to G-protein-coupled receptors and through activation of adenylyl cyclase elevate the intracellular levels of cAMP. Atrial natriuretic factor has intrinsic G-cyclase properties. Bradykinin and acetylcholine bind to specific *endothelial* G-protein receptors and elevate intracellular Ca^+ which stimulates endothelial production of NO. If the endothelium is damaged, acetylcholine causes vasoconstriction by acting directly on muscarinic receptors on vascular smooth muscle.

Regulation of intracellular cAMP and cGMP concentrations is also influenced by the rate of their degradation, performed mainly by one of the phosphodiesterases (PDEs). Inhibition of the PDEs potentiates the effects of the vasodilators (e.g., milrinone and sildenafil for cAMP and cGMP, respectively).

15.8.8 Vasomediators in the Pathogenesis of Pulmonary Artery Hypertension (PAH)

An imbalance between endogenous vasoconstrictors and vasodilators may contribute to pulmonary hypertension.

In most patients with pulmonary hypertension, the resting vascular tone is increased. Vascular remodeling also is widely observed and consists of small artery smooth muscle thickening and extension of smooth muscle fibers into the nonmuscular small arterioles. There are likely multiple mechanisms resulting in PAH. For example, high blood flow and shear stimulates thromboxane production, which stimulates vascular smooth muscle growth. In other patients, increased endothelin is thought to lead to vasoconstriction and remodeling in pulmonary hypertension.

Many endogenous vasoconstrictors stimulate smooth muscle proliferation.

In patients with idiopathic pulmonary hypertension, urinary excretion of prostacyclin metabolites is decreased, but the excretion of thromboxane metabolites is comparable to normal controls. It also has been observed that endothelial nitric oxide synthase (eNOS) and PGI_2 synthase expression is reduced in resistance arteries of patients with pulmonary hypertension, suggesting that NO and PGI_2 production is decreased (Fig. 15.6). Additionally, increased expression of endothelin mRNA was observed in the small arteries of patients in the same population. Increased local expression of angiotensin-converting enzyme and circulating levels of ET-1 and serotonin were also documented in some idiopathic pulmonary hypertension patients. ET-1 acts on two receptors: ET_A and ET_B; both receptors on VSMC induce vasoconstriction, but ET_B on endothelial cells stimulates NO production. This has clinical implications since nonselective endothelin receptor antagonists are not as effective as selective ET_A antagonists in patients with pulmonary hypertension.

Many vasodilators also are antiproliferative agents.

Patients with pulmonary hypertension have increased circulating levels of ANP, BNP, and adrenomedullin, suggesting that there is an intrinsic effort to compensate via endogenous vasodilators and antiproliferative pathways. When the effects of the upregulated pathways of these factors can no longer compensate, vasoconstricting pathways dominate and severe pulmonary hypertension develops. Of note, monitoring the concentration of BNP may be useful to assess the severity and response to therapy in infants and children with PAH.

Selective ET_A receptor antagonists are preferred in the treatment of pulmonary artery hypertension.

Measuring BNP concentrations may be useful to monitor the response to therapy in children with PAH.

15.8.9 Autonomic Neural Regulation of Pulmonary Vascular Tone

Innervation of the pulmonary vascular bed by sympathetic and parasympathetic nerves is relatively sparse in comparison with that of the systemic circulation. There is relatively more innervation of the larger vessels and less of the smaller, more muscular vessels. There does not appear to be any autonomic innervation of vessels smaller than 30 μm in diameter, and there appears to be little innervation of the intrapulmonary veins and venules.

This autonomic innervation may have evolved to ensure that when the body is stressed by blood loss or some other major stress, increased autonomic activity will not elevate PVR to assure that the right ventricle can maintain cardiac output to the systemic circulation.

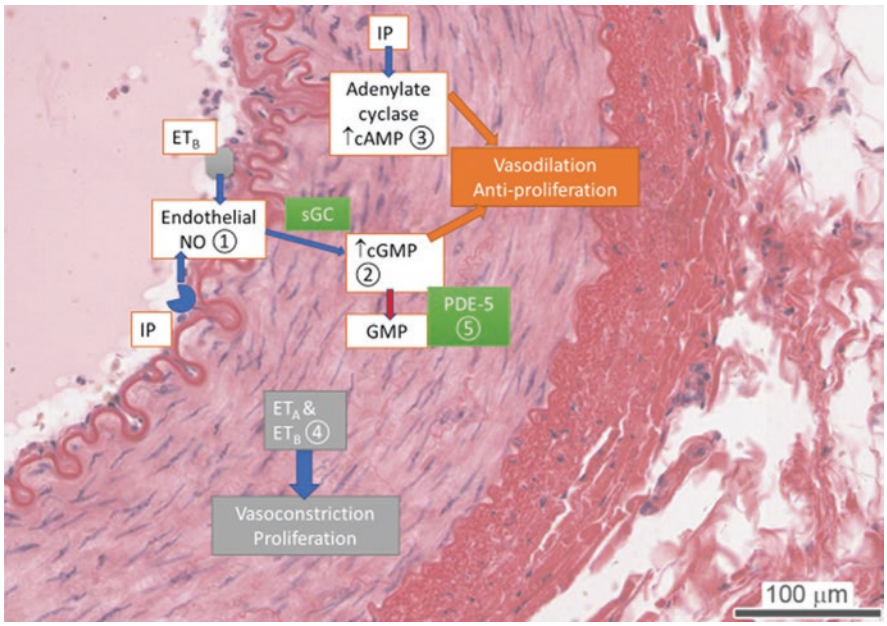


Fig. 15.6 Mechanisms associated with the treatment of pulmonary artery smooth muscle hypertrophy, proliferation, and vasoconstriction leading to pulmonary artery hypertension (PAH). ① Endothelial prostacyclin receptor (IP) and ET_B receptor stimulation increases endothelial production of nitric oxide (NO). The latter diffuses into VSMC cells, stimulating increased production of cGMP. Prostacyclin analogs are used to treat PAH and selective ET_A endothelin receptor antagonists are preferred in PAH treatment to avoid inhibiting the endothelial ET_B receptor. ② Increased intracellular cGMP concentration activates several pathways resulting in vasodilation and inhibiting muscle cell proliferation. ③ VSMC IP receptor stimulation activates adenylate cyclase, increasing intracellular cAMP concentration. Through several mechanisms, the latter produces vasodilation and inhibits smooth muscle proliferation. ④ VSMC endothelin receptor stimulation activates several pathways that produce vasoconstriction and stimulate smooth muscle proliferation. ET_A receptor inhibitors are beneficial in the treatment of PAH. ⑤ cGMP is degraded by phosphodiesterase type 5 (PDE-5) to GMP. Inhibiting PDE-5 activity in patients with PAH maintains higher intracellular cGMP concentrations and thus vasodilation. sGC is soluble guanylate cyclase

15

The main sympathetic nerve effect is due to α_1-adrenoceptor-mediated vasoconstriction; when there is increased endogenous SNS activation, vasodilation results from β_2-adrenoceptor activation by circulating endogenous epinephrine or exogenous agonists.

The autonomic nervous system plays a modest role in the control of pulmonary vascular tone.

Cholinergic innervation causes mainly vasodilation, whereas sympathetic innervation causes predominantly vasoconstriction.

Neurogenic pulmonary edema in the presence of increased intracranial pressure or other brain injuries appears to result from a sudden increase in sympathetic activity that acutely results in volume and pressure overload of the pulmonary capillaries leading to pulmonary edema that can range from hydrostatic to hemorrhagic.

The vasoconstricting properties observed with sympathetic nerve stimulation are mainly due to α_1- and α_2-adrenoceptor activation. The effects are reduced by the α_1-adrenoceptor receptor antagonist prazosin. In this setting, vasodilation may be enhanced by activation of hormonal β_2-adrenoceptors by circulating epinephrine. Propranolol abolishes this vasodilation, whereas the β_2-adrenoceptor agonist albuterol relaxes pulmonary (and systemic) vascular tone and can at least partly overcome hypoxic pulmonary vasoconstriction; the latter action leads to increased intrapulmonary shunting and lower pulse oximetry saturations sometimes observed with albuterol use in patients with acute asthma.

Parasympathetic blockade does not alter the resting vascular tone, and therefore it appears that it does not play a crucial role in the maintenance of basal vasomotor tone. Vagal nerve stimulation has mixed effects because the vagus nerve carries both parasympathetic and sympathetic fibers. Intravenous administration of acetylcholine causes vasoconstriction at low vasomotor tone but vasodilation when the basal tone is elevated. Those responses are blocked by atropine, indicating that the action is secondary to muscarinic receptor activation. Studies in humans, rabbits, and guinea pigs showed that muscarinic M3 receptors located on endothelial cells mediate the vasodilatory response to acetylcholine by activating endothelial NO production.

Pulmonary edema secondary to catastrophic neurologic events is termed neurogenic pulmonary edema. It is thought that high intracranial pressure or other brain injuries (especially intracranial hemorrhage) are responsible for a reflex hyper-sympathetic state with sympathetic nerve overactivity and marked adrenal release of catecholamines. The marked increase in cardiac output combined with increased pulmonary vasoconstriction and increased tone in the

capacitance venous system shifts blood volume into the intrapulmonary circulation leading to acute elevation of pulmonary capillary hydrostatic pressure leading to acute hydrostatic pulmonary edema. In some patients, the high capillary pressures disrupt capillaries leading to hemorrhagic pulmonary edema.

15.9 Renal Circulation

The kidneys play a vital role not only in the maintenance of electrolytic balance and intravascular volume but also in the regulation of blood pressure. The latter is achieved by controlling water and sodium homeostasis and contributing to humoral control of systemic arterial tone through the renin-angiotensin-aldosterone system (RAAS). The importance of the kidneys is underscored by the fact that despite constituting only ~0.5% of human body mass, they receive about 20% of the cardiac output. On a weight basis, renal blood flow is more than four times greater than that of the heart. Since much of the high blood flow maintains the glomerular filtration rate (GFR) and is not needed for cellular oxygen delivery, oxygen extraction by the kidney is much lower than other organs, which is a major contributor to the higher venous oxygen saturation observed in the inferior compared with the superior vena cava.

The kidneys receive ~20% of the cardiac output, which is well in excess of its metabolic demand, to regulate water and sodium homeostasis and blood pressure through the RAAS.

Since much of the renal blood flow is to support GFR and not for oxygen delivery, renal vein oxygen saturation is normally elevated.

15.9.1 Major Arteries

The two major renal arteries (right and left) divide into the anterior and posterior main branches prior to their entry into the renal parenchyma. The anterior branch gives rise to four segmental arteries and supplies most of the anterior-apical surface and the lower pole. The posterior branch supplies the remainder of the kidney. Many branching variations exist with the most common being a separate renal artery originating from the aorta and perfusing the lower pole. A consequence of the renal arterial flow distribution is that the segmental arteries are terminal arteries that do not form collaterals or anastomoses with each other. Thus, an obstruction in one of the segmental arteries results in infarction.

Segmental arteries divide into smaller arteries. Blood from the arcuate arteries that course over the pyramids between the medulla and the cortex then enters perpendicular arteries that course from the arcuate arteries and branch into numerous arterioles, each of which enters a glomerulus as the afferent arteriole. After blood exits the glomerulus through a single efferent arteriole, most subdivide into a second set of capillaries, called the peritubular capillaries. These capillaries are widely distributed throughout the cortex in close proximity to the tubular segments. The peritubular capillaries then rejoin to form venules that drain into the renal venous system that exits the kidneys.

The renal segmental arteries are terminal arteries and do not form anastomoses. Obstruction in the segmental arteries results in infarction.

Arterioles at the border of the medulla and cortex give rise to deep penetrating bundles of arterioles, which are called vasa recta. The vasa recta provide the arterioles that surround Henle's loops and collecting ducts. They also supply blood flow to the inner medulla. After they reach the inner medulla, they reform the ascending vasa recta on their way back to the cortex.

Each glomerulus has an afferent and efferent arteriole.

The vasa recta, which are derived from the juxtaglomerular efferent arterioles, initially contain a smooth muscle layer which they lose as they penetrate deeper into the medulla where they evolve into capillaries. The ascending vasa recta have characteristic fenestrated endothelium. This histological change

Efferent arterioles at the border of the medulla and cortex give rise to deep penetrating bundles of arterioles which are called the vasa recta.

The ascending vasa recta have characteristic fenestrated endothelium that plays an important role in water and solute exchange in the medulla helping to maintain the osmotic gradient.

underscores the role of the vasa recta in not only providing nutrients and oxygen but also participating in water and solute exchange between the ascending and descending limbs of the vasa recta in the medulla, which helps maintain the osmotic gradient.

Blood that is relatively hemoconcentrated exits the glomerulus via the efferent arterioles at each nephron and continues into the peritubular capillaries and then subsequently into the venous system. Blood from the efferent arteriole provides nutrients to the distal portion of the proximal tubule, the loop of Henle, and the distal tubule. The corticomedullary junction glomeruli are responsible for modulating blood flow into the medulla. It is estimated that only 5–15% of total renal blood flow (RBF) is directed to the medulla with the outer medulla having higher blood flow (130–340 mL/100 g tissue/min) than the inner medulla (22–69 mL/100 g/min).

Only ~5–15% of the total renal blood flow enters into the medulla.

Approximately 15–20% of the plasma entering the kidneys is filtered into Bowman's space, which is the plasma filtration fraction.

Renal plasma flow is the amount of plasma flowing into the glomeruli. Clinically, renal plasma flow is difficult to measure directly and instead is estimated from renal blood flow and the hematocrit. If the cardiac output is 3.0 L/min/m^2 and 20% of this output flows to the kidney, then the renal blood flow is ~600 mL/min/m^2. With a hematocrit of 40%, the plasma component is thus 60%, so the renal plasma flow is ~360 mL/min/m^2. Approximately 15–20% of renal plasma is filtered in the glomerulus (i.e., glomerular filtration rate (GFR)), which is ~54–72 mL/min/m^2; the percentage of the plasma filtered is the plasma *filtration fraction* (Fig. 15.7). In an adult, this filtration generates 180 L/day, most of which is reabsorbed.

15.9.2 Renal Blood Flow and Autoregulation

Blood flow is regulated by the perfusion pressure difference between the arterial and venous vascular beds and the resistance of the arteries, arterioles, and capillaries. RBF regulation is unique since there are two sets of arterioles (afferent and efferent) and two sets of capillaries (glomerular and tubular). The main renal arteries and proximal arteries play a minimal role in resistance to flow. Most renal vascular resistance is determined by the afferent and efferent arterioles; under normal conditions, resistance is evenly distributed between the two.

15

Because the afferent and efferent arterioles are arranged in series, their resistances are additive; thus, when they both contract, the total RBF will significantly decrease. Should the resistances within the afferent and efferent arterioles change in opposite directions, the net effect on total RBF is small; the effect on GFR depends on the change in hydrostatic pressure within the glomerular capillaries since they are positioned between the two arterioles. The independent adjustment of afferent and efferent vascular resistance allows for regulation of the glomerular capillary bed pressure over a wide range of systemic arterial pressures, which helps maintain a relatively constant GFR.

Regulation of renal vascular resistance is complicated by having two sets of arterioles (afferent and efferent with their own autoregulation and regulation by various mediators) and two sets of capillaries (glomerular and tubular).

The typical glomerular capillary hydraulic pressure is 60 mm Hg. The Bowman's space pressure is 18 mm Hg and the capillary oncotic pressure is ~29 mm Hg so the net glomerular filtration pressure is ~13 mm Hg.

The typical glomerular hydraulic pressure in adults is about 60 mm Hg. In contrast, the pressure within Bowman's space and the proximal tubules is approximately 18 mm Hg, and the capillary oncotic pressure is ~29 mm Hg. The net filtration pressure is capillary hydrostatic pressure - (Bowman's space pressure + capillary oncotic pressure), which gives a filtration pressure gradient of ~13 mm Hg. Since the glomerular capillary pressure is about 60 mm Hg and the peritubular capillary pressure is approximately 18–20 mm Hg, the perfusion pressure through the proximal nephron is ~40–42 mm Hg (Fig. 15.8). A detailed discussion on the formation and regulation of glomerular filtrate is beyond the scope of this chapter and is only discussed with respect to the effect it has on renal oxygen demand.

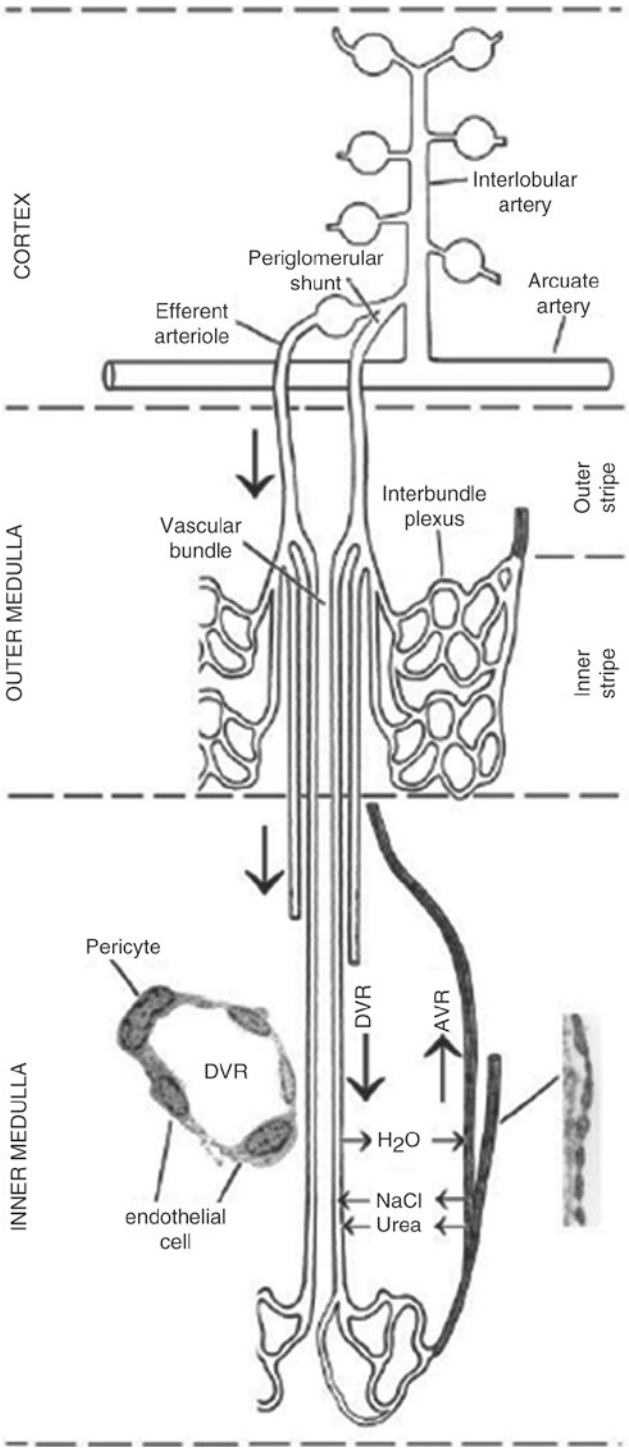

Fig. 15.7 Anatomy of the medullary microcirculation. In the cortex, interlobular arteries arise from the arcuate artery and ascend toward the cortical surface. Juxtamedullary glomeruli arise at a perpendicular angle from the interlobular artery. Most of the blood flow reaches the medulla through juxtamedullary efferent arterioles; however, some may also be from periglomerular shunt pathways. In the outer medulla, juxtamedullary efferent arterioles in the outer stripe give rise to descending vasa recta (DVR) that coalesce to form vascular bundles in the inner stripe. DVR on the periphery of vascular bundles give rise to the interbundle capillary plexus that perfuses nephrons (thick ascending limb, collecting duct, long looped thin descending limbs; not shown). DVR in the center continue across the inner-outer medullary junction to perfuse the inner medulla. Thin descending limbs of short looped nephrons may also associate with the vascular bundles in a manner that is species dependent (not shown). Inner medulla: vascular bundles disappear in the inner medulla, and vasa recta become dispersed with nephron segments. Ascending vasa recta (AVR) that arise from the sparse capillary plexus of the inner medulla return to the cortex by passing through outer medullary vascular bundles. DVR have a continuous endothelium (*inset*) and are surrounded by contractile pericytes. The number of pericytes decreases with depth in the medulla. AVR are highly fenestrated vessels (*inset*). As blood flows toward the papillary tip, NaCl and urea diffuse into DVR and out of AVR. Transmural gradients of NaCl and urea extract water across the DVR wall across aquaporin-1 water channels (Pallone et al. 2003)

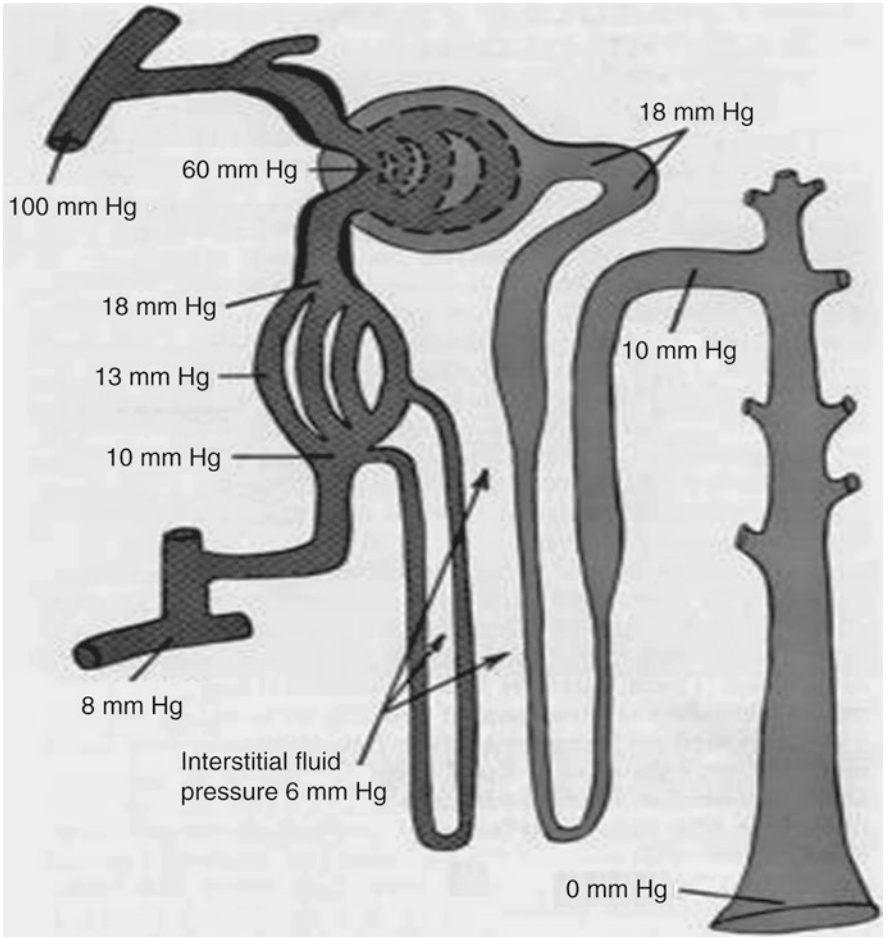

Fig. 15.8 Hydrostatic pressures in different parts of the kidney. Notice the perfusion pressure of the Bowman's capsule's arterioles is about 40–42 mm Hg (60–18 = 42 mm Hg). This figure does not illustrate the influence of the capillary oncotic pressure, which counteracts the capillary hydrostatic pressure

The kidneys regulate blood flow over a wide range of blood pressures to maintain relatively stable GFR. Within a range of normal mean arterial pressures of 60–180 mm Hg in adults, there is only a slight increase of GFR as pressures increase. Once the upper autoregulatory range is reached, further increases in blood pressure result in a steep increase in GFR. When the MAP falls below 60 mm Hg, the GFR declines significantly down to zero as the MAP falls. There are normal fluctuations in blood pressure throughout the day. To avoid exaggerated changes in GFR as a result of these variations in blood pressure, the kidneys employ two basic mechanisms to adjust vascular resistance: (1) the myogenic reflex and (2) tubuloglomerular feedback. When the renal perfusion pressure rises, the transmural pressure in the afferent arterioles stretches them leading to constriction (myogenic reflex). This mechanism is very fast (200–300 msec) and helps protect the glomerular capillaries that already experience a higher pressure than other systemic capillaries. Conversely, when perfusion pressure falls, afferent arteriole tone rapidly falls.

The tubuloglomerular reflex is a slower mechanism that adjusts afferent vascular resistance as well as sodium reabsorption. When the perfusion pressure increases, the myogenic reflex does not restore capillary hydrostatic pressure to normal, so the volume of filtrate increases, which delivers more sodium

and chloride to the distal tubule. The macula densa is located at the point where the nephron passes between the afferent and efferent arterioles. Increased sodium chloride delivery to the macula densa results in a vasoconstrictive response in the afferent arteriole that reduces glomerular filtration. Specifically, an increased uptake of chloride ions by the macula densa leads to ATP release into the surrounding extracellular space, which is then converted into adenosine and diffuses to bind to A_1 adenosine receptors on the afferent arterioles. Conversely, low sodium chloride delivery to the macula densa inhibits adenosine release leading to afferent arteriolar relaxation. Note that in the afferent arteriole, adenosine acts as a vasoconstrictor rather than a vasodilator.

To limit exaggerated changes in GFR, the kidneys respond to changes in systemic blood pressure with almost proportional changes in vascular resistance mediated by the myogenic reflex and tubuloglomerular feedback.

15.9.3 Medullary Blood Flow and Oxygen Demand

To achieve its complex function, the kidney needs an adequate supply of oxygen to maintain oxygen-dependent ATP production. The largest proportion of renal oxygen consumption occurs from activity of the Na/K-ATPase in the proximal renal tubule and medullary thick ascending loop of Henle. The reason for the high energy requirement is easy to understand when considering the implications of the filtration fraction. Roughly 20% of renal plasma flow is filtered at the glomerulus (i.e., ~140 mL/min or ~200 L/day in an adult). The plasma sodium concentration is ~140 mM, so the average adult filters 28 mol of sodium each day, equivalent to ~1.6 kg of NaCl. With a normal sodium intake of ~8 g/day, the kidney must reabsorb 99.5% of this filtered sodium load to stay in balance.

Within a range of normal mean arterial pressures of 60–180 mm Hg in adults, there is only a slight increase of GFR as pressures increase. Once the upper autoregulatory range is reached, further increases in blood pressure result in a steep increase in GFR.

When the MAP falls below 60 mm Hg, the GFR declines significantly down to zero as MAP falls.

The tubuloglomerular reflex is a significant intrarenal mechanism of vascular tone regulation.

High NaCl sensed by the macula densa leads to afferent arteriolar constriction mediated by extracellular adenosine that acts at afferent arteriole A_1 receptors to decrease local GFR.

Low NaCl sensed by the macula densa inhibits afferent arteriole constriction leading to an increase in GFR.

Achieving this reabsorption requires a considerable amount of energy from ATP production, which in turn requires consistent oxygen delivery to the renal tubular cells. It is estimated that ~80% of renal oxygen consumption is to fuel sodium chloride reabsorption in the kidney under normal physiologic conditions. This high level of renal tubular oxygen requirement explains why these cells are at increased risk of injury from tissue hypoxia.

In most organs, blood flow is determined by organ energy demand (metabolic activity). For example, skeletal muscle blood flow increases markedly when needed by exercising muscles. These actions are mediated by the local effects of NO, adenosine, and prostanoids. In contrast, increased renal blood flow often increases GFR, and the latter determines tissue oxygen requirements by increasing the sodium load to the tubules. Thus, rather than increasing blood flow to meet increased oxygen demand, preglomerular afferent arteriolar constriction reduces GFR which reduces Na delivery to the proximal and distal tubules, so less energy is required, producing a better match between oxygen delivery and demand.

It is likely that a differential response to renal tissue hypoxia developed to aid survival. For example, if blood volume needs to be conserved because of blood loss, reducing renal vascular resistance to preserve RBF in response to renal tissue hypoxia in this setting would result in more GFR and increased renal oxygen demand. Instead, the kidney needs to preserve intravascular volume *and* reduce GFR. The kidney has a diminished response to hypoxia, as observed in animal models ventilated with a hypoxic gas mixture; in this setting, blood flow increased to the brain and skeletal muscles, but not to the kidney.

Some tissues, like skeletal muscle, can use glycolysis and anaerobic metabolism for short-term energy production. The renal tubules, like neurons, require a continuous supply of oxygen to maintain their function (i.e., the tubule cells are obligate aerobic metabolizers). Interestingly, not only is the proximal tubule poor at glycolysis, but it is also actually a site for gluconeogenesis. Tubular cells in the thick ascending limb of the loop of Henle have the capacity for glycoly-

sis and thus can generate ATP in low oxygen environments. Even so, their sodium chloride transport activity can only be maintained by oxidative metabolism, and they are damaged in the absence of oxygen.

The kidney also appears to have limited capacity for angiogenesis. This may have evolved because the kidney is the "critometer" that responds to diminished oxygen delivery secondary to anemia (or hypoxemia in children with cyanotic heart disease) by increasing the production of erythropoietin, which is stimulated by hypoxia-inducible factor (HIF) in response to tissue hypoxia. To maintain that oxygen sensing function, the kidney cannot grow new blood vessels to increase tissue oxygen delivery. The price for this physiologic mechanism is increased renal susceptibility to capillary loss over time and thus increased risk of injury from tissue hypoxia.

15.9.4 Medullary Blood Flow

The high metabolic activity of the loop of Henle and the countercurrent flow of the descending and ascending vasa recta that are in close proximity allows oxygen to diffuse from the descending into the ascending vasa recta so that the PaO_2 in the deep medulla is only 10–15 mm Hg. This hypoxic environment explains why this region of the kidney is predisposed to injury when blood flow is decreased.

Although it was thought that medullary blood flow was heavily influenced by sympathetic nerve activation, more recent investigations revealed that medullary blood flow is minimally influenced by sympathetic nerve activation, especially when compared to the cortical renal blood flow. Medullary blood flow appears to be refractory to increases in circulating catecholamines within the physiological range. Only under extremely high concentrations of norepinephrine does medullary blood flow decrease. Two mechanisms are considered to be responsible for these unique physiologic property of the medulla: (i) the counterregulatory role of NO and (ii) paradoxical vasodilation in response to the effect of angiotensin II. It is thought that the different geometrical and environmental properties of the medulla are also responsible for the different response of medullary blood flow to sympathetic stimulation. Since the medulla is hypoxic at baseline, the medullary microenvironment is likely to produce mediators such as NO to preserve blood flow.

Medullary blood flow increases when metabolic activity increases. Acetylcholine, NO, kinins, adenosine, atrial peptides, and prostaglandins increase medullary blood flow. Angiotensin II (perhaps), vasopressin, endothelin, and extreme increases in renal sympathetic nerve activity can decrease medullary blood flow (Fig. 15.9).

Medullary blood flow seems to be refractory to increases in circulating catecholamines within the physiological range.

Two mechanisms are considered to be responsible for the unique blood flow characteristics of the medulla: (i) counterregulatory role of NO and (ii) paradoxical vasodilation in response to angiotensin II.

15.9.5 Cortical Blood Flow

Differences in regional blood flow within the kidney are well recognized; cortical blood flow declines from the outer to more inner layers. The outer cortical blood flow, calculated with various methods, is 500–600 mL/100 g/min, and the inner cortex has a blood flow of 200–300 mL/100 g/min. This mirrors the glomerular density gradient; there are more glomeruli in the outer than the inner cortex. During stress and hypotension, such as after significant hemorrhage, renal blood flow to the cortex is markedly restricted and is redirected to the medulla, which helps preserve oxygen delivery to meet the much higher metabolic activity in the medulla compared with the cortex. The mechanism for redirecting blood flow is possibly through a medullary bypass or shunt mechanism.

Outer cortical blood flow is double inner cortical flow.

During stress and hypotension, such as after significant hemorrhage, renal blood flow is redirected to the medulla possibly through a medullary bypass or shunt mechanism.

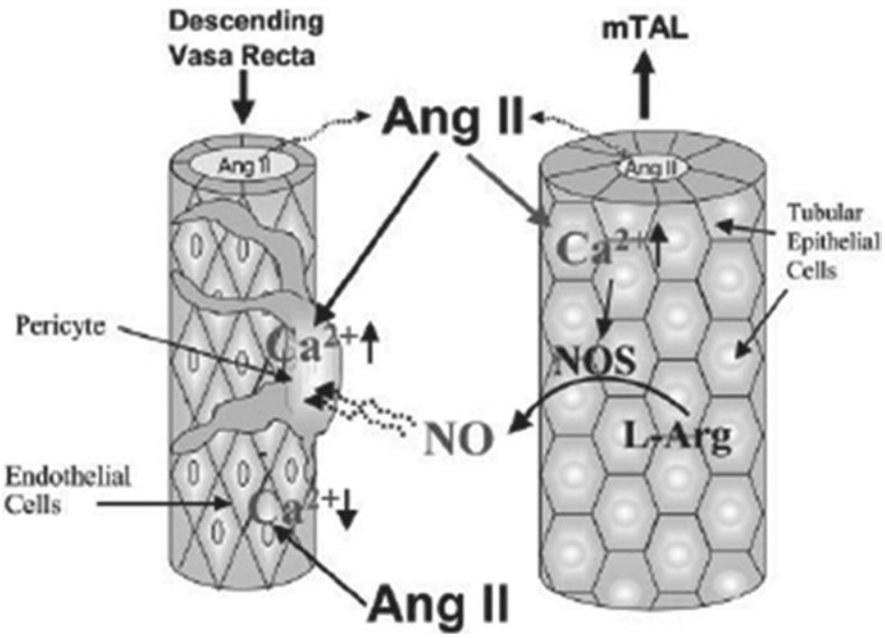

Fig. 15.9 Summary of the observed actions of ANG II on NO levels and intracellular Ca^{2+} concentration ($[Ca^{2+}]i$) in outer medullary vascular bundles. ANG II increases $[Ca^{2+}]i$ in pericytes of the descending vasa recta and reduces $[Ca^{2+}]i$ in the endothelium of the descending vasa recta. ANG II also increases [NO]i in the pericytes of the descending vasa recta but only when these cells are in proximity to the medullary thick ascending limb (mTAL) surrounding the outer medullary vascular bundles. ANG II increases $[Ca^{2+}]i$ and [NO]i in the mTAL even when these tubules were studied in isolation. These observations indicate that ANG II exerts a constrictor effect on the descending vasa recta by direct action on pericytes and that this constrictor action is buffered by NO diffusing from mTALs to the pericytes of the descending vasa recta (From Dickhout et al. (2002))

15.9.6 Sympathetic Nervous System (SNS) and Renin-Angiotensin-Aldosterone System (RAAS) Effects on Renal Blood Flow

Both the afferent and efferent arterioles are richly innervated. SNS activation by baroreceptors in the carotid artery and aortic arch respond to a fall in blood pressure in the carotid artery and aortic arch responds to a fall in blood pressure by rapidly increasing SNS activity, which increases arteriole tone to redirect blood flow from the kidney. This is mediated by activation of α_1-adrenoceptors, which reduces RBF, and thus renal solute and water filtration preserving intravascular volume.

Other physiologic stimuli for increased SNS activity are exercise and hypoxemia; the latter is mediated by chemoreceptors located in the carotid arteries. Hypoxemia also stimulates increased production of intracellular hypoxia-inducible factor (HIF), which is likely more than one mediator that activates various gene products depending on the cell.

The RAAS is activated by the SNS and via tubuloglomerular feedback where increased levels of angiotensin II (AII) reduce RBF and GFR by vasoconstriction of afferent arterioles more than the efferent arterioles. Renin is an enzyme formed and stored in granular cells of the afferent arterioles of the juxtaglomerular apparatus. Decreased afferent blood pressure, increased renal SNS activity (through activation of ß-adrenergic receptors on the juxtaglomerular cells), and decreased Na^+ concentration in the distal convoluted tubule filtrate are considered triggers for the release of renin. Renin increases AII; the latter has direct vasoconstricting effects through receptors on VSMC. AII also stimulates SNS activity by action at presynaptic receptors on sympathetic nerves to increase norepinephrine release, and AII stimulates the synthesis and release of aldosterone.

Increased SNS and RAAS activity in response to a decrease in blood pressure increases afferent and efferent arteriolar tone, redirecting blood flow from the kidney and preserving intravascular volume by reducing glomerular filtration.

Renin is released from granular cells in the afferent arteriole in response to ß-adrenoceptor stimulation, usually in response to a fall in blood pressure and/or reduced Na^+ concentration in the distal convoluted tubule.

15.9.7 Vasoactive Mediators

As in other vascular beds, there are a host of mediators that can affect renal vascular tone; some of the mediators produce different responses in the kidney compared with other vascular beds (e.g., adenosine). The net effect of any one mediator is difficult to predict since there often are competing signals received by the VSMC based on the local milieu.

Dopamine, acetylcholine, prostaglandin E_1, and prostacyclin dilate the afferent arteriole in rabbit preparations; bradykinin, adenosine, and prostaglandins D_2 and F_2 do not. The efferent arteriole dilates in response to dopamine, acetylcholine, prostacyclin, bradykinin, and adenosine. Other prostaglandins have no effect. The importance of vasodilator prostaglandins on RBF is clinically recognized by the adverse effects of nonsteroidal anti-inflammatory drugs (NSAIDs), which can compromise renal function even in the absence of critical illness if used in excessive doses or for prolonged periods (e.g., ketorolac).

Angiotensin II and endothelin cause afferent arteriolar constriction via direct action on VSMC.

AII and endothelin cause afferent arteriolar constriction through VSMC receptors, but both mediators also act on vascular endothelium to modulate NO production and regulation. Similar to the ET_A and ET_B receptors for endothelin, the angiotensin I receptor (AT1) is responsible for the vasoconstrictive action of AII, whereas the action of AII at the AT2 receptor on endothelial cells causes a dose-dependent dilation of the afferent arteriole by stimulating endothelial release of NO. All three endothelins, ET_1, ET_2, and ET_3 are potent vasoconstrictors of the renal vasculature through action at ET_A receptors on VSMC. ET_B receptors are also located on endothelial cells; stimulation of these receptors increases NO production. Of note, the ratio of ET_A:ET_B receptors in the medulla is 30:70, which is higher than in the cortex and may help maintain blood flow in the medulla when circulating endothelin is increased.

Both AII and endothelin also act through specific endothelial receptors (AT2 and ET_B) to increase NO production and release.

Nitric Oxide: Nitric oxide exerts tonic control on the afferent but *not* the efferent arterioles of the renal *cortex*. However, NO dilates both the afferent and efferent arterioles of the *juxtamedullary* nephrons. These different physiologic actions result from a distinctive physiological difference between the efferent arterioles of the cortex and medulla. Inhibiting NO synthase (NOS) enhances angiotensin II-induced afferent arteriolar constriction, suggesting that NO modulates the vasoconstrictor effects of angiotensin II on arterioles when angiotensin II levels are elevated. In the medulla, NO production serves an important counterregulatory role to blunt vasoconstrictor hormone-induced reduction of medullary blood flow and medullary tissue oxygen levels. When NOS activity is reduced within the renal medulla, sensitivity to vasoconstrictors increases dramatically and hypertension develops. Thus, renal medullary NO production plays a very important role in sodium and water homeostasis and the long-term control of arterial pressure.

Prostaglandins are important mediators of renal blood flow; use of potent or high-dose nonsteroidal anti-inflammatory agents can adversely affect RBF and renal function.

Nitric oxide exerts tonic control on afferent but not efferent arterioles of the cortex.

Nitric oxide dilates both the afferent and efferent arterioles of the juxtamedullary nephrons.

Medullary NO production serves as an important counterregulatory mediator to blunt vasoconstrictor hormone-induced reduction of medullary blood flow and tissue oxygen levels.

15.9.8 Adenosine and Renal Circulation

Adenosine is a breakdown product of ATP that has vasodilator properties in most vascular beds. Adenosine contributes to the microcirculatory metabolic control of organ perfusion, matching oxygen demand to delivery. However, as noted in the discussion on tubuloglomerular feedback, adenosine vasoconstricts the afferent arteriole when increased NaCl delivery is sensed by the macula densa. This action is mediated by A_1 adenosine receptors (A_1AR), which on afferent arterioles are selectively activated on the *interstitial* aspect of the vessel away from the vessels' interface with circulating blood. This property

dissociates A_1AR activation from changes in vascular adenosine concentration, a characteristic that is ideally suited for the role of renal adenosine as a paracrine factor in the control of glomerular function.

The initial renal vasoconstriction elicited by an intravenous infusion of adenosine is short lasting and is quickly followed within 1–2 min by vasodilation. It appears that the steady-state response to an adenosine infusion is global renal vasorelaxation due to action at A_2AR receptors on endothelial cells in most parts of the renal vasculature. The A_2AR-mediated vasorelaxation is probably facilitated by the endothelial location of these receptors, which cause the release of NO and other endothelial relaxing factors. Isolated perfused afferent arterioles, especially in their most distal segment at the entrance to the glomerulus, respond to adenosine with persistent vasoconstriction, indicating predominant or exclusive expression of A_1AR at this location to mediate the signal from the macula densa.

There are two adenosine receptors: A_1AR and A_2AR. Adenosine causes vasoconstriction in the afferent arterioles via activation of A_1AR located on the *interstitial* aspect of the afferent arteriole in close proximity to the juxtaglomerular apparatus.

Adenosine release from the macula densa mediates the tubuloglomerular feedback mechanism to reduce NaCl delivery to the macula densa by vasoconstricting the local nephron's afferent arteriole.

Efferent arteriolar vasodilation is caused by activation of A_2AR located on the vascular endothelium resulting in the release of NO and other vasodilator mediators.

15.10 Splanchnic Circulation

The splanchnic circulation regulates the blood flow to the gastrointestinal organs. Macro- and microvascular circulation is crucial to the functions of the gastrointestinal system, which includes digestion and absorption of nutrients as well as prevention of systemic infiltration from bacteria and antigens.

15.10.1 Vascular Anatomy and Distribution

Three different arterial branches originating from the aorta supply almost the entire gastrointestinal system: the celiac, the superior mesenteric (SMA), and the inferior mesenteric (IMA) arteries. The celiac artery supplies the stomach, upper duodenum, liver, spleen, and pancreas; the SMA, being the largest branch off the abdominal aorta, supplies the entire small intestine, proximal colon, and pancreas; the IMA delivers blood flow to the remainder of the colon down to the proximal rectum. Splanchnic blood flow is about 20% of the total cardiac output and is characterized by extensive collateral arteriolar overlap that helps ensure adequate perfusion. Approximately 30% of the circulating blood volume under normal conditions is located within the splanchnic circulation; ~70–75% of this volume is in the postcapillary venous system. Resting intestinal blood flow per gram weight is about 10 times higher than skeletal muscle (◘ Table 15.1) reflecting the higher baseline metabolic activity in the splanchnic circulation. Blood flow to the intestine and stomach increases substantially during a meal and returns to baseline levels as the chyme passes the specific region. The blood flow increase is independent of the hollow organ stretch and is primarily dependent on the chyme constituents.

Venous drainage from the intestines enters the portal venous system. Thus, the perfusion pressure for much of the splanchnic circulation equals the MAP minus portal venous pressure rather than the CVP. Perfusion to the GI tract may be impacted by cirrhosis and other factors that raise portal venous pressure. In addition, increased intra-abdominal pressure may compromise intestinal perfusion by reducing the perfusion pressure.

In the hollow organs of the gastrointestinal tract, the mucosal layer receives ~75% of the blood flow. All the other layers receive the remainder of the blood flow with the submucosal layer receiving less than 5%. Mucosal blood flow is primarily directed to the end loop arterioles of the villi and secondarily supplies the intestinal crypts and goblet cells. Similar to the renal medulla, there is

Three arterial branches supply the gastrointestinal system: the celiac, the superior mesenteric, and the inferior mesenteric arteries.

The basal splanchnic blood flow is ~20% of cardiac output.

Approximately 30% of circulating blood volume is located in the splanchnic circulation; most of the blood is in the postcapillary venous system.

a countercurrent blood flow exchange system perfusing the numerous intestinal villi responsible for nutrient absorption. The arteriole and venule are in close proximity so that oxygen can diffuse from the arteriole into the venule; thus, the distal villi have a relatively low tissue pO_2, which explains why the villi are the most sensitive portion of the splanchnic organs to reduced oxygen delivery.

During a meal, splanchnic blood flow increases up to 250% and returns to normal 2–3 h later.

Splanchnic blood flow during a meal increases up to 250% and is sustained at that level for up to 2–3 h before returning to baseline. This significant increase in blood flow is accomplished through arteriolar recruitment and vasodilation, but the control mechanisms are currently unclear.

The intestinal villi are perfused with a countercurrent blood supply, which creates low tissue oxygen tension in the distal intestinal villi and makes this tissue more sensitive to reduced splanchnic perfusion.

15.10.2 Baseline Vascular Tone Regulation

The principal vascular tone regulator of the large arteries and conduit vessels of the splanchnic circulation is the autonomic nervous system (sympathetic and parasympathetic). Increased parasympathetic activity increases intestinal motility and secretions, which indirectly increases blood flow secondary to increased metabolic demand. Various humoral agents that are commonly activated in critical illness or injury also play an important role in regulating splanchnic flow. At the microcirculation level, blood flow is predominantly controlled by the balance between a host of paracrine and metabolic mediators (◘ Table 15.4). Blood flow to the three layers of the intestine (mucosa, submucosa, and muscular) is regulated by metabolic demands and byproducts of metabolism such as pO_2, pH, PCO_2, and/or adenosine.

Large arterial tone is regulated primarily by the sympathetic nervous system; parasympathetic effects on the intestinal smooth muscle and glands increase metabolic demand, which secondarily increases blood flow.

Large arteries are under the direct tonic control of the vasomotor center of the central nervous system. Within larger arteries (>50 μm), the α-adrenergic tonic effect is more potent than the β-adrenergic effect resulting in a baseline vasoconstricted state. Intestinal blood flow autoregulation can sustain oxygen delivery over a wide range of perfusion pressures (MAP – portal venous pressure) between 40 and 120 mm Hg in adults.

Baseline vascular tone in the larger arteries is maintained by a predominance of α-adrenergic stimulation.

Autoregulation of intestinal blood flow sustains oxygen delivery over a wide range of perfusion pressures between 40 and 120 mm Hg in adults.

15.10.3 Postprandial Blood Flow Regulation

Blood flow to the intestinal and gastric mucosa can increase ~2.5-fold during a meal. Important triggers for the postprandial hyperemia are thought to be different nutrients and bile salts. During the anticipation and ingestion phases of a meal, the sympathetic nervous system increases blood pressure, heart rate, and cardiac output. In addition, it increases splanchnic vascular resistance. During the digestion and absorption stages and as the stomach fills with food, blood flow is increased to the stomach and duodenum in response to the chyme. Increased blood flow is specific to the segment that is in contact with the nutrients and lasts for as long as the flow of nutrients is sustained. Blood flow in each segment decreases as soon as the nutrients have passed through. During digestion, muscle and skin blood flow decreases while cardiac output and splanchnic flow increase.

Postprandial hyperemia is thought to be triggered by different nutrients and bile salts.

The hydrolytic products of food, especially glucose and the combination of fatty acids with bile salts, are responsible for the greatest increase in blood flow and hyperemia. How these nutrients control the increase of splanchnic blood flow is still not clear. There are five proposed mechanisms for postprandial hyperemia: (1) direct effects of absorbed nutrients, (2) enteric nervous system interactions and reflexes, (3) hormones and peptides, (4) local non-metabolic vasoactive mediators, and (5) local metabolic mediators. All these mechanisms

Hyperemia is regional; the increase in blood flow is sustained in the region as long as the flow of nutrients is sustained.

Table 15.4 Vasoactive mediators of the enteric circulation

Vasoconstrictors	Vasodilators
Neural mediators	
↑ Sympathetic tone (adrenergic)	↓ Sympathetic tone
Neuropeptide Y, peptide YY	↑ Parasympathetic tone (indirect effect)
Calcitonin gene-related peptide (CGRPa)	Vasoactive intestinal polypeptide (VIP)
Circulating humoral mediators	
Epinephrine (except in liver and muscle)	Epinephrine (only in liver and muscle) and dopamine
Angiotensin II	Histamine
Vasopressin	Bradykinin
Serotonin	Activated complement (C3a, C5a)
Activated complement (C5a)	Adrenomedullin
Paracrine and autocrine mediators	
Endothelin-1 (vascular smooth muscle cells)	Endothelium-derived relaxing factor (NO)
Platelet-activating factor	Endothelium-derived hyperpolarizing factor (EDHF)
Constrictor prostaglandins (e.g., F2α)	Dilator prostaglandins (e.g., prostacyclin)
Angiotensin II	Cholecystokinin and substance P
Metabolic vasodilators	
↑ pO_2	↓ pO_2
↓ PCO_2	↑ PCO_2
↑ pH	↓ pH
↓ Metabolites (K^+, lactate, adenosine, etc.)	↑ Metabolites

are designed to increase oxygen delivery to meet increased oxygen demand. For example, absorption of nutrients requires oxygen to generate the ATP needed; lipid micelle transport requires the largest oxygen consumption. In addition, the osmolarity of villus lymph and interstitial fluid increases from ~400 mOsm during the resting state to more than 600 mOsm during the absorption state. It is now believed that oxygen and osmolarity-dependent metabolic mechanisms play a crucial role in the initiation and maintenance of splanchnic hyperemia.

Direct effects of absorbed nutrients: Some nutrients act as direct vasodilators of the intestinal microcirculation after entering the bloodstream. For example, bile salts and micellar solutions can cause direct arteriolar dilation when injected intra-arterially. Some amino acids, as well as luminal carbon dioxide, when diffused across the epithelial mucosal barrier, can initiate vasodilation of the microvessels.

Enteric nervous system and reflexes: Sympathetic and parasympathetic innervation is not necessary for postprandial hyperemia, which implicates non-adrenergic and non-cholinergic neurons in the regulation of postprandial

There are five proposed mechanisms that control postprandial hyperemia: (1) direct effects of absorbed nutrients, (2) enteric nervous system interactions and reflexes, (3) hormones and peptides, (4) local non-metabolic vasoactive mediators, and (5) local metabolic mediators. All these mechanisms are designed to increase oxygen delivery to meet increased oxygen demand.

Oxygen and osmolarity-dependent metabolic mechanisms play a crucial role for the initiation and maintenance of splanchnic hyperemia.

Bile salts, amino acids, and a micellar solution can cause direct microvascular vasodilation.

Sympathetic and parasympathetic innervation does not contribute significantly to postprandial hyperemia.

Unidentified neurons have a regulating role in postprandial hyperemia.

Histamine, bradykinin, and serotonin are potent vasodilators in the intestinal microcirculation.

Partial pressure of oxygen, H^+ concentration, adenosine, and nitric oxide all contribute to local hyperemic regulation.

hyperemia. In addition, capsaicin and lidocaine can prevent micelle-induced jejunal hyperemia, suggesting that capsaicin-sensitive afferent fibers may also be involved.

Hormones and peptides: Many vasoactive hormones and peptides have been identified in the gastrointestinal system (gastrin, vasoactive intestinal peptide (VIP), cholecystokinin (CCK), substance P, secretin, gastric inhibitory polypeptide, neurotensin, calcitonin gene-related peptide, glucagon, enkephalins, somatostatin, and peptide YY), but they do *not* appear to have a role in postprandial hyperemia of the whole organ at physiologic concentrations.

Local non-metabolic mediators: Although the release of serotonin, histamine, bradykinin, and prostaglandins occurs in response to a wide range of physiological and pathological conditions, their role in regulation and control of intestinal hyperemia is unclear. Histamine, bradykinin, and serotonin are potent vasodilators in the intestinal microcirculation; histamine blockade of H_1 but not H_2 receptors diminishes the hyperemic response in the jejunum.

Local metabolic mediators: Increased oxygen demand, consumption, and debt in the villi stimulate active hyperemia. Reversal of hyperemia is coincident with a return to normal metabolic activity resulting in restoration of the tissue partial pressure of oxygen. From these observations, it is logical that increased local oxygen uptake and reduced tissue partial pressure of oxygen are the initial mediators for hyperemia. Increased levels of hydrogen ions and adenosine also promote direct vasodilation of the splanchnic vascular bed. Adenosine concentrations in the portal circulation increase 3–10 min before the mucosal increase of oxygen uptake and blood flow. Nitric oxide is also thought to have a synergistic role in combination with adenosine for local hyperemic regulation.

15.10.4 Pathological States

During shock states, splanchnic vasoconstriction induced by high sympathetic tone leads to critically low intestinal mucosal blood flow.

Unlike tissues that have high capillary density and low oxygen extraction at baseline, such as skeletal muscle that can recruit capillaries when metabolic demand increases, organs such as the intestinal tract are unable to recruit additional capillaries to maintain oxygen delivery. Conversely, much of the oxygen demand in the intestinal tract is mediated by active absorption of nutrients, which can be suspended during stress. Thus, during cardiogenic, septic, or hemorrhagic shock, perfusion of the intestinal mucosa may be reduced to 10% of basal blood flow due to SNS-mediated vasoconstriction of the large arteries and the arterioles at the level of the villi. Contraction of the venous system shifts blood volume back to the heart to support perfusion of the heart and brain. When blood flow to the mucosa is decreased substantially, the epithelial/mucosal barrier breaks down which contributes to a poor clinical outcome despite resuscitation and restoration of adequate blood pressure and cardiac output. This is thought to be due to the translocation of endotoxin and/or bacteria from the intestinal lumen, which activates an inflammatory response.

With resuscitation from intestinal ischemia, ischemic-reperfusion injury amplifies the initial injury. This injury is thought to be mediated initially by reactive oxygen metabolites followed by activation of polymorphonuclear neutrophils. Injury to the intestinal mucosa was thought to disrupt the normal gut-barrier function allowing endotoxin and bacteria to enter the portal circulation, but studies in animals and limited clinical studies do not consistently find endotoxin in the portal circulation. More recently, experimental data suggest that altered gut permeability leads to the delivery of pro-inflammatory

mediators via the mesenteric lymphatics, which drain into the thoracic duct, bypassing the liver, and instead are more likely to injure the lungs.

Increasing metabolic demand from enteral nutrition should theoretically worsen the mismatch between blood flow and oxygen demand during critical illness and may steal blood flow from other organs when cardiac output is low, but clinical studies found that providing enteral nutrition appears to protect the intestine from extreme vasoconstriction, even when the patient is receiving vasopressor infusions. This protective effect may be because enteral nutrition provides needed energy substrates for the intestinal epithelium. Conversely, total parenteral nutrition "starves" the intestinal epithelium and is associated with an increase in intestinal permeability following an ischemic-reperfusion injury; the latter is associated with higher mortality when compared with patients receiving enteral nutrition in different shock states. Intraluminal glutamine also was shown to be more protective to the mucosa during reperfusion injury than alanine.

Ischemic-reperfusion injury following resuscitation from shock is thought to be mediated by reactive oxygen metabolites followed by activation of polymorphonuclear neutrophils.

Intraluminal nutrients increase blood flow to the intestinal wall, which protects these cells from extreme vasoconstriction; this is at least partly by providing needed substrate to the intestinal epithelium.

Total parenteral nutrition cannot provide substrate to poorly perfused intestinal epithelium and is associated with an increase in intestinal permeability following ischemic-reperfusion injury. These effects lead to higher mortality when compared with enteral nutrition in different shock states.

Once reperfusion is achieved, enteral nutrition appears to limit further mucosal damage and reduces ischemic-reperfusion injury.

15.11 Cutaneous Circulation

The skin is the largest organ of the human body and serves as a barrier and thermoregulator. In addition, the skin provides environmental information processed by the brain to help regulate body temperature. The skin has significant blood flow (~5% of the total cardiac output at rest) that can be modified over a wide range for thermoregulation (◘ Table 15.1).

Thermoregulation is centrally controlled and adjusts blood flow to the skin. When the core temperature (Tc) is low or the temperature set point is increased, blood flow to the skin is reduced to limit radiant and conductive heat loss. Thus, as the temperature is *rising* in an infant or child, the skin will appear pale and cool to touch. If the core temperature is increased by increased muscle activity, or the temperature set point is reduced from an elevated level, such as after giving an antipyretic, skin perfusion increases markedly, and the patient appears flushed with warm skin to touch. These changes are mediated by neural and local mechanisms that directly influence the arterial tone and blood flow to the skin. With severe hyperemia, such as during heat shock, up to 60% of cardiac output is directed to the skin.

Regulation of cutaneous blood flow is a critical component of body temperature regulation mechanisms.

The arterioles of the glabrous areas of the skin (i.e., palms, lips, and soles of feet) are innervated only by sympathetic nerves, which are the primary regulators of blood flow. In the rest of the skin, blood flow is regulated by the balance between sympathetic and cholinergic parasympathetic nerves in addition to the effects of local skin temperature.

The balance between the sympathetic and parasympathetic nervous systems is critical for the regulation of nonglabrous skin blood flow.

During normothermia and resting conditions, there is no sympathetic stimulation so that the arteriole smooth muscles are at their basal tone. When heat loss is needed, neuronal regulation increases skin blood flow. If the skin temperature is increased along with the core temperature due to high ambient temperatures (as during heat stress), there is complete withdrawal of sympathetic tone on the arterioles. After complete suppression of sympathetic activity, sweating occurs, and if the core temperature continues to rise, parasympathetic vasodilatory tone increases leading to active maximal hyperemia.

When core temperature increases, cutaneous vasodilation occurs first by suppression of sympathetic baseline vasoconstriction, followed later by active parasympathetic-mediated vasodilation if the core temperature does not decrease toward baseline.

15.11.1 Cutaneous Vasodilation

Data suggests that stimulation of muscarinic cholinergic receptors is responsible for vasodilation mediated by parasympathetic activation. Data also sug-

The increase in blood flow due to active vasodilation in conjunction with sweating leads to heat dissipation and thermoregulation.

gests that cholinergic nerves release a co-neurotransmitter with acetylcholine; vasoactive intestinal peptide (VIP) has been implicated, but its role remains unclear.

Simultaneous release of acetylcholine and a co-mediator (VIP, NO) from parasympathetic neurons is thought to contribute to active hyperemia during heat stress.

Increased NO has also been associated with thermoregulatory vasodilation, and recent work showed that VIP-induced release of histamine from skin mast cells may lead to an increase in NO. Furthermore, acetylcholine mediates endothelial NO production early in the process. Excess NO production during sepsis has been implicated as a cause for "warm shock" characterized by excessive vasodilation with flushed skin. High local NO concentrations also blunt the vasoconstrictive response to agonist action at α-adrenoceptors.

Increased NO production is implicated in mediating the clinical picture of warm septic shock with cutaneous vasodilation.

15.11.2 Cutaneous Vasoconstriction

Vasoconstriction in the cutaneous arterioles is primarily controlled by α_1- and α_2-adrenoceptor stimulation through activation of sympathetic nerves and the action of circulating epinephrine, respectively. Vascular β_2-adrenoceptors are also stimulated by circulating epinephrine, and this action counteracts the effect of α-adrenoceptor stimulation. Thus, β_2-adrenoceptor blockade increases vasoconstriction even further. In addition, blockade of α- and β-adrenoceptors does not abolish cutaneous vasoconstriction due to cold exposure in humans. However, if complete prejunctional α- and β-adrenoceptor blockade is achieved, cold-induced vasoconstriction is abolished completely, suggesting that there is a co-transmitter released with norepinephrine. That co-transmitter is currently believed to be neuropeptide Y (NPY). Combined blockade of the NPY receptor and peripheral α- and β-adrenoceptors leads to total loss of vasoconstriction due to cold.

Although vasoconstriction is primarily thought to be secondary to α-adrenoceptor activation, blockade of β_2-adrenoceptors further increases vasoconstriction.

Neuropeptide Y, released with norepinephrine from sympathetic nerves, appears to contribute to cold-induced cutaneous vasoconstriction.

15.11.3 Local Temperature Control of Cutaneous Blood Flow

When the skin is heated, there is an independent mechanism of local arteriolar vasodilation that leads to increased skin blood flow proportional to the temperature increase with a maximum reached at 42 °C that lasts for 30–50 min. The initial pronounced vasodilation is followed by a plateau phase. Currently, it is thought that an unidentified local mediator is responsible for the vasodilatory response to local thermal stimulus.

Local warming of the skin leads to an increase of blood flow proportional to the increase in skin temperature up to 42 °C.

Local skin cooling significantly increases cutaneous arteriolar tone via sympathetic receptor activation and NPY activity pathways as described above. This local effect is independent of any core temperature changes. Local cold sensing nerves act as the afferent pathway that leads to norepinephrine and NPY release from sympathetic nerves. Continuous local cooling results in a non-neurally mediated continuous vasoconstriction; the mechanism for this effect is currently unknown.

Local skin cooling results in a significant increase of the cutaneous arteriolar tone via the activation of noradrenergic receptor activation and NPY excretion pathway.

Review Questions

1. Which of the following mediators has different effects on vascular tone in different vascular beds?
   A. Prostacyclin
   B. Bradykinin
   C. Endothelin
   D. Nitric oxide
   E. Oxygen

2. The right and left ventricles receive most of their blood flow during which phase of the cardiac cycle?
   A. Both during diastole
   B. Both during systole
   C. Left during diastole and right during systole
   D. Left during diastole and right continuously
   E. Left during systole and right during diastole

3. In which of the following conditions is the vasodilatory effect of elevated $PaCO_2$ in the cerebral circulation lost or blunted?
   A. Core body temperature of 32 °C
   B. Mean arterial pressure of 90 mm Hg with an intracranial pressure of 18 mm Hg
   C. Mean arterial pressure of 90 mm Hg with an intracranial pressure of 28 mm Hg
   D. Severe hypertension
   E. All of the above

4. What is the mechanism of hypoxic pulmonary vasoconstriction?
   A. A direct action on vascular smooth muscle
   B. Local release of a vasoconstrictor mediator
   C. Local suppression of a vasodilator mediator
   D. All of the above
   E. None of the above

5. Medullary blood flow of the kidneys appears to be refractory to increases in circulating catecholamines within the physiological range. Medullary blood flow decreases only with extremely high concentrations of norepinephrine. Which of the following mechanisms is responsible for this unique property?
   A. Counterregulatory role of nitric oxide
   B. Endothelin-induced vasodilation
   C. Paradoxical vasodilation as a response to the effect of angiotensin II
   D. Vasopressin-induced vasodilation
   E. A and C

6. In order to abolish human cutaneous vasoconstriction, what pharmacological blockade is necessary?
   A. Peripheral alpha and beta blockade
   B. Peripheral alpha blockade
   C. Peripheral beta blockade
   D. Peripheral alpha, beta, and neuropeptide Y blockade
   E. Peripheral neuropeptide Y blockade

7. Pulmonary vascular tone is regulated by a complex interplay of local mediators and neural regulation. Which mediator primarily causes pulmonary vasoconstriction?
   A. Acetylcholine
   B. Endothelin
   C. Bradykinin
   D. Natriuretic peptides
   E. Nitric oxide

8. Which is the most correct statement regarding regulation of splanchnic circulation?
   A. Increased local blood flow after a meal depends on the degree of hollow organ stretch.
   B. Hydrolytic products of food, especially glucose and fatty acids with bile salts, are triggers responsible for the greatest increase in blood flow in the prandial and postprandial states.
   C. The tone of larger splanchnic arteries is regulated by β-adrenergic effects more than the α-adrenergic effects resulting in a baseline vasodilated state.
   D. Sympathetic and parasympathetic innervation is primarily responsible for postprandial hyperemia.
   E. Vasoactive hormones and peptides have a significant role in postprandial hyperemia.

9. Which of the following is **NOT** a potential explanation for altered microcirculatory flow?
   A. Heterogeneity in microcirculatory perfusion
   B. Excess vasoconstriction mediated by increased adenosine concentrations
   C. Hemodilution, which reduces oxygen carrying capacity
   D. Vasoconstriction or tamponade of venous return
   E. Tissue edema increasing oxygen diffusion distance

10. Which of the following statements regarding splanchnic circulation is correct?
   A. Normal splanchnic perfusion pressure is the mean arterial pressure minus the intra-abdominal pressure.
   B. The most metabolically active tissue is the submucosa.
   C. Normal splanchnic perfusion pressure is the mean arterial pressure minus the portal venous pressure.
   D. Parasympathetic innervation of the vascular smooth muscle results in vasodilation.
   E. Most of the splanchnic blood volume is located in the arterioles and capillaries.

Assessment of Cardiovascular Function

Frank A. Maffei

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_16

Learning Objectives

- Describe physical examination findings that aid in assessing the cardiovascular status of a critically ill child.
- Describe arterial pressure measurements and waveforms and how they are affected by various disease states.
- Describe central venous pressure measurements and waveforms and how they are affected by various disease states.
- Describe the utility of functional hemodynamics in the assessment of cardiovascular function.
- Describe the conservation of mass and Fick principles and how they relate to cardiac output measurement.
- Describe pulmonary artery pressure monitoring including estimation of cardiac output by thermodilution and measurement of pulmonary capillary wedge pressure.
- Identify the limitations of pulmonary artery catheterization.
- Describe pulse contour analysis tools used for the estimation of cardiac output in critically ill children.
- Identify and describe biochemical markers of cardiovascular function – specifically mixed venous and central venous oxygen saturations, lactate, B-type natriuretic peptide, and troponin measurements.

16.1 Noninvasive and Minimally Invasive Assessment of Cardiovascular Status

The physical examination remains the primary means to assess cardiovascular function. This includes evaluation of skin temperature, pulse rate and quality, capillary refill, and blood pressure. Altered mental status also may be associated with abnormal cardiovascular function.

With rapid access to portable bedside ultrasound and advances in noninvasive hemodynamic monitoring, the cardiovascular exam has been de-emphasized and physical examination skills among all levels of providers are at risk for deterioration. Despite inherent limitations, the physical examination remains the primary means by which intensivists assess cardiovascular function. Serial examinations are a readily available and inexpensive assessment tool that provides important physiologic data. In addition, the performance of serial examinations enables clinicians to build trust and rapport with children and families. An understanding of the clinical utility and limitations of examination findings is essential for the care of the critically ill child.

16.1.1 Physical Examination

A child with cardiovascular dysfunction can have important findings on general inspection. Cyanosis, a bluish discoloration of the skin and mucous membranes, may be either peripheral or central. Cyanosis is clinically recognized when *capillary* deoxygenated hemoglobin exceeds 5 g/dL; thus, a polycythemic patient with a hemoglobin of 16 g/dL experiencing a state of reduced peripheral perfusion may develop acrocyanosis with normal arterial oxygen saturation. Conversely, an anemic patient (e.g., a child with sickle cell disease and a hemoglobin of 6.5 g/dL) would not demonstrate capillary cyanosis even with an arterial oxygen saturation of 60%. Peripheral cyanosis is commonly due to cutaneous vasoconstriction secondary to exposure to cold or can be seen in low cardiac output states including hypovolemia, myocardial dysfunction, or septic shock. Central cyanosis is characterized by decreased arterial oxygen saturation (typically <85% assuming a normal hemoglobin concentration). Central cyanosis may be due to severe shock, venous admixture (e.g., cyanotic congenital heart disease), or dysfunctional hemoglobin (e.g., methemoglobinemia).

The jugular veins should be inspected. Presence of jugular venous distention (JVD) is a highly specific but not sensitive sign of elevated right atrial pressure (RAP). Distention is best assessed on the right side with the supine patient first lying flat and then with the head elevated 45°. Persistent distension at 45° and the absence of collapse during inspiration are suggestive of elevated RAP. Elevated RAP with restriction of right heart filling can occur with pericardial tamponade, tension pneumothorax, tricuspid valve stenosis, right heart failure, superior vena cava obstruction, or fluid overload.

JVD suggests elevated right atrial pressure, which may be secondary to restriction of right heart filling due to pericardial tamponade, tension pneumothorax, superior vena cava (SVC) obstruction, or tricuspid stenosis.

Tissue edema is most apparent in dependent regions including the lower extremities, sacrum, scrotum, and labia. Edema may be pitting when pressure is applied. Generalized edema is often due to disorders that produce low oncotic capillary pressure (e.g., nephrotic syndrome, malnutrition, liver disease) or those that increase capillary hydrostatic pressure (e.g., cardiac failure). Disorders such as sepsis and anaphylaxis may alter capillary permeability and also produce generalized edema.

Palpation of the pulse allows determination of rate, pulse quality, and skin temperature. Tachycardia is an early compensatory sign of cardiovascular compromise and is present in illnesses that decrease preload, increase afterload (e.g., catecholamine excess states), and decrease afterload (e.g., distributive shock) and conditions that compromise contractility (e.g., myocarditis).

Bradycardia often results from increased vagal tone but also may be due to sinus node dysfunction, atrioventricular block, drug toxicity, raised intracranial pressure, or hypoxemia. Abnormalities in the heart rhythm are a sensitive indicator of cardiac dysfunction. Rhythm alterations may be appreciated on palpation, but electrocardiography provides definitive evidence of an abnormal rhythm. Electrocardiography and continuous telemetry should occur in all children with suspected cardiovascular dysfunction.

Tachycardia or bradycardia alone is not a sensitive or specific indicator of compromised cardiovascular function. Fear, fever, dyspnea, and pain, all common in ill children, can also produce substantial tachycardia in the setting of normal or even high cardiac output states. Benign sinus bradycardia may be seen in the well-conditioned athlete or during deep sleep. Age-related differences may lead to the misinterpretation of high or low heart rates as abnormal by inexperienced examiners. The heart rate should always be assessed in the context of the patient's overall state (e.g., anxious, in pain, or sleeping) and not just compared to "normal" values for age.

Conditions that decrease the effective circulating volume such as dehydration, blood loss, excessive vasodilation, and capillary leakage of intravascular fluid can decrease preload and, subsequently, reduce cardiac output. Physical exam findings consistent with reduced preload include dry mucous membranes, sunken eyes, tachycardia, poor peripheral pulses, pulsus paradoxus, cool skin, delayed capillary refill, and ultimately hypotension.

Skin temperature and capillary refill can provide further assessments of tissue perfusion. Decreased cardiac output and a compensatory increase in systemic vascular resistance produce cool and poorly perfused extremities.

The peripheral skin temperature is usually measured as a toe temperature and normally is in the range of 32–34 °C. The ambient room temperature range is approximately 20–25 °C (68–77 °F). The delta peripheral-to-ambient (dTp-a) temperature gradient, also referred to as the toe-to-room temperature gradient, measures the difference in temperatures taken on the peripheral skin (toe) versus the ambient room temperature. The delta central-to-peripheral (dTc-p) temperature gradient measures the difference between skin temperatures obtained on the core (thorax) versus the periphery (toe). Both gradients have been studied as early markers of hemodynamic instability. With a stable ambient temperature, the dTp-a decreases and the dTc-p increases during states of high systemic vascular resistance. During vasoconstriction, the temperature of the skin falls, thus causing the dTp-a gradient to decrease. Heat conduction from the core decreases during vasoconstriction causing the central temperature to rise and the dTc-p gradient to increase.

Trending changes in skin temperature and gradient measurements are valuable adjuncts to the clinical assessment of microcirculatory integrity. Recent studies in patients with severe infections have supported the use of gradient changes, especially a decreasing peripheral-to-ambient (toe-to-room temperature) gradient, as a reflection of compromised microcirculation.

Since Beecher's original description in 1947, the assessment of capillary refill time (CRT) has been both revered and maligned in the medical literature. Like other bedside clinical observations, CRT can be affected by interobserver, environmental, and physiologic variables. Normal CRT after applying 5 seconds of pressure to the skin should be less than 2 seconds. CRT should be measured when the ambient temperature is between 20 and 25 °C.

Environmental factors such as low ambient temperature and poor lighting have been shown to decrease CRT utility. Cooler ambient temperatures produce prolonged CRT versus warmer temperatures. The anatomic site where CRT is assessed has important implications for its clinical utility. To properly assess CRT, the extremity should be above the level of the heart to avoid the influence of venous congestion. If CRT is assessed with the extremity lower than the level of the heart, CRT may reflect venous capillary refill as opposed to the desired arteriolar capillary refill. Severe anemia also makes assessment of CRT less reliable.

Prolonged CRT is a specific, but not sensitive, sign of low cardiac output states. Children with prolonged CRT have a greater risk of progressive shock than children with normal capillary refill time. However, its low sensitivity means that a normal CRT does not rule out cardiovascular dysfunction. Despite inherent limitations, CRT remains a useful clinical tool to serially assess cardiovascular function in the critically ill child.

Environmental factors (e.g., low ambient temperature and poor lighting), venous congestion, and anemia decrease the reliability of capillary refill time.

Although prolongation of CRT is often associated with compromised cardiac output, the examiner should also be aware of hyperbrisk or "flash" capillary refill. Disease states associated with low systemic vascular tone and normal or even increased cardiac output can produce rapid refill time. Flash capillary refill can be seen in certain forms of septic ("warm") and distributive shock.

Palpation of the liver is an important part of the cardiovascular exam. Hepatomegaly, edema, and jugular venous distention may be present in acute or chronic heart failure especially if the right heart is predominately affected.

Cardiac auscultation should occur over the tricuspid, pulmonary, mitral, and aortic areas with the bell and diaphragm of the stethoscope. The first heart sound (S1) is produced by mitral and tricuspid valve closure. S1 marks the end of diastole and the beginning of systole and is best heard over the lower left sternal border. The second heart sound (S2) is crisper and shorter than S1 and is produced by aortic and pulmonary valve closure. The physiologic splitting of the S2 into first aortic valve closure and subsequent pulmonic valve closure is best heard during inspiration over the upper left sternal border. Recall, inspiration increases right heart volume and will therefore slightly delay closure of the pulmonic valve.

Conditions that delay pulmonary valve closure can widen splitting and include right bundle branch block, pulmonary valve stenosis, and pulmonary hypertension. Right heart overload lesions may result in a widened and or fixed splitting of the S2. Fixed splitting occurs when S2 remains split in both inspiration and expiration. Conditions that produce large left to right shunts such as atrial septal defects and anomalous pulmonary venous connections into the right atrium can result in fixed splitting of S2.

Conditions such as right heart volume overload, pulmonary stenosis, pulmonary hypertension, and right bundle branch block result in a widened S2 split because pulmonary valve closure is delayed.

Careful auscultation can also identify new or changing murmurs, extra heart sounds (e.g., gallops), or abnormal sounds such as rubs, clicks, or muffled sounds. It is important to discern the timing (systole versus diastole) and the intensity of the abnormal sound.

16.1.1.1 Respiratory Signs

Although respiratory rate and work of breathing are considered respiratory signs, they can also be useful signs in children with suspected cardiovascular dysfunction. Quiet tachypnea (i.e., increased respiratory rate without an increase in the work of breathing) may be a sign of respiratory compensation for the presence of a perfusion-related metabolic acidosis. In an infant or child with signs of impaired perfusion, increased work of breathing may be due to increased pulmonary venous pressure and cardiogenic pulmonary edema.

16.1.1.2 Urine Output

Although not a true examination finding, urine output remains an important surrogate for end-organ perfusion. The kidney receives the second highest blood flow, relative to its mass, of any organ in the body. Urine output reflects the glomerular filtration rate, which in turn reflects renal blood flow; in the setting of shock, urine output reflects vital organ perfusion. The measurement of urine output serves as an excellent proxy to detect poor cardiac output from abnormalities in preload, afterload, and/or contractility. A normal urine output is approximately 1 mL/kg/h and should be a therapeutic target during resuscitation of hypovolemic, septic, and distributive shock.

Urine output should not be used as a proxy of organ perfusion when inappropriate diuresis occurs due to toxic ingestions (e.g., osmotic agents, diuretics), hyperosmolar states (e.g., diabetic ketoacidosis), diabetes insipidus, and cerebral salt wasting. A vigorous urine output in these cases may ultimately lead to intravascular volume depletion. Alternatively, children with inappropriate antidiuretic hormone release may have decreased urine output that may not be reflective of intravascular volume depletion but rather may be more consistent with volume overload.

16.1.2 Noninvasive Blood Pressure

A variety of physiologic factors contribute to the components of blood pressure.

16.1.2.1 Systolic Arterial Pressure

Systolic pressure is determined primarily by the force and volume of the blood ejected by the left ventricle (LV) and the compliance of the arteries the blood is ejected into. LV ejection results in distention of arterial walls and pulse waves that "bounce" back off the arterial walls. Both the pressure generated by ejection and reflected pulsatile waves off arterial walls contribute to the systolic pressure. Stiffer, less compliant arteries produce reflected waves that contribute far greater to the systolic pressure than do compliant arteries. Compliant arteries act to absorb rather than reflect pressure waves.

16.1.2.2 Diastolic Arterial Pressure

Diastolic pressure is determined by the time needed for systolic pressure to dissipate (pressure decay) and the resistance to volume displacement in the arterial tree (arterial distensibility). Blood flows more rapidly from the arterial system when the arteriolar resistance is low or when there is a connection to a low resistance system (e.g., a patent ductus arteriosus or large arteriovenous malformation)., Additionally, if there is incompetence of either the aortic or pulmonary valve, retrograde blood flow will cause a decrease in respective dia-

stolic pressures. In general, diastolic blood pressure correlates with the SVR; when SVR is low, the diastolic blood pressure will be low.

16.1.2.3 Pulse Pressure

Narrow pulse pressure is seen in aortic stenosis or low cardiac output states such as occurs with hemorrhage, tamponade, and cardiogenic shock. Widened pulse pressure is seen with PDA, systemic to pulmonary shunts, severe aortic regurgitation, and low SVR states such as distributive shock and vasodilated septic shock.

Systolic pressure minus the diastolic pressure equals the pulse pressure. Monitoring changes in pulse pressure can be clinically useful. Pulse pressure can be increased with conditions that raise stroke volume and thus systolic pressure, such as hyperadrenergic states (e.g., fever, pain, exogenous catecholamines, hyperthyroidism) and in states with increased arterial rigidity that increase the contribution of reflected waves to the systolic pressure (e.g., aging, arteriosclerosis).

Pulse pressure may also be increased in conditions that lower diastolic pressure due to abnormal runoff of blood into a lower resistance circuit as noted above or due to low systemic vascular resistance (SVR) states (e.g., warm sepsis, anaphylaxis, spinal shock, exogenous vasodilators). Patients with significant anemia (e.g., sickle cell disease) need a high cardiac output to maintain normal tissue oxygen delivery; thus, SVR is low in these patients who characteristically have a wide pulse pressure. In general, the normal diastolic blood pressure is approximately two-thirds of the systolic pressure; a wide pulse pressure may be clinically recognized by a diastolic blood pressure ≤ one-half the systolic blood pressure.

Narrowing pulse pressure due to falling stroke volume and systolic pressure with compensatory preservation in diastolic pressure is often a sign of worsening shock. Conversely, a diastolic blood pressure ≤ one-half the systolic blood pressure suggests a low SVR state such as seen in warm sepsis.

A narrowed pulse pressure can be seen in children with aortic stenosis or low cardiac output states. Hemorrhage, tamponade, and cardiogenic shock can cause progressive narrowing of pulse pressure. As stroke volume and systolic pressure decrease, compensatory mechanisms that increase SVR help preserve mean and diastolic pressure. Left unchecked, a rapidly narrowing pulse pressure can be an ominous sign.

16.1.2.4 Mean Arterial Pressure (MAP)

Physiologically, the MAP is determined by the force of blood ejected from the LV, vascular tone of the arterial system, and central venous pressure (CVP). This relationship is reflected in the formula:

$$\mathrm{MAP} = \left(\mathrm{CO} \times \mathrm{SVR}\right) + \mathrm{CVP}$$

CO (cardiac output) and SVR are often not readily quantifiable at the bedside. MAP can be approximated by utilizing the diastolic and pulse pressure:

$$\mathrm{MAP} \approx \text{Diastolic Pressure} + 1/3 * \text{Pulse Pressure}$$

MAP is not an absolute mean of diastolic and systolic pressures because the duration of diastole is longer than systole. As heart rate increases and systole shortens, the MAP approaches the true arithmetic mean of systolic and diastolic pressures.

Noninvasive methods of blood pressure determination include auscultatory and oscillometric methods. Auscultatory determination of blood pressure requires the identification of Korotkoff sounds as the extremity cuff pressure decreases. The initial sound is produced by turbulent flow in the artery and marks the systolic pressure. The disappearance of these sounds determines the diastolic pressure.

Oscillometric determination of blood pressure is accomplished by automated blood pressure devices such as the Dinamap (device for indirect noninvasive mean arterial pressure). As the cuff pressure declines and blood flows through arteries, the pressure in the cuff oscillates. The start of measurable oscillations marks systolic pressure, whereas the maximal level of arterial wall

oscillations marks MAP. The diastolic pressure is recorded at the point when the oscillations stabilize. It is commonly observed that the oscillometric method underestimates diastolic blood pressure since it is not directly measured and instead is estimated based on the algorithm used by the manufacturer.

Both auscultatory and oscillometric determination of blood pressure are limited by technical and physiologic factors. Inappropriate cuff size can lead to underestimating (cuff too large) or overestimating (cuff too small) true arterial pressure. An appropriate size cuff should have a bladder width at least 40% of arm circumference. The inflatable bladder length should cover 80% of the circumference of the arm. Noninvasive methods are less reliable in children with low cardiac output states, peripheral arterial disease, excessive extremity edema, subclavian artery abnormality (e.g., Blalock-Thomas-Taussig shunt), and during arrhythmias.

Too large cuff size can lead to underestimating blood pressure, and too small cuff size leads to overestimating blood pressure. If the distal pulse cannot be palpated, oscillometric blood pressure determination is unreliable.

16.1.3 Echocardiography

Over the last decade, use of focused cardiac ultrasound (FoCUS) to assess hemodynamics has increased dramatically in pediatric critical care. Bedside ultrasound allows the rapid assessment of pericardial disease, cardiac function, and functional hemodynamics such as fluid responsiveness. The ability to rapidly obtain high-quality images allows the intensivist to corroborate physical examination findings or alternatively, to appreciate hemodynamic changes that are not apparent on the examination.

The performance of echocardiography by non-cardiologists should occur after formal training and be limited in scope. FoCUS in critically ill children can often aid in the differentiation of shock (e.g., distributive, hypovolemic, obstructive, or cardiogenic) and allow targeted and prompt therapeutics.

16.1.3.1 Pericardial Disease

Pericardial effusions can be rapidly identified during FoCUS evaluation (◘ Fig. 16.1). The nature of the effusion (e.g., free flowing versus loculated) and its physiologic impact can be assessed. Tamponade physiology occurs when raised intrapericardial pressure overcomes chamber pressures and compromises cardiac filling. An echocardiographic feature of cardiac tamponade is collapse of the right atrium and the right ventricle. Chamber collapse occurs during atrial and ventricular relaxation phases, when intra chamber pressures are lower than pericardial pressures. Therefore, right atrial collapse usually occurs during systole and right ventricle collapse during diastole. Atrial collapse during systole often precedes diastolic ventricular collapse. Collapse of the left atrium is rarely observed, but its presence in conjunction with right atrial collapse increases the likelihood of cardiac tamponade. Dilation of the inferior vena cava due to high atrial pressures is an additional echocardiographic feature consistent with tamponade.

If drainage of a pericardial effusion is necessary, utilizing ultrasound to provide real-time guidance during pericardiocentesis or pericardial catheter placement greatly improves safety and success rates.

16.1.3.2 Systolic Function

Myocardial contractile function can be initially assessed in a nonquantitative manner. Experienced examiners can often quickly determine if a ventricular contraction appears to be robust or reduced. However, serial assessments, especially if done by multiple examiners, require objective measurements to

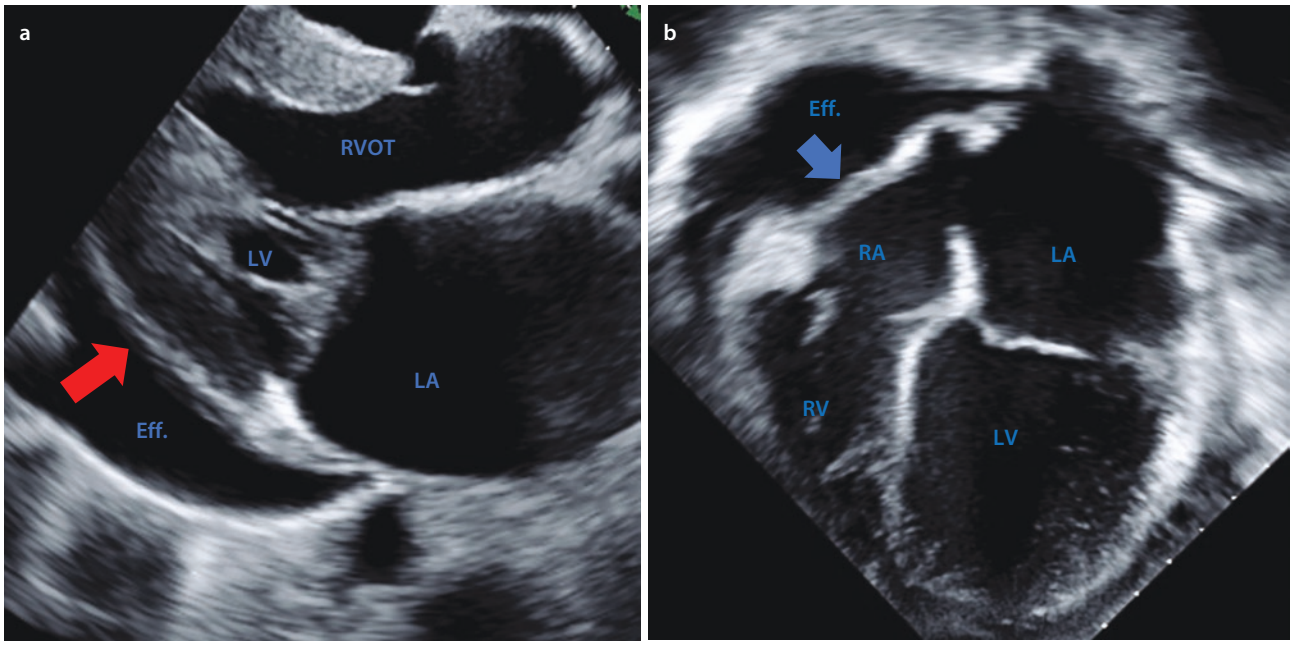

Fig. 16.1 **a** Moderate to large sized pericardial effusion (Eff.) present on FoCUS parasternal long-axis view. The effusion is increased along the left ventricular free wall (red arrow). **b** Right atrial collapse is noted (blue arrow)

describe systolic function. Ejection fraction (EF) and fractional shortening (FS) are common quantitative measurements obtained using FoCUS. It is important to appreciate that both EF and SF can be affected by aberrations in afterload and preload. If preload or afterload is not optimized, EF and SF will be abnormal and may not reflect intrinsic myocardial function.

EF utilizes the change in ventricular volume that occurs from systole to diastole to assess systolic function. Using the standard 2D mode, apical views are obtained. End-systolic and end-diastolic LV internal diameters are measured at the level of the mitral leaflet tips in the parasternal long-axis view. These measurements are then used to estimate the end-systolic and end-diastolic volumes (ESV, EDV), respectively. Using Simpson's method, EF is calculated using the equation:

$$\mathrm{EF}(\%) = \left[(\mathrm{EDV} - \mathrm{ESV})/\mathrm{EDV}\right] \times 100$$

16

Ejection fraction utilizes the change in LV volume that occurs from systole to diastole (i.e., the SV) to assess systolic function, whereas fractional shortening utilizes changes in LV dimension that occurs at end-diastole and end-systole (LVEDD and LVESD).

EF is categorized as normal (≥55%), slightly reduced (41–55%), moderately reduced (31–40%), and markedly reduced (≤30%).

M-mode is used to estimate wall thickness and chamber dimensions and is obtained from parasternal or long-axis views. Left ventricular function can be estimated by measuring the left ventricular dimension in end-diastole and end-systole (LVEDD and LVESD). The fractional shortening (FS) is calculated using the following equation:

$$\mathrm{FS}(\%) = \left[(\mathrm{LVEDD} - \mathrm{LVESD})/\mathrm{LVEDD}\right] \times 100$$

Normal values for FS in infants and children are between 28% and 46%. The fractional shortening assumes that the ventricle has a symmetric cylindrical shape. Diseases with abnormally shaped ventricles (e.g., hypoplastic left ventricle) and those causing asymmetric wall abnormalities reduce the ability of FS to reflect overall systolic function.

16.1.3.3 Volume Status and Fluid Responsiveness

The evaluation of preload and the cardiac output response to fluid administration is difficult to predict in children. Central venous pressure (CVP) and pulmonary capillary wedge pressure have inherent limitations and require invasive catheter placement.

Left ventricular size can be assessed rapidly by FoCUS and has been utilized to assess preload. However, only extremes in size tend to provide clinical utility. A very small hyperdynamic LV suggests hypovolemia and fluid responsiveness.

FoCUS also utilizes the measurements of the maximal inferior vena cava (IVC) diameter, collapsibility index (the percentage decrease in IVC diameter with inspiration), and the IVC/aorta diameter ratio to assess preload. Adult studies found FoCUS assessment of preload and fluid responsiveness to be clinically useful. Multiple small pediatric studies evaluating the utility of FoCUS to determine volume status have yielded inconsistent data. FoCUS should be used with caution as a stand-alone measure of preload and fluid responsiveness in critically ill children.

16.1.3.4 Pulmonary Artery Systolic Pressure

Understanding the normal RV and LV relationship can aid in the diagnoses of pulmonary hypertension. The RV is thin walled and has an anterior triangular shape and crescent cross-sectional shape. When visualized in the short-axis and apical four-chamber views, the RV cavity area appears smaller than the LV with a normal RV to LV area ratio range between 0.65 and 0.90. An increase in this ratio occurs with acute elevation in PA pressures (RV distension) or with chronic pulmonary hypertension (RV dilation). Right ventricular area equal to LV area indicates mild dilation, while area ratios approaching 2:1 indicate severe dilation.

During a normal cardiac cycle, LV pressures exceed RV pressures and the ventricular septum can be seen bowing into the RV. Elevated right ventricular pressures cause the intraventricular septum to flatten or even bow into the LV cavity. This change in the normal position of the septum is best appreciated in the parasternal long- or short-axis view during diastole and systole and is a sensitive marker of right ventricular hypertension in children (◘ Fig. 16.2). On the short-axis view, the dilated RV causes flattening of the septum and the LV cavity takes on the appearance of the letter D.

Measuring the maximal tricuspid valve regurgitation (TRV, m/s) is used to estimate pulmonary artery systolic pressure. The pulmonary artery systolic pressure (PASP) is quantified using the modified Bernoulli equation:

$$\mathrm{PASP} = 4 \times \left(\mathrm{TRV\,max}\right)^2$$

The normal estimated pulmonary artery systolic pressure (PASP) is <30 mm Hg.

Adding the right atrial pressure, if known, to the PASP estimates the RV systolic pressure (RVSP):

$$\mathrm{RVSP} = 4 \times \left(\mathrm{TRV\,max}\right)^2 + \mathrm{RA\ pressure}$$

16.1.4 Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) technology is predicated on the physical properties defined by the Beer-Lambert law. The law states that there is a linear relationship between the absorbance of light passing through a solution and the concentration of an absorbing substance (known as chromophores).

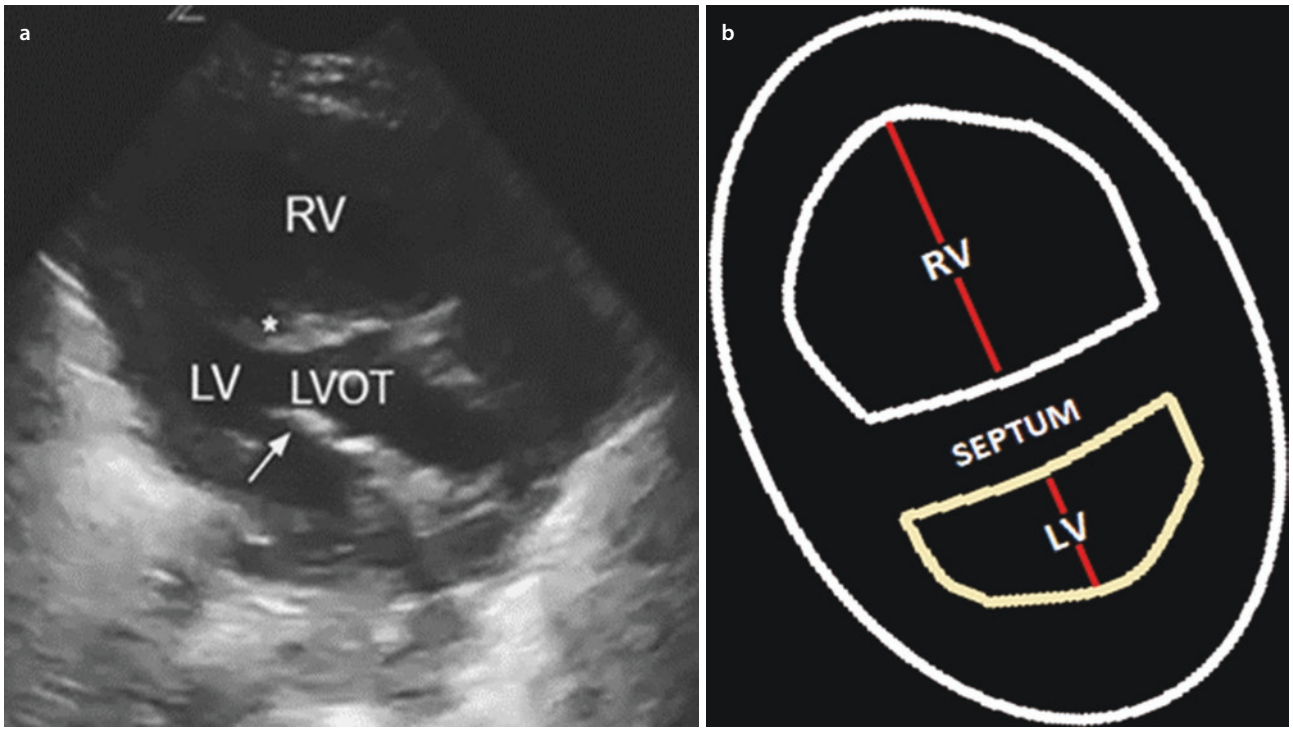

Fig. 16.2 **a** Parasternal view shows a severely dilated RV, septal bowing (asterisk). (Image courtesy of Dr. Shira Shore). **b** Graphic displaying D-sign seen in parasternal short-axis view. RV dilation causes septal flattening and D-shaped LV. The D-sign can be due to RV pressure overload (e.g., pulmonary embolism, pulmonary hypertension) or volume overload (e.g., tricuspid regurgitation, aggressive fluid resuscitation). D-sign seen during diastole and systole is likely due to pressure overload, whereas D-sign seen only in diastole is likely due to volume overload

16

NIRS utilizes the different light absorptive qualities of oxygenated and deoxygenated hemoglobin to estimate oxygen saturations mainly in the venous compartment of tissue beds 2–3 cm below the skin surface. It does not require pulsatility and can be used to assess regional saturations of the cerebral, splanchnic, and renal microcirculations.

In applying NIRS technology to evaluate tissue perfusion, the solution that the light is transmitted through is blood in the arteriolar, capillary, and venule compartments. The main chromophores in the solution are oxygenated and deoxygenated hemoglobin (Hb). Each form of Hb has differential absorption of light in the near-infrared spectrum (700–1150 nm). Deoxygenated Hb is absorbed at 650–1000 nm and oxygenated Hb 700–1150 nm. Using a mathematic algorithm, NIRS can subtract the effects of weak chromophores (e.g., adipose tissue) to focus on the light absorption of Hb in the oxygenated and deoxygenated states.

The amount of blood in the arteriolar, capillary, and venular compartments exists in a ratio of 10:20:70%, respectively. Thus, the majority of the NIRS measurement occurs in the post-oxygen extraction venule compartment and reflects a value similar to a mixed venous oxygen saturation (SvO_2). Unlike pulse oximetry that is dependent upon pulsatility to determine arterial oxygen saturation, NIRS technology does not require pulsatility and may have greater utility during states of poor peripheral perfusion.

The NIRS measurement reflects the regional oxyhemoglobin saturation (rSO_2) in tissues 2–3 cm below the sensor. Light photons in the NIR spectrum are capable of penetrating dense structures such as the skull. Thus, cerebral NIRS penetrates the forehead to assess cerebral tissue perfusion in the frontal cortex.

Common sites for regional somatic measurements are the forearm, flank, or upper chest. NIRS-derived saturations are referred to as ScO_2 (cerebral), StO_2 (tissue), or rSO_2 (regional). StO_2 and rSO_2 have been used interchangeably. A NIRS sensor placed over a kidney or intestinal area may be referred to as renal StO_2 (Fig. 16.3) and splanchnic StO_2, respectively.

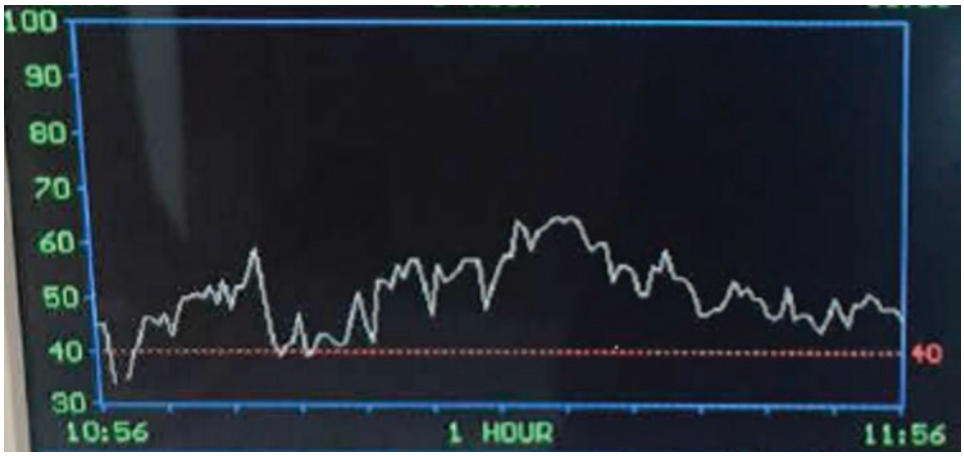

Fig. 16.3 Renal StO_2 displaying improved oxygen saturations after intervention. The subsequent decline is consistent with persistent circulatory dysfunction on examination. (Courtesy of Dr. Ravi Samraj)

Table 16.1 Summary of patient-related and technologic limitations of NIRS for the assessment of regional tissue perfusion

Patient-related limitations	Technologic limitations
Skin conditions: Burn Overlying infection Hyperpigmentation Overlying scar Excessive underlying adipose tissue	Regional saturations may not reflect global perfusion
Pigment conditions: Hyperbilirubinemia Excessive myoglobin	Lack of standardization across devices and lack of absolute values
Hemoglobin abnormalities: Polycythemia	Cost

NIRS has been used as a microcirculatory proxy for central venous oxygen saturation ($ScvO_2$) to assess the adequacy of oxygen delivery in critically ill infants and children. Populations in which NIRS has been utilized include children with shock, acute neurologic disease, and those postoperative from congenital heart disease (CHD) repair.

In infants postoperative from CHD repair, NIRS-derived saturations correlate with $ScvO_2$. Both cerebral and renal StO_2 of less than 65% correlate with postoperative hyperlactatemia (>3 mmol/L) in neonates postoperative from CHD repair. NIRS may have particular utility in the single ventricle population. Low regional cerebral oxygen saturation in the first 48 h after the Norwood procedure had a strong association with adverse outcome.

NIRS has both technologic and patient-related limitations that are summarized in Table 16.1. Cerebral NIRS values may not reflect the perfusion of less proximate brain tissue and other regional circulations. In addition, cerebral NIRS values that reflect clinically significant cerebral tissue desaturation remain undefined. Multiple studies have used different thresholds of ScO_2 for interventions ranging from 50% to 70%. Some authors have defined cerebral tissue desaturation as greater than a 20% reduction from baseline. Due to the lack of absolute values, most authors advocate for utilizing cerebral and somatic NIRS technology to monitor trends in perfusion. Cerebral NIRS in traumatic brain injury may be limited as cerebral edema or hematoma may affect the ability to accurately detect changes in perfusion in underlying tissue.

Due to multiple potential limitations, cerebral NIRS values must not be interpreted in isolation. Consideration of macrocirculatory oxygen delivery indicators (e.g., examination, functional hemodynamic measures, $ScvO_2$, lactate, pH) in conjunction with NIRS measurements will provide a more accurate assessment of the physiologic state of the child.

16.2 Invasive Measures of Cardiovascular Function

16.2.1 Arterial Waveform Analysis

Intravascular arterial catheters provide continuous monitoring of arterial pressure as well as important physiologic data derived from waveform analysis. The normal waveform begins with aortic valve opening and the onset of LV ejection (Fig. 16.4). This is seen as a sharp upstroke in the waveform referred to as the *anacrotic limb*. After its peak, aortic pressure declines as LV ejection slows. The descending limb is interrupted by a small rise in pressure. When arterial pressure is measured in the aorta, this rise in pressure produces a notch termed the *incisura* and is related to the elastic recoil of the aortic valve after its closure. When arterial pressure is measured peripherally, this rise in pressure is referred to as the *dicrotic notch.* During peripheral intra-arterial monitoring, the notch is not due to the recoil following aortic valve closure as is commonly thought, but rather, it is due to reflected waves back from distal arterial walls and branch sites. Diastolic runoff and end-diastolic pressure complete the waveform.

Several changes in the arterial pressure waveform occur as the pulse wave is transmitted distally. The systolic peak increases, the dicrotic notch occurs later, and the diastolic pressure becomes lower. Consequently, a larger pulse pressure is measured in distal arteries. Despite these changes, the MAP is only slightly

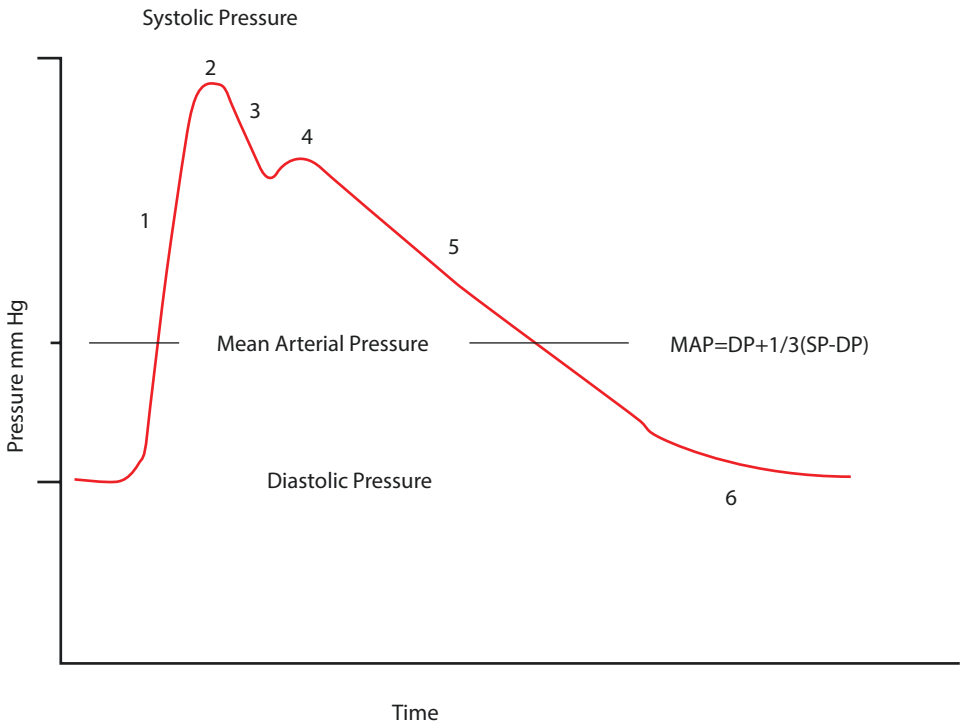

Fig. 16.4 Normal arterial waveform analysis: (*1*) sharp upstroke – *anacrotic limb*, (*2*) peak systolic pressure, (*3*) decline in aortic pressure as LV ejection slows, (*4*) notch in descending limb – *incisura* or *dicrotic notch*, (*5*) diastolic runoff, and (*6*) end-diastolic pressure

lower in the periphery than in the aorta. These changes are due to the phenomenon of *distal wave amplification*. Although blood flow rate from the aorta to the distal arteries falls only slightly, flow rate falls markedly at the arteriolar level. This is due to the significant increase in resistance encountered at the arteriolar level. The high resistance to flow diminishes pressure pulsations to the small downstream vessels, but also causes pressure pulsations to reflect back upstream. Therefore, the contour of a peripheral arterial waveform is determined by both forward pulsations originating from LV ejection (stroke volume) *and* reflected pulsatile waves from distal vessel walls and bifurcation points. Clinically, these reflected waves become more pronounced with stiff noncompliant arteries. In the elderly, systolic hypertension is due, in part, to a loss in the arterial distensibility causing reflected waves to add to the systolic peak.

16.2.1.1 Arterial Waveform Technical Considerations

Prior to ascribing an abnormal arterial waveform to a physiological perturbation, it is essential to rule out a mechanical artifact. To better understand the technical limitations of intra-arterial monitoring, a brief discussion regarding the technical principles that govern pressure waves is helpful.

Wave Frequency and Resonance

Invasive arterial monitoring systems consist of an intravascular catheter connected to low-compliance, saline-filled tubing that provides a continuous fluid column to an electronic transducer. The pressure waveform of the arterial pulse is transmitted via the column of fluid to the pressure transducer where it is converted into an electrical signal. These signals are then amplified, displayed, and recorded. The pressure waveform generated by a pulse is not a simple single sine wave that is transmitted through the fluid column. Instead, it is a combination of a *fundamental* wave (also referred to as the first harmonic wave) which corresponds to waves produced by LV ejection and a series of *harmonic* waves which correspond to waves produced by reverberations reflected back from the vascular tree. The fundamental frequency corresponds to pulse rate; by convention, a pulse of 60 beats per minute equals 1 Hz (cycle/s). Harmonic waves are smaller waves whose frequencies are multiples of the fundamental frequency and can occur at rates of 2, 3, 4 Hz, etc. Fourier's theory states that any complex waveform, such as an arterial pressure waveform, is constructed from the sum of all waveform frequencies (Fig. 16.5). Fourier analysis is the mathematical process of converting a complex waveform (with all its constituent sine waves) into a single pressure waveform.

The contour of a peripheral arterial waveform is determined by both forward pulsations originating from LV ejection and reflected waves from distal vessels and bifurcation points.

In an ideal environment, the summation wave produced by LV ejection and arterial reverberations would be the only wave the transducer would convert into an electrical signal. As in any complex system, however, the ideal is seldom realized. Instead, the arterial pressure wave causes the monitoring system to

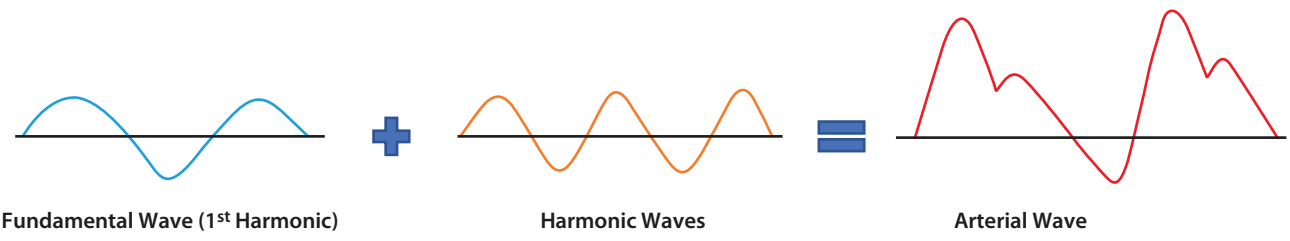

Fig. 16.5 The arterial waveform is made up of the sum of the fundamental sine wave and the harmonic waves. Although a simplified representation, the shape of the arterial waveform is due to the additive effects of the fundamental sine wave (pulse wave from ejection) and subsequent harmonic waves (pulse waves reflected off arterial walls)

oscillate freely and thus produce its own set of sine waves. The frequency of the oscillations is called the system's *natural frequency*. If the natural frequency of the system is in the same range as the natural frequency of the arterial waveform, the amplitudes of the waves become additive or *resonant*. Clinically, resonant augmentation of the arterial pressure wave causes an artifactual increase in systolic pressure and a decrease in diastolic pressure. Systolic pressures may be falsely increased by as much as 30%.

Resonant augmentation of the arterial pressure wave can cause an artifactual increase in systolic pressure and a decrease in diastolic pressure with systolic pressures falsely increased by as much as 30%.

Resonance becomes problematic when the monitoring system has a low natural frequency and the heart rate is high. Therefore, resonance amplification can occur when the natural frequency of the system approximates the frequency of the constituent sine waves that make up the arterial pulse. Accurate measurement of an arterial pressure is accomplished by assuring the natural frequency of the measurement system is at least eight times higher than the frequency of the arterial pressure wave, which is equal to the heart rate. Thus, an accurate monitoring system at heart rates of 120 bpm (i.e., 2 Hz) should have a natural frequency equal to or above 16 Hz. The desired frequency is obtained by first converting pulse rate to Hz and then multiplying by a factor of 8:

Accurate measurement of an arterial pressure is accomplished by assuring the natural frequency of the measurement system is at least eight times higher than the frequency of the arterial pressure wave.

$$(120\,\text{bpm} / 60\,\text{Hz}) \times 8 = 16\,\text{Hz}$$

Damping

In addition to the effects of the natural frequency of the monitoring system (potential for resonance), the system's own physical forces may interfere with accurate measurement of the arterial pressure. Damping describes the interaction between the oscillatory energy of a wave and the physical properties of the monitoring system. Damping causes a progressive diminution of a system's inherent oscillations. In an ideal system with no damping effects, the oscillations of a wave would continue indefinitely at the system's *undamped natural frequency*. However, in reality, wave oscillations are always affected by the physical forces of the monitoring system (i.e., friction, compliance, and elastance) so that the frequency of oscillations occurs at the system's *damped natural frequency*. A monitoring system is optimally damped if it dissipates the physical forces produced by its components and selectively conducts the oscillations of the pressure waveform. Optimal damping is difficult to achieve. Inadequately damped systems (*underdamping*) result in the system producing many sequentially decreasing reverberation waves that occur in response to each pulse wave. When the frequency of these reverberation waves (also referred to as ringing) approaches the arterial pulse wave frequency, resonance occurs, and systolic pressure is overestimated. An underdamped waveform is characterized by a high initial spike in the waveform. Underdamped systems may be due to excessive tubing length or vasoconstriction. Long tubing causing an underdamped system seems counterintuitive; if there is more tubing, then it seems logical that the tubing would absorb energy, causing overdamping. However, this is not the case. As the tubing length increases, the natural frequency of the system approaches the patient's pulse wave frequency. The system then resonates, amplifying the signal. Thus, excessive tubing length causes resonance in the system, and consequently the system will be underdamped.

Underdamping results in excessive resonance which in turn artificially increases systolic pressure.

A system is overdamped when the oscillatory energy of the pressure wave is reduced by the physical forces of the system. O*verdamping* results in an artificially low systolic blood pressure. Causes of overdamping include multiple stopcocks, leaks, bubbles, clots, compliant tubing, or kinks in the cannula or tubing (Fig. 16.6).

Overdamping causes the oscillatory energy of the pressure wave to be reduced by the system's physical forces and results in an artificially low systolic blood pressure.

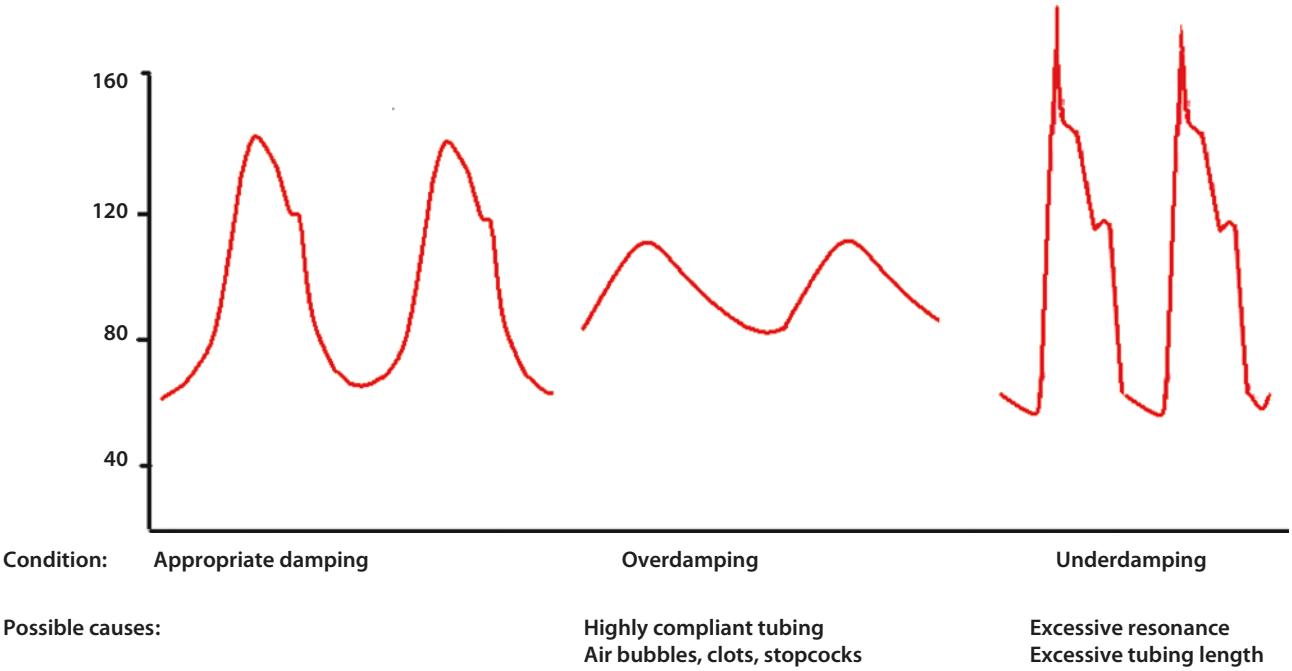

Fig. 16.6 Effect of damping on arterial waveform appearance

As a general rule, underdamped systems augment energy of the oscillating waves and artificially increase the system's output, whereas overdamped systems absorb energy and artificially decrease the system's output.

Fast Flush Test

The fast flush test allows for quantification of excessive resonance within the system.

Understanding that underdamped systems can lead to resonance, a simple bedside test can identify the presence of resonant waves. Delivering a small "fast flush" to the system allows quantification of excessive resonance within the system. The initial change on the arterial waveform monitor consists of a large square wave reflecting the abrupt and large pressure change the system has undergone due to the fast flush. The large square wave is followed by a series of resonant waves prior to returning to the arterial pressure wave. In an appropriately damped system, only one resonant wave is seen. In an underdamped system, multiple waves are seen prior to the return to the artificially elevated systolic pressure waveform (often due to excessive tubing length). In an overdamped system, no waves are seen (Fig. 16.7). There may be a rounded or scooped appearance on the tracing prior to returning to the artificially lowered systolic pressure waveform. This is often due to excessive tubing compliance, bubbles, or leaks.

Leveling and Zeroing

Arterial and central venous pressure monitoring devices must be leveled to the phlebostatic axis to have the contribution of hydrostatic pressure in the system negated. The phlebostatic axis is the external reference point of the atria and is found by locating the junction of the vertical line drawn down from the fourth anterior intercostal space (usually located near the nipple) and the horizontal midaxillary line (Fig. 16.8). Atmospheric pressure is discounted from the pressure measurement by opening the system to the atmosphere and calibrating the pressure reading to zero at the phlebostatic axis.

Failure to level the system results in an error due to the addition of hydrostatic pressure of the fluid in the column to the blood pressure transducer.

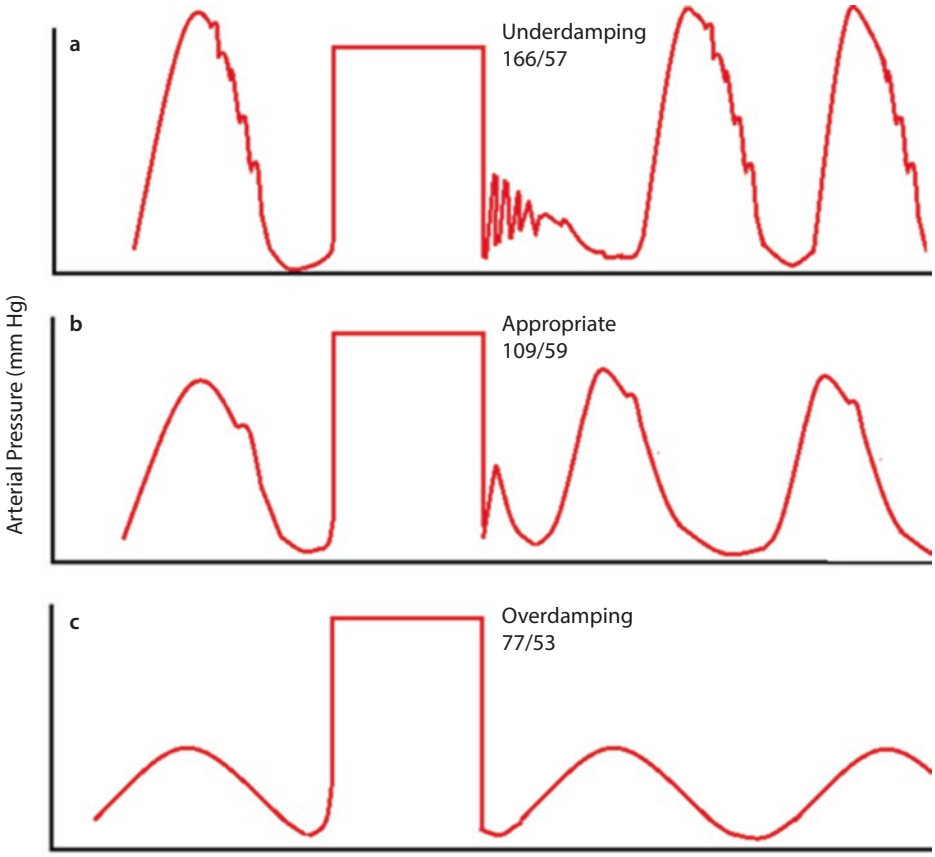

Fig. 16.7 Fast flush test to determine effect of damping. Panel **a** – Multiple resonant waves after fast flush indicative of underdamping, increased resonance, and artificial increase in systolic blood pressure and decreased diastolic blood pressure. Panel **b** – Appropriate degree of damping with one resonant wave evident after fast flush. Panel **c** – Absence of resonant waves and scoop after fast flush indicative of overdamping and artificial decrease in systolic blood pressure

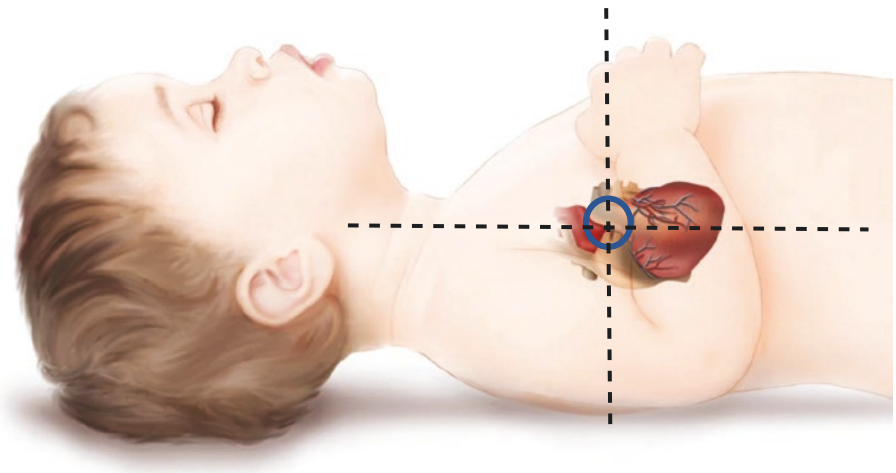

Fig. 16.8 Phlebostatic axis. Junction of vertical line down from the fourth intercostal space and the horizontal midaxillary line. Ana Truqui

Every 10 cm error in leveling can result in a 7.4 mm Hg error in the pressure measured. A transducer that is zeroed below the patient's heart produces falsely elevated pressures, whereas a transducer zeroed above the patient's heart produces falsely low pressures. Thus, when the patient's position is changed, the transducer position should be readjusted to the patient's phlebostatic axis.

16.2.1.2 Variations in Arterial Waveforms

Pulsus Paradoxus

Pulsus paradoxus is a true misnomer. It is not a paradoxical phenomenon but instead an exaggeration of a normal hemodynamic response to inspiration (Fig. 16.9). Pulsus paradoxus is defined as an exaggerated fall in systolic blood pressure, usually greater than 10 mm Hg (normal is about 5 mm Hg), occurring during a negative pressure inspiration. There are several mechanisms responsible for this fall in systolic pressure. It is important to appreciate these mechanisms in the healthy state to better understand how their effects are increased in pathological states such as hypovolemia, tamponade, and obstructive airway disease.

The normal fall in systolic pressure during inspiration is due to several hemodynamic events:

1. Inspiration causes pooling of pulmonary venous blood and therefore decreased left heart preload.
2. Inspiration causes increased venous return to the right heart. However, this is not immediately translated to increased LV preload. Instead, the increased right ventricular volume causes a further decrease in LV size and preload by the mechanism of *ventricular interdependence*. That is, the increased RV size causes septal shift to the left and hence transient decreased LV size.
3. Negative intrathoracic pressure relative to atmospheric pressure also causes an increase in ventricular transmural pressure leading to an increase in LV afterload.

Exaggerated falls in systolic pressure during inspiration occur in a variety of pathological states. In diseases that create lower airway obstruction (e.g., asthma), the greater negative intrathoracic pressure generated during inspiration accentuates the above effects. In addition, with air trapping and hyperinflated lungs, the diaphragm flattens, which tightens the pericardium around the

Pulsus paradoxus is not a paradoxical phenomenon but rather is an exaggeration of the normal fall in systolic pressure in response to the hemodynamic changes induced by negative pressure inspiration.

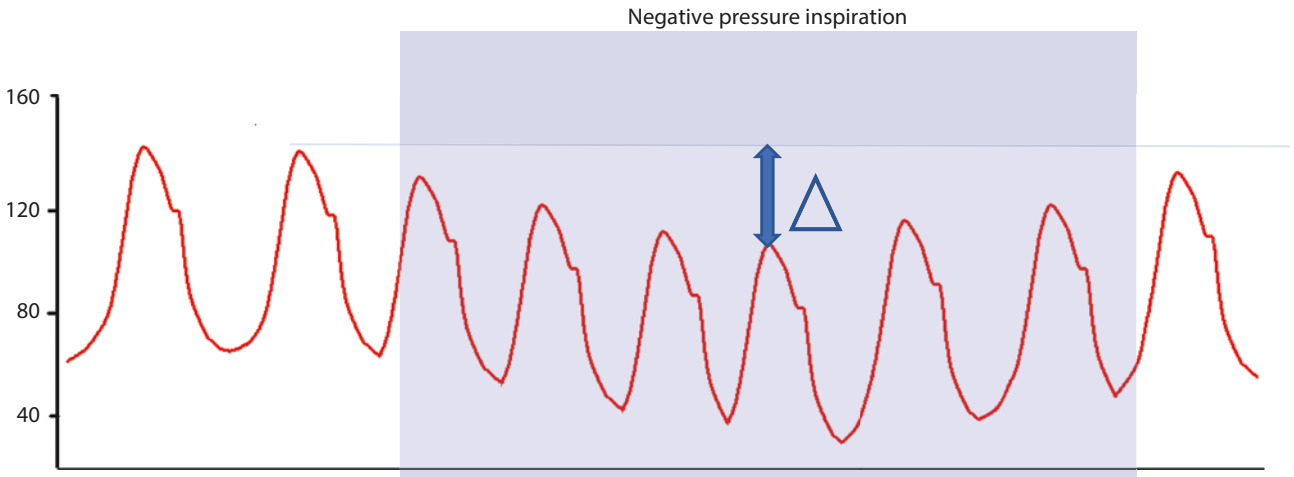

Fig. 16.9 Pulsus paradoxus occurs when the normal fall in systolic pressure due to inspiration (shaded area) is exaggerated to >10 mm Hg. Pulsus paradoxus is described during negative pressure breathing

heart limiting cardiac chamber size since the parietal pericardium attaches to the diaphragm. These changes lead to the characteristic narrow cardiac silhouette seen on chest x-ray. In tamponade states, compromised cardiac filling and the leftward septal bulging that occurs during inspiration further accentuate pulsus paradoxus. Any condition associated with hypovolemia and decreased circulating volume will also result in an exaggerated fall in systolic blood pressure during inspiration.

Systolic Pressure Variation

The hemodynamic principles that govern systolic pressure variation are similar to those in pulsus paradoxus. Instead of a fall in pressure during negative pressure breathing, there is an early rise in pressure during the inspiratory phase of positive pressure breathing.

Systolic pressure variation (SPV) refers to the arterial pressure waveform changes that occur during positive pressure mechanical ventilation. The hemodynamic principles are similar to those that create pulsus paradoxus, but instead of a fall in pressure during negative pressure breathing, there is a rise in pressure during the inspiratory phase of positive pressure breathing. At times, this phenomenon is referred to as *reverse pulsus paradoxus*; however, *systolic pressure variation* is the preferred term.

A single positive pressure breath normally affects the arterial pressure in a biphasic manner (Fig. 16.10). The initial hemodynamic effect of a positive pressure breath is to "squeeze" pulmonary vascular blood into the LA leading to an increase in LV preload and systolic pressure. In addition, positive intrathoracic pressure reduces the afterload on the LV further augmenting this early rise in arterial pressure. This is referred to as the Δ up component of *SPV*. Note that while LA preload is augmented early in the positive pressure breath, the RA preload is decreased as the positive intrathoracic pressure decreases venous return. Following the Δ up, a fall in systolic pressure follows due to the initial decreased venous return to the right heart "catching up," and ultimately, result-

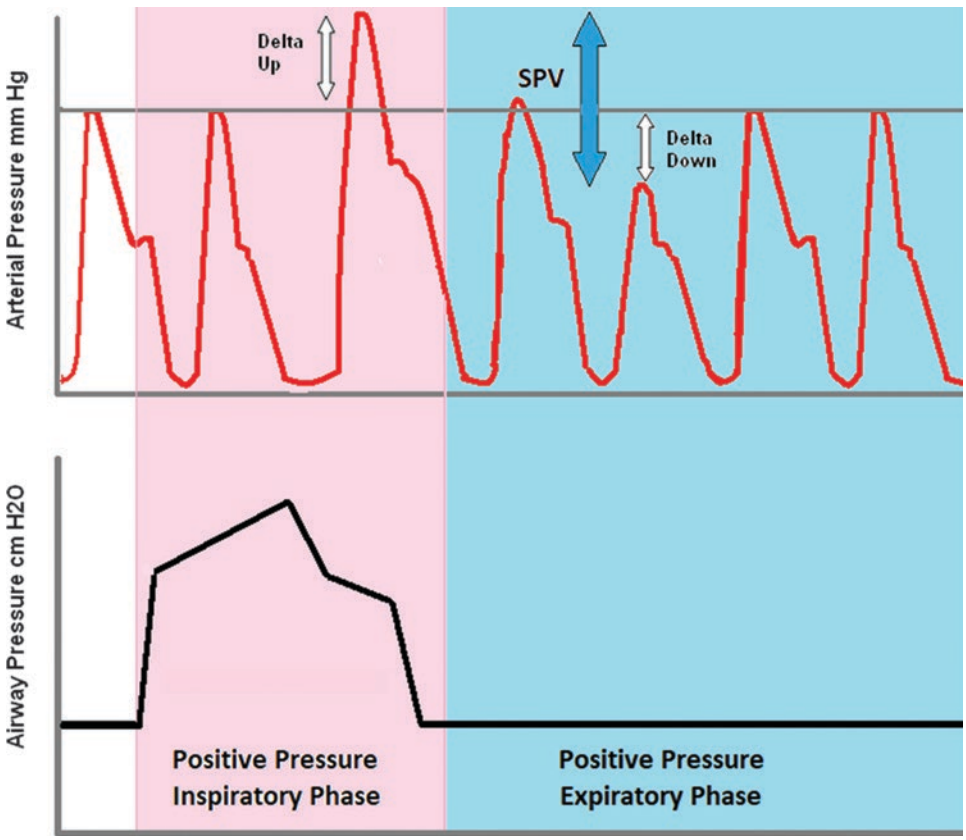

Fig. 16.10 Systolic pressure variation (SPV) during single positive pressure breath. *Delta up* – Increase in systolic pressure at the initiation of positive pressure breath. *Delta down* – Decrease in systolic pressure occurring during expiratory phase of a positive pressure breath. SPV = sum of delta up and down

ing in decreased left-sided preload. The reduction in LV preload and output leads to a smaller LV stroke volume and a brief reduction in arterial pressure that occurs during the expiratory phase of a positive pressure breath (Δ down).

An increased SPV (>10 mm Hg) can occur if the Δ down component is lowered or if the Δ up component is elevated. Hypovolemia has been found to cause an increased SPV (>10 mm Hg). Positive pressure amplifies the effects of decreased effective circulating volume and causes a greater fall in the Δ down component of SPV secondary to a substantial decline in venous return. Several adult studies demonstrated that an increase in the SPV occurs prior to a fall in arterial pressure and may be predictive of clinically significant hypovolemia. Excessive positive pressure during mechanical ventilation can also increase the magnitude of the Δ down component by compromising venous return in patients without hypovolemia.

The Δ up component of SPV reflects augmentation of systolic blood pressure early in the positive pressure breath due to an initial increase in LV preload and decrease in LV afterload. The Δ down reflects a fall in systolic pressure during the expiratory phase of the positive pressure breath as decreased venous return to the RV results in a subsequent decrease in LV preload.

During a positive pressure breath, an increased SPV due to an increased initial Δ up component may be observed in the setting of myocardial dysfunction. This increased SPV is not due to hypovolemia; rather, it reflects improved left ventricular ejection secondary to reducing left ventricular afterload with each positive pressure breath.

During mechanical ventilation, an increased delta down component of the systolic pressure variation can be associated with decreased preload due to hypovolemia and/or excessive positive pressure.

The measurement of SPV in mechanically ventilated children is an excellent example of *functional hemodynamic assessment*. Traditionally, many hemodynamic measurements, such as central venous pressure and pulmonary capillary wedge pressure, have been static values obtained by bedside measurement of invasive pressures. When hemodynamic measurements are taken in the context of a physical maneuver (e.g., application of a positive pressure breath, straight leg raise) or a therapeutic challenge (e.g., volume infusion), the hemodynamic data are dynamic and may provide far more useful information than static measurements alone.

Commonly used dynamic measurements are based on beat-to-beat changes in LV output during positive pressure ventilation. Measures such as stroke volume variation, pulse pressure variation, and systolic pressure variation have been found to be clinically reliable variables for predicting fluid responsiveness in adults. These measurements have not been extensively studied in children; however, a recent meta-analysis suggests that stroke volume variation was of diagnostic value in predicting fluid responsiveness in children undergoing positive pressure ventilation.

Functional hemodynamics such as systolic pressure variation are measurements taken in the context of a physical maneuver (e.g., application of a positive pressure breath, straight leg raise) or therapeutic challenge (e.g., volume infusion).

16.2.1.3 Complications of Invasive Arterial Pressure Monitoring

There are multiple complications that may occur during placement and maintenance of an arterial line (◘ Box 16.1). A large retrospective pediatric cohort study demonstrated that up to 10% of indwelling arterial lines resulted in complications. The number of complications is significantly greater if arterial line malfunction is also considered. Two complications that deserve special consideration are ischemia and infection.

Box 16.1 Complications of Arterial Cannulation

Arterial line complications

- Vasospasm
- Distal ischemia
- Arterial thrombosis
- Embolism (air, clot, or other material)
- Infection
- Hematoma
- Hemorrhage from inadvertent disconnection
- Nerve injury
- Aneurysm formation

Ischemic Injury

Indwelling peripheral artery catheters allow continuous recording of blood pressure and access to arterial sampling. Maintaining an indwelling catheter is relatively safe with a very low incidence of permanent distal ischemic injury. Several interventions that attempt to mitigate the risk of ischemia include Allen testing for collateral flow when placing a radial line, continuous infusion of low-dose heparin, in-line air filter, and utilizing papaverine as an antispasmodic.

Although vascular supply to the hand varies greatly, adequate collateral flow is present in most children. Procedures that use the radial artery as an entry site for cardiac catheterization have provided new insight into the assessment of ulnar collateral blood flow to the hand – specifically the utility of the Allen test. The modified Allen test has been the most frequently used method to clinically assess adequacy of ulnar artery collateral flow. It is performed by instructing the patient to clench his/her fist, or if the patient is unable, the hand is closed tightly. Direct occlusive pressure is applied to both the ulnar and radial arteries, thereby temporarily obstructing blood flow to the hand. Blanching of the palm and fingers should occur. The occlusive pressure on the ulnar artery is released, and the hand should reperfuse and flush within 5–10 s. Flushing denotes that the ulnar artery is patent and provides adequate collateral blood flow. If the hand does not flush, the ulnar circulation is inadequate, and the radial artery should not be instrumented. However, the utility of the modified Allen test has been questioned, and it may have no direct correlation with ischemic complications of radial artery catheterization. It is a subjective clinical test that lacks interobserver reliability. Multiple reports documented adequate collateral flow via Doppler or angiography when the modified Allen test suggested a lack of ulnar collateral flow. Its use may be limited as a bedside screening test. An Allen test that demonstrates no collateral flow from the ulnar artery may not preclude the use of a radial arterial line. A Doppler or angiographic study should be obtained to verify an Allen test that suggests no collateral flow.

The use of a continuous saline infusion with a low-dose heparin (e.g., 1–2 units heparin/mL at 3 mL of flush solution per hour) has been utilized in children with indwelling arterial catheters. The practice is commonly used in adults; however, a 2014 meta-analysis revealed the cumulative adult evidence is of poor quality and does not provide sufficient evidence to support the practice. Pediatric evidence suggests there is a benefit of continuous infusion of saline over intermittent manual flushing of arterial catheters; however, data regarding the addition of low-dose heparin is not conclusive.

The radial, femoral, axillary, dorsalis pedis, and posterior tibial arteries are commonly used sites for arterial line placement. The placement of an arterial catheter in the brachial artery traditionally has been avoided due to lack of sufficient collateral flow. However, adult and pediatric studies reported that brachial artery catheterization may not carry an increased risk of ischemic complications as previously believed. Nonetheless, until larger studies are conducted regarding the safety of brachial artery catheterization, it should not be used as a primary site for intra-arterial pressure monitoring.

Infection

Arterial catheters traditionally were thought to have a lower infection rate compared to venous catheters due to the high flow and oxygen tension present in arteries. However, the incidence of arterial-related catheter infection is similar to rates observed in central venous catheters; infection rates of 1–7% have been reported. Young age and the femoral site appear to increase the risk of infection. As with central venous catheters, the risk increases incrementally with the duration of catheter use. Understanding the impact that bloodstream infections have on intensive care morbidity and mortality, arterial catheters should be treated with the same vigilance as central venous catheters. Methods

to decrease infections from arterial catheters should include selective use, early removal, and adherence to proven protocols to assure appropriate insertion and maintenance techniques.

Vasospasm and Catheter Malfunction

Maintaining indwelling catheter patency and function can be challenging, especially in infants.

Providing continuous fluid flowing through the catheter and careful serial assessments are accepted practices. Papaverine is a direct arterial vasodilator that has been used extensively in the neonatal population to decrease vasospasm induced by peripheral arterial catheters. Limited data suggests papaverine (30 mg/250 mL) added to the continuous saline infusion may prolong the patency of peripheral arterial catheters in children and neonates.

16.2.2 Central Venous Pressure Monitoring

The central venous pressure (CVP) may provide important hemodynamic data in a variety of disease states encountered in the PICU. In addition, it provides a route for monitoring central venous oxygen saturation, which helps assess perfusion as discussed later in this chapter. The optimal site for monitoring CVP is at the junction of the superior vena cava and the upper portion of the right atrium (RA). CVP varies with changes in intrapleural pressures. The measured CVP most closely approximates transmural filling pressures at end-expiration when the intrapleural pressure approaches atmospheric pressure.

A CVP can reflect right ventricular end-diastolic pressure (RVEDP), which has been used to estimate right ventricular end-diastolic volume (RVEDV). The RVEDP is dependent on the underlying status of the RV; hence:

$$\text{RVEDP} = \text{RVEDV} \times \text{RV compliance}$$

CVP provides information regarding RVEDP but may not accurately predict the RVEDV or how the ventricle will respond to volume administration.

It is critical to appreciate that CVP provides information regarding RVEDP; however, it may *not* accurately predict the RVEDV or how the ventricle will respond to volume administration. Right ventricular end-diastolic volume is affected by tricuspid regurgitation and poor ventricular compliance, both of which may be present in hemodynamically unstable children. Although CVP is clinically used to assess cardiac preload, multiple adult studies have proven that CVP does not correlate well with RVEDV. Changes in right ventricular compliance may affect right atrial pressure and volume in a manner that is difficult to predict. Although very high or very low values for the CVP may provide important data regarding the volume status of the RV, most intermediate CVP readings provide little clinically useful information.

In addition to its numerical value, the CVP waveform can provide clues to clinical conditions including arrhythmias, atrioventricular (AV) valve dysfunction, and tamponade states. The normal CVP waveform reflects the right heart events that occur during the cardiac cycle (Fig. 16.11). The first and most prominent positive deflection is the ***a wave***, which represents the increase in intra-atrial pressure observed during atrial contraction. Atrial contraction occurs at the end of ventricular diastole and marks the start of ventricular systole. The atrial contraction serves to "top off" ventricular filling and can contribute significantly to cardiac output, especially when ventricular function is reduced. The decline in atrial pressure after atrial contraction is interrupted by the next positive deflection termed the *c wave*. This bump in pressure reflects the displacement of the tricuspid valve up toward the atrium during isovolumic ventricular contraction. The pressure in the atrium then declines during atrial relaxation. The downward displacement of the tricuspid valve that occurs during ventricular contraction further reduces atrial pressure and is *reflected in the x descent* of the CVP waveform.

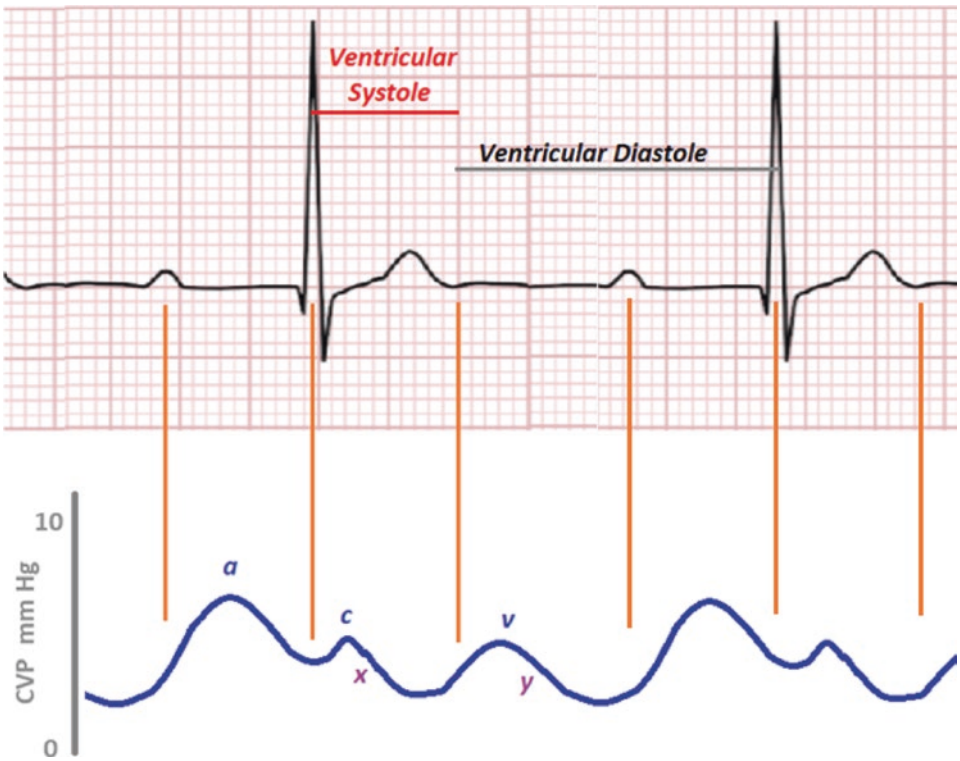

Fig. 16.11 Components of central venous pressure waveform with corresponding electrocardiogram

Following the *x descent*, atrial pressure rises slowly during the end of ventricular systole as the atrium fills with venous blood from the inferior and superior vena cava and is reflected in the *v wave*. After atrial filling, the tricuspid valve opens and a fall in atrial pressure occurs as the atrium is drained (*y descent*). The *a wave* follows again as the atrium contracts to "top off" the ventricle. The *a wave* occurs after the P wave of the ECG. The c wave, if present, occurs at the end of the QRS complex and the v wave occurs after the T wave of the ECG. To obtain a numerical value of the CVP, it is best to measure the mean pressure of the *a wave*.

16.2.2.1 Variations in CVP Waveform

Various conditions can be diagnosed or confirmed by careful examination of the CVP waveform. Arrhythmias can produce characteristic changes in the waveform. AV dissociation will cause significant elevations in atrial pressure as asynchronous atrial contraction occurs against a closed tricuspid valve. These elevations are referred to as *cannon a waves* on the CVP tracing (Fig. 16.12). They can also be seen during ventricular pacing where normal atrioventricular synchrony is lost. Large *a waves* may be also seen with a poorly compliant RV or in the setting of tricuspid stenosis.

Atrial fibrillation causes the a wave to be lost and the c wave to become more prominent. This is due to a greater atrial volume present at the onset of ventricular systole because of the absence of effective atrial contraction and emptying.

Multiple causes of large a waves on a CVP tracing include AV dissociation, RV noncompliance, asynchronous pacing, and tricuspid stenosis.

Tricuspid regurgitation causes additional filling of the atrium through the incompetent valve during ventricular isovolumic contraction and ejection. The CVP waveform will display an exaggerated c and v wave with an attenuated x descent, sometimes referred to as a cv wave. The entire waveform becomes "ventricularized" during severe tricuspid regurgitation and resembles the right ventricular pressure tracing (Fig. 16.13).

Tamponade physiology causes elevation of the CVP and equalization of diastolic filling pressures (CVP = RVEDP = PADP = PAWP). The *y descent* may be lost or blunted, owing to restricted ventricular filling due to a reduced chamber size and high diastolic pressures.

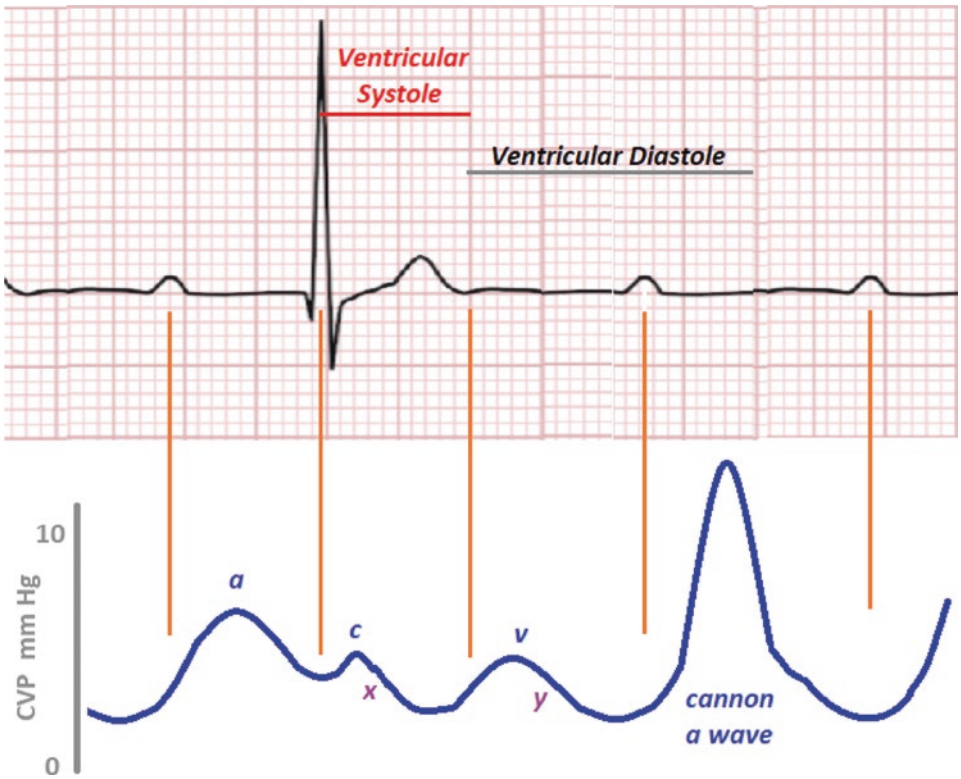

Fig. 16.12 Enlarged a waves, often referred to as cannon a waves, can be seen in arrythmias that produce atrioventricular dissociation. Examples include junctional rhythm, asynchronous cardiac pacing and complete AV block as seen in figure

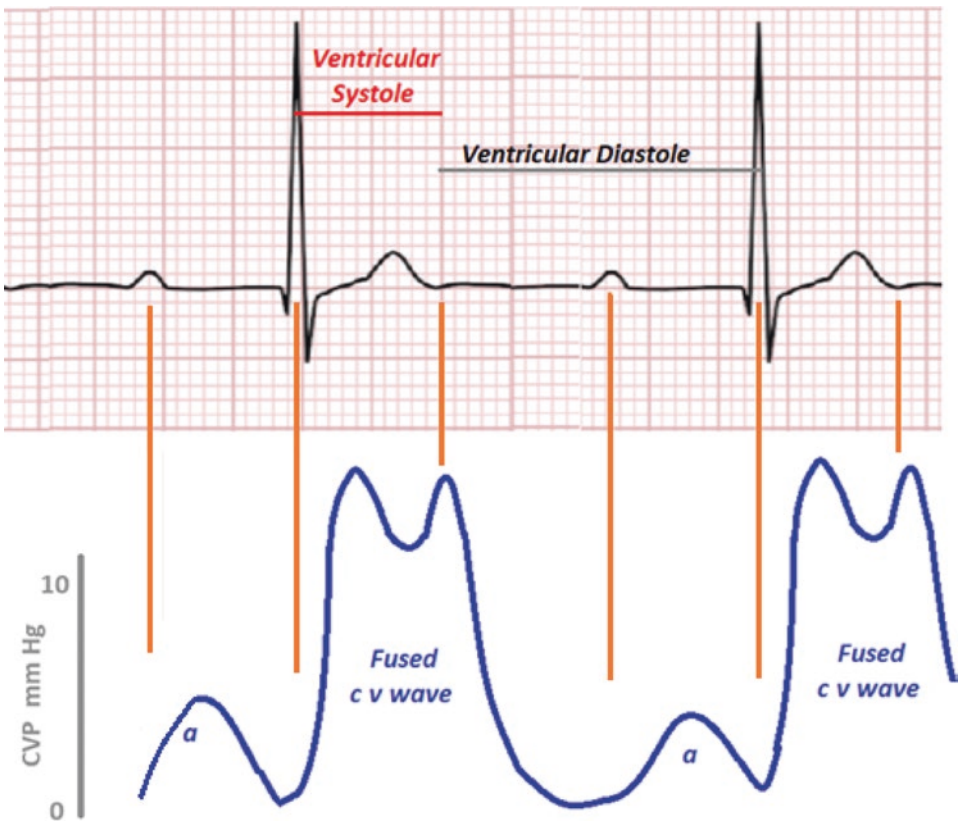

Fig. 16.13 Central venous pressure waveform demonstrating severe tricuspid regurgitation. Regurgitant blood entering the atrium during RV contraction results in an increased c and v waves (also referred to as the cv wave)

16.2.2.2 Complications of Central Venous Catheters

The placement of a central venous catheter (CVC) can be associated with significant morbidity. The placement should only occur after careful evaluation of CVC necessity and should never be deemed routine. Up to 15% of patients with central venous catheters experience complications. These complications can be categorized as mechanical, infectious, or thrombotic (Box 16.2).

Mechanical complications are more common when using the subclavian and internal jugular approach. Pneumothorax is of particular concern during subclavian cannulation. Cannulation of the right subclavian vein may offer some theoretical advantage as the lung apex is lower on the right and injury to the left-sided thoracic duct is avoided.

Although any CVC site is associated with a risk of both local infection and central line-associated bloodstream infection (CLABSI), the femoral site in postpubescent children is associated with an increased risk. CVC infections are more likely to occur during the maintenance of the catheter rather than during insertion of the catheter. Immunocompromise states and prolonged duration of catheter use substantially increase the CLABSI risk. Detailed review of CLABSI definitions, risks, prevention, and treatment is covered in ▶ Chap. 37, "Nosocomial Infections."

Box 16.2 Complications of Central Venous Catheters

Mechanical

- Arterial puncture
- Catheter occlusion due to precipitants
- Hematoma
- Hemorrhage (increased risk with coagulopathy)
- Pneumothorax/hemothorax (subclavian, internal jugular approach)
- Retention of foreign body (guidewire, catheter fragment)
- Arrhythmia
- Cardiac puncture/tamponade
- Non-thrombotic occlusion (kink)

Infectious

- Local site infection (cellulitis, thrombophlebitis)
- Central line-associated bloodstream infection (CLABSI) (bacteremia, sepsis)

Thrombotic

- Catheter occlusion due to thrombosis
- Venous thrombosis
- Embolization of thrombi

Occlusion by a thrombus within the catheter lumen is common, occurring in up to one-third of children with CVCs. The fibrinolytic tissue plasminogen activator (t-PA) has high efficacy and low risk in treating CVC occlusions in children. Several pediatric trials have found that t-PA, also known as alteplase, administered and allowed to dwell produced catheter clearance rates of over 80%. Typical pediatric alteplase doses range from 0.5 to 2 mg instilled into the lumen with dwell times ranging from 1 to 4 h followed by aspiration.

Owing to an increased use of CVCs, the rate of catheter-related venous thrombosis (CRVT) has increased dramatically over the last 20 years. CRVT is the most frequent cause of pediatric deep vein thrombosis. There are multiple factors that place the critically ill child at risk for CRVT (Box 16.3). The incidence of CRVT is increased in children who are prothrombotic (e.g., malignan-

cies) and those at risk for hyperviscosity (e.g., severe dehydration secondary to diabetic ketoacidosis). Small vessel size in relation to catheter size and venous stasis also have been implicated as conditions increasing CRVT risk in children. Technical issues during insertion play a significant role in thrombus initiation. Multiple failed attempts cause endothelial injury and tissue factor release from damaged endothelium. Tissue factor (thromboplastin) forms a complex with factor VIIa and activates factor IX and X, thereby initiating a procoagulant cascade that generates thrombin. Thrombin is a potent platelet activator. Activated platelets arrive at the area of endothelial injury and act to propagate the thrombus.

All mechanical, infectious, and thrombotic complications of CVCs can be dramatically reduced by a methodical approach to their insertion and maintenance. Evidence-based bundles that guide selection of sites, utilize ultrasound guidance during insertion, maximize adherence to aseptic techniques during maintenance, and promote daily review of line necessity will have the greatest impact in reducing institutional CLABSI rates.

CVC necessity should be reviewed daily. The risk of CLABSIs increases with the duration of time the catheter is left in place.

Box 16.3 Factors Increasing Risk of Catheter-Related Thrombosis

Underlying disease
- Malignancy
- Sepsis
- Hypercoagulable states (e.g., malignancy, nephrotic syndrome, cyanotic congenital heart disease, sepsis, endogenous anticoagulant deficiency)
- Dehydration (e.g., diabetic ketoacidosis)

Multiple initial attempts
Prolonged duration of use
Use of hyperosmolar solutions
Immobility
Procoagulant medications (e.g., oral contraceptives)

16.2.3 Invasive Measurement of Cardiac Output

Physical examination, waveform analysis, biochemical markers, and imaging provide indirect assessments of cardiac output (CO). At times, direct measurement of CO and specific intracardiac hemodynamic data is required. A review of the principles behind CO determination is important in understanding the utility and limitations of directly measuring CO. The following principles will be discussed:
- Conservation of mass
- Dye dilution method of determining cardiac output
- Thermodilution method of determining cardiac output
- Fick method of determining cardiac output

16.2.3.1 Conservation of Mass

The law of conservation of mass states that mass can neither be created nor destroyed but that it can be changed. The conservation of mass states that what comes out of a system must equal what went into the system plus or minus any change that occurred in between. Using this principle, the measurement of an unknown volume in a static system, such as a glass beaker, can be determined. If a substance is added to a solution, and the initial and final concentrations of the substance in the solution are known, then the volume of the beaker can be solved mathematically by:

$$\text{Volume}\ (\text{L}) = \frac{\text{Amount of substance added}\,(\text{gms})}{[\text{Final concentration}\,(\text{gms/L}) - \text{Initial concentration}\,(\text{gms/L})]}$$

Using the law of conservation of mass as a foundation, cardiac output can be determined by the dye dilution, thermodilution, or the Fick method.

16.2.3.2 Dye Dilution

In a non-static system, flow (Q) can be determined using the same conservation of mass principle. Instead of determining the static volume, the dynamic variable of flow can be determined in the following manner: A known amount of a substance is added to a flowing solution upstream and the change in concentration of the solution is determined by continuously plotting the concentrations from its first appearance (t_1) to its downstream disappearance (t_2) and then calculating the area under the curve (Fig. 16.14). The flow of a system can be solved mathematically by:

$$Q(\text{L/min}) = \frac{\text{Amount of substance}\,(\text{mg})}{\text{Average Concentration}\,(\text{mg/L})(t_2\ \text{min} - t_1\ \text{min})}$$

The equation to determine flow in a dynamic system essentially describes the dye dilution method for determining cardiac output. Substance I is the indicator dye that is injected into the venous side of the circulation ("upstream"). The heart serves as a mixer of the dye and sampling of the dye occurs at a distal artery ("downstream," which can be the pulmonary or systemic artery) where t(s) is the time in seconds between the initial and final sampling of the indicator dye concentration:

$$\text{CO}(\text{L/min}) = \frac{I\ \text{amount}\,(\text{g}) \times 60\,\text{s/min}}{\text{Concentration}\,(\text{g/L}) \times t\,(\text{s})}$$

Measurement of the dye in the distal artery is complicated by the recirculation phenomenon. Concentration of the dye will peak early on and subsequently drop off as the slower particles arrive. However, before all the slower ones

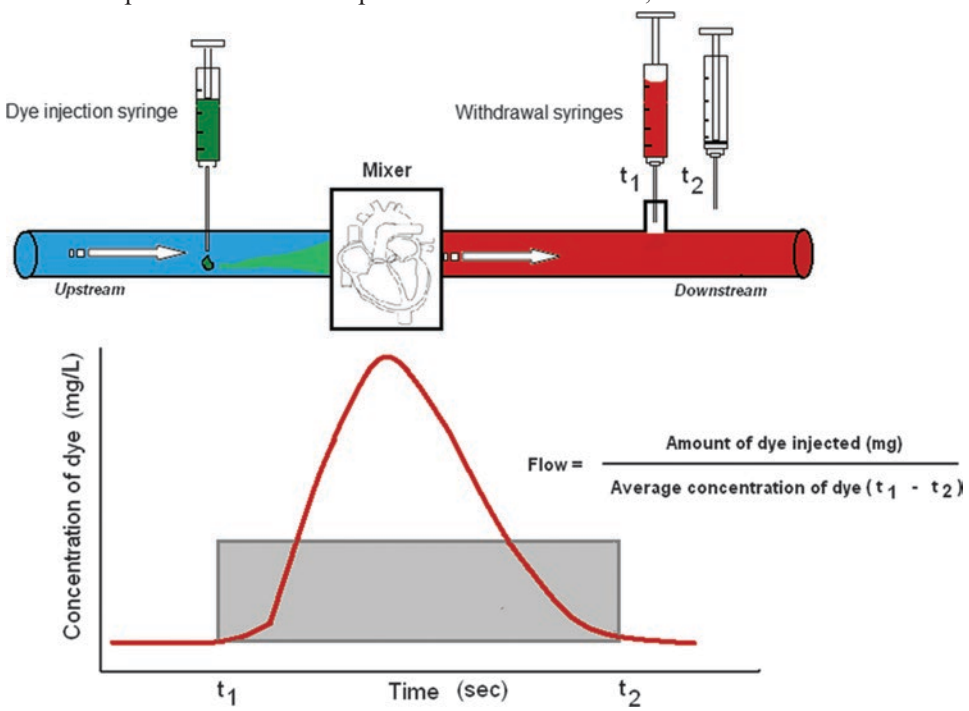

Fig. 16.14 Determination of flow using conservation of mass law. The flow of a system is determined by plotting changes in concentration of an added substance (dye) over time. Dye is added upstream to flowing venous blood. The dye is uniformly mixed by the heart. The concentration of the dye is measured serially downstream from the arterial port. Time one (t_1) is the time the dye is first detected and time 2 (t_2) is the time when it disappears. The average concentration of the dye over time is depicted in the gray box. Flow is determined using the modified conservation of mass equation

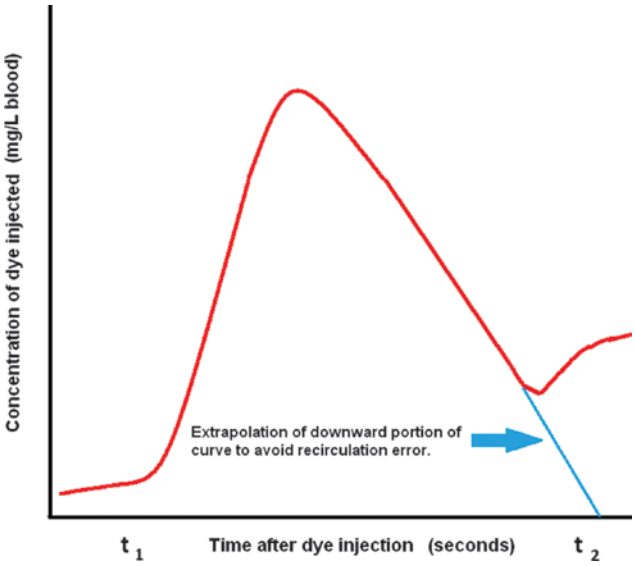

Fig. 16.15 To avoid error due to recirculation of dye, the downslope of the area under the curve is mathematically extrapolated to determine t_2

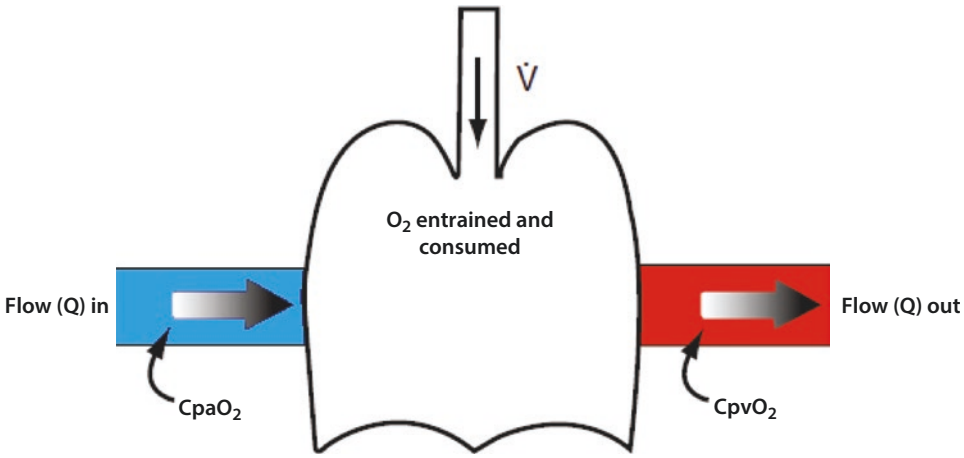

Fig. 16.16 Fick method for determination of cardiac output by using oxygen as the physiologic indicator. $C_{pa}O_2$ and $C_{pv}O_2$ are the oxygen content of pulmonary artery and pulmonary venous blood, respectively

arrive, the faster particles recirculate causing a falsely elevated value for the arterial concentration. To correct for this recirculation phenomenon, the downslope of the curve is extrapolated (Fig. 16.15).

16.2.3.3 Fick Method

In 1870, Adolph Fick, using the conservation of mass principle, described a physiological method of determining CO. Instead of using a dye as the "indicator," oxygen is used. He postulated, in a steady state, the quantity of oxygen in the pulmonary veins should equal the amount entering the lung via the pulmonary artery plus the amount of oxygen entrained during breathing (Fig. 16.16).

Cardiac output is calculated using the Fick method by accounting for flow (Q) and oxygen content (C_xO_2) on both ends of the circuit. For the pulmonary circuit, the "in" is equal to the pulmonary blood flow (Q_{pul}) multiplied by the pulmonary artery content of oxygen ($C_{pa}O_2$) plus the entrained oxygen from the lungs, which at steady state equals the oxygen consumed by the body's metabolism (VO_2). The VO_2 is the difference between the oxygen delivered to the tissue (arterial side) and the oxygen returned by the tissue (venous side). Since oxygen is added to blood across the pulmonary circuit, the entrained oxygen is added to the input.

The "out" is equal to the pulmonary blood flow (Q_{pul}) multiplied by the pulmonary vein content of oxygen ($C_{pv}O_2$). Since the output must equal the input plus or minus any change that occurred within the system, the equation can be described mathematically as:

$$\left[Q_{pul}\left(C_{pa}O_2\right)\right] + VO_2 = Q_{pul}\left(C_{pv}O_2\right)$$

$$\text{Solving for } Q_{pul}: \quad Q_{pul} = \frac{VO_2}{C_{pv}O_2 - C_{pa}O_2}$$

Systemic blood flow (Q_{syst}) can be similarly calculated. Assuming right heart output equals left heart output and the change in oxygen content across the systemic circulation equals ($C_{Ao}O_2 - C_{pa}O_2$), then Qsyst can be described mathematically as:

$$\text{Solving for } Q_{syst}: \quad Q_{syst} = \frac{VO_2}{C_{Ao}O_2 - C_{pa}O_2}$$

- $C_{Ao}O_2$ = aortic O_2 content (may also use distal arterial sample)
- $C_{pa}O_2$ = pulmonary artery O_2 content (may also use right atrial-superior cava junction sample)

If the PA is unable to be sampled, blood from the superior portion of the RA can be used. Sampling from the inferior RA should be avoided as it may result in a lower calculated oxygen content due to the entrainment of poorly saturated coronary venous blood in the sample. Furthermore, during shock states, sampling in the low portion of the RA may result in lower oxygen saturations than a true mixed venous saturation due to the inflow of poorly saturated IVC blood (see below discussion on mixed venous and central venous oxygen saturations).

Assuming no intracardiac shunt and ignoring the relatively low coronary artery blood flow returning to the right atrium via the coronary sinus, blood flow through the lungs is virtually equal to that through the body, that is, $Q_{pul} = Q_{syst}$ = cardiac output:

$$CO = \frac{VO_2}{C_{Ao}O_2 - C_{ra}O_2}$$

Measurement of cardiac output by the Fick method requires independent measurement of oxygen consumption (e.g., indirect calorimetry) or an assumption of normal oxygen consumption. The former is cumbersome, and the latter is not accurate since oxygen consumption varies greatly with critical illness. Due to these limitations, the Fick method is not routinely used as a bedside tool to calculate CO.

If an intracardiac shunt is present, the magnitude of the shunt can be calculated as Q_{pul}/Q_{syst}:

$$\frac{Q_{pul} = \dfrac{VO_2}{C_{pv}O_2 - C_{pa}O_2}}{Q_{syst} = \dfrac{VO_2}{C_{Ao}O_2 - C_{pa}O_2}}$$

Note that the estimation of the intracardiac shunt fraction does not require measurement of VO_2; it is expressed as follows after canceling VO_2, cross multiplying, and substituting oxygen saturation for oxygen content:

$$Q_{pul} / Q_{syst} = \frac{Sat_{Ao} - Sat_{ra}}{Sat_{pv\,or\,la} - Sat_{pa}}$$

The identification and quantification of a left to right (L to R) shunt can be of critical importance in understanding a child's underlying hemodynamic status. In the absence of lung disease, $Sat_{pv\ or\ la}$ is assumed to be 100%. Calculation of Q_{pul}/Q_{syst} may identify an otherwise unappreciated L to R lesion (e.g., PDA or major aortopulmonary collateral arteries). Postoperatively, the presence of an unexpected shunt following congenital heart disease surgery may reflect a residual lesion that requires repair (e.g., patch leak across a repaired VSD). The degree of a surgically created left to right shunt (e.g., modified Blalock-Taussig shunt) can also be quantified. $Q_{pul}/Q_{syst} > 1$ is indicative of some degree of L to R shunting. Generally, a Q_{pul}/Q_{syst} of > 2/1 is considered clinically significant.

16.2.3.4 Thermodilution

The thermodilution method to calculate CO utilizes the same fundamental principles employed in the derivation of the Fick equation. Rather than a change in dye concentration or oxygen content over time, thermodilution uses a change in blood temperature over time. Cardiac output can be determined using this method during right heart catheterization. In the absence of intracardiac shunting, right heart CO should equal left heart output. To perform thermodilution CO measurement, a fixed volume of fluid with a known temperature is injected into the right atrium. The downstream change in temperature is measured in the distal pulmonary artery. The change in temperature is plotted against time to generate a thermodilution curve (Fig. 16.17).

Using the data derived from the thermodilution curve, the CO can be calculated using the Stewart-Hamilton formula:

$$CO = \frac{V_1 (T_B - T_I) K_1 K_2}{\int (\Delta T_B dt)}$$

- V_1 = injectate volume
- T_B = blood temperature
- T_I = injectate temperature
- K_1 = empiric factor used to correct for warming of injectate through catheter
- K_2 = computation constants for the specific gravity and specific heat of blood and the injectate
- $\int \Delta T_B dt$ = change in blood temperature over time (AUC)

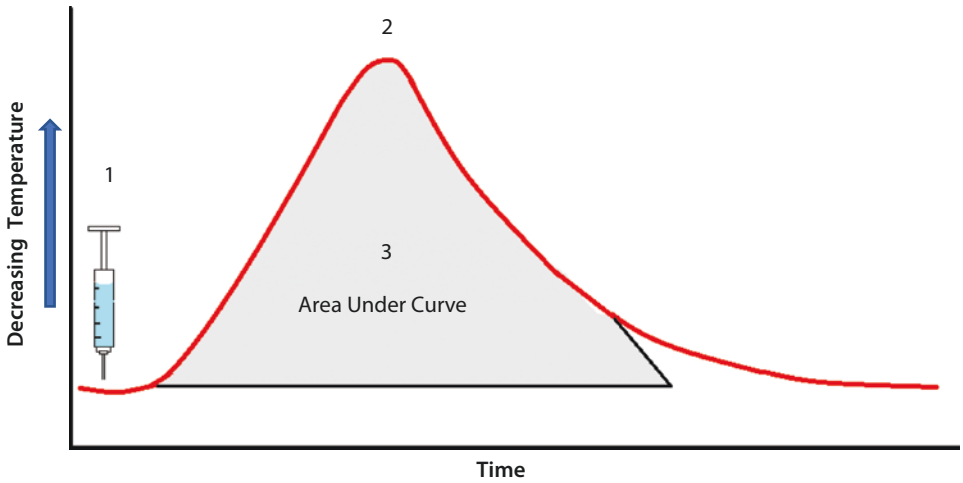

Fig. 16.17 Thermodilution curve. The curve represents a change from warmer blood temperature to cooler (due to the cold injectate) and then back to warmer temperature. 1. Bolus cold saline injected. 2. Peak temperature change which corresponds to the maximal amount of cooling ("thermodiluting") of the blood. 3. Calculated area under the curve. A normal curve characteristically shows a sharp upstroke from rapid injection of the injectate

16.2.3.5 Pulmonary Artery Catheterization

In 1970, Swan, Ganz, and colleagues introduced the use of bedside right heart catheterization for hemodynamic monitoring. Placement of a pulmonary artery catheter (PAC) allows for serial measurement of important cardiovascular parameters including cardiac output and intracardiac pressures. The technique gained widespread use in adults with acute cardiac dysfunction often secondary to coronary artery disease. However, its use declined after multiple studies failed to show a reduction in mortality and raised concerns of inappropriate use and unnecessary morbidity. In addition, the possibility of "overtreatment" was raised since interventions based on PAC data often did not demonstrate desired clinical benefit. In 2012, the American College of Cardiology Foundation published guidelines on the appropriate use of diagnostic pulmonary artery catheterization in adults. The primary indication is delineation of the presence and magnitude of cardiac dysfunction secondary to suspected acute coronary syndrome.

Due to its technical difficulties and lack of convincing efficacy data in children, the use of the PAC in the pediatric intensive care unit has fallen out of favor. The emergence of novel and less invasive forms of CO determination has further reduced its use. These novel methods include ultrasound-based techniques (e.g., transthoracic echocardiography) and those that utilize transpulmonary thermodilution and pulse contour analysis.

A pulmonary artery catheter should only be placed if a specific question regarding a patient's hemodynamic status cannot be satisfactorily answered by using standard hemodynamic tools and if the answer could impact therapy.

In selected patients, pulmonary artery catheters can be clinically useful allowing for the measurement of the CO, detection of shunts and pulmonary hypertension, and serial monitoring of intracardiac pressures. However, a pulmonary artery catheter should be employed judiciously by a highly experienced physician and for the shortest time period possible.

The interplay of the physiologic variables that a PAC attempts to quantify is valuable from an educational perspective. The appreciation of these interactions allows for a comprehensive understanding of hemodynamics and will be reviewed.

Cardiac Output Determination Using Pulmonary Artery Catheterization

Pulmonary artery catheterization utilizes thermodilution to determine CO. Although only right ventricular output is measured, in the absence of an intracardiac shunt, the right heart CO equals the left heart output. To perform thermodilution CO measurement, a fixed volume of fluid with a known temperature is rapidly injected into the RA via the proximal port of the pulmonary artery catheter. The downstream change in temperature is measured in the pulmonary artery by a thermistor located at the distal end of the catheter. After a thermodilution curve is generated, CO is determined using the Stewart-Hamilton formula.

Accurate CO determination is highly reliant on the area under the curve (AUC) generated during thermodilution. Since the AUC is in the denominator of the Stewart-Hamilton formula, the area under the curve (AUC) is inversely related to CO.

The calculated CO is highly reliant on the area under the curve (AUC) generated during thermodilution. The change in temperature over time determines the AUC. Since the AUC is in the denominator of the equation, the AUC is inversely related to CO. In high CO states, because of rapid mixing and rapid transit of the injectate (cold water), a peak drop in temperature is reached earlier, and the downslope is sharper. This yields a smaller AUC. In low CO states, the transit time diminishes, making the downslope less acute, and therefore the AUC increases (◘ Fig. 16.18). A fundamental assumption is that the fluid injected into the RA will have complete and anatomically appropriate mixing in the RV. Therefore, conditions such as shunts and tricuspid regurgitation can invalidate results.

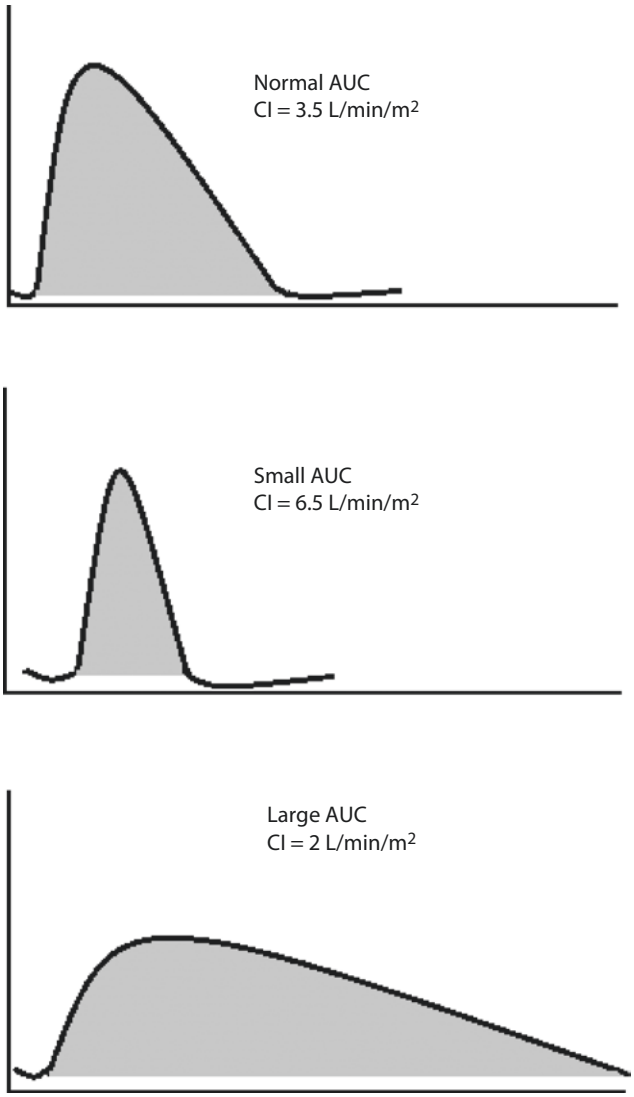

Fig. 16.18 Area under the curve (temperature versus time) and cardiac output relationships

Measuring CO via thermodilution requires expertise and a complete understanding of the technology and the myriad possible analytic errors. Common errors are listed in Table 16.2 and can be summarized as follows: any error leading to a smaller temperature change will decrease the AUC and thus falsely elevate CO, conversely, any error leading to a greater temperature change will increase the AUC and thus falsely lower CO.

When cardiac output is low, more time is required for the blood temperature to return to baseline, producing a larger area under the curve. With high cardiac output, the cooler injectate is carried more quickly through the heart, and the temperature returns to baseline faster. This produces a narrow high peak in the temperature curve with a smaller area under the curve.

Intracardiac Pressure Determination Using Pulmonary Artery Catheterization

Multiple intracardiac pressures can be obtained using a pulmonary artery catheter including right atrial pressure; right ventricular systolic, diastolic, and mean pressures; pulmonary artery systolic, diastolic, and mean pressures; and pulmonary artery occlusion pressure (PAOP) also referred to as the pulmonary capillary "wedge" pressure (Fig. 16.19 and Table 16.3).

The placement of a pulmonary artery catheter allows indirect assessment of left heart pressures. The PAOP is measured at a distal segment of the pulmonary artery and approximates left atrial pressure (LAP). In the absence of

Table 16.2 Potential pitfalls using thermodilution via pulmonary artery catheter to measure cardiac output

Technique error or physiologic anomaly	CO measurement	Explanation
Injectate volume too small	Falsely high CO	Thermistor detects less temperature change and returns to basal temperature sooner, leading to smaller AUC
Injectate volume too large	Falsely low CO	Thermistor detects greater temperature change and returns to basal temperature later, leading to larger AUC
Injectate colder than reference temperature	Falsely low CO	Thermistor detects greater temperature change and returns to basal temperature later, leading to larger AUC
Injectate warmer than reference temperature	Falsely high CO	Thermistor detects less temperature change and returns to basal temperature sooner, leading to smaller AUC
Injection rate too slow	Falsely high CO	Blood remains warm during slow injection. Thermistor detects return to basal temperature sooner, leading to smaller AUC
Tricuspid regurgitation	Falsely low CO[a]	Cold injectate is recycled from RV to RA leading to delayed downstream (PA) temperature change. Thermistor detects return to basal temperature later, leading to larger AUC
Right to left shunt	Falsely high CO	Premature loss of indicator across shunt. Thermistor detects return to basal temperature sooner, leading to smaller AUC
Left to right shunt	Falsely low CO	Cold injectate recycled back to right heart. Thermistor detects return to basal temperature later, leading to larger AUC

[a]Tricuspid regurgitation has also been reported to falsely elevate CO. Cold injectate is warmed as it contacts greater surface area of endocardium. Therefore, thermistor detects return to basal temperature sooner, leading to smaller AUC and falsely high CO

16

significant mitral valve disease, LAP approximates left ventricular end-diastolic pressure (LVEDP). If the PAOP and pulmonary artery end-diastolic pressure correlate well, the pulmonary artery diastolic pressure (PADP) can likewise be used as an indirect assessment of LVEDP. LVEDP is generally reduced with low preload or increased with poor LV compliance. Typically, the mean value of the PAOP is similar to the PADP. Therefore, in ideal physiological conditions:

PAOP approximates LAP, which in turn reflects LVEDP. If the PADP correlates with the PAOP, the PADP can be used to approximate LAP.

Pulmonary artery occlusion pressure approximates left atrial pressure which reflects left ventricular end-diastolic pressure (LVEDP). LVEDP is generally reduced with low preload or increased with poor LV compliance.

It is important that the catheter tip is in a branch of the pulmonary artery that is least affected by alveolar pressure. This condition is met near the base of the lung, West Zone 3, where $P_{art} > P_{vein} > P_{alv}$ (Fig. 16.20). Zone 3 provides a continuous column of blood from the balloon tip to the pulmonary vein and is least affected by alveolar pressure.

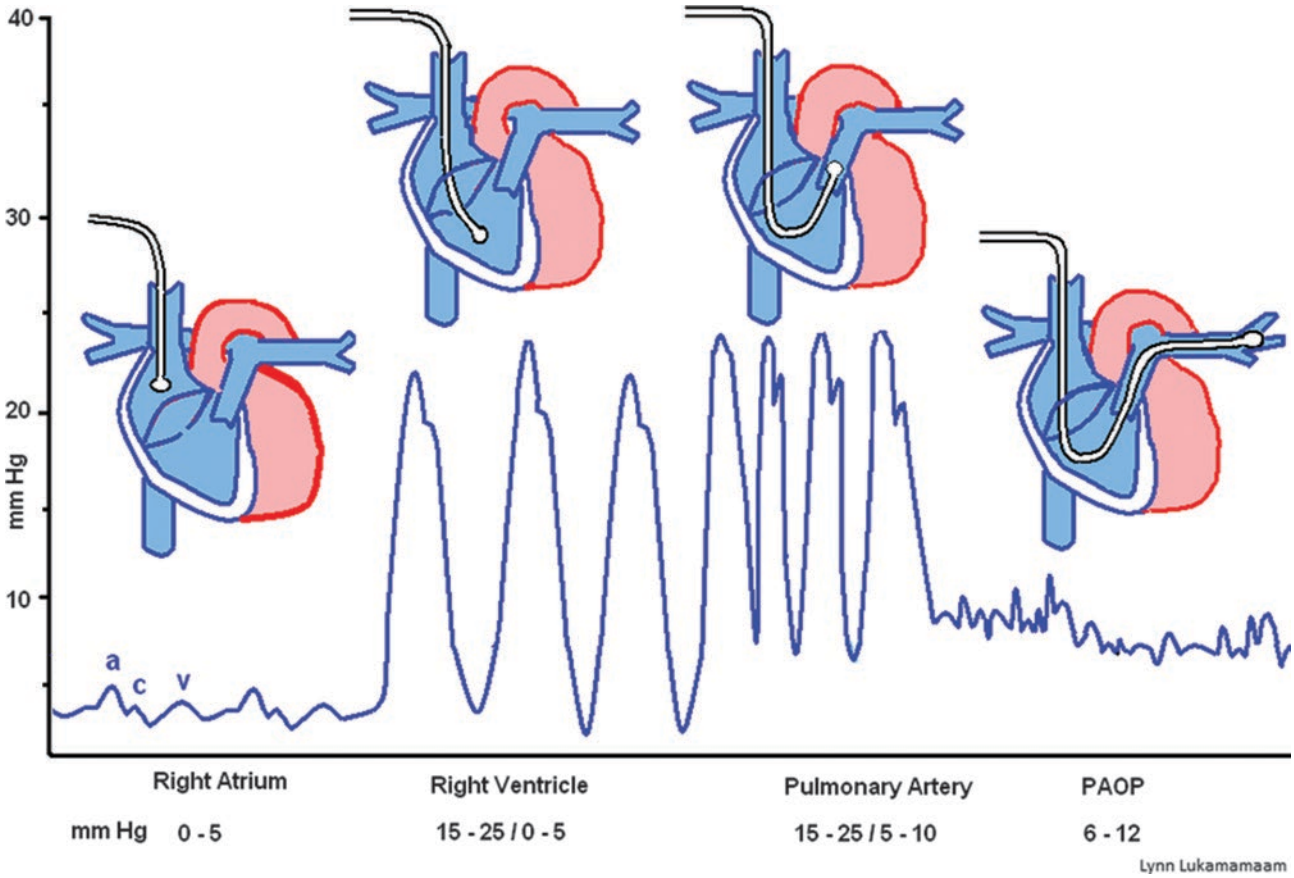

Fig. 16.19 Right heart pressure waveforms and normal values as obtained by pulmonary artery catheterization

Table 16.3 Normal ranges for intracardiac pressures and oxygen saturations

Parameter	Normal pressure range (mm Hg)	Normal oxygen saturation range
Right atrial pressure	0–6	65–80%[a]
Right ventricle systolic/diastolic	15–25/0–10	70–75%
Pulmonary artery systolic/diastolic	15–25/5–10	70–75%
Pulmonary wedge pressure	6–12	N/A
Left atrium	4–12	100%
Left ventricle	60–90[b]/4–12	100%

[a]Oxygen saturations in the central veins or right atrium should be measured using co-oximetry and interpreted according to the exact sampling site. With stable hemodynamics, superior vena cava oxygen saturations are generally lower than inferior vena cave saturations due to greater cerebral oxygen extraction. Catheters placed deep in the right atrium may have lower saturations due to coronary sinus blood sampling, which is normally markedly desaturated

[b]Ventricular pressures are age dependent and increase from infancy to older children

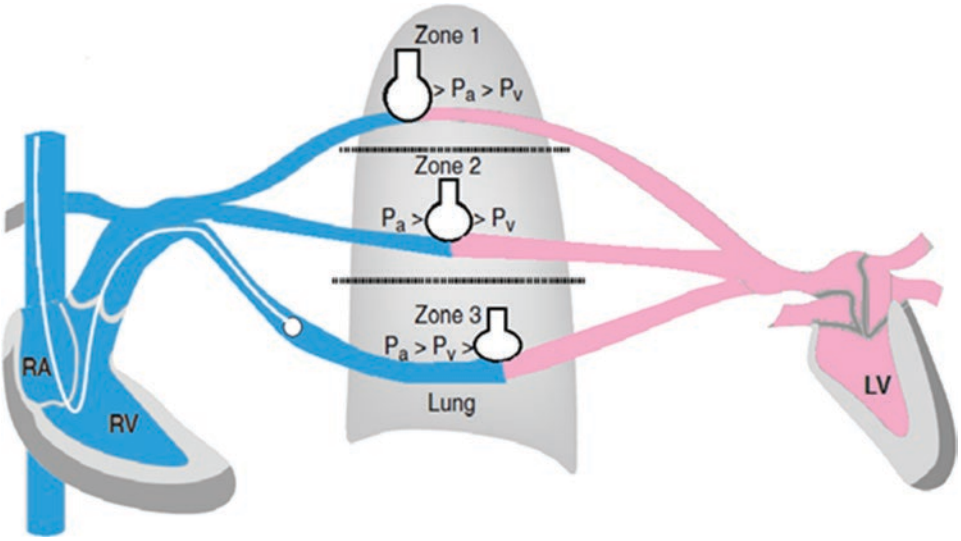

Fig. 16.20 West zones and the relationship of alveolar, pulmonary artery, and pulmonary vein pressures. *Zone 1*, $P_{Alveoli} > P_{artery} > P_{vein}$; *Zone 2*, $P_{artery} > P_{Alveoli} > P_{vein}$; and *Zone 3*, $P_{artery} > P_{vein} > P_{Alveoli}$. The PAC should ideally wedge into a branch of the pulmonary vasculature contributing to West Zone 3 of the lung. P_A, alveolar pressure; P_a, arteriolar pressure; P_V, pulmonary venous pressure; P Art, pulmonary artery; P Veins, pulmonary veins; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle

The tip of the PAC during PAOP measurement should be in Zone 3 near the base of the lung, where $P_{art} > P_{vein} > P_{alv}$.

Obtaining and Interpreting Pulmonary Artery Occlusion Pressures

When utilizing a pulmonary artery catheter, PAOP measurement is a proxy for left heart hemodynamics. A small balloon located at the tip of the pulmonary artery catheter facilitates the measurement of PAOP. The balloon is inflated and "floated" into a distal branch of the pulmonary artery where it becomes "wedged." With the balloon inflated, flow in the distal segment of the pulmonary artery is occluded creating a continuous uninterrupted column of blood from the tip of the pulmonary artery catheter to the left atrium. Once wedged, the waveform changes from a pulmonary artery waveform to an atrial waveform with characteristic ***a*** and ***v*** waves. Once the PAOP measurement is obtained, the balloon should be deflated to avoid distal pulmonary artery injury.

Abnormal PAOP values should be assessed concomitantly with stroke volume index (SVI). An elevated PAOP (>18 mm Hg) and low SVI are consistent with poor LV compliance and reduced contractility. A low PAOP < 6 mm Hg in the context of a low SVI is consistent with decreased LV preload.

A normal PAOP is 6–12 mm Hg. An abnormally high or low PAOP value should be assessed in the context of myocardial performance, which is best reflected by the stroke volume index (SVI, which is SV/body surface area). An elevated PAOP (>18 mm Hg) and decreased SVI suggest poor LV compliance and reduced contractility. Conditions such as congestive heart failure, myocardial infarction, cardiac tamponade, and cardiomyopathy are associated with a high PAOP and low SVI. In these circumstances, titrating fluid management to PAOP may help avoid worsening cardiogenic pulmonary edema. A low PAOP <6 mm Hg and decreased SVI are consistent with decreased LV preload that may occur in conditions such as dehydration, hemorrhage, and loss of effective circulating volume (e.g., third spacing of vascular fluid from capillary leak).

The interpretation of PAOP and its relationship to LVEDP requires an appreciation of possible coexisting pathologies and technical limitations (Box 16.4). Valvular disease, in particular, affects the ability of PAOP to accurately reflect LVEDP. PAOP will overestimate the LVEDP in mitral valve disease such as mitral stenosis. The high LAP (and therefore PAOP) associated with mitral stenosis does not reflect the end-diastolic volume or compliance of the LV.

The PAOP may at times not be reflective of the true LVEDP during states of increased pulmonary vascular resistance as the fluid column transmits the high pressure from the vascular bed and not the left heart. Aortic regurgitation causes PAOP to underestimate the true LVEDP. During aortic regurgitation, the mitral valve closes prematurely as retrograde aortic flow continues to fill the LV and add to LVEDP.

PAOP will also underestimate LVEDP in the setting of poor left ventricular compliance. Atrial contraction into a stiff ventricle produces a rapid rise in LVEDP that causes premature closure of the mitral valve. Therefore, the LA and PAOP will be "protected" from transmission of high LVEDP; however, a prominent ***a*** wave will be appreciated as the LA contracts against a poorly compliant LV. In this setting, measuring the ***a*** wave of the PAOP rather than the mean PAOP may be more reflective of LVEDP.

Box 16.4 Conditions Resulting in Discrepant PAOP and LVEDP Measurements

PAOP overestimates LVEDP

- Excessive positive mean airway pressure
- Placement of catheter in West Zone I or II
- Mitral valve disease
- Increased pulmonary vascular resistance
- Atrial myxoma

PAOP underestimates LVEDP

- Aortic regurgitation
- Low LV compliance

Pulmonary Artery Diastolic Pressure (PADP)

The PADP is sometimes used in place of the PAOP to assess LVEDP. The pulmonary artery waveform is characterized by a rapid upstroke and a rounded peak followed by a rapid downstroke as right ventricular blood is ejected into the pulmonary artery. Similar to the aortic arterial waveform, a notch is observed on the downslope and is caused by the closure of the pulmonic valve (recall that the closure of the aortic valve causes the incisura present on the aortic waveform). The waveform pressure falls off progressively during diastole. To identify pulmonary artery peak systolic and end-diastolic pressures, the corresponding ECG tracing should be examined; end-diastole occurs at the end of the QRS complex and peak systole occurs within the T wave.

It is technically easier and safer to measure PADP rather than performing repetitive wedging to obtain serial PAOPs. In addition to PAOP limitations previously described, PADP may be altered by other pathologies. Pulmonic valve regurgitation causes PADP to underestimate LVEDP because of bidirectional runoff of pulmonary artery blood during diastole. Tachycardia can also cause PADP to overestimate the LVEDP. Tachycardia causes a shorter diastole so there is less time for blood to flow from the pulmonary veins to left heart, and therefore, the pressure gradients do not have time to equilibrate and PADP will increase. Consequently, tachycardia-induced increase in PADP overestimates LVEDP.

Derived Hemodynamic Variables

In addition to monitoring intracardiac pressures and CO determination, data obtained from a pulmonary artery catheter provides variables for multiple hemodynamic calculations such as systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR), which are typically normalized to BSA (SVRI and PVRI). Because of the multiple factors that affect afterload, true afterload cannot be measured using a pulmonary artery catheter. However, systemic and pulmonary vascular resistance, a component of LV and RV afterload, respectively, can be calculated using a pulmonary artery catheter.

Table 16.4 Derived hemodynamic calculations

Variable	Formula	Normal range
Cardiac index (CI)	CO/BSA[a]	3.0–5.5 L/min/m^2
Stroke volume (SV)	CO/HR	60–100 mL/beat
Stroke volume index (SVI)	CI/HR or SV/BSA	30–60 mL/beat/m^2
Systemic vascular resistance index (SVRI)[b, c]	MAP – RAP/CI × 80	800–1600 dyne-s/cm^5/m^2
Pulmonary vascular resistance index (PVRI)[b, c]	MPAP – PAOP/CI × 80	80–200 dyne-s/cm^5/m^2
Arterial oxygen content (CaO_2)	Hgb × 1.34 mL O_2/g Hgb × SaO_2 + (.003 × PaO_2)	17–20 mL/dL
Mixed venous oxygen content ($CmvO_2$)	Hgb × 1.34 mL O_2/g Hgb × SvO_2 + (.003 × PvO_2)	12–15 mL/dL
Oxygen delivery index (DO_2I)[d]	CaO_2 × CI × 10	550–680 mL/min/m^2
Arterial-mixed venous oxygen difference (a-vDO_2)	CaO_2 – CvO_2	3–5 mL/dL or 30–50 mL/L
Oxygen extraction ratio (O_2ER)	(CaO_2 – CvO_2)/CaO_2 or (SaO_2 – SvO_2)/SaO_2 or VO_2/DO_2	0.24–0.28
Oxygen consumption index (VO_2I)[d]	(CaO_2 – $CmvO_2$) × CI × 10	120–200 mL/min/m^2

[a]Cardiac output in relation to body size is high in the neonatal period. The cardiac index of a newborn slowly diminishes to adult values (3.0–4.0 L/min/m^2) by early adolescence

[b]Both SVR and PVR are typically indexed to body surface area (SVRI and PVRI). The ranges of normal values for SVRI and PVRI vary accordingly based on the child's body surface area and age. By normalizing the calculation using CI rather than CO, the variation by age is less with PVRI and SVRI compared with PVR and SVR

[c]To convert dyne-s/cm^5 to Wood units, divide by a factor of 80. The normal range of SVRI is approximately 10–20 Wood units/m^2 and PVRI is approximately <1–3 Wood units/m^2

[d]Since CI is measured in L/min and oxygen content is measured in ml/100 mL of blood, the formula includes multiplication by "10" to convert the oxygen content to ml/L of blood

The quantification of SVRI can aid in tailoring inotropic, pressor, and vasodilator therapy. Similarly, therapies directed at treating pulmonary hypertension (e.g., hyperoxia, alkalosis, nitric oxide, etc.) can be monitored with continuous PVRI data. Hemodynamic parameters that can be calculated during pulmonary artery catheterization are summarized in Table 16.4.

The potential complications of pulmonary artery catheter placement are numerous and include life-threatening arrhythmias and pulmonary artery or intracardiac injury. Complications may occur during insertion and manipulation or be related to maintenance of the pulmonary artery catheter (Box 16.5). Although not a true complication, a potential risk in using the PAC for decision making is the use of erroneous data or overestimating the clinical significance of appropriately obtained data.

Box 16.5 Complications Related to Pulmonary Artery Catheter Insertion and Use

Pulmonary artery catheter complications
Arrhythmias
Heart block
Inability to withdraw catheter due to knotting
Valve injury
Endocardial injury
Pulmonary infarction
Endocarditis
Pulmonary artery rupture
Pulmonary artery pseudoaneurysm
Misinterpretation of the data

16.2.4 Novel Techniques for Cardiac Output Assessment

16.2.4.1 Pulse Contour Analysis

Pulse contour analysis is based on the principle that the area under the curve (AUC) of the systolic portion of an arterial waveform correlates with the stroke volume. The estimation of the stroke volume from pulse contour analysis during heart rate monitoring allows for beat-to-beat CO assessment. A limitation of this technology involves the contribution of arterial compliance to the arterial pulse waveform. Recall that the arterial waveform is produced by LV ejection stroke volume *and* the pulsatile waves reflecting back from arterial walls. The reflection of pulse waves off arterial walls is dependent upon the compliance characteristics of the arterial tree. The aortic and arterial compliance is highly variable between individuals and during disease states. The compliance of the aorta and the distal arteries impacts the shape of the waveform with less compliant arteries causing an increase in the systolic peak. Due to the dynamic nature of arterial compli-

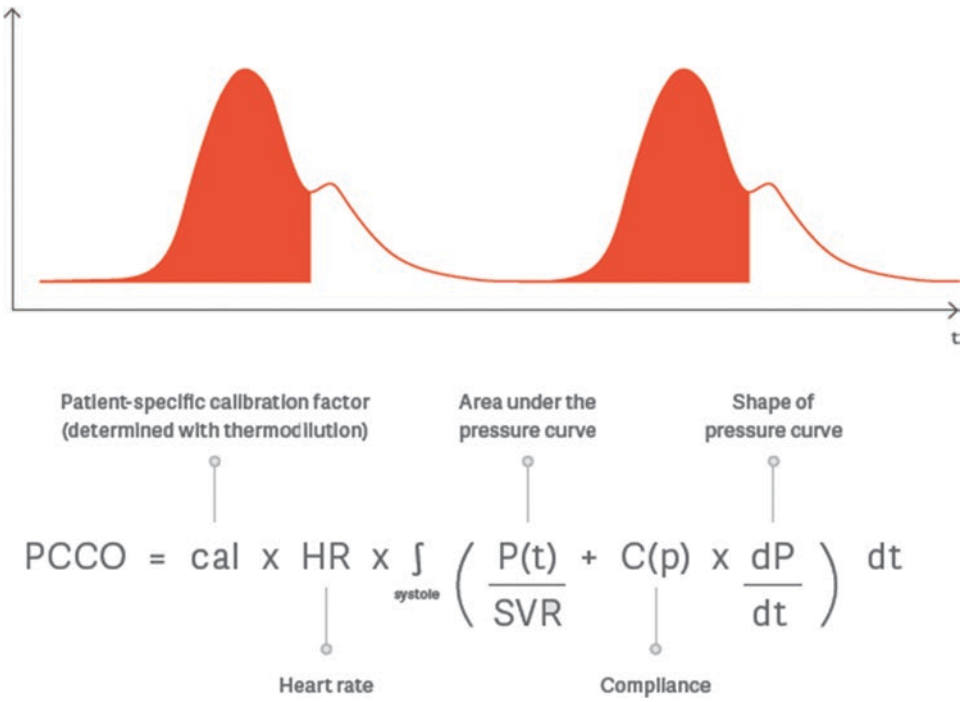

Fig. 16.21 Graphical and mathematical display of improved pulse contour algorithm for determination of cardiac output. Pulsion Medical Systems

ance, the use of pulse contour analysis requires serial calibration with another method of CO determination. Serial calibration is especially important in the critically ill patient due to patient-specific differences in the arterial physical properties, changes in the vascular tone, and varied volume status.

There are two methods for calibration that are currently in use. The pulse-induced contour cardiac output (PiCCO) system uses the transpulmonary thermodilution method to calibrate CO with pulse contour analysis. Transpulmonary thermodilution (TPTd) uses the principle of thermodilution to determine CO but measures temperature changes in a central artery (usually the femoral) following an injection of a cold saline bolus into a central vein with the injectate traversing the pulmonary circulation. Multiple studies found the PiCCO system to correlate well with values obtained using the direct Fick and pulmonary artery catheter-based thermodilution methods. The mathematic algorithm used to determine beat-to-beat CO has undergone refinements that have added to its reliability (◘ Fig. 16.21). In addition, preload can be measured periodically along with intrathoracic blood volume (ITBV), global EDV (GEDV), and extravascular lung water (EVLW).

The lithium dilution cardiac output (LiDCO™) system uses a lithium calibration technique. With lithium cardiac output determination, instead of temperature change over time producing an AUC, the change in lithium concentration over time produces an AUC that is used to compute CO. During calibration, a small known dose of lithium is injected into a vein. In a peripheral artery, an ion-selective electrode sensor plots the concentration of lithium over time to calculate the CO. Once a calibration factor is determined, the system calculates CO using a proprietary algorithm that converts an arterial blood pressure waveform-based signal into an arterial blood flow measurement. A limitation of this technique is the need for lithium injection, which is less safe and more costly than saline injection.

Other systems (e.g., Flo Trac/Vigileo, LiDCOrapid) do not use a second method for CO determination for calibration. In contrast to the PiCCO and LiDCO, these systems use algorithms that integrate physiologic assumptions based on the patient's demographic and physical characteristics to predict stroke volume. These physiologic assumptions include compliance and systemic vascular resistance.

Both the calibrated and non-calibrated systems continue to undergo validation studies to assess their ability to estimate CO in different clinical conditions. Studies have demonstrated that during hemodynamic instability, measured CO based on continuous arterial pulse contour analysis shows only limited agreement with PAC-based thermodilution. The calibrated systems may provide more accurate measurements than the non-calibrated systems. Limited data exist in children; however, pulse contour analysis has shown poor agreement with PAC-based cardiac output determination in children with congenital heart disease, pulmonary hypertension, and cardiomyopathy. Currently, both calibrated and non-calibrated pulse contour technologies are not recommended for routine use in the pediatric intensive care unit.

Pulse contour waveform analysis evaluates the AUC of the systolic portion of the arterial waveform and equates it to stroke volume. The estimation of the stroke volume from pulse contour analysis during heart rate monitoring allows for beat-to-beat CO assessment. The compliance of the arterial tree must be considered when using pulse contour analysis.

Due to the dynamic nature of arterial compliance, the use of pulse contour analysis requires serial calibration with another method of CO determination such as transpulmonary thermodilution.

16.2.4.2 Transesophageal Doppler Echocardiography

Cardiac echocardiography is a proven tool in the evaluation of cardiac anatomy and function in critically ill children. Transesophageal Doppler echocardiography (TDE) measures aortic flow velocity via a carefully positioned Doppler probe. Cardiac output can then be calculated by the product of the aortic velocity time integral (VTI), the cross-sectional area (CSA) of the aorta, and the heart rate:

$$\text{CO} = \text{Aortic CSA cm}^2 \times \text{VTI} \times \text{heart rate}$$

These measurements require optimal positioning of the probe and precise timing during systole when flow is measured. The technique requires specialized training and equipment. Although studies in children have found good correlation between TDE and thermodilution, the technique is highly dependent upon proper positioning of the probe with overestimation and underestimation of CO not uncommon. The value of TDE may be limited in clinical practice due to the need for precise probe placement, lack of continuous data, need for sedation during probe placement, and operator variability.

16.2.4.3 Inadequate Oxygen Delivery Index (IDO_2)

At every critical care bedside, a plethora of real-time continuous physiologic data is being recorded. The ability to integrate and analyze meaningful portions of this data to improve outcomes is increasingly challenging. Clinical support algorithms based on reliable continuous data are being developed to identify adverse clinical trends that may lead to poor outcomes.

An example of software that analyzes continuous physiologic data is data aggregation and visualization software (Etiometry, Inc., Boston, MA) which is FDA cleared for use in critically ill children. The software collects, visualizes, and stores PICU data in near real time and provides a patient-specific risk of inadequate delivery of oxygen (IDO_2). Ten physiologic values from the bedside monitor and standard laboratory values are inputted into an algorithm, and an IDO_2 index is computed in real time. The index is calculated at 5 s intervals and provides the probability (between 0 and 100) of the measured mixed systemic venous saturation being less than 40%. Therefore, an increasing IDO_2 index value may identify children at increased risk of inadequate oxygen delivery and tissue hypoxia.

Although the technology appears promising, early study results are mixed. A retrospective cohort study demonstrated that an increasing IDO_2 in neonates who were post-operative from congenital heart disease repair was associated with an increased risk of cardiac arrest. However, a retrospective study comparing a modified low cardiac output syndrome score (LCOSS) and the IDO_2 found the LCOSS had a stronger association with postoperative adverse events. The LCOSS uses postoperative tachycardia, low urine output (<1 mL/kg/h), low temperature (<30 °C), raised inotropic requirement, increased volume administration (>30 mL/kg/d), decreased NIRS measurement (cerebral and renal NIRS <50% and 75% of arterial saturations, respectively), and elevated arterial lactate (>2 mmol/L) as markers of deterioration. The brain and myocardium are high extractors, consuming 35–40% and 50–65% of oxygen delivered respectively, whereas the skin and kidney are low extractors.

16.2.5 Cardiac Biomarkers

16.2.5.1 Mixed Venous and Central Venous Oxygen Saturation

At rest, the body normally extracts only 25% of the total amount of oxygen delivered. This can be remembered by recalling that each hemoglobin molecule carries four oxygen molecules, one of which is normally consumed during transit from the arterial to venous circulation. Provided that cardiac output is adequate to meet tissue oxygen demand and the hemoglobin concentration is in the normal range, only approximately 25% of the delivered oxygen is consumed.

In a healthy steady state, DO_2 is luxurious when compared to oxygen demand with approximately 75% of the oxygen delivered remaining unused. Oxygen extraction varies across organ beds. The brain and myocardium are high extractors, consuming 35–40% and 50–65% of oxygen delivered respectively, whereas the skin and kidney are low extractors. A true mixed venous

Provided that cardiac output is adequate to meet tissue oxygen demand and the hemoglobin concentration is in the normal range, only approximately 25% of the delivered oxygen is consumed.

Oxygen extraction varies across organ beds. The brain and myocardium are high extractors, consuming 35–40% and 50–65% of oxygen delivered respectively, whereas the skin and kidney are low extractors.

saturation ($SmvO_2$) allows for a global assessment of the body's oxygen extraction. The measurement must occur after venous return from all organ beds is "mixed" to avoid having the $SmvO_2$ reflect a single organ bed's oxygen extraction. Using a pulmonary artery catheter, the $SmvO_2$ is obtained in the pulmonary artery. Without a pulmonary artery catheter in place, the pulmonary artery $SmvO_2$ can be closely approximated by sampling venous blood from a central catheter with its tip at the SVC-RA junction. When a venous blood oxygen saturation is determined from the SVC-RA junction or other central site, it is referred to as a central venous oxygen saturation ($ScvO_2$) or right atrial saturation. Since venous oxygen saturation is on the steep portion of the oxyhemoglobin dissociation curve, it is essential that the oxygen saturation is measured using co-oximetry rather than the calculated oxygen saturation from a standard or bedside blood gas machine since critical illness can alter the normal dissociation curve.

Central venous oxygen saturation values below 60% indicate increased oxygen extraction by the tissues. This may be due to either a decrease in oxygen delivery or an increase in tissue oxygen demands.

The normal oxygen saturation of central venous blood returning to the right heart ($ScvO_2$) is between 65% and 75%, assuming normal arterial oxygen saturation. Central venous oxygen saturation values below 60% indicate increased oxygen extraction by the tissues. This may be due to either a decrease in oxygen delivery or an increase in tissue oxygen demands. Common causes of decreased oxygen delivery include reduced cardiac output, anemia, and/or low arterial oxygen saturation (hypoxemia). Alternatively, a low $ScvO_2$ may reflect increased tissue oxygen demands such as due to increased work of breathing, fever (oxygen consumption increases by ~10% per degree increase in temperature), seizures, shivering, pain, physical activity, or catheter migration near or into the coronary sinus. Low $ScvO_2$ values below 60% are often accompanied by acidosis due to a shift to anaerobic metabolism (see lactate below). A normal or high $ScvO_2$ may also be associated with tissue hypoxia. An elevated $ScvO_2$ may occur with appropriate or even supranormal DO_2 in the setting of impaired cellular and/or mitochondrial oxygen uptake (e.g., cyanide toxicity). In addition, the ScvO2 may be preserved if microcirculatory shunting results in excess blood flow to some tissue beds while other regions remain ischemic. This microcirculatory shunting may be observed in the setting of severe vasodilatory sepsis.

ScvO2 may vary based on catheter position, disease state, and even age of the child. In the healthy state, the superior vena cava (SVC) has a slightly lower venous oxygen saturation than the inferior vena cava (IVC) in part due to high cerebral oxygen extraction and low renal oxygen extraction.

It is important to note that, although a good surrogate for $SmvO_2$, $ScvO_2$ may vary based on catheter position, disease state, and even age of the child. In the healthy state, the superior vena cava (SVC) has a slightly lower venous saturation than the inferior vena cava (IVC) in part due to high cerebral oxygen extraction and low renal oxygen extraction. This is especially true in small children where the relatively large growing brain is a major oxygen extractor. Therefore, the $SmvO_2$ is greater than $ScvO_2$ by about 2–3%. The relationship between the SVC and IVC saturation may reverse in the setting of shock (Fig. 16.22). In adults with cardiogenic or hypovolemic shock, mesenteric and renal blood flow decreases, and oxygen extraction increases causing the IVC saturation to become lower than the SVC. Therefore, during certain shock states, the $ScvO_2$ may become greater than $SmvO_2$. Despite these differences, most authors believe that changes in $ScvO_2$ closely reflect changes in $SmvO_2$ and therefore remain a good marker of oxygen delivery and extraction.

In summary, a decreased $ScvO_2$ is associated with decrements in cardiac output, hemoglobin concentration, and/or arterial oxygen saturation, and it varies inversely with oxygen consumption. It is an extremely useful marker for tissue hypoperfusion. Measurements can be followed serially, or continuously using a fiber-optic central venous catheter, to assess the impact of therapeutic maneuvers such as fluid resuscitation, blood transfusion, and inotropic support (Table 16.5). Achievement of $ScvO_2 \geq 70\%$ is a therapeutic endpoint in the resuscitation from sepsis and septic shock as articulated in the Surviving Sepsis Campaign sponsored by the Society of Critical Care Medicine.

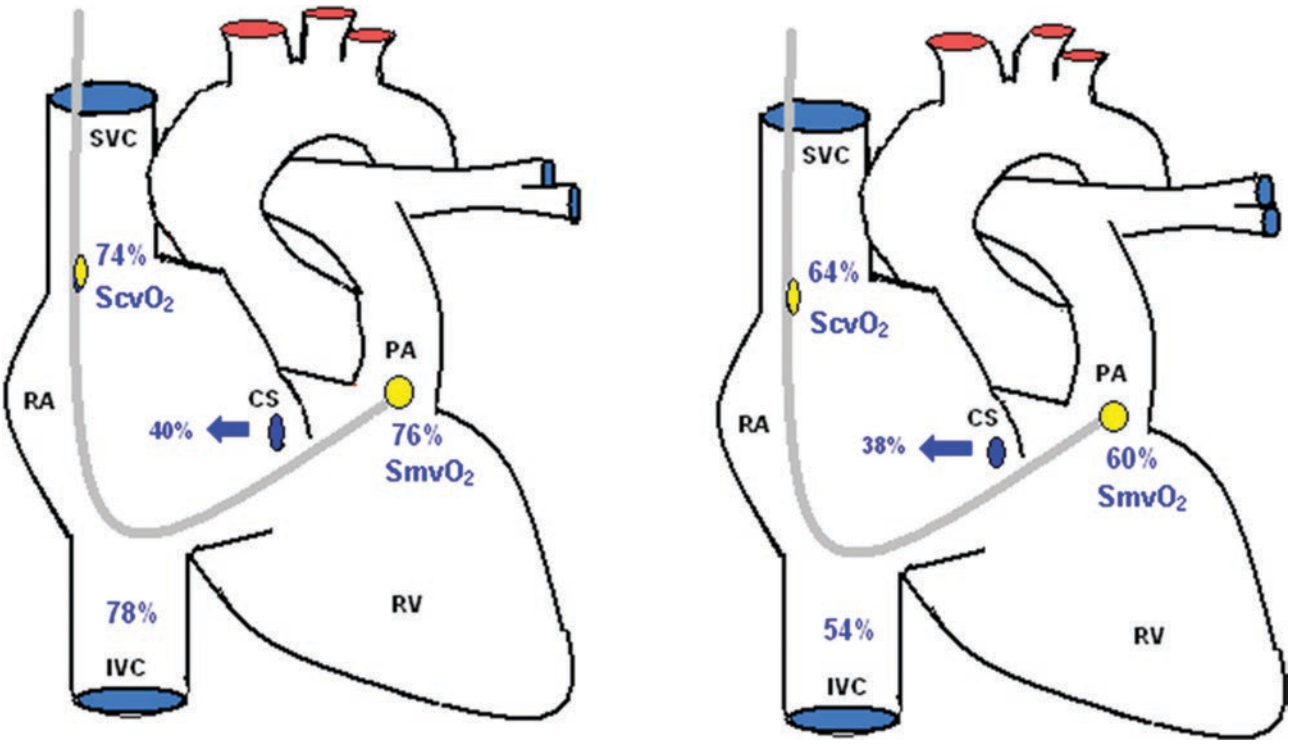

Fig. 16.22 Relationship between central venous oxygen saturation ($ScvO_2$) and mixed venous saturation ($SmvO_2$) during health (left) and cardiogenic or hypovolemic shock (right). Normally, the $SmvO_2$ will be slightly higher than the $ScvO_2$, whereas shock states may produce a reversal of this relationship. SVC superior vena cava, IVC inferior vena cava, RA right atrium, CS coronary sinus, RV right ventricle

Table 16.5 Troubleshooting abnormalities in mixed or central venous oxygen saturations

Low $ScvO_2$	High $ScvO_2$
Anemia	High cardiac output states
Low cardiac output states	Defect in oxygen extraction
Hypoxemia	Decreased metabolic rate
Increased metabolic rate	Supranormal oxygen delivery

16.2.5.2 Lactate

Lactate metabolism is complex, and its production is highly dependent upon the physiological milieu at the cellular level. Although lactic acidosis is often used as a marker of cellular hypoxia, lactate may be elevated in non-hypoxemic environments without accompanying metabolic acidosis. It is important to recognize that the laboratory measures only the lactate anion; thus, an increased lactate concentration may not always be accompanied by metabolic acidosis.

A biochemical review of lactate production is helpful in understanding hyperlactatemia during critical illness. Cellular respiration is the process by which glucose is utilized to produce cellular energy in the form of adenosine triphosphate (ATP) (Fig. 16.23). The cytosolic component of the process does not require oxygen and consists of glycolysis, whereas the mitochondrial portion is highly dependent on oxygen and consists of the tricarboxylic acid

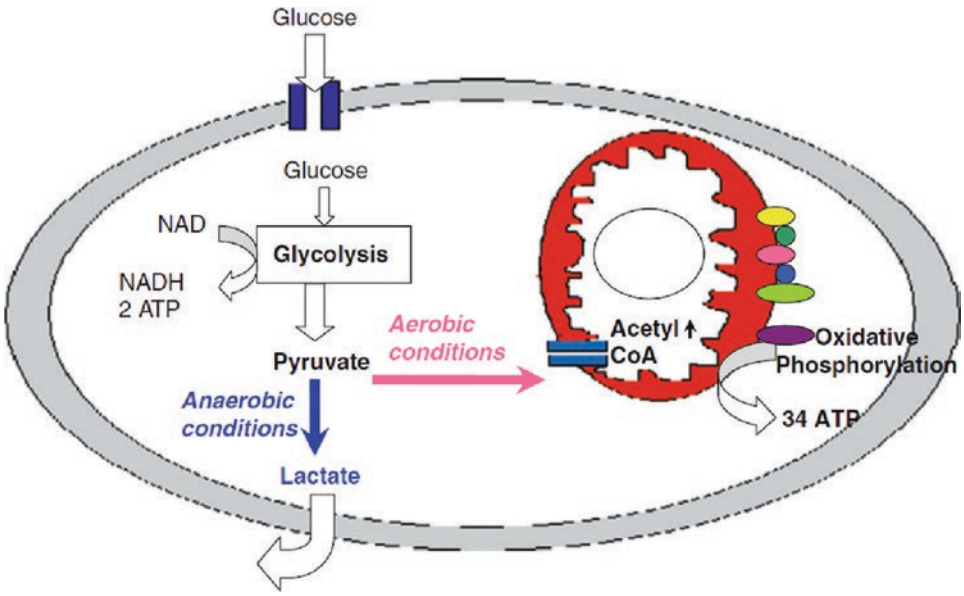

Fig. 16.23 Overview of cellular respiration and lactate production

(TCA) cycle (also known as citric acid cycle or Krebs cycle) and oxidative phosphorylation (also referred to as mitochondrial membrane electron transport). During glycolysis, glucose is converted to pyruvate with the net production of 2 molecules of ATP. Most of the energy production from glucose metabolism occurs in the mitochondria during the tricarboxylic acid cycle (2 ATP) and oxidative phosphorylation (32 ATP). A small amount of lactate is normally produced during glycolysis, but it is rapidly metabolized by the liver and excreted by the kidney. Thus, normal serum lactate levels remain less than 2 mmol/L.

During hypoxia, shunting of pyruvate towards anaerobic metabolism results in an elevated plasma lactate and an elevation in the lactate-to-pyruvate ratio (normal 10:1). Elevated lactate in the setting of acidosis has been used as a marker of tissue hypoperfusion.

Lactate production is increased dramatically during hypoxia. Due to low intracellular oxygen tension, pyruvate can no longer undergo aerobic metabolism in the mitochondria and is shunted toward lactate production. Hypoxia is also known to decrease the activity of pyruvate dehydrogenase, which converts pyruvate to acetyl-CoA. The continued shunting of pyruvate toward lactate production results in an elevated plasma lactate and an elevation in the lactate-to-pyruvate ratio (normal 10:1).

Lactic acidosis due to hypoperfusion has been traditionally referred to as type A lactic acidosis and is associated with an elevated lactate-to-pyruvate ratio. Elevated lactate in the setting of acidosis has been used as a marker of tissue hypoperfusion and anaerobic metabolism. Multiple studies have correlated rising lactate levels and mortality in patients with a variety of critical illnesses. However, studies utilizing lactate as a resuscitation endpoint to improve survival have been inconclusive.

Hyperlactatemia in critical illness may not be solely due to cellular hypoxia. Non-hypoxemic (type B lactic acidosis) elevations of serum lactate may occur during normal perfusion or after hypoperfusion has been corrected.

Hyperlactatemia in critical illness may not be solely due to cellular hypoxia. Non-hypoxemic (type B lactic acidosis) elevations of serum lactate may occur during normal perfusion or after hypoperfusion has been corrected. Lactate production may be increased during states of "hyperglycolysis." Excessive catecholamine states have been found to stimulate glycolysis at a rate that exceeds the oxidative capacity of the mitochondria and lead to type B lactic acidosis. Increased skeletal muscle and hepatic glycolysis results in increases in both pyruvate and lactate production, thus maintaining the lactate-to-pyruvate ratio. The resultant increased pyruvate is then metabolized to lactate at a much higher than normal rate. Hyperadrenergic states are common in the

pediatric ICU and include exogenous administration of catecholamines and disorders associated with a vigorous systemic inflammatory response (e.g., acute lung injury, trauma, sepsis, burns). Type A or type B lactic acidosis may be further accentuated in the setting of decreased hepatic metabolism and/or renal clearance.

Hyperlactatemia may also occur due to drug or toxin effects. Any drug that interferes with the TCA cycle or oxidative phosphorylation may lead to excessive lactate production. These medications include metformin, salicylates, HMG CoA reductase inhibitors, cyanide, iron, and propofol. Inborn errors of metabolism may also present with profound elevations in serum lactate concentration. Examples of inborn errors of metabolism that may present with lactic acidosis include pyruvate dehydrogenase deficiency, pyruvate decarboxylase deficiency, glucose-6-phosphatase deficiency, fructose-1,6-diphosphatase deficiency, and mitochondrial disorders. In addition, certain malignancies may be associated with hyperlactatemia. Finally, hyperlactatemia may be caused by elevation in the D-isomer of lactate. This is usually observed in states of intestinal bacterial overgrowth as occurs in short gut syndrome.

Studies have shown an association between persistently elevated plasma lactate levels and mortality in critically ill children and neonates. The ability of a single admission or first postoperative lactate level to predict adverse outcomes is poor. However, like many biomarkers, lactate is best used as trended data. Persistently elevated lactate levels 6–12 h after cardiac surgery have been associated with an increased risk of major adverse events.

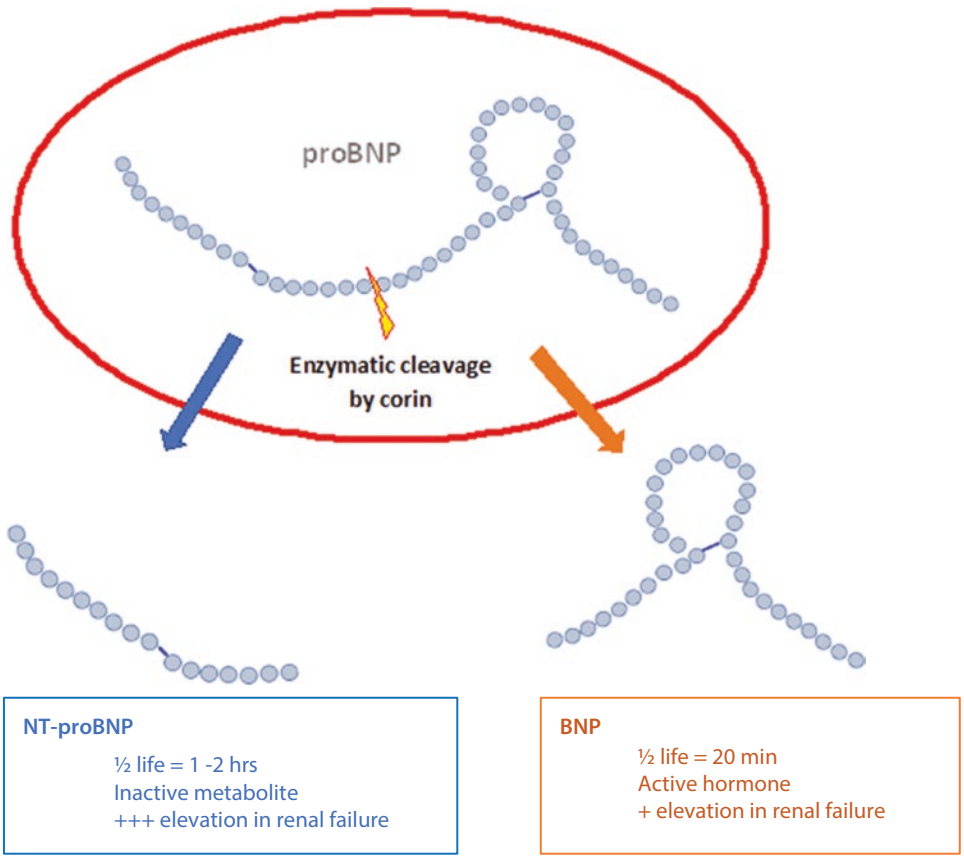

Fig. 16.24 Overview of proBNP metabolism and comparison between NT-proBNP and BNP

16.2.5.3 B-Type Natriuretic Peptide

B-type natriuretic peptide, initially isolated in porcine brains, was previously referred to as brain natriuretic peptide. The peptide was later found to be produced mainly by ventricular myocytes, leading to its more appropriate name – B-type natriuretic peptide (BNP). ProBNP is enzymatically cleaved to N-terminal proBNP (NT-proBNP) and the physiologically active BNP (Fig. 16.24). BNP synthesis occurs in response to increased ventricular wall stress caused by volume or pressure overload.

BNP has several physiologic effects that contribute to cardiovascular compensation in the setting of heart failure. The peptide increases cGMP in vascular smooth muscle resulting in vasodilation, venodilation, and afterload reduction. BNP suppresses the renin-angiotensin-aldosterone system, thus promoting diuresis and natriuresis. In addition, BNP may have a beneficial role in the prevention of pathologic myocardial remodeling that may occur in advanced heart failure.

Both BNP and NT-proBNP can be easily measured in whole blood. Assays for NT-proBNP likely measure a mixture of NT-proBNP and proBNP. The advantage of measuring NT-proBNP versus BNP is its longer half-life (1–2 h versus 20 min) and longer stability at room temperature (72 h versus 24 h). Variability in assays must be considered when interpreting serial BNP or NT-proBNP results. Biologic variation also occurs among individuals based on age, sex, and body mass.

Multiple adult studies confirmed the utility of both markers in ruling out heart failure and to gauge therapeutic response. Using a cutoff of 100 pg/ml, the BNP assay has a clinical specificity for heart failure of >96%. The ability to rule in heart failure (sensitivity) is lower. Data in children suggest the markers can aid in the diagnosis and management of a variety of pediatric cardiovascular diseases (e.g., congenital heart defects, cardiomyopathy, and pulmonary hypertension). Normal pediatric values are BNP of less than 25 pg/ml and a NT-proBNP level less than 70 pg/ml. Levels of both peptides are higher in newborns but normalize by the second week of postnatal life.

16.2.5.4 Cardiac Troponin

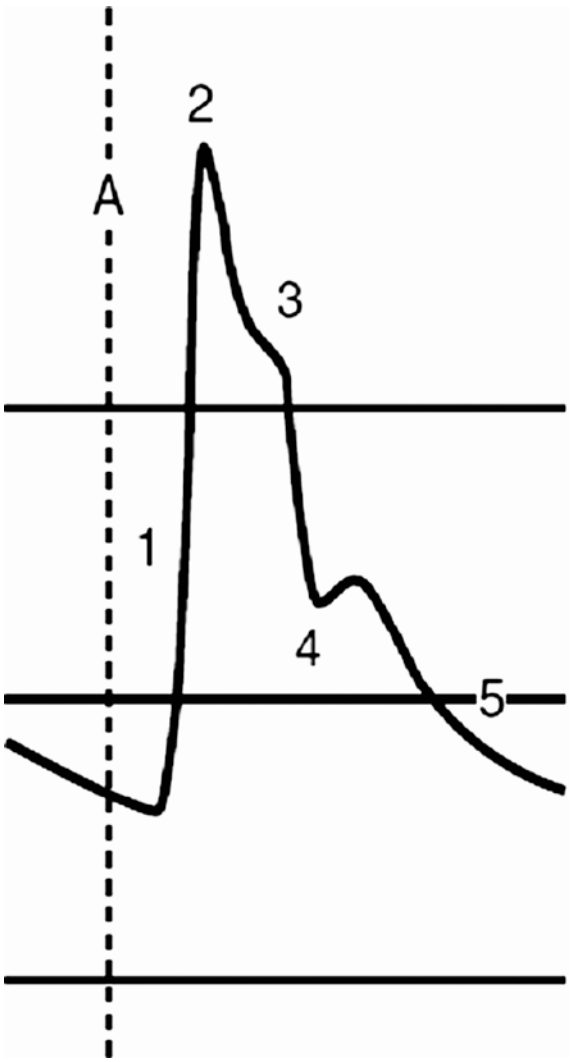
Troponin modulates calcium-mediated actin and myosin coupling in striated muscle. Cardiac troponin is made up of troponin I, C, and T subunits. Cardiac troponin I (cTnI) and cardiac troponin T (cTnT) have a unique N-terminal amino acid that allows differentiation from their skeletal muscle counterparts. cTnI is exclusively released from the myocardium, while cTnT can be released in small amounts from striated muscle. cTnT may be increased in renal failure, while cTnI is unaffected.

cTnI and cTnT were found to be highly sensitive and specific markers for myocardial damage in children and adults. Following myocardial injury, levels rise within 3–4 h, peak at 12 h, and are detectable for 10–14 days. Troponin levels have been utilized to support the diagnosis of myocarditis and/or pericarditis but do not reliably predict outcome. Troponin levels were found to correlate with the degree of myocardial injury in neonatal asphyxia and following congenital heart surgery. Of note, healthy newborns may demonstrate elevated troponin concentrations without clinical evidence of myocardial disease, which may be related to cesarean section delivery and/or intrauterine exposure to tocolytic therapy.

Review Questions

1. Which statement accurately reflects the utility of the physical assessment of the cardiovascular status of a child?
   A. Capillary refill time is independent of ambient temperature.
   B. Pulse pressure is decreased in conditions characterized by low systemic vascular resistance.
   C. Tachycardia, in and of itself, is a sensitive and specific sign of hemodynamic instability.
   D. The peripheral skin to ambient temperature gradient (dTp-a) decreases during states of high systemic vascular resistance.
   E. Urine output of 0.25–0.5 ml/kg/h is an appropriate therapeutic target during resuscitation of hypovolemic, septic, and distributive shock.

For questions 2–4, please refer to the arterial waveform figure below.

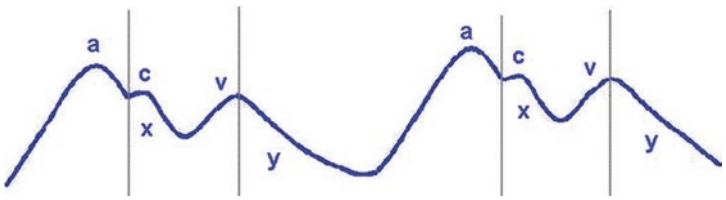


2. In the above illustration of an arterial waveform, which number identifies the incisura or dicrotic notch?
   A. 1
   B. 2
   C. 3
   D. 4
   E. 5

3. In the above illustration of an arterial waveform, which number identifies peak left ventricular ejection?
   A. 1
   B. 2
   C. 3
   D. 4
   E. 5

4. In the above illustration of an arterial waveform, which number identifies diastolic runoff?
   A. 1
   B. 2
   C. 3
   D. 4
   E. 5

For questions 5–8, please refer to the central venous pressure waveform figure below.



5. In assessing a normal central venous pressure (CVP) waveform, the c wave represents which of the following?
   A. The decline in atrial pressure that occurs during atrial relaxation and ventricular systole
   B. The displacement of the tricuspid valve toward the atrium during isovolumic ventricular contraction
   C. The fall in atrial pressure that occurs as the tricuspid valve opens and the atrium is drained
   D. The increase in intra-atrial pressure observed during atrial contraction that occurs at the end of ventricular diastole
   E. The rise in atrial pressure during the end of ventricular systole as the atrium fills with venous blood from the inferior and superior venous cava

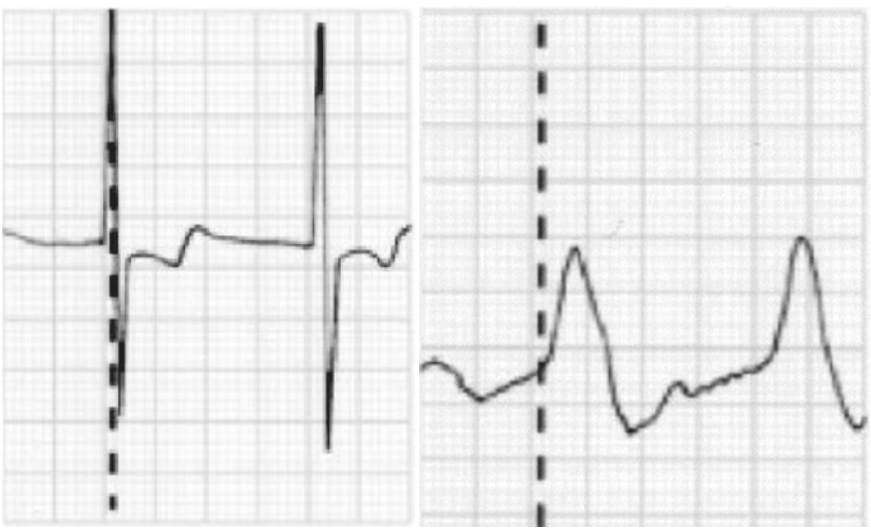
6. In assessing a normal central venous pressure (CVP) waveform, the x descent represents which of the following?
   A. The decline in atrial pressure that occurs during atrial relaxation and ventricular systole
   B. The displacement of the tricuspid valve toward the atrium during isovolumic ventricular contraction
   C. The fall in atrial pressure that occurs as the tricuspid valve opens and the atrium is drained
   D. The increase in intra-atrial pressure observed during atrial contraction that occurs at the end of ventricular diastole
   E. The rise in atrial pressure during the end of ventricular systole as the atrium fills with venous blood from the inferior and superior venous cava

7. In assessing a normal central venous pressure (CVP) waveform, the v wave represents which of the following?
   A. The decline in atrial pressure that occurs during atrial relaxation and ventricular systole

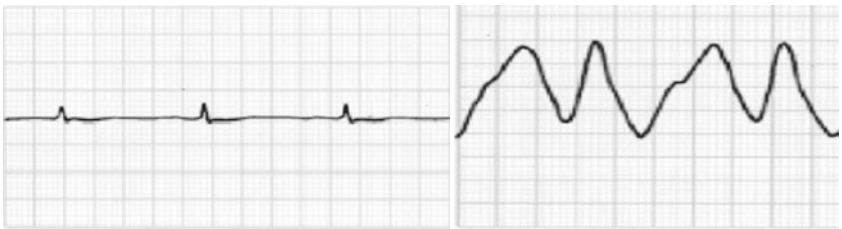
B. The displacement of the tricuspid valve toward the atrium during isovolumic ventricular contraction
C. The fall in atrial pressure that occurs as the tricuspid valve opens and the atrium is drained
D. The increase in intra-atrial pressure observed during atrial contraction that occurs at the end of ventricular diastole
E. The rise in atrial pressure during the end of ventricular systole as the atrium fills with venous blood from the inferior and superior venous cava

8. In assessing a normal central venous pressure (CVP) waveform, the y descent represents which of the following?
   A. The decline in atrial pressure that occurs during atrial relaxation and ventricular systole
   B. The displacement of the tricuspid valve toward the atrium during isovolumic ventricular contraction
   C. The fall in atrial pressure that occurs as the tricuspid valve opens and the atrium is drained
   D. The increase in intra-atrial pressure observed during atrial contraction that occurs at the end of ventricular diastole
   E. The rise in atrial pressure during the end of ventricular systole as the atrium fills with venous blood from the inferior and superior venous cava

9. Which statement is correct regarding arterial pressure monitoring systems?
   A. Damping describes the interaction between the oscillatory energy of a wave and the electrical properties of the monitoring system.
   B. Due to the turbulent flow and the high oxygen tension found in arteries, infections associated with arterial catheters are extremely uncommon.
   C. Pressure monitoring devices must be leveled to the point at which the catheter enters the artery.
   D. The delivery of a small "fast flush" to the arterial catheter allows for quantification of excessive resonance within the system.
   E. The phlebostatic axis is determined by locating the junction of the vertical line drawn down from the clavicle and the horizontal midaxillary line.



10. In assessing the above ECG and central venous pressure (CVP) waveform, which of the following is most likely?
    A. Severe tricuspid regurgitation
    B. Pulmonary hypertension
    C. AV dissociation
    D. Displacement of the tricuspid valve toward the atrium during isovolumic ventricular contraction
    E. Excessive rise in atrial pressure due to volume overload



11. In assessing the above ECG and central venous pressure (CVP) waveform, which of the following is most likely?
    A. Severe tricuspid regurgitation resulting in increased v wave
    B. RV noncompliance transmitting high diastolic pressure to atrium
    C. Tamponade physiology causing elevation of the CVP and equalization of diastolic filling pressures
    D. Tricuspid valve displacement toward the atrium during isovolumic ventricular contraction
    E. Atrial fibrillation

12. The right ventricular (RV) waveform and the pulmonary artery (PA) waveform can be distinguished from each other by which of the following?
    A. It is difficult to distinguish the waveforms without fluoroscopic visualization of the catheter tip.
    B. The PA diastolic pressure is usually greater than the RV diastolic pressure.
    C. The PA systolic pressure is usually greater than the RV systolic pressure.
    D. The RV diastolic pressure is usually greater than the PA diastolic pressure.
    E. The RV systolic pressure is usually greater than the PA systolic pressure.

13. Which disease state is most consistent with the following hemodynamic profile in a critically ill 10-year-old child?
    Heart rate: 129 bpm
    Blood pressure: 81/68 mm Hg
    Pulmonary artery occlusion pressure (PAOP): 24 mm Hg
    Pulmonary vascular resistance index (PVRI): 128 dyne-s/cm^5/m^2
    Cardiac index (CI): 2.0 L/min/m^2
    Central venous/right atrial pressure: 6 mm Hg
    Stroke volume index (SVI): 20 mL/beat/m^2
    Lactate: 10 mmol/L
    $SmvO_2$: 50%
    SaO_2: 91%
    A. Cardiomyopathy with biventricular dysfunction
    B. Congestive heart failure secondary to a large atrial septal defect with left to right shunting

C. Gastroenteritis with hypovolemia
D. Myocarditis with left ventricular dysfunction
E. Pulmonary hypertension with right ventricular dysfunction

14. Which of the following Fick derived equations is correct?

A. $CO = \frac{DO_2}{C_{Ao}O_2 - C_{pa}O_2}$

B. $Q_{pul} = \frac{C_{Ao}O_2}{C_{pv}O_2 - C_{pa}O_2}$

C. $Q_{pul}(C_{pv}O_2) = [Q_{pul}(C_{pa}O_2)] + DO_2$

D. $Q_{syst}(C_{pv}O_2) = [Q_{syst}(C_{Ao}O_2)] - VO_2$

E. $Q_{syst} = \frac{VO_2}{C_{Ao}O_2 - C_{pa}O_2}$

15. Which statement regarding the use of thermodilution to determine cardiac output is *MOST* correct?
A. A fundamental assumption during thermodilution is that the fluid injected into the right atrium will have complete and anatomically appropriate mixing prior to reaching the pulmonary artery.
B. A high cardiac output state results in a large area under the thermodilution curve.
C. Right heart cardiac output should equal left heart output even in the presence of an intracardiac shunt.
D. The area under the thermodilution curve is determined by the change in flow over time.
E. The area under the thermodilution curve is in the numerator of the Stewart-Hamilton formula used to calculate cardiac output.

16. A 6-year-old boy with chronic granulomatous disease presents with septic shock. Prior to arrival in the pediatric intensive care unit, he is intubated, is treated with antibiotics, receives fluid resuscitation with a total of 80 mL/kg of crystalloid, and is started on an infusion of dopamine at 15 mcg/kg/min. He has central arterial and venous access that allow for intermittent transpulmonary thermodilution and continuous pulse contour analysis for determination of the cardiac output.
The following hemodynamic data are obtained:
Heart rate: 138 bpm
Blood pressure: 88/34 mm Hg
Cardiac index (CI): 3.5 L/min/m^2
Central venous pressure: 6 mm Hg
Stroke volume variation (SVV) = 15% (normal <10%)
Systemic vascular resistance index (SVRI): 860 dyne-s/cm^5/m^2
Lactate: 12 mmol/L
$ScvO_2$: 45% (right atrium)
SaO_2: 91%
Hemoglobin: 8.5 mg/dL
Positive end-expiratory pressure (PEEP): 8 cm H_2O
Fraction of inspired oxygen (FiO_2): 0.65
The most appropriate next step in the management of this boy would be to:
A. Begin an infusion of epinephrine at 0.05 mcg/kg/min.
B. Begin an infusion of milrinone at 0.5 mcg/kg/min.
C. Begin an infusion of norepinephrine at 0.05 mcg/kg/min.
D. Continue volume resuscitation with an additional 20 ml/kg crystalloid.
E. Increase PEEP to 10 cm H_2O.

17. A 9-month-old infant with dilated cardiomyopathy presents in shock with severe left ventricular dysfunction. He requires intubation and the initiation of a milrinone infusion. He requires the addition of a nitroprusside infusion for afterload reduction. The nitroprusside infusion is titrated to 4 mcg/kg/min to maintain systolic blood pressure between 70 and 85 mm Hg. On the 6th PICU day, he develops a new metabolic acidosis with a base deficit (−7 mmol/L). A plasma lactate level is elevated (7.3 mmol/L) and the superior vena cava oxygen saturation is 88%. Which of the following explanations for an elevated lactate level is most worrisome in this clinical scenario?
    A. Decreased lactate clearance secondary to impaired renal clearance
    B. Elevated lactate production secondary to catecholamine-induced "hyperglycolysis"
    C. Impaired lactate metabolism secondary to an inborn error of metabolism
    D. Increased lactate production from tissue hypoperfusion
    E. Increased lactate production secondary to cellular inability to extract delivered oxygen

18. A 12-year-old girl with acute lymphoblastic leukemia is neutropenic and develops septic shock. Prior to arrival in the pediatric intensive care unit, she is treated with antibiotics and is fluid resuscitated with a total of 80 mL/kg of isotonic intravenous crystalloid fluids. She has both central arterial and venous catheters placed that allow intermittent transpulmonary thermodilution and continuous pulse contour analysis for cardiac output determination. She appears toxic and flushed and has a hyperbrisk capillary refill.
    The following hemodynamic data are obtained:
    Heart rate: 127 bpm
    Respiratory rate: 32 breaths per minute
    Blood pressure: 100/34 mm Hg
    Cardiac index (CI): 6.5 L/min/m^2.
    Central venous pressure: 16 mm Hg.
    Stroke volume index (SVI): 51 mL/beat/m^2
    Stroke volume variation (SVV) < 10% (normal <10%)
    Systemic vascular resistance index (SVRI): 400 dyne-s/cm^5/m^2
    Lactate: 9 mmol/L
    $ScvO_2$: 88% (right atrium)
    SaO_2: 100%
    Hemoglobin: 8.5 mg/dL
    The most appropriate next step would be to:
    A. Begin an infusion of epinephrine at 0.1 mcg/kg/min.
    B. Begin a transfusion of 15 ml/kg PRBCs.
    C. Begin an infusion of norepinephrine at 0.1 mcg/kg/min.
    D. Intubate and mechanically ventilate for impending respiratory failure.
    E. Diurese with furosemide (1 mg/kg).

19. A 12-year-old girl with acute lymphoblastic leukemia is neutropenic and develops septic shock. Prior to arrival in the pediatric intensive care unit, she is treated with antibiotics and is fluid resuscitated with a total of 80 mL/kg of isotonic intravenous crystalloid fluids. She has both central arterial and venous catheters placed that allow intermittent transpulmonary thermodilution and continuous pulse contour analysis for cardiac output determination. She appears toxic and flushed and has a hyperbrisk capillary refill.

The following hemodynamic data are obtained:
Heart rate: 127 bpm
Blood pressure: 100/34 mm Hg
Cardiac index (CI): 6.5 L/min/m^2
Central venous pressure: 16 mm Hg
Stroke volume index (SVI): 51 mL/beat/m^2
Stroke volume variation (SVV) < 10% (normal <10%)
Systemic vascular resistance index (SVRI): 400 dyne-s/cm^5/m^2
Lactate: 9 mmol/L
$ScvO_2$: 88% (right atrium)
SaO_2: 100%
Hemoglobin: 9.5 mg/dL
The elevated $S_{CV}O_2$ (88%) is likely indicative of which of the following?

A. Catheter tip positioning near the orifice of the coronary sinus
B. Drug toxicity
C. Inadequate oxygen uptake at the cellular level
D. Insufficient cardiac output to provide tissue perfusion
E. Successful resuscitation.

20. Which of the following is correct regarding central venous oxygen saturation ($ScvO_2$) and mixed venous oxygen saturation ($SmvO_2$)?

A. Decreased oxygen delivery raises both $ScvO_2$ and $SmvO_2$.
B. Decreased oxygen consumption lowers both $ScvO_2$ and $SmvO_2$.
C. In normal conditions, $SmvO_2$ is slightly higher than the $ScvO_2$.
D. $ScvO_2$ is best measured in the lower right atrium to reliably predict $SmvO_2$.
E. $SmvO_2$ is best measured in the right ventricle just below the tricuspid valve.

21. A 6-month-old male infant is 2 weeks postoperative from repair of tetralogy of Fallot. He underwent patch closure of the ventricular septal defect and relief of the right ventricular outflow obstruction with sparing of the pulmonary valve. He developed respiratory distress, poor oral intake, and progressive lethargy. He is admitted to the PICU with pneumonia, respiratory failure, and presumed septic shock. He is endotracheally intubated and administered saline fluid boluses (total = 20 mL/kg) and antibiotics. He remains cool and his pulses are weak. His capillary refill is 5 s. He has no JVD and his liver is palpated 1 cm below the right costal margin. His positive end-expiratory pressure (PEEP) is set at 7 cm H_2O and his peak inspiratory pressures range from 26 to 29 cm H_2O. An internal jugular central venous catheter with the tip positioned at the superior vena cava/right atrial junction and a radial arterial catheter are placed. His arterial catheter demonstrates a 25 mm Hg systolic pressure variation during a positive pressure breath. The following hemodynamic data are available:
Heart rate: 189 bpm
Blood pressure: 67/45 mm Hg
Central venous pressure: 14 mm Hg
Central venous oxygen saturation: 53%
Arterial oxygen saturation: 89% on 80% FiO_2
Arterial lactate: 6 mmol/L
Which one of the following statements is MOST correct?

A. The central venous pressure is consistent with adequate volume replacement.
B. The decreased arterial oxygen saturation is likely due to left to right shunting across a residual ventricular septal defect.

C. The hypotension is best corrected by the addition of an infusion of epinephrine.
D. The positive end-expiratory pressure needs to be reduced to increase right ventricular preload.
E. The hypotension is best corrected by additional intravenous volume replacement.

22. Which statement best describes wave frequency and resonance of pressure monitoring?
A. A system with high resonance may falsely increase the diastolic pressure by as much as 30%.
B. An accurate monitoring system at heart rates of ~180 beats per minute (bpm) should have its natural frequency equal 6 Hz.
C. If the frequency of the system is in the same range as the frequency of the arterial waveform, the amplitudes of the waves become additive and can overestimate the systolic pressure.
D. Resonant augmentation of the arterial pressure wave causes an artifactual increase in both systolic and diastolic recorded pressures.
E. The effect of resonance becomes less problematic when the monitoring system has a low natural frequency and the heart rate is high.

23. Which statement best describes the utility of focused cardiac ultrasound (FoCUS) in the PICU?
A. Ejection fraction utilizes the changes in LV volume, whereas fractional shortening utilizes changes in LV dimension to assess diastolic relaxation.
B. Assessments of systolic function, pericardial disease, valvular competence, and the presence of an intracardiac lesion can be rapidly assessed by FoCUS.
C. Normal values for FS in infants and children are between 20 and 30% assuming the ventricle has a symmetric cylindrical shape.
D. Measuring the maximal tricuspid valve regurgitation (TRV, m/sec) is used to estimate pulmonary artery systolic pressure utilizing the following equation: $\text{PASP} = 4 \times (\text{TRV max})^2$
E. The RV systolic pressure can be estimated by doubling the pulmonary artery systolic pressure: $\text{RVSP} = 2 \times \text{PASP}$

24. Which statement regarding near-infrared spectroscopy is correct?
A. NIRS technology is predicated on light absorption of three main chromophores: plasma proteins, oxygenated hemoglobin, and deoxygenated hemoglobin.
B. The majority of the NIRS measurement occurs in the venule compartment.
C. Light photons in the NIR spectrum are unable to penetrate dense structures such as the skull.
D. NIRS data provides absolute values for regional oxygen extraction.
E. Cerebral NIRS has been found to have greater utility in monitoring children status posttraumatic brain injury than in postoperative congenital heart repair.

25. Match the cardiac biomarker with the correct descriptions. Descriptions can be used more than once or not at all for each biomarker.
    Lactate
    NT-proBNP
    Troponin
    $ScvO_2$
    A. Following myocardial injury, levels rise within 3–4 h, peak at 12 h, and are detectable for 10–14 days.
    B. Using a cutoff of 100 pg/ml, the biomarker has a clinical specificity for heart failure of >96%.
    C. Levels can be elevated in newborns.
    D. Has been used as a marker of tissue hypoperfusion and anaerobic metabolism.
    E. Elevations may occur in the setting of impaired cellular and/or mitochondrial oxygen uptake.
    F. Is made up of three distinct subunits.
    G. Must be obtained from the central circulation.

Circulatory Failure/Shock

Stephen Pfeiffer and Hector R. Wong

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_17

Learning Objectives

- Define shock.
- Describe the pathophysiologic changes that occur with the different classifications of shock.
- Understand the molecules that mediate the changes in the cardiovascular system during shock.
- Describe the role of cardiovascular monitoring in circulatory failure.
- State the mechanistic principles of goal-directed therapies (including use of lactate concentrations and venous oxygen saturations) aimed at improving outcome in children with circulatory failure.
- Define and understand the pathophysiology of multiple organ dysfunction syndrome.

17.1 Introduction

Shock is a common manifestation of many forms of critical illness. Although a patient with hypotension can have shock, shock is not necessarily defined by hypotension. That is, a patient can have a "normal" blood pressure and have shock concurrently. Accordingly, the definition of shock is based upon the balance between oxygen delivery, the circulation-related factors that govern oxygen delivery, and tissue oxygen requirements. When tissue oxygen requirements are not met by the circulatory system, be it due to poor myocardial function, hypovolemia, and/or hypotension, a patient is said to be in shock.

17.2 Shock Classifications

There are four broad forms and a miscellaneous category for shock, but other classifications may be used. The four forms are hypovolemic, distributive, cardiogenic, and septic. The latter may have elements of the other three categories. A fifth miscellaneous category includes obstructive forms of shock (e.g., tension pneumothorax, pulmonary embolus, and pericardial tamponade) as well as congenital cardiac lesions obstructing left or right ventricular output.

There are several classification schemes for shock, but a useful classification scheme is based on four broad forms of shock: cardiogenic shock, hypovolemic shock, distributive shock, and septic shock. Table 17.1 outlines the various subclassifications/etiologies that fall into these broad categories, as well as a miscellaneous classification. *Cardiogenic shock* implies primary myocardial failure such that there is an impaired ability of the heart to generate an adequate cardiac output to meet the tissue oxygen requirements. *Hypovolemic shock* implies that the intravascular volume has decreased to a level that reduces cardiac output, reduces tissue perfusion pressure, and/or reduces oxygen carrying capacity to levels that cannot meet the tissue oxygen requirements. *Distributive shock* can also be thought of as pathologic vasodilation. This implies a condition in which cardiac output and intravascular volume status may be adequate to meet tissue oxygen requirements, but blood flow is distributed in an aberrant manner (secondary to pathologic vasodilation) such that effective tissue perfusion is inadequate to meet the tissue oxygen requirements. In addition, increased venous capacitance secondary to venodilation can impair venous return to the heart. *Septic shock* merits a separate classification in that it can have concomitant manifestations of cardiogenic shock, hypovolemic shock, and distributive shock to varying degrees.

17.3 Determinants of Oxygen Delivery

In order to understand and treat shock, it is imperative to understand the determinants of oxygen delivery. Oxygen delivery is globally defined by the following equation:

$$\text{Oxygen Delivery} = \text{Cardiac Output} \times \text{Arterial Oxygen Content}$$

Table 17.1 Major classifications of shock and their subclassifications/etiologies

Major shock classification	Subclassification/etiology
Hypovolemic shock	Hemorrhagic shock
	Dehydration secondary to GI disorders
	Postoperative "third spacing"
	Fluid loss from surgical wounds or burns
Distributive shock	Anaphylactic shock
	Spinal shock secondary to spinal cord injury
	Unbalanced single ventricle physiology
Cardiogenic shock	Cardiomyopathy: dilated or restrictive myocarditis
	Postoperative low cardiac output syndrome
	Pulmonary hypertension
	Valve disease: regurgitant
	Bradycardia and tachyarrhythmia
Septic shock	Bacterial
	Viral
	Fungal
Miscellaneous	Left or right ventricular outflow obstruction
	Tension pneumothorax
	Pulmonary embolism
	Cardiac tamponade

The two major determinants of *cardiac output* are heart rate and stroke volume. Heart rate is a particularly important variable in the pediatric population due to age-dependent variations in heart rate (i.e., the newborn requires a higher heart rate for normal cardiac output than a 12-year-old child) and the remarkable capacity of the developing host to increase heart rate as a primary mechanism to compensate for shock. In addition, it is important to note that infants have a relatively fixed stroke volume, thus magnifying the impact of heart rate on cardiac output. The three major determinants of *stroke volume* are preload, afterload, and contractility. With these concepts in mind, it can be seen how hypovolemia (abnormal preload), pathologic vasodilation (abnormal afterload), and myocardial failure (abnormal contractility) can independently lead to decreased effective cardiac output and hence shock.

Arterial oxygen content (CaO_2) is determined by the hemoglobin concentration (Hgb), the arterial hemoglobin oxygen saturation (SaO_2), and the arterial partial pressure of oxygen (PaO_2):

$$CaO_2 = (1.34 \times Hgb \times SaO_2) + (0.003 \times PaO_2)$$

The factor of 1.34 refers to the oxygen carrying capacity of hemoglobin in mL O_2/g of hemoglobin, whereas the factor of 0.003 refers to the solubility coefficient of oxygen (mL oxygen/mm Hg) in plasma at 37 °C. From this equation, it can be seen that hemoglobin oxygen saturation and hemoglobin concentra-

Cardiac output is the product of heart rate and stroke volume; the latter is determined by preload, afterload, and cardiac contractility. The product of cardiac output and arterial oxygen content determines oxygen delivery.

Arterial oxygen content is determined mainly by the product of hemoglobin concentration and oxygen saturation with a minor contribution from the oxygen dissolved in plasma.

tion are the most important factors determining arterial oxygen content and the latter accounts, in large part, for the pathophysiology of hemorrhagic shock from the standpoint of oxygen delivery (see also ► Chap. 2).

17.4 Cardiogenic Shock

As stated previously, cardiogenic shock implies that there is primary failure of the myocardium such that the heart cannot generate a sufficient cardiac output to meet the tissue oxygen requirements. The most common form of cardiogenic shock results from systolic dysfunction as seen in myocarditis, cardiomyopathy, and low cardiac output syndrome following cardiopulmonary bypass and aortic cross-clamping during cardiac surgery. In this condition, there is decreased contractility leading to decreased stroke volume despite adequate preload and an appropriate afterload.

Cardiogenic shock is typically perceived to result from poor systolic pumping function, but cardiogenic shock less commonly results from abnormalities in diastolic function or from low or high heart rate. In the latter state, the diastolic filling time for coronary artery perfusion is compromised as myocardial oxygen demand increases. In addition, very rapid rates, especially if not coordinated with atrial contraction, may not provide adequate time and efficiency of ventricular filling leading to a low stroke volume.

Although systolic dysfunction is the more common cause of cardiogenic shock, abnormalities of heart rate or diastolic dysfunction, in the setting of normal systolic function, can also lead to cardiogenic shock. Thus, significant bradycardia can lead to low cardiac output and shock despite a normal stroke volume. Conversely, tachyarrhythmias can lead to cardiogenic shock secondary to compromise of diastolic filling time and/or eventual systolic dysfunction from excessive myocardial oxygen demand. Diastolic dysfunction occurs when there is decreased myocardial compliance such that ventricular filling during diastole is inadequate to generate a normal stroke volume during the subsequent systolic component of the cardiac cycle. A common clinical scenario in which right ventricular diastolic dysfunction is encountered is in the postoperative patient who has undergone tetralogy of Fallot repair. Many of these patients will have low cardiac output secondary to diastolic dysfunction during the immediate postoperative period until the hypertrophied right ventricle is able to "relax" and accommodate a normal systemic venous return (preload) in the setting of a closed ventricular septal defect. Other conditions that lead to low cardiac output and shock secondary to diastolic dysfunction include restrictive cardiomyopathies and cardiac tamponade.

17.5 Hypovolemic Shock

Any clinical condition that leads to a substantial net loss of intravascular fluid can lead to hypovolemic shock. For example, gastrointestinal diseases associated with vomiting and/or diarrhea are leading causes of death from hypovolemic shock in children worldwide, particularly in underdeveloped countries. Another example is the patient who has undergone an extensive surgical procedure and develops capillary leak syndrome during the postoperative period. These patients are prone to "third space" fluid in the extravascular compartment during the postoperative period. Although these patients can have a net positive fluid balance, they are at risk for developing hypovolemic shock, irrespective of postoperative bleeding, because the effective intravascular volume is inadequate to maintain a normal cardiac output. Thus, hypovolemic shock can be thought of as a preload abnormality. As intravascular fluid volume is decreased, the heart has less venous return during diastole (preload) and the resulting stroke volume is decreased, leading to shock. Shock secondary to hypovolemia typically implies a substantial net loss of intravascular volume given the compensatory mechanisms that can be activated in response to fluid loss. Children in particular are able to substantially increase their heart rate and thus maintain an adequate cardiac output despite a low intravascular volume/low stroke volume. Other compensatory mechanisms include reabsorp-

tion of fluid at the level of the kidneys by complex humoral mechanisms (e.g., vasopressin and the renin-angiotensin axis), shunting of blood to "more vital organs" (e.g., brain and heart) by complex vascular mechanisms involving the sympathetic and parasympathetic nervous systems, and mobilization of blood volume from the venous system.

Hemorrhagic shock is a more complex and somewhat unique form of hypovolemic shock for two broad reasons. First is the added and sometimes devastating component of decreased oxygen carrying capacity secondary to reductions in red blood cell mass. Thus, the patient with hemorrhagic shock is affected by both the aforementioned problems associated with a net decrease of intravascular volume (decreased cardiac output), as well as a reduced oxygen carrying capacity. The second factor is that patients with hemorrhagic shock will often develop multiple organ dysfunction syndrome (MODS) several days after their initial event. This syndrome can occur despite adequate surgical control of blood loss sources and seemingly adequate restoration of intravascular volume and red cell mass. It appears that massive blood loss activates a systemic reaction in the host, which causes tissue injury disproportionate to the initial insult of decreased intravascular volume and decreased red blood cell mass. This tissue and organ injury is also a manifestation of complex host mechanisms including activation of neutrophils, activation of endothelial cells, and oxidant injury related to the phenomenon of ischemia-reperfusion injury. In addition, massive requirement for transfusion of packed red blood cells, particularly red blood cells that have been in storage for several weeks, is associated with the development of transfusion-related acute lung injury.

Hypovolemic shock is the most common type in children. It is characterized by inadequate intravascular volume leading to impaired venous return and thus stroke volume, which compromises cardiac output. The typical compensatory mechanism to maintain cardiac output is tachycardia, remembering that cardiac output is the product of stroke volume and heart rate. Note that hypovolemia specifically refers to the intravascular volume; thus, children with capillary leak, such as after cardiopulmonary bypass or burn injury, may have increased total body water but inadequate *intravascular* volume.

Hemorrhagic shock is a more complex form of hypovolemic shock since tissue oxygen delivery is compromised both by low cardiac output and low arterial oxygen content if there is significant blood loss. Hemorrhagic shock can lead to multiple organ dysfunction that develops up to several days after the initial event due to complex mechanisms activated by ischemia-reperfusion.

17.6 Distributive Shock

Distributive shock typically results from profound abnormalities in vascular motor tone, otherwise known as pathologic vasodilation. On the arterial side of the circulation, pathologic vasodilation leads to profound hypotension, leading to decreased tissue perfusion pressure. Unlike other categories of shock where vasoconstriction leads to thready pulses with a narrow pulse pressure, patients with inappropriate vasodilation may maintain palpable distal pulses even with low blood pressure and the pulse pressure is characteristically wide. Although in pure distributive shock cardiac output is typically normal to supernormal, profound decreases in perfusion pressure can eventually lead to decreased coronary artery perfusion pressure and eventual myocardial dysfunction. Pathologic arterial dilation can lead to a maldistribution of blood flow such that arterial blood is shunted away from the vascular beds of vital organs to less vital regions such as the skin and muscle. There can also be maldistribution of blood flow within organs at the microcirculatory level and venodilation leading to increased capacitance of the vascular compartment leading to decreased preload. Anaphylaxis is the classic example of distributive shock seen in the clinical setting. In addition, anaphylaxis leads to loss of effective intravascular volume due to increased capillary permeability. Other conditions that can lead to distributive shock include spinal cord injuries, spinal or epidural anesthesia, and overdoses of medications with vasodilator properties.

Children with single ventricle physiology, particularly in the preoperative period and following a first stage Norwood operation, can also manifest a form of shock that can be considered a form of distributive shock. In this scenario, however, the manifestation of distributive shock is not secondary to pathologic vasodilation per se. Rather, it is due to the fact that the pulmonary and systemic vascular circulations have parallel connections (as opposed to the serial connection characteristic of normal physiology) supplied by a single ventricle

Distributive shock is characterized by pathologic vasodilation leading to maldistribution of blood flow at the macro- or microcirculatory level. Some organs may receive blood flow in excess of metabolic demand, while other organs, such as the splanchnic circulation, receive inadequate flow. Distributive shock is characterized by a wide pulse pressure with a low diastolic blood pressure. The vasodilation is not limited to the arterial circulation; relaxation of the capacitance venous system can lead to reduced venous return, exacerbating the hypotension that may occur in distributive shock. Anaphylaxis is the classic cause; spinal cord injury, epidural anesthesia, and overdoses of vasodilator medications are additional causes. Maldistribution of blood flow is also seen in patients with septic shock.

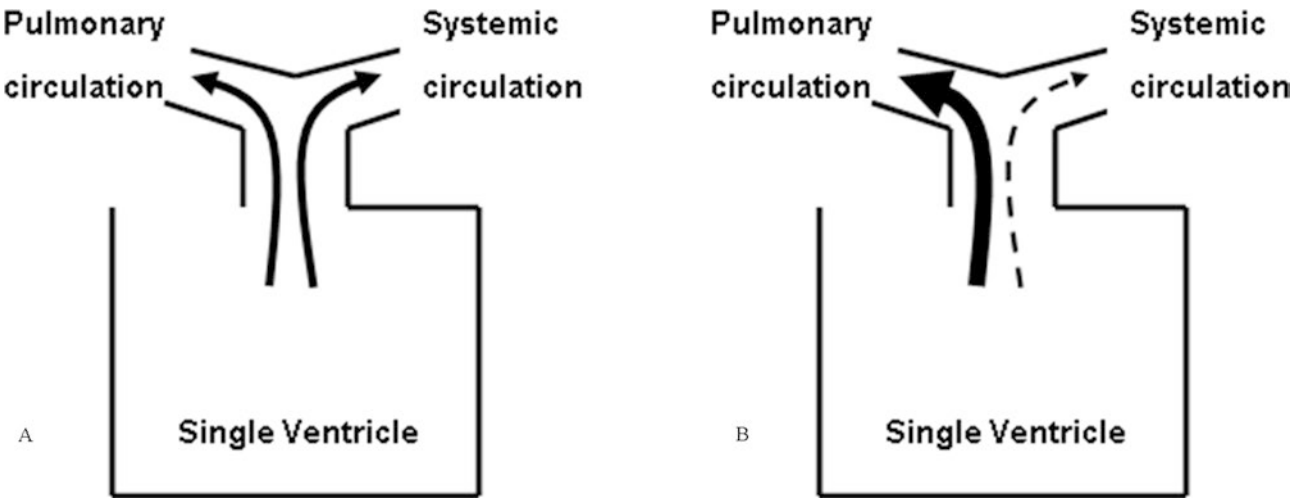

Fig. 17.1 Box diagram depicting single ventricle physiology in which one ventricle supplies pulmonary and systemic blood flow in a parallel circuit. In panel A, the resistances of the pulmonary and systemic circuits are well matched such that blood flow distribution is well balanced between the pulmonary and systemic vasculature. In panel B, the resistances of the pulmonary and systemic circuits are poorly balanced (decreased resistance in the pulmonary circuit and/or increased resistance in the systemic circuit) such that pulmonary blood flow is substantially increased at the expense of the systemic circulation. This situation can be considered as a form of distributive shock

Single ventricle physiology may cause a special form of distributive shock whereby systemic blood flow depends on maintaining a relatively high pulmonary vascular resistance to avoid pulmonary overcirculation and compromised systemic cardiac output.

(Fig. 17.1). In this condition, blood exits the single ventricle and can enter either the pulmonary circulation or the systemic circulation. The physical laws of fluid mechanics dictate that blood will preferentially flow along the path of least resistance. Thus, if the pulmonary vascular resistance is low and/or the source of pulmonary blood flow is not sufficiently restrictive, blood will preferentially flow into the pulmonary vasculature at the expense of the systemic vasculature. This results in a form of distributive shock because of decreased systemic blood flow (decreased systemic oxygen delivery), while the pulmonary vasculature is said to be "overcirculated" relative to the systemic vasculature.

17.7 Septic Shock

Septic shock is one of the most common conditions seen in pediatric critical care medicine. The clinical symptoms represent a manifestation of systemic infection as well as the host response to the infection. There are over 42,000 cases per year of pediatric septic shock in the United States, with a mortality rate of approximately 10%. Management of a patient with septic shock embodies the discipline of pediatric critical care medicine. The typical patient with septic shock has simultaneous derangements of cardiovascular function, intravascular volume status, respiratory function, immune/inflammatory regulation, renal function, coagulation, hepatic function, and/or metabolic function. The degree to which any of these derangements are manifest in a given patient is highly variable and influenced by multiple host and non-host factors including developmental stage, the presence or absence of comorbidities, the causative agent of septic shock, the primary site of infection, the host's immune/inflammatory state, and the host's genetic background. These factors combine, in turn, to profoundly influence the ultimate outcome of septic shock.

As stated previously, septic shock can be classified as a unique entity because it may have manifestations of all three aforementioned major classifications of shock: cardiogenic shock, distributive shock, and hypovolemic shock. Which of the three components predominates or is present in any given individual patient is highly variable, thereby presenting a significant therapeu-

tic challenge. The cardiogenic component of septic shock is manifested as a profound decrease in myocardial systolic function. Primary myocardial dysfunction is well documented in the setting of septic shock and is thought to be due to "myocardial depressant factors" in the serum of patients with septic shock. Compelling data suggest that tumor necrosis factor-α, interleukin-1β, and nitric oxide may all be responsible for this depressant activity. In addition, it has been suggested that primary myocardial dysfunction is a more common clinical scenario in the pediatric patient with fluid refractory septic shock compared with the adult patient with septic shock.

The distributive shock component of septic shock is similar to that previously described. That is, septic shock can be characterized by pathologic venodilation and vasodilation leading to profound hypotension and maldistribution of blood flow. The patient with septic shock that is primarily distributive is said to be in "warm shock," which is characterized by a vasodilated (warm/red skin, brisk pulses/capillary refill, and wide pulse pressure) and high cardiac output state. It has been suggested that this type of presentation of septic shock is much less common in the pediatric patient with fluid refractory septic shock compared to the adult patient with septic shock. Warm shock is more commonly observed in children with hospital-acquired septic shock, often associated with central venous catheters or other technology-associated devices, whereas cold shock is more commonly observed in community-acquired sepsis.

The hypovolemic shock component of septic shock is multifactorial. Many patients with septic shock have a net decrease of intravascular volume secondary to increased fluid losses (e.g., fever, vomiting, and diarrhea) and decreased fluid intake (e.g., transient anorexia). In addition, patients with septic shock can develop a profound capillary leak syndrome secondary to the generation of vasoactive mediators, which leads to "third spacing" of fluid into the extravascular space with a decreased effective intravascular volume. Finally, septic shock leads to pathologic venous and arterial dilation, as described above. Venodilation leads to decreased venous return. The consequence of this is increased intravascular capacitance such that the intravascular space is effectively increased relative to normal, thus creating a relative form of hypovolemia independent of fluid losses or the phenomenon of "third spacing."

Septic shock is a complex syndrome with variable pathophysiologic mechanisms leading to abnormalities in vascular tone, myocardial contractility, and intravascular fluid loss. The degree to which any of these derangements manifest in a given patient is highly variable and influenced by multiple host and non-host factors including the patient's developmental stage, the presence or absence of comorbidities, the causative agent of septic shock, the primary site of infection, the host's immune/inflammatory state, and the host's genetic background.

Since septic shock has different degrees of distributive, hypovolemic, and cardiogenic shock elements, careful patient assessment and individualized treatment should be based on your assessment of the patient's hemodynamic state, which may evolve over time.

17.8 Shock at the Cellular Level

The cellular manifestations of shock are protean. At the most fundamental level, however, shock is characterized by oxygen debt at the cellular level. This oxygen debt leads to interruption of oxidative phosphorylation, reliance on inefficient anaerobic metabolism, and subsequent depletion of ATP. If shock is sufficiently profound, ATP depletion leads to complete energy failure and necrotic cell death. If a significant number of cells undergo necrotic cell death, then whole organs begin to irreversibly fail leading to death of the patient secondary to MODS.

It is now well recognized that MODS occurs in patients despite seemingly adequate reversal of the shock state (i.e., normal cardiac output, normal intravascular volume status, normal blood pressure, and/or normal red blood cell mass). This realization has given rise to a large investigative discipline focused on the cellular responses that occur in the setting of shock. These investigations have provided substantial insight into the cellular and molecular mechanisms that lead to cell injury and death following shock. Some of these mechanisms will be discussed in the sections below.

Table 17.2 Characteristics of apoptosis and necrosis

Apoptosis	Necrosis
Single cells die	Groups of neighboring cells die
Cellular shrinkage and fragmentation	Cellular swelling
Plasma membranes intact	Cellular lysis
Mitochondria swell and release contents	Mitochondria swell; disordered structure
Organelles contract	Organelles swell; organelle disruption
Nuclear clumping and fragmentation	Nuclear membrane disruption
Internucleosomal DNA fragmentation	Diffuse and random DNA fragmentation
Phagocytosis of apoptotic cells with no inflammation	Inflammation; macrophage infiltration

At a cellular level, shock is characterized by inadequate oxygen delivery to the cell to meet its metabolic needs. Necrosis from cellular energy failure was thought to be the main outcome from this physiologic state, but shock may also stimulate programmed cell death (apoptosis), which is recognized as an additional important mechanism that may lead to MODS following shock resuscitation.

Failure of apoptosis by inflammatory cells may represent an important mechanism of ongoing tissue inflammation and consequent tissue damage that can occur following resuscitation from shock.

Apoptosis Apoptosis, or programmed cell death, refers to a form of cell death that is distinct from necrotic cell death. Although there are important overlaps and a continuum between these two forms of cell death, for purposes of discussion, the respective characteristics of apoptotic cell death and necrotic cell death are highlighted in Table 17.2. An important feature of apoptosis, from a therapeutic standpoint, is that it is an active and regulated process that requires energy and the coordinated expression and repression, respectively, of pro-apoptotic genes ("cell suicide" genes) and anti-apoptotic genes. In fetal biology, apoptosis is a normal occurrence that is crucial to normal organ and limb development. Apoptosis is also important in normal cell turnover (e.g., the gut epithelium) and in removal of potentially deleterious cell types (e.g., cancer). Thus, apoptosis can be viewed as being "beneficial" to the host. It has become increasingly recognized, however, that apoptosis also occurs in response to shock and in this setting apoptosis may be "detrimental" to the host. Evidence for widespread apoptosis abounds in animal models of shock as well as in humans with shock and is generally believed to be a maladaptive response that accounts, in part, for shock-associated MODS. One notable exception is apoptosis of neutrophils, which is thought to be an important mechanism for resolution of tissue inflammation. It has been suggested that failure of neutrophil apoptosis accounts, in part, for the prolonged tissue inflammation (and consequent tissue damage) that can occur during shock states. Nevertheless, shock-associated apoptosis has become an attractive therapeutic target because it is an active and regulated process and as such is potentially reversible through pharmacologic or genetic intervention.

Nitric oxide Nitric oxide (NO) is a gaseous molecule that is produced endogenously by a broad variety of cell types. It is produced during the conversion of arginine to citrulline by the enzyme nitric oxide synthase (NOS). There are three broad isoforms of NOS. The constitutive human isoforms, formerly referred to as neuronal NOS (nNOS) and endothelial NOS (eNOS), are now known as NOS 1 and NOS 3, respectively, based on the order in which they were cloned. Generally speaking, the constitutive isoforms are responsible for production of low levels of NO that are highly important in the regulation of various homeostatic processes

including vascular tone, signal transduction, and neurotransmission. NOS 2 is an inducible isoform (formerly known as inducible NOS, or iNOS) and is responsible for high and prolonged output of NO during various normal and pathologic biological conditions. High production of NO is thought to mediate pathologic vasodilation, myocardial suppression, and direct cellular toxicity.

Because NO has such a broad variety of biological functions, the exact role of NO in shock states remains controversial. This is particularly true in septic shock, where experimental evidence indicates that NO has both detrimental and beneficial effects in the setting of septic shock. For example, overproduction of NO has been clearly demonstrated in both adults and children with septic shock. In children, the amount of NO production has been correlated with non-survival and with vascular hyporesponsiveness to vasoconstrictors. Despite this evidence, as well as compelling preclinical data, therapeutic strategies targeting inhibition of NO production in human septic shock have not been of benefit.

Nitric oxide (NO) is an important secondary messenger that regulates numerous cellular systems such as signal transduction, neurotransmission, and microvascular tone. High production of NO facilitated by induction of NOS 2 is thought to mediate pathologic vasodilation, depression of myocardial contractility, and direct cellular toxicity, but inhibition of NO production in human septic shock trials was not beneficial.

PARP-1 Poly(ADP-ribose) polymerase-1 (PARP-1) is a nuclear protein that senses and repairs DNA strand breaks that occur during various forms of cellular stress. In this capacity, PARP-1 is thought to play a beneficial role in shock states. In certain shock states, however, PARP-1 is thought to be overactivated and leads to cellular injury. This occurs because high level PARP-1 activity consumes NAD(+) and can consequently deplete ATP, thereby leading to cellular death secondary to energy failure. In addition, PARP-1 activation plays a role in the apoptosis pathway. Accordingly, there is a great deal of ongoing research focused on inhibition of PARP-1 activity in shock states.

NF-κB As previously mentioned, many shock states are characterized by a highly activated inflammatory response. Many of these inflammatory responses are centrally regulated by nuclear factor-κB (NF-κB). NF-κB is a transcription factor that regulates the expression of many genes involved in the innate immune response and inflammation pathways. These include cytokines, chemokines, and NOS 2. In addition, NF-κB has both pro- and anti-apoptotic activity. Because NF-κB is a central regulator of inflammation, there has been considerable interest in elucidating the role of NF-κB in shock states. Studies have clearly demonstrated increased activation of NF-κB in shock states; inhibition of NF-κB activation has been demonstrated to be beneficial in various animal models of shock. In humans with septic shock, the degree and duration of NF-κB activation has been correlated with mortality. In this regard, it is interesting to note that corticosteroids are potent inhibitors of NF-κB activation.

HIF-1 Hypoxia-inducible factor-1 (HIF-1) is also a transcription factor, which functions as a cellular-level "sensor" of hypoxia, a common manifestation of all shock states. Active HIF-1 is composed of two subunits: HIF-1α and HIF-1β. Both subunits are constitutively present in the cytoplasm, but under conditions of normoxia, the HIF-1α subunit is degraded by the ubiquitin-proteasome pathway. Under conditions of cellular hypoxia, however, the degradation of HIF-1α is terminated, thus allowing for the formation of HIF-1α/HIF-1β heterodimers, which are active and can translocate to the nucleus to increase the expression of various genes required for adaptation to hypoxia. These include erythropoietin, vascular endothelial growth factor, heme oxygenase, NOS 2, and various genes related to glucose metabolism. Thus, HIF-1 activation is potentially an important compensatory/adaptive mechanism during shock, and its regulation during shock states is a fruitful area of investigation.

Ischemia-reperfusion/oxidant injury All forms of shock have the potential to lead to ischemia-reperfusion injury. As the term for this form of injury implies, cellular injury is a manifestation of both the duration of low blood flow/low oxygen delivery (ischemia) and the restoration of normal blood flow/normal oxygen delivery (reperfusion). Thus, while the latter is an obvious therapeutic goal in the clinical setting, paradoxically, when blood flow and oxygen delivery are restored to normal (sometimes supernormal) levels, this process can itself exacerbate cellular and tissue injury, which has led to the recommendation to avoid arterial oxygen saturations greater than 96% in acutely ill patients. The process of reperfusion injury is highly complex but seems to be mediated in large part by the generation of free radical oxygen species during restoration of normal blood flow and oxygenation. The oxygen free radicals are intrinsically injurious to cells and tissues by damaging intracellular proteins and cellular membranes. In addition, these oxygen-derived free radicals can act as signaling molecules that can lead to various potentially cytotoxic events such as neutrophil and endothelial activation, cytokine production, activation of apoptosis, complement activation, expression of NOS 2, and PARP-1 activation. Accordingly, another important investigative effort is focused on ameliorating the potentially deleterious effects of reperfusion injury by free radical scavenging strategies.

Toll-like receptors Toll-like receptors (TLRs) are central to the cellular response to pathogens. TLRs are molecules that recognize pathogen-associated molecular patterns (PAMPs). Well-described PAMPs include lipopolysaccharide (gram-negative bacteria), peptidoglycan and lipoteichoic acid (gram-positive bacteria), double-stranded RNA (viruses), bacterial DNA, and flagellin (bacteria that possess flagella). TLRs are membrane-associated receptors that allow cells of the innate immune system to detect the presence of pathogens associated with septic shock. While pathogen recognition is vital for host defense mechanisms, TLR activation can also lead to the initiation of the various inflammatory cascades that contribute to the pathophysiology of septic shock. This has led to some investigation of TLRs (specifically TLR4) as therapeutic targets in sepsis. Some of the more well-studied TLRs and the specific PAMPS that are recognized by them are listed in ◘ Table 17.3.

Heat shock proteins Heat shock proteins (HSPs) are a broad group of intracellular proteins that serve as molecular chaperones. In this capacity, HSPs serve to stabilize, transport, and refold damaged intracellular proteins. HSP expression was first described in response to hyperthermia, hence the term "heat shock pro-

Multiple mediators operating at the cellular level affect the outcome of patients with shock. These include the following:

- *Poly(ADP-ribose) polymerase-1* (*PARP-1*) is a nuclear protein that senses and repairs DNA strands and is thought to cause injury during cellular hypoxia because it consumes NAD(+) which depletes ATP, thereby leading to cellular death secondary to energy failure.
- Many shock states are characterized by an activated inflammatory response, which is at least partly centrally regulated by *nuclear factor-κB* (NF-κB). NF-κB is a transcription factor that regulates the expression of many genes involved in the innate immune response and inflammation pathways.
- *Hypoxia-inducible factor-1* (*HIF-1*) is also a transcription factor, which functions as a cellular-level "sensor" of hypoxia, a common manifestation of all shock states. HIF-1 activation is potentially an important compensatory/

17

◘ **Table 17.3** Selected Toll-like receptors (TLRs) and their respective pathogen ligands

Receptor	Ligand
TLR1	Lipopeptides (bacteria)
TLR2	Peptidoglycan and lipoteichoic acid (gram-positive bacteria), HSP70
TLR3	Double-stranded RNA (viruses)
TLR4	Lipopolysaccharide (gram-negative bacteria), several HSPs
TLR5	Flagellin (flagella-bearing bacteria)
TLR6	Lipopeptides (mycoplasma)
TLR9	Bacterial DNA

teins." It is now known, however, that HSPs are also highly expressed in various forms of cellular stress, including shock. In this capacity, HSPs confer cellular protection against various forms of cellular injury including ischemia-reperfusion, hypoxia, and oxidant stress. Much of these cytoprotective effects appear to be mediated by the inducible isoform of HSP70. Apart from their molecular chaperone properties, activation of heat shock proteins also appears to have an inhibitory effect on activation of the NF-κB pathway described above. Extracellular levels of both HSP70 and HSP60 were found to be elevated in children with septic shock.

17.9 Clinical Monitoring of Shock

Clinical Despite technological advances in critical care medicine, physical exams and basic clinical parameters continue to be important "monitors" of shock. The following are key physical signs and basic clinical parameters that can assist in both detecting shock states and gauging the patient's response to therapy. *Low blood pressure* is highly suggestive of shock, but always remember that shock can be present in the setting of a normal blood pressure. Thus, restoration of a normal blood pressure should not be the only endpoint for shock-related therapy. Indeed, the optimal blood pressure is not known and achieving a specified blood pressure by excessive vasoactive drug-induced vasoconstriction may actually impair the goal of shock therapy: restoring adequate tissue perfusion. *Tachycardia* is a fundamental compensation for shock and resolution of tachycardia, particularly in hypovolemic shock, is a good indicator that the appropriate therapeutic endpoint (i.e., volume restoration) has been reached. *Decreases in pulse amplitude and/or perfusion* are also good clinical indicators of shock and are often evident before the onset of hypotension. *The pulse pressure* can also be highly informative. For example, a narrow pulse pressure is expected in the setting of hypovolemic or cardiogenic shock. Alternatively, a wide pulse pressure (manifested as bounding pulses and very brisk perfusion) can be seen in distributive shock and hyperdynamic septic shock. *Heart auscultation* can reveal an S_3 or S_4 sound ("gallop" rhythm) indicative of myocardial dysfunction. *Alterations in mental status* can also be a manifestation of shock, but it should be remembered that this is a relatively late sign of shock due to the various compensatory mechanisms that maintain cerebral blood flow. In sepsis, however, alterations in mental status may occur as an early manifestation. More often, other clinical signs of shock are likely to be present in other types of shock before alterations in mental status are clinically evident. *Increased work of breathing* with grunting may be seen in children with cardiogenic shock due to pulmonary edema, but may also be seen in children with pneumonia and sepsis. Finally, adequate *urine output* remains a valuable indicator of shock or shock resolution. Interpretation of urine output, however, must be made in the context of various confounding factors such as concomitant use of diuretics and/or intrinsic renal disease.

Acid-base status Since shock is defined by an insufficient delivery of oxygen to meet tissue oxygen demands, it is expected that shock leads to abnormalities in acid-base status. Specifically, shock can lead to increased dependence on anaerobic metabolism, which results in overproduction of lactate and protons. The classic scenario in shock states is the presence of an increased anion gap metabolic acidosis secondary to increased lactate production. Thus, serial measurement of arterial blood gases to identify the presence of a metabolic acidosis, and lactate concentration can serve as a guide for the severity, evolution, and resolution of shock. It should be stressed that serial measurements are of more practical value than isolated measurements.

adaptive mechanism during shock, and its regulation during shock states is a fruitful area of investigation.

- All forms of shock may cause *ischemia-reperfusion injury*. Reperfusion injury is a highly complex process that seems to be mediated in large part by the generation of free radical oxygen species during restoration of normal blood flow and oxygenation. The oxygen free radicals injure cells and tissues by damaging intracellular proteins and cellular membranes. In addition, they can act as signaling molecules leading to various potentially cytotoxic events such as neutrophil and endothelial activation, cytokine production, activation of apoptosis, complement activation, expression of NOS 2, and PARP-1 activation. To reduce reperfusion injury, many post-shock/resuscitation guidelines recommend maintaining arterial oxygen saturation <97%.
- *Toll-like receptors* (*TLRs*) are central to the cellular response to pathogens. TLRs are molecules that recognize pathogen-associated molecular patterns (PAMPs). While pathogen recognition is vital for host defense mechanisms, TLR activation can also initiate various inflammatory cascades that contribute to the pathophysiology of septic shock.
- *Heat shock proteins* (*HSPs*) are a broad group of intracellular proteins that serve to stabilize, transport, and refold damaged intracellular proteins. In addition to hyperthermia, HSPs are also highly expressed in various forms of cellular stress, including shock. In this capacity, HSPs confer cellular protection against various forms of cellular injury including ischemia-reperfusion, hypoxia, and oxidant stress.

Clinical signs provide insight into the type of shock. Low blood pressure is not required to diagnose shock. Tachycardia is a common compensatory response to a fall in stroke volume. A narrow pulse pressure (weak pulse) with decreased clinical perfusion is consistent with hypovolemic or cardiogenic shock, whereas a wide pulse pressure is characteristic of distributive shock and is common in septic shock. The presence of a gallop rhythm is consistent with cardiogenic shock. Alterations in mental status are often a late sign of shock but may be an early sign in sepsis.

An increased work of breathing with grunting suggests pulmonary edema due to cardiogenic shock or pneumonia and septic shock.

Increased lactate concentrations are often considered a marker of anaerobic metabolism and shock but should be interpreted in the context of the patient's acid-base balance since lactate may be increased for reasons unrelated to tissue hypoxia, such as increased gluconeogenesis mediated by endogenous or exogenous corticosteroids.

It should also be stressed that multiple factors, other than insufficient oxygen delivery, can affect acid-base status and lactate concentration. For example, liver dysfunction is associated with decreased metabolism of lactate, which in turn can lead to increased blood lactate concentrations that do not necessarily reflect increased lactate production. Furthermore, the laboratory measures lactate and not lactic acid; lactate may be increased without a metabolic acidosis, such as due to increased gluconeogenesis stimulated by endogenous or exogenous corticosteroids. Another notable example is loss of bicarbonate in the setting of severe diarrhea (hypovolemic shock). In this setting, patients can have a mixed source of metabolic acidosis: normal anion gap metabolic acidosis secondary to bicarbonate loss plus an anion gap acidosis (lactic acidosis) secondary to hypovolemic shock. Infusion of large amounts of fluid with high chloride content (e.g., normal saline) can also lead to a non-anion gap hyperchloremic metabolic acidosis, and there are recent reports of an independent association between hyperchloremia and poor outcomes among children with septic shock. Comorbid conditions also need to be considered when assessing acid-base status in the setting of shock. For example, a patient who has been on chronic, high-dose diuretic therapy or a patient that has chronic respiratory failure (hypercarbia) is likely to have a high baseline bicarbonate concentration. When these patients develop metabolic acidosis secondary to shock, the serum bicarbonate concentration may be in a normal range, but it should be recognized that their bicarbonate concentration has decreased significantly from the higher pre-shock level. Thus, it is imperative that serial measurements of arterial blood gases and lactate, in the setting of shock, be interpreted within the context of the multiple factors that can affect acid-base status independently of shock.

Pulmonary artery catheter The pulmonary artery catheter (PAC) remains the gold standard for objectively assessing oxygen delivery in the critically ill patient. ▶ Box 17.1 provides a condensed list of the variables that can be directly measured by a PAC and the variables that can be derived from these measurements. In this context, the PAC would seem to be an indispensable tool for the management of shock. Indeed, for many years, PACs were placed routinely in adults for a broad range of clinical conditions. Insertion of a PAC, however, carries important risks to the patient that are likely to be exacerbated in the smaller pediatric patient. Importantly, the utility and appropriateness of routine PAC insertion have come under very strong criticism, with some leaders in the field going as far as proposing a ban on the use of PACs. As this debate continues with considerable intensity, it is difficult to advocate for the routine use of PACs in pediatric patients with shock. It seems reasonable, however, to consider insertion of a PAC in pediatric patients with severe and complex forms of shock. As always, this must be considered in the context of the potential iatrogenic complications that can occur with PAC placement and the available clinical experience necessary to accurately interpret PAC-derived data.

Box 17.1 Selected variables measured by pulmonary artery catheters

Direct measurements

- Cardiac output
- Central venous pressure
- Pulmonary artery pressure
- Pulmonary capillary wedge pressure
- Mixed venous oxygen saturation

Derived measurements
- Oxygen delivery
- Oxygen consumption
- Oxygen extraction ratio
- Systemic vascular resistance
- Pulmonary vascular resistance

Mixed venous oxygen saturation Mixed venous oxygen saturation ($S_{mv}O_2$) is measured in the pulmonary artery after complete mixing of the venous return; this parameter can serve as a valuable objective measurement of oxygen delivery and consumption in shock states. The relationship between oxygen delivery and $S_{mv}O_2$ can be understood by the Fick principle:

$$\text{Oxygen Consumption} = \text{Cardiac Output} \times \left(\text{Arterial } O_2 \text{ content} - \text{Venous } O_2 \text{ content}\right)$$

This equation can be solved for cardiac output as follows:

$$\text{Cardiac Output} = \text{Oxygen Consumption} \div \left(\text{Arterial } O_2 \text{ content} - \text{Venous } O_2 \text{ content}\right)$$

The equation can be further modified by changing arterial O_2 content to arterial saturation (S_aO_2) and venous O_2 content to $S_{mv}O_2$:

$$\text{Cardiac Output} \cong \text{Oxygen Consumption} \div \left(S_aO_2 - S_{mv}O_2\right)$$

From this last equation, it can be seen that decreased $S_{mv}O_2$ yields a larger number in the denominator of the equation. If oxygen consumption and arterial oxygen content are constant, then a lower $S_{mv}O_2$ reflects a lower cardiac output. Physiologically, the fall in $S_{mv}O_2$ results from increased tissue uptake of oxygen when tissue blood flow and/or arterial oxygen content is reduced. Thus, decreases of $S_{mv}O_2$ suggest a decrease of oxygen delivery secondary to decreased cardiac output. The variables in this equation, however, are not always constant in the critically ill patient. For example, hypoxemia and/or anemia decreases arterial oxygen content. If the cardiac output and oxygen consumption are relatively constant in this context, then the $S_{mv}O_2$ would have to be lower based on this equation. In a similar manner, if oxygen consumption is increased, and cardiac output and arterial oxygen content are constant, then the $S_{mv}O_2$ also would have to decrease based on this equation.

In the absence of a pulmonary artery catheter, the oxyhemoglobin saturation of central venous blood sampled from the high right atrium ($S_{cv}O_2$) has become a widely accepted estimate of the mixed venous oxyhemoglobin saturation ($S_{mv}O_2$). Serial measurements of $S_{cv}O_2$ can serve as objective, indirect measurements of global oxygen delivery. Decreased $S_{cv}O_2$ can be indicative of inadequate oxygen delivery, while increases of $S_{cv}O_2$ in response to therapy can be indicative of effective therapy for shock. As stated above, however, changes in $S_{cv}O_2$ can also be indicative of changes in oxygen consumption or changes in arterial oxygen content. The latter can be readily estimated at the bedside (i.e., hemoglobin and pulse oximetry), thus leaving oxygen consumption as the only other "unknown" variable. This is important because it cannot be assumed that oxygen consumption is constant in the critically ill patient. For example, oxygen consumption increases by 10–13% for each 1 °C increase in temperature; thus, significant fever can lead to decreased $S_{cv}O_2$. Alternatively, some

Ideally, mixed venous oxygen saturation ($S_{mv}O_2$) is measured in the pulmonary artery after complete mixing of the venous return, but since pulmonary artery catheters are uncommonly used, central venous oxygen saturation ($S_{cv}O_2$) measured just above the right atrium is often used instead. This parameter can provide a valuable objective assessment of the balance between oxygen delivery and consumption in shock states. Serial measurements of $S_{cv}O_2$ are especially useful as an indirect measurements of changes in global oxygen delivery and consumption in response to therapy.

Factors that can decrease $S_{cv}O_2$ are decreased cardiac output, decreased arterial oxygen content (low hemoglobin and/or low arterial oxygen saturation), and increased tissue metabolic demand.

patients with shock (particularly septic shock) are unable to adequately consume oxygen. This would be reflected as a high or normal S_vO_2 that could be inappropriately interpreted as a sign of adequate oxygen delivery.

Even when a central venous catheter is not available, relatively recent technology based on near-infrared and visible light spectroscopy provides noninvasive and clinically feasible estimates of $S_{cv}O_2$. These probes may be placed on the forehead and over the liver, kidney, or other organ to continuously estimate venous oxygen saturation in that body region.

Variables that can affect $S_{mv}O_2$ include intracardiac shunts (left to right) and catheter tip placement. As stated above, the ideal catheter tip placement for measuring $S_{mv}O_2$ is the pulmonary artery since this site represents the most complete mixing of venous blood return. It has been demonstrated, however, that placement of a catheter tip at the junction of the superior vena cava and the right atrium ($S_{cv}O_2$) provides a clinically reasonable estimate of $S_{mv}O_2$.

The value of superior vena cava-derived $S_{cv}O_2$ data was demonstrated in a randomized trial involving adult patients with septic shock. Patients were randomized to one of two treatment protocols, and importantly, protocol-based therapy was instituted during the first 6 hours of presentation to the emergency department, prior to transfer to the intensive care unit. In one protocol cohort, patients received therapy targeting "traditional" endpoints such as central venous pressure, blood pressure, and urine output (standard therapy group). The other protocol cohort targeted similar endpoints but added $S_{cv}O_2$ measurements ($\geq$70%) as the goal endpoint for therapy (goal-directed therapy group). $S_{cv}O_2$ measurements were taken from central venous catheters placed in the superior vena cava.

While this initial study showed improved survival, more recent trials (ProCESS, ARISE, ProMISe) have not shown an attributable survival benefit for $S_{cv}O_2$ measurement-directed therapy, relative to standard care. In addition, $S_{cv}O_2$ measurement-directed therapy increases the cost of care. While not studied extensively in the pediatric patient in shock, there are some data suggesting that resuscitation directed at normalization of $S_{cv}O_2$ (i.e., an oxygen saturation $\geq$70%) can improve outcomes in the setting of pediatric septic shock, but the sample size was small and the baseline mortality rate of the standard care group was relatively high, thus calling into question the generalizability of these data.

17.10 Therapy for Shock

For all forms of shock, there are two equally important levels of therapy: etiology-specific therapy and supportive therapy. In all cases of shock, the direct cause of shock should be addressed if possible. For example, in hemorrhagic shock, there often needs to be surgical intervention to curtail ongoing blood loss. In septic shock, antibiotics and source removal continue to be mainstays of therapy. In anaphylactic shock, it is crucial to discontinue and avoid further contact with the antigenic stimulus, when known. In cardiogenic shock, anatomic causes of myocardial failure (e.g., coarctation of the aorta) need to be addressed surgically.

Often, however, there are no specific therapeutic strategies to address the underlying cause of shock. In this scenario, supportive therapy becomes the mainstay of therapy. These supportive therapies will be the focus of the subsequent sections and will not include mechanical approaches such as extracorporeal membrane oxygenation, ventricular assist devices, and intra-aortic balloon pumps. The need to address the specific cause of shock, when feasible, cannot

be overstated but will not be repeated in each of the following sections. The therapeutic endpoints discussed in the previous section are potentially applicable for all of the following supportive therapies.

Hypovolemic shock The primary supportive therapy for hypovolemic shock is restoration of intravascular volume. The type of intravenous fluid that is used for volume restoration will vary depending on the cause of hypovolemia. In hypovolemic shock secondary to vomiting and diarrhea, crystalloid replacement is usually sufficient. The type of crystalloid depends on the presence or absence of associated electrolyte disturbances (e.g., hypo- or hypernatremia). The use of albumin as the replacement fluid for hypovolemic shock is probably best reserved for situations associated with direct loss of albumin (e.g., burns, open wounds, protein-losing enteropathies). In cases of hemorrhagic shock, volume replacement with crystalloid or albumin can be appropriate, but with significant blood loss, replacement of red blood cell mass will eventually become a necessity. In the setting of large volume red blood cell transfusion requirements, consideration also needs to be given to replacement of other blood components such as platelets and plasma. Ongoing work in the adult trauma literature, including studies related to battlefield casualties, indicates that the ratio of red blood cells to other blood components (i.e., plasma and platelets) is a critical outcome factor for patients with massive hemorrhage and that the ratio may be lower than advocated by traditional practice (e.g., plasma-to-RBC ratio between 1:1 and 1:2).

While most patients with hypovolemic shock tolerate relatively rapid correction of intravascular volume depletion, there are some notable exceptions that may require less rapid correction. For example, in cases of hypovolemic shock that are accompanied by significant metabolic/electrolyte derangements (e.g., hypernatremia or diabetic ketoacidosis), volume deficit correction must be tempered so as to not correct the accompanying metabolic/electrolyte abnormalities too rapidly. In patients with underlying myocardial dysfunction, correction of hypovolemic shock must be done more judiciously than that of a patient with normal myocardial function so as to not further compromise myocardial function. Finally, there may be trauma-specific situations in which very aggressive volume resuscitation for hemorrhagic shock is not appropriate until surgical control of hemorrhage is achieved.

Shock treatment consists of etiology-specific therapy and general supportive measures. In hypovolemic shock, the main supportive therapy is restoration of intravascular volume, typically provided with isotonic crystalloid. In most children, this can be infused rapidly, but fluid should be given more slowly in children with diabetic ketoacidosis or concomitant impaired cardiac function. If there is blood loss, such as with trauma, red blood cells may be required. If there is a need for substantial blood transfusion, fresh frozen plasma and platelets should also be given.

Cardiogenic shock Assuming that the heart rate is appropriate, the therapeutic strategies for cardiogenic shock are focused on optimizing stroke volume. This entails optimization of the three aforementioned components of stroke volume: preload, afterload, and contractility. In addition, consideration can be given to decreasing metabolic demand, when feasible. For example, fever can be reduced pharmacologically or mechanically, and increased respiratory effort can be mitigated with mechanical ventilation as a means to reduce metabolic demand.

Optimization of preload can consist of either administration of volume to increase preload or administration of diuretics to decrease preload. The physiologic principle for basing this decision is depicted in ◘ Fig. 17.2, a theoretical Starling curve. Admittedly, it is sometimes difficult to correctly assess clinically where on the Starling curve a particular patient is functioning. Helpful adjuncts include central venous pressure (CVP), responses to fluid challenge, and chest radiographs. The optimal CVP will vary from patient to patient because CVP is influenced by factors other than intravascular volume including myocardial compliance, intrathoracic pressure, and catheter tip placement. All of these factors must be taken into consideration when interpreting and optimizing CVP. There is, in fact, a degree of "trial and error" that must sometimes occur in order to optimize CVP at the bedside. For example, a fluid challenge that

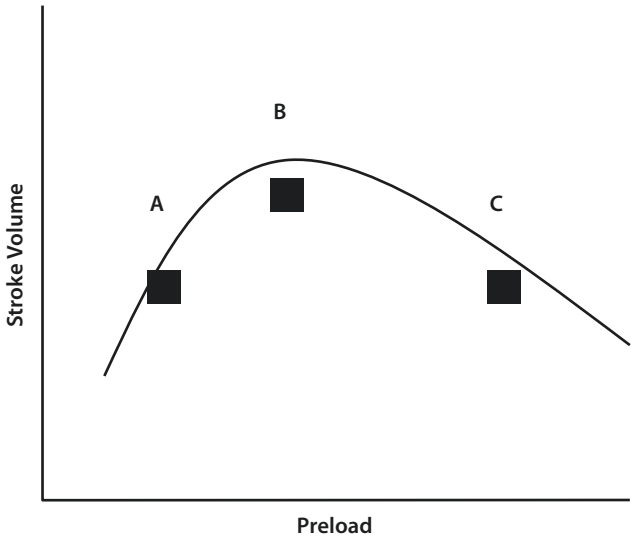

Fig. 17.2 Theoretical Starling curve in which stroke volume (y-axis) is dependent on preload (x-axis) with the assumption that myocardial contractility and afterload are constant. Point B is the ideal preload at which stroke volume is maximal for a given state of contractility and afterload. Point A depicts a condition in which additional preload (i.e., intravascular volume) is necessary to optimize stroke volume. Point C depicts a condition in which less preload (i.e., diuretic administration) is necessary to optimize stroke volume. Note that preload is not the same as CVP; changes in ventricular compliance complicate the estimation of preload from filling pressure

does not change CVP, but leads to a decrease of heart rate and an improvement in perfusion and urine output, likely means that the patient needs further, judicious administration of fluid to optimize preload. Conversely, a fluid challenge that leads to a large increase in CVP with increased heart size and pulmonary edema on chest radiograph, but no concomitant improvement in urine output or perfusion, likely means that the patient needs diuretics to optimize preload.

Additional bedside metrics to help assess fluid balance include the use of the passive leg raise (PLR) test. The PLR consists of using continuous cardiopulmonary monitoring while laying the patient flat and elevating one or both legs to 45°, which effectively displaces fluid from the leg(s) into the intrathoracic cavity. This ultimately gives the patient a fluid bolus of approximately 5% of their blood volume that if deleterious can be quickly removed by lowering the leg. A patient is deemed fluid responsive if stroke volume increases by approximately 10%, which if present carries a high degree of sensitivity and specificity for fluid responsiveness.

The use of ultrasound to assess IVC caliber as a measure of fluid responsiveness has also been investigated. To date, the degree of clinician variability in assessing IVC caliber and thereby fluid responsiveness makes the use of ultrasound less reliable in predicting fluid responsiveness.

Afterload reduction (reduction of systemic and/or pulmonary vascular resistance) can be a very effective approach to optimizing stroke volume. The rationale for afterload reduction is based on the equation describing systemic vascular resistance (SVR):

$$\text{SVR} = \left(\text{Mean Arterial Pressure} - \text{Central Venous Pressure}\right) \div \text{Cardiac Output}$$

Solving this equation for cardiac output yields the following equation:

$$\text{Cardiac Output} = \left(\text{Mean Arterial Pressure} - \text{Central Venous Pressure}\right) \div \text{SVR}$$

From this equation, it can be seen that if mean arterial pressure and central venous pressure remain relatively constant, then a reduction in SVR is accompanied by an increase in cardiac output (stroke volume). Measuring SVR requires direct measurement of cardiac output (e.g., pulmonary artery catheter). It is clinically feasible and appropriate, however, to manipulate SVR without the use of invasive monitoring. In this more common scenario, medications for afterload reduction are titrated to clinical improvements in cardiac output (described previously) with the limiting factor being hypotension. Common medications for afterload reduction include sodium nitroprusside, milrinone, angiotensin-converting enzyme inhibitors, and nicardipine. An important caveat to optimal afterload reduction is that the patient first needs to have an optimal preload. Furthermore, since many of these agents increase venous compliance, fluid may be needed to maintain the intravascular volume with an expanded vascular capacitance.

Contractility is manipulated through the use of inotropic medications. These include direct β-adrenergic agonists (e.g., epinephrine and dobutamine) and phosphodiesterase inhibitors (e.g., milrinone). Calcium chloride infusions may also be of benefit in cardiogenic shock, particularly in younger children who seem to derive a substantial contractility benefit from increased extracellular calcium concentrations. Similar to afterload reduction, these medications can be titrated based on invasive measurements or clinical improvements in cardiac output. Limiting factors for β-adrenergic agonists include increased myocardial oxygen consumption, tachycardia and other arrhythmias, and undesired increases of SVR or PVR. Limiting factors for phosphodiesterase inhibitors include hypotension (i.e., excessive afterload reduction and/or vasodilation), which may occur secondary to increased drug accumulation in the setting of renal dysfunction.

A more recent trend in the management of patients with established cardiomyopathies (i.e., chronically compensated cardiogenic shock) deemphasizes the use of β-adrenergic agonists due to obligate increases of myocardial oxygen consumption and cellular level changes leading to further cardiomyocyte dysfunction. In fact, some of these patients benefit from long-term use of highly selective β_1-adrenergic antagonists in combination with afterload reduction and diuretics, once they are no longer in acute cardiogenic shock.

Assuming that the heart rate is appropriate, the therapeutic strategies for cardiogenic shock focus on optimizing stroke volume by treatments that optimize preload, reduce afterload, and increase contractility. In addition, decreasing metabolic demand, when feasible, can improve the balance between oxygen delivery and demand. Cautious fluid boluses or passive leg raise is used to test if the patient is preload responsive. If the patient has signs of edema and/or documented increased cardiac preload (e.g., by echocardiography), then diuretics are indicated.

In patients with cardiac dysfunction and low stroke volume, afterload-reducing agents can improve stroke volume with little effect on the patient's mean arterial pressure. Unlike inotropic agents, afterload-reducing agents improve stroke volume while simultaneously reducing myocardial oxygen demand. Inotropic agents may be needed in the short term, but they increase myocardial oxygen demand and increase the risk of tachyarrhythmias; depending on the agent, they may increase afterload. Patients with chronic heart failure may benefit from long-term use of highly selective β_1-adrenergic antagonists in combination with afterload reduction and diuretics.

Distributive shock: Treatment for pure distributive shock includes restoration of vascular tone and intravascular volume expansion. Since the primary cardiovascular mechanism in distributive shock is pathologic vasodilation, the use of vasoactive medications that restore vascular tone is appropriate as a primary supportive therapy. These include norepinephrine and phenylephrine infusions. Epinephrine infusions can also be used, but its β_1-adrenergic agonist effect on the myocardium may not be necessary and could be detrimental. Furthermore, epinephrine's β_2-adrenergic agonist action on vascular smooth muscle may further reduce vascular tone. Intramuscular epinephrine injections are typically used at the onset of anaphylactic shock and help reduce bronchospasm through its β_2-adrenergic effects as well as inhibit mediator release from mast cells. The need for intravascular volume expansion is predicated on the concept that pathologic vasodilation leads to increase vascular capacitance leading to relative hypovolemia with decreased venous return. Adjunctive therapies for distributive shock secondary to anaphylaxis include corticosteroids and antihistamines. Older therapies that are garnering re-discussion include angiotensin II (ATII) for its favorable vasopressor effects through vasoconstriction and increased aldosterone production. Recent studies have shown the positive benefits of ATII in distributive shock by decreasing the total dose of catecholamines needed. Endogenous

Treatment for pure distributive shock includes restoration of vascular tone and intravascular volume expansion. Epinephrine is used to treat anaphylactic shock, but norepinephrine is preferred for spinal shock.

angiotensin II is created by the angiotensin-converting enzyme (ACE) converting angiotensin I to II. In states of stress, there can be reduced ACE activity and therefore a decreased production of angiotensin II, thus accounting for the benefit of an ATII infusion. Additional studies have found a benefit of ATII when prescribing continuous renal replacement therapy (CRRT). The benefit in this setting reflects an improved ability to remove fluid while avoiding hypotension and decreasing renal oxygen consumption when compared to catecholamines alone.

Septic shock As mentioned earlier in this chapter, septic shock is characterized by all three major classifications of shock: hypovolemic, cardiogenic, and distributive shock. Accordingly, all of the aforementioned supportive therapies and therapeutic endpoints are potentially applicable to the management of septic shock. The clinical challenge lies in the recognition that the degree to which any one of these three forms of shock is present in a given patient can be highly variable and may change over time. Aggressive intravascular support, however, is generally accepted as a primary supportive therapy for all patients with septic shock, at least in developed countries where there is access to advanced care and technologies. This recommendation is supported by historical data demonstrating improved outcomes for children with septic shock that received >40 mL/kg of fluid administration during the first hour of presentation. In the setting of aggressive fluid management, the clinical challenge then becomes whether the patient should be supported primarily for cardiogenic shock, distributive shock, or some combination of the two. Physical exam in combination with CVP response to a fluid challenge and echocardiography are typically sufficient data to make this decision. For certain patients, insertion of a PAC may provide further useful information on which to base therapeutic decisions. Specific recommendations and guidelines for supportive cardiovascular therapy in pediatric septic shock were published by a task force composed of pediatric critical care practitioners sponsored by the American College of Critical Care Medicine and the Society of Critical Care Medicine. The recommendations include serial examination for signs of intravascular fluid overload during volume loading in order to avoid iatrogenic injury from volume overload. Additionally, there are a subset of patients who require continued aggressive fluid resuscitation due to ongoing losses. It is prudent to ensure that acute fluid balance goals are achieved.

Historically, high-dose, short-term corticosteroids were used for patients with septic shock, but when this approach was subjected to formal, randomized trials, they were proven to not be of benefit and perhaps were detrimental. However, the use of corticosteroids in septic shock has been reconsidered and coupled with the concepts of longer term therapy, lower doses, and "relative adrenal insufficiency." The latter is based on an ACTH stimulation test followed by serial measurements of serum cortisol levels. Previously, relative adrenal insufficiency was defined as a serum cortisol concentration <9 μg/dL following ACTH stimulation. Using these criteria for initiation of corticosteroid replacement therapy, a significant survival benefit was demonstrated in adult patients treated with a combination of hydrocortisone and fludrocortisone. However, a subsequent trial based on a similar strategy failed to show a survival benefit secondary to adjunctive hydrocortisone. Further, a recent consensus conference was unable to generate a universally accepted definition of relative adrenal insufficiency.

There have been two recent large trials testing the efficacy of adjunctive corticosteroids in adults with septic shock, neither of which used ACTH stimulation and cortisol measurements. The ADRENAL trial randomized 3800 septic patients in Australia and New Zealand to hydrocortisone or placebo and

found no difference in all cause mortality at 90 days, although those treated with hydrocortisone had faster resolution of shock. The APROCCHSS trial randomized 1241 patients to hydrocortisone plus fludrocortisone or placebo. Those receiving hydrocortisone plus fludrocortisone had a 90-day mortality rate of 43%, whereas those in the placebo group had a 90-day mortality rate of 49% ($p = 0.03$; NNT ≅ 17).

Pediatric sepsis guidelines notwithstanding, there are no analogous large clinical trials involving children to inform the use of adjunctive corticosteroids in pediatric septic shock. A meta-analysis of available trials did not demonstrate a survival benefit. Observational studies have also failed to show efficacy, and some suggest harm. This important question regarding the role of adjunctive corticosteroids for pediatric septic shock can only be answered via a large randomized trial, which is currently in the planning stages.

Ultimate progress in further advancing therapeutic strategies in both adults and children with septic shock may be predicated on the development of stratification strategies. Because septic shock is a heterogeneous syndrome, rather than a distinct disease, several subclasses of patients with septic shock are likely to exist based on the host response to an infectious challenge. Unfortunately, clinical trials for septic shock fail to address this heterogeneity. Current translational research efforts in pediatric septic shock are directly addressing this challenge of heterogeneity by systematically deriving septic shock stratification tools based on biomarkers and gene expression signatures. The ultimate goals of these stratification strategies is to more rationally conduct clinical trials in more biologically homogeneous populations and to better inform individual patient management.

Septic shock may be characterized by components of all three major classifications of shock: hypovolemic, cardiogenic, and distributive shock. Initial aggressive intravascular support is generally accepted as a primary supportive therapy for all patients with septic shock, at least in developed countries. Fluid refractory septic patients are more likely to have myocardial dysfunction with or without abnormal vascular tone.

Because septic shock is a heterogeneous syndrome, rather than a distinct disease, several subclasses of patients with septic shock are likely to exist based on the patients' host response to an infectious challenge. Clinical sepsis trials fail to address this heterogeneity, but current translational research is directly addressing this challenge of heterogeneity by systematically deriving septic shock stratification tools based on biomarkers and gene expression signatures. These trials may help identify, for example, which patients may benefit from corticosteroid therapy, a therapy that remains quite controversial.

Review Questions

1. The statement that best describes physiologic alterations observed in shock is:
   A. Cardiogenic shock is more often the result of diastolic dysfunction than systolic dysfunction.
   B. Distributive shock is characterized by reduced cardiac output and pathologic vasodilation.
   C. Hemorrhagic shock produces an acute reduction in oxygen carrying capacity and may be complicated by multiple organ dysfunction syndrome.
   D. Increasing the partial pressure of oxygen often results in the greatest increase in oxygen carrying capacity.
   E. Septic shock often displays a predictable hemodynamic profile across multiple hosts.

2. Shock at the cellular level may be characterized by:
   A. Compromised oxidative phosphorylation and rapid accumulation of cytosolic ATP
   B. Decreased activation of nuclear factor-κB activation
   C. Failure of neutrophil apoptosis causing prolonged tissue inflammation
   D. Low levels of poly(ADP-ribose) polymerase-1 activity leading to ATP depletion
   E. Overproduction of nitric oxide leading to pathologic vasoconstriction

3. The most correct statement regarding the monitoring of therapeutic interventions during shock is that:
   A. Decreased $S_{cv}O_2$ can be indicative of inadequate oxygen delivery or decreased oxygen consumption, while increases of $S_{cv}O_2$ in response to therapy can be indicative of effective therapy for shock.

B. Due to the variable clinical examination findings in shock, serial examinations have been supplanted by more objective measures of shock such as lactate and mixed venous oxygen saturation determinations.
C. Insertion of a pulmonary artery catheter is often necessary early in the treatment of septic shock.
D. Mixed venous oxygen saturation is best measured from a pulmonary artery catheter with the tip in the pulmonary artery or alternatively by a central venous line with the tip at the inferior portion of the right atrium.
E. Serial examinations and serial measurements of mixed venous or central venous oxygen saturation and lactate can serve as a guide for the severity, evolution, and resolution of shock.

4. A 6-year-old, 20 kg boy recently diagnosed with acute lymphocytic leukemia is undergoing induction chemotherapy. He develops fever and is found to be neutropenic (absolute neutrophil count 410 cells/μL), anemic (hemoglobin 8.1 gm/dL), and thrombocytopenic (platelet count 108,000/μL). In the clinic, he is cool distally, has poor pulses, and has a delayed capillary refill of 5 seconds. He develops sustained tachycardia to 180 beats per minute and has a blood pressure of 85/67 mm Hg. He is given a 400 mL bolus of normal saline and is transferred to the PICU. Upon PICU arrival, he is agitated, is poorly perfused, and remains tachycardic (167 beats per minute). His blood pressure is 94/78 mm Hg. Central venous blood obtained from a Broviac catheter (tip located at the superior portion of the right atrium) reveals a central venous oxygen saturation of 55% and a lactate of 3.4 mmol/L. He has made minimal urine since his admission. The most correct statement regarding his management is which of the following?
A. An additional 20 mL/kg normal saline should be administered while awaiting the arrival of packed red blood cells for transfusion.
B. Further volume resuscitation should be withheld pending results of a STAT echocardiogram.
C. No further volume resuscitation is required. He requires rapid initiation of inotropic support.
D. No further volume resuscitation is required. He requires rapid initiation of vasopressor support.
E. No further volume resuscitation is required. He requires rapid initiation of afterload reduction.

5. A 17-year-old adolescent boy is transferred from an outlying facility to the PICU for treatment of refractory pneumonia. He had a 10-day viral prodrome consisting of low-grade fever, progressive fatigue, and dyspnea. His initial chest radiograph revealed bilateral basilar infiltrates. His current exam reveals tachypnea (34 breaths per minute), tachycardia (132 beats per minute), and a blood pressure of 110/91 mm Hg. He is cold distally and has a capillary refill time of 5 seconds. He is anxious and complains of chest pain. Repeat chest radiograph reveals diffuse bilateral infiltrates and cardiomegaly. Bedside ultrasound demonstrates no pericardial or pleural effusion, dilated ventricles, and depressed contractility. His oxygen saturation is 98% on 2 liters oxygen via nasal cannula. An arterial lactate is 7.8 mmol/L. Which of the following statements best describes the etiology and treatment of this patient?
A. He has become fluid overloaded from overzealous fluid administration and requires aggressive diuresis.

B. His pneumonia is now complicated by ARDS and septic shock. He requires endotracheal intubation and initiation of epinephrine at 0.1 mcg/kg/minute.
C. Myocarditis should be strongly suspected. He should undergo rapid endotracheal intubation and have an epinephrine infusion initiated at 0.5 mcg/kg/minute.
D. Myocarditis should be strongly suspected. Furosemide should be administered and a dopamine infusion initiated at 20 mcg/kg/minute.
E. Myocarditis should be strongly suspected. Milrinone should be initiated at 0.5 mcg/kg/minute while awaiting echocardiography.

6. A 16-year-old female develops fever, rigors, diffuse erythema, and syncope. In the emergency department, she is found to have tachycardia (162 beats per minute) and a blood pressure of 98/35 mm Hg. She is warm distally and has a capillary refill time of less than 1 second. She is anxious and complains of diffuse myalgias. She again becomes syncopal when sitting up. She is placed in the Trendelenburg position and is given three 20 mL/kg normal saline boluses over 1 hour. Her perfusion is unchanged and repeat blood pressure is 100/22 mm Hg. She is given an additional 20 mL/kg fluid bolus upon arrival to the PICU and has a central venous catheter placed. ST changes are noted on the bedside cardiac monitor. Which of the following statements best describes the etiology and treatment of this patient?
   A. She has cardiogenic shock complicating sepsis and requires the institution of a milrinone infusion.
   B. She has a distributive type of septic shock and requires more fluid resuscitation.
   C. She has a distributive type of septic shock and requires the initiation of a high-dose dopamine infusion.
   D. She has a distributive type of septic shock and requires the rapid institution of a vasopressor such as norepinephrine.
   E. She has overwhelming hypodynamic sepsis and requires the institution of an epinephrine infusion.

7. The correct statement regarding acid-base status and shock is that:
   A. A bicarbonate infusion following volume resuscitation is often necessary to correct systemic acidosis.
   B. Increased anion gap metabolic acidosis is often due to bicarbonate loss.
   C. Initial measurements of arterial blood gases and lactate, in the setting of shock, are highly predictive of outcome.
   D. Multiple factors, other than insufficient oxygen delivery, can affect acid-base status and include liver dysfunction and infusions of normal saline.
   E. Shock can lead to increased dependence on aerobic metabolism, which results in overproduction of pyruvate.

Learning Objectives

- Summarize the physiology of the cardiac action potential.
- Summarize how antiarrhythmic medications alter cardiac conduction.
- Discuss the various mechanisms that generate tachyarrhythmias (increased automaticity, reentrant tachycardias, and triggered activity).
- Describe how to identify and treat common pediatric tachyarrhythmias.
- Describe the causes and treatment of bradycardia.
- Describe basic pacemaker functionality.
- Summarize the natural history and treatment of common pediatric rhythm disorders.

18.1 Fundamental Electrophysiology

Cardiac cells maintain a net negative charge, resulting in a transmembrane gradient that allows for action potential generation.

A fundamental understanding of cardiac electrophysiology allows the clinician to manipulate cardiac conduction in the clinical setting. The normal myocardium has the ability to generate, contract in response to, and propagate an action potential. Cardiac cells maintain an ion gradient across the cell membrane with an overall negative intracellular charge. This *transmembrane gradient* facilitates ion flow and the generation of the action potential, which is the driving force for cardiac activity (Fig. 18.1). Cardiac cells maintain high intracellular potassium (140 mM/L) and low intracellular sodium (10 mM/L) concentrations as the major source of the transmembrane gradient. Low intracytoplasmic calcium levels (10^{-4} mM/L) also contribute to the resting equilibrium potential. These values have clinical implications. For example, a rise of the extracellular potassium concentration (hyperkalemia) decreases the cardiac transmembrane potential, which, if severe, can ultimately lead to asystole. Conversely, bolus intravenous calcium administration augments the calcium component of the transmembrane gradient, which counteracts some of the negative electrophysiologic effects that are induced by abnormally high serum potassium concentrations.

The low cytoplasmic calcium concentration also highlights the remarkable energy-based pumping function of the cardiac cell to maintain an ~10,000-fold calcium concentration gradient between the inside and outside of the cell.

Low intracellular Na and Ca with high intracellular K concentrations maintain the transmembrane gradient.

Cardiac cells generate the action potential largely by maintaining low intracellular Na^+ and Ca^{++} concentrations, together with a high intracellular K^+ concentration.

Sinus node tissue usually demonstrates the fastest phase 4 depolarization, thereby controlling the heart rate. Sinus node and other automatic tissue increase their phase 4 depolarization rate in response to heat (fever) and catecholamine stimulation. Similar effects may be seen in nodal tissue with the removal of parasympathetic input.

The cardiac action potential begins with rapid, phase 0 depolarization. Phase 0 activity results from rapid Na^+ influx (I_{Na}) through newly opened sodium channels and produces a transient decrease (positive deflection) of the transmembrane potential. Depolarization of a single cell stimulates opening of sodium channels on neighboring cells, producing a spreading cur-

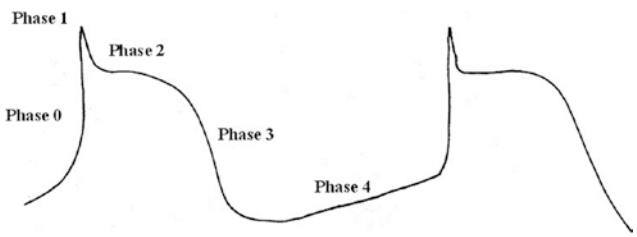

Fig. 18.1 Action potential of a cardiac myocyte: Phase 0, rapid depolarization caused by rapid sodium influx; phase 1, early phase of repolarization caused by rapid inactivation of sodium channels and opening of potassium channels; phase 2, plateau phase of repolarization characterized by slow calcium influx; phase 3, late repolarization with calcium channels closing and an outward transmembrane flow of potassium down its concentration gradient to assist in restoring the negative intracellular charge and return to resting potential; phase 4, early depolarization

rent across the entire heart. Per convention, the depolarization wave is read as a positive reflection as it moves toward a surface electrode on a standard electrocardiogram; conversely, a downward reflection is recorded as the depolarization wave moves away from a surface electrocardiogram lead. Following contraction, the myocyte must repolarize in order to undergo subsequent conduction/contraction cycles. Repolarization comprises phases 1–3 of the action potential and is mediated via a number of ion channels with complex and yet to be fully elucidated cellular and molecular interactions. Unlike nerve cells, cardiac cells have a prolonged action potential (thus delaying repolarization) as is represented by the flattened plateau phase 2 and slope of phase 3. Delayed phase 2 repolarization is mediated by the balance of inward calcium (I_{Ca}) and outward potassium flow (I_K), with the cell returning to its resting potential at the conclusion of phase 3. In general, cardiac cells are unable to conduct a new impulse until they have completed phase 3 repolarization. The duration of phases 1–3 of the action potential approximates the *refractory period* of the tissue. Cardiac cells differ in their rate of phase 4 depolarization. In the normal state, sinus node tissue demonstrates the fastest rate of phase 4 depolarization, thereby providing innate pacemaker function.

Antiarrhythmic drugs typically affect specific ion channels and therefore alter specific portions of the action potential. For example, by binding to channel proteins and inhibiting sodium ion influx, class I drugs slow the rate of phase 0 depolarization and slow cardiac conduction velocity. In the 1970s, E. M. Vaughan Williams proposed an antiarrhythmic drug classification based mainly on empiric experimental data. This classification system remains relevant today and is presented in Table 18.1.

Antiarrhythmic medications affect specific portions of the action potential in order to alter cardiac conduction and intrinsic pacemaker activity. Medication choice is often targeted to achieve a particular response, depending on the arrhythmia being treated.

An exhaustive discussion of antiarrhythmic pharmacology is beyond the scope of this text. However, individual agents will be discussed in the context of specific arrhythmias and their treatment.

Table 18.1 Vaughan Williams drug classification

Class	Action	Drug examples
I	Sodium channel blockers	
IA	Prolong the action potential duration	Procainamide, disopyramide
IB	Shorten (or do not change) action potential duration	Lidocaine, phenytoin
IC	Mildly prolong the action potential	Flecainide, propafenone
II	Beta-adrenergic blockers	Atenolol, propranolol, etc.
III	Potassium channel efflux blockers (prolong the action potential by inhibiting phase 4 depolarization)	Amiodarone, sotalol
IV	Calcium channel blockers	Diltiazem, verapamil
V	Miscellaneous commonly used agents	Adenosine, digoxin

18.2 General Arrhythmia Mechanisms

Most *tachyarrhythmias* can be classified as being caused by reentry, increased automaticity, or triggered activity.

Three general mechanisms produce most tachyarrhythmias: (1) *reentry*, which involves circular, self-propagating rhythm cycles; (2) *increased automaticity*, produced by abnormal impulse generations; and (3) *triggered activity*, arising due to "afterdepolarizations" in diseased heart muscle. Specific tachyarrhythmias are largely named/identified based on where in the heart these mechanisms arise (see Fig. 18.2).

For example, a reentrant circuit confined to the atria may produce atrial flutter, whereas a reentrant circuit located in the ventricle produces a ventricular tachycardia. Similarly, atrial-level triggered activity has been described in some patients with multifocal atrial tachycardia, which may be well tolerated in the short term, but can lead to cardiomyopathy when chronic. Conversely, triggered activity arising in the ventricle may produce torsades de pointes, a potentially fatal rhythm associated with the congenital long QT syndrome.

18.2.1 Reentry Disorders

Reentry is the most frequent mechanism of tachyarrhythmias and is defined as a cardiac impulse generating subsequent depolarizations in a sequential, predictable manner.

Reentry is the most frequent mechanism producing tachyarrhythmias. *Reentrant circuits* are responsible for a variety of supraventricular tachyarrhythmias (SVTs) including bypass tract-mediated tachycardias, atrial flutter, and atrioventricular nodal reentrant tachycardias (AVNRT). Reentrant phenomena are also commonly associated with ventricular tachycardia in the adult, where ischemia and infarction may produce variations in local conduction properties. Reentry can be defined as a cardiac impulse that generates subsequent depolarizations in a sequential, predictable manner. *During reentry, a single heartbeat regenerates itself*. For this to occur, a variety of conditions must be met. First, a nonuniform conduction pathway must be present that typically differs from normal in both (i) conduction velocity and (ii) refractory period. Second, to initiate the reentrant circuit, a premature impulse must arrive at a time when the more slowly repolarizing arm of the circuit is refractory. Finally, the specific geometry and timing characteristics of the circuit must be precise in order for the arrhythmia to be sustainable. Any manipulation of circuit conduction characteristics (e.g., slowing conduction with a class

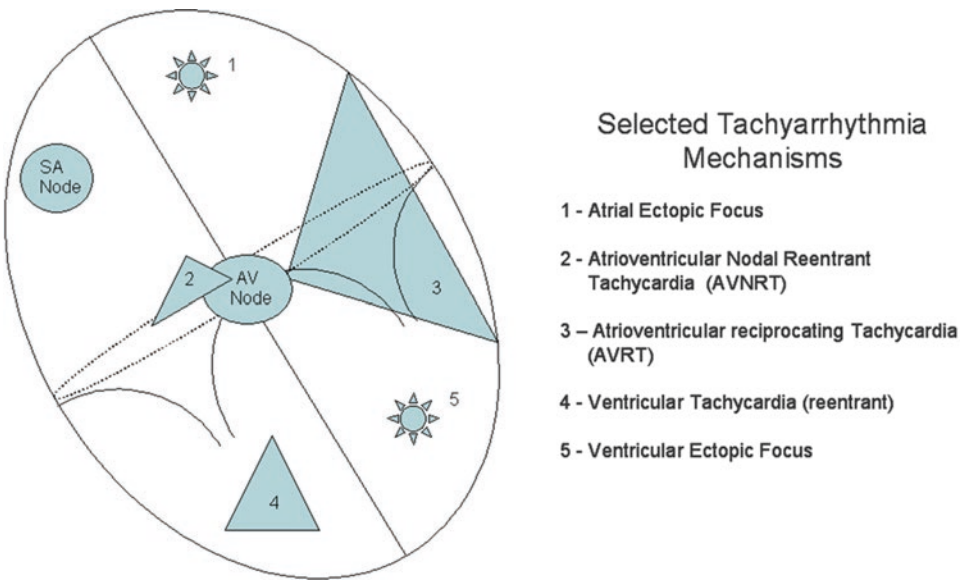

Fig. 18.2 Selected tachyarrhythmia mechanisms

I agent or slowing repolarization with a class III agent) may render the circuit unsustainable and thereby prevent or terminate an arrhythmic event.

Clinically observable or described characteristics of an arrhythmia may offer some insight as to the underlying mechanism. Reentrant circuits are either "on" or "off." Reentrant supraventricular tachycardia (SVT) begins suddenly (in paroxysms) typically with no warning or prodromal symptoms. Additionally, since reentrant circuits are "hardwired," heart rates tend to vary little from one event to another. Patients generally experience similar, increasingly familiar symptoms from event to event. A teenager with episodes of SVT with a documented heart rate of 189 bpm during one event will likely have nearly the same heart rate during their next event. Duration of their event may vary, but quality and severity of their tachycardia-related symptoms typically do not. This predictability is an important factor for risk assessment and overall patient management. Response to treatment may also aid in differentiating reentrant disorders from those due to abnormal automaticity. Reentrant tachycardias often terminate in response to any brief interruption of the regenerating circuit. For example, electrical cardioversion interrupts nearly any reentrant rhythm. Adenosine, which temporarily interrupts AV nodal conduction, is frequently effective in terminating atrioventricular or atrioventricular nodal reentrant tachycardias, which are commonly seen in infants and adolescents, respectively. In contrast, disorders of automaticity are typically refractory to cardioversion or adenosine administration.

Reentrant SVT begins suddenly and most often has a fixed heart rate.

Most children with normal hearts tolerate brief periods of SVT without profound hemodynamic compromise; however, SVT may not be tolerated in children with congenital heart disease, or when unrecognized and prolonged in young infants. These symptomatic infants or children may require emergent cardioversion and subsequent hemodynamic support.

While most brief SVT episodes are well tolerated, prolonged SVT or SVT in a patient with congenital heart disease may become hemodynamically significant.

18.2.2 Disorders of Automaticity

Automatic arrhythmias may be more variable, and therefore less clinically predictable, than reentrant arrhythmias. Automatic rhythms result from increased and often variable rates of depolarization in specific areas of the heart referred to as *ectopic foci*. Ectopic foci can occur in the atria, great veins near their atrial insertion points, near the AV node, or in the ventricles. Similar to sinus node tissue, ectopic foci typically increase their rate of phase 4 depolarization in response to increasing temperature, catecholamine stress, or stimulant exposure. When the rate of an ectopic focus is similar to that of the sinus node, only occasional extra or early beats may be seen. Patients may or may not sense these ectopic beats. With increasing rates, ectopic foci may overtake the sinus node and drive a tachycardia. Automatic tachycardias often demonstrate gradual rate increases (warm up) and may be prolonged (incessant), lasting for multiple hours in a day. Incessant atrial tachycardias are often, but not always, identified by the presence of abnormal P-waves on a 12-lead ECG. Identification and treatment of chronic atrial tachycardia is important, since this type of arrhythmia has been associated with the development of tachycardia-associated cardiomyopathy and end-stage heart failure.

18.2.3 Triggered Tachycardias

As noted, triggered tachycardias result from abnormal *afterdepolarizations* that occur following normal cardiac depolarization. These abnormal afterdepolarizations typically occur during phase 2, 3, or early in phase 4 of the action

Triggered tachycardias are due to abnormal afterdepolarizations.

potential. When they occur, they interrupt normal repolarization. Afterdepolarizations with subsequent triggered tachyarrhythmias (e.g., torsades de pointes) often occur in conditions where the action potential is prolonged such as with prolonged QT syndrome, digitalis toxicity, and generalized critical illness.

18.2.4 Rapid Evaluation of Acute Arrhythmia

Findings from a rhythm strip should be rapidly verified and identified as hemodynamically significant or insignificant based on auscultation and pulse assessment.

Ectopic atrial tachycardia should be looked for and ruled out in any child presenting with a newly diagnosed dilated cardiomyopathy. A 12-lead ECG should be quickly performed, when possible, in all children being evaluated for a tachycardia.

When evaluating an acute arrhythmia, the practitioner must first evaluate the clinical status of the patient. Visual inspection alone is often sufficient to establish the state of consciousness and evaluate a patient's level of distress or discomfort. Brief examination of the extremities reveals the character of distal pulses and provides an assessment of overall perfusion. Auscultation and pulse assessment are critically important parts of patient evaluation and are necessary to confirm cardiac monitor and rhythm strip findings. Motor activity (shivering or tremor), chest physiotherapy, lead displacement, and monitor dysfunction can all lead to false arrhythmia alarms. Importantly, when evaluating a newly identified arrhythmia, one should strive to obtain a 12-lead electrocardiogram (ECG) as soon as patient stability allows. A multi-lead ECG provides a much more detailed and standardized analysis of a rhythm disorder, as compared with a single rhythm strip generated from a patient's bedside monitor. Documentation with a 12-lead ECG should be emphasized as a mandatory step for identification and treatment of most rhythm disorders observed on a patient's bedside monitor.

18.3 Specific Arrhythmias and Their Treatment

18.3.1 Bradycardia

Bradycardia is a frequent occurrence in the critical care unit and can have myriad causes (see ► Box 18.1).

Bradycardia is frequently encountered in critically ill children as a secondary and reversible response to excessive vagal stimulus, hypoxia, or myocardial hypoperfusion. Bradycardia also can result from primary congenital conduction system abnormalities as well as a variety of surgical, immunologic, or pharmacologic insults to nodal or conductive tissue (see ► Box 18.1). The myocardium relies heavily upon aerobic metabolism, and pacemaker cells are exquisitely sensitive to the effects of hypoxemia. Intensivists must quickly identify, evaluate, and correct the myriad issues that can lead to acute hypoventilation, hypoxemia, and myocardial hypoperfusion in the intensive care unit. Acutely ill children quickly become bradycardic and may progress to full cardiac arrest if abnormal gas exchange is not rapidly addressed and corrected.

Box 18.1 Selected Causes of Bradycardia in Children

- Hypoxemia
- Hypothermia
- Hypotension (severe)
- Hyperkalemia
- Increased vagal tone (athletes, airway interventions, intracranial injury)
- Drug effects (β-blockers, digoxin, calcium channel blockers, clonidine, tricyclic antidepressants, etc.)
- Sinus bradycardia
- Sinus node dysfunction

- Congenital heart block
  (a) Anatomic with complex congenital heart disease (e.g., heterotaxy patients, L-transposition)
  (b) Immune-mediated (e.g., maternal lupus)
- Acquired AV block (surgical)
- Toxin exposure (e.g., carbon monoxide, snake venom, some plants)

Nodal cells are exquisitely sensitive to hypoxemia, which is the most common cause of bradycardia in children. Prompt airway evaluation and intervention prevents most cardiac arrests in children.

Vagal stimulation occurs in the ICU during such common procedures as endotracheal intubation and tracheal suctioning. Sinus bradycardia with marked sinus arrhythmia is commonly present in even mildly brain-injured children. It is important to recall that a state of autonomic imbalance exists in infancy; sympathetic innervation of the myocardium is functionally immature. Although the density of cardiac β-adrenergic receptors is high, β-receptor-adenylate cyclase coupling mechanisms are inefficient. Conversely, vagal innervation of the myocardium is complete and functional at birth. This leads to a state of parasympathetic dominance in early infancy and thus a propensity toward bradycardic events. Increased parasympathetic output also contributes to the infantile laryngeal reflex, which has been implicated as a cause of apnea and bradycardia seen in association with gastroesophageal reflux disease (GERD) and formula aspiration. Vagal-mediated acetylcholine release at the level of both the sinus and AV nodes affects pacemaker cells in a dual fashion, causing a hyperpolarization of cardiac tissue (a more negative intracellular baseline polarization) and a decrease of the slope (rate) of phase 4 depolarization. This combined effect greatly slows pacemaker function and may even cause a cessation of sinus node activity.

Atropine and glycopyrrolate can be used to attenuate vagal-mediated bradycardia, although epinephrine remains the PALS drug of choice in a bradycardic arrest requiring resuscitation.

Vagal-mediated bradycardia can be attenuated by the muscarinic receptor antagonists atropine and glycopyrrolate; the latter has the advantage of not causing any CNS side effects and can be given orally if needed for chronic suppression of increased vagal activity. Muscarinic antagonists prevent acetylcholine from binding to cholinergic receptor cells in the heart, smooth muscle, gland cells, and elsewhere. Atropine premedication is often recommended prior to performing laryngoscopy or tracheal intubation in infants and small children to prevent reflex bradycardia and to decrease the production of airway secretions. However, prospective data suggest that this widespread practice may not be necessary or effective for all pediatric patients. Atropine is generally dosed at 0.02 mg/kg intravenously with a minimal dose of 0.1 mg and a maximal adult bolus dose of 1 mg. The minimal dose is recommended to reduce the risk of a paradoxical bradycardic response that can occur with smaller doses. Intravenous atropine administration may produce pupillary dilatation, which is an important consideration when assessing a patient's neurological status following a resuscitative event. In the adult, maximal pupillary dilatation occurs after total atropine doses >2 mg. In children, atropine has an approximate half-life of 2–3 h. Atropine use in pediatrics is most appropriate for the treatment of symptomatic bradycardia with suspected parasympathetic excess or for treatment of anticholinesterase or other similar poisonings.

Atropine is one treatment option for vagally mediated bradycardia. The dose is 0.02 mg/kg with a minimum and maximum of 0.1 mg and 1 mg, respectively. The minimal dose is recommended to reduce the risk of a paradoxical bradycardic response that can occur with smaller doses.

Isoproterenol is a nonselective β-adrenergic agonist which leads to increased heart rate and contractility with no α-adrenergic affinity.

Non-vagal causes of bradycardia are less frequent in children. In general, low heart rates are well tolerated in otherwise healthy children, particularly if there is a gradual onset of bradycardia. In contrast, the sudden onset of complete AV block may not be hemodynamically tolerated; in this setting, atropine use may be attempted. Adrenergic agonists may also provide benefit by increasing nodal conduction and the automaticity of accessory pacemaker tissue. Remember that resuscitation guidelines recommend epinephrine as the first-line agent for symptomatic bradycardia in children. Historically, many intensivists used isoproterenol (Isuprel™) as an effective agent to increase sinus node rate and AV nodal conductivity. Isoproterenol is a nonselective β-adrenergic agonist with no affinity for α-adrenergic receptors. This unopposed β-adrenergic stimulation increases the heart rate and can temporarily stabilize patients prior to pacemaker insertion. Due to its strong β_2-adrenergic effects producing systemic vasodilation, intravascular volume status should be optimized concurrent with its use. Aggressive β_2 stimulation is contraindicated in children with left ventricular outflow tract obstruction (LVOTO) (e.g., subaortic stenosis, hypertrophic cardiomyopathy), as it may increase the outflow gradient by decreasing aortic diastolic pressure, and these effects can decrease diastolic myocardial perfusion. Additionally, pure β-adrenergic agonists should be avoided in children with lesions associated with low diastolic pressures (e.g., systemic-pulmonary shunts, aortic regurgitation), as they further decrease diastolic pressure and coronary filling. Pediatric isoproterenol dosing is generally titrated between 0.05 and 0.5 mcg/kg/min; higher infusion rates up to 2 mcg/kg/min have been reported.

External pacing capability is built into most cardiac defibrillators but should only be used as a temporizing method.

External transcutaneous pacing is a reliable method to treat acute bradycardia related to pacemaker dysfunction or other acute conduction failure in any age patient. It is ineffective and not indicated for treatment of the terminal asystole following unsuccessful resuscitation efforts in a non-rhythm-related cardiac arrest. External pacing capability is built into most cardiac defibrillators, but transthoracic pacing should only be used as a temporizing method.

Symptomatic bradycardia that is unresponsive to pharmacologic intervention requires pacemaker support. Temporary pacing is indicated until a permanent pacemaker can be placed. Temporary pacing can be accomplished by external transcutaneous or transvenous techniques in most patients. Transesophageal left atrial pacing is another option when an intact conduction system is present. External pacing capability is built into most cardiac defibrillators used in the hospital environment. *External pacing* is a widely available, potentially uncomfortable, but lifesaving procedure that should be considered in selected settings with profound bradycardia. External pacing can temporize bradycardia seen with some drug ingestions, permanent pacemaker failures, or profound electrolyte disturbances. Importantly, external pacing has not been shown to be helpful, and is therefore not indicated, for the treatment of terminal asystole seen during an unsuccessful resuscitation originating from a non-arrhythmic origin. External pacing can be performed in all ages, although full thickness burns have been reported with its prolonged use in a premature infant. External pacing is generally performed using multipurpose pacer/defibrillation pads commonly used with modern hospital-based defibrillators. Following pad placement, the operator dials in an age-appropriate desired heart rate, which is generally 10–20 bpm higher than the patient's normal resting heart rate. Pacer output (milliamps) is sequentially increased until ventricular capture occurs, which is identified by the loss of the intrinsic rhythm and the onset of a "spike and wave" pattern showing a wide complex QRS pattern with associated T-waves. Capture must always be confirmed by the presence of an arterial waveform or palpable pulse. Sedation and analgesia should be offered to the awake patient, which may necessitate airway support. In most situations, external pacing should be considered a bridge to either transvenous or permanent pacer placement.

Transesophageal and transvenous pacing for infants and small children is typically performed following consultation with an electrophysiologist or other cardiology subspecialist. Transvenous pacing wires can be connected to standard bedside external pacemaker generators. Successful transvenous pacer placement has been reported in newborns and young children using all central venous access sites (internal jugular, subclavian, or femoral vein) often utilizing fluoroscopic guidance. In the adult-sized adolescent, the cephalic vein can be used with the catheter advanced blindly into the right heart guided by ECG evidence of signal capture. Alternatively, ultrasound has been reported as a useful tool to guide correct catheter position. Transesophageal pacing is a safe and technically straightforward method of pacing both pediatric and adult patients when there is intact atrial to ventricular conduction. The esophagus abuts the left atrium and allows the recording of a high-amplitude atrial electrogram with reliable atrial pacing. Ventricular pacing via the esophagus is possible but is less reliable and often requires an uncomfortable amount of current to assure pacing capture. Electrophysiologists also use esophageal recordings to diagnose and treat atrial tachyarrhythmias. Temporary epicardial pacer wires are also frequently placed during congenital heart surgery. Atrial or esophageal leads can be directly connected and recorded on a standard 12-lead ECG to directly measure the atrial electrogram. Atrial electrograms clearly identify P-wave activity and can help distinguish between rhythms such as atrial flutter, AV reentrant tachycardias, and junctional rhythms. Reentrant SVT and atrial flutter can be effectively treated by overdrive (burst) atrial pacing. Transesophageal atrial pacing carries some risk of inducing ventricular fibrillation, so equipment to provide defibrillation shocks should always be readily available when using this technique.

While transesophageal atrial pacing can be useful, it does carry the risk of inducing ventricular fibrillation, so a defibrillator should always be available.

Permanent pacemaker implantation is indicated for children with a variety of rhythm disorders. Infants may develop complete heart block in association with structural heart disease (e.g., L-transposition) or in the setting of maternal systemic lupus erythematosus (SLE). Maternal autoantibodies to SSA/Ro and SSB/La proteins can cross the placenta and destroy fetal conductive tissue. The resultant third-degree AV block is permanent and leads to a high incidence of fetal congestive heart failure (*hydrops fetalis*). Infants may tolerate third-degree heart block if they have an adequate ventricular escape rate, but neonates are typically symptomatic when the ventricular rate is below 55–60 bpm. Pacemaker implantation is indicated for symptom relief in such infants. Increasing global experience and pacer availability led to the publication of standardized indications for pacemaker placement in children. As an example, pacer placement is a class I recommendation for infants with congenital third-degree heart block with a ventricular escape rate of less than 50–55 bpm. Evidence also supports permanent pacer implantation in symptomatic infants with higher heart rates, those with associated structural heart disease, a wide complex QRS escape pattern, or pause-dependent ventricular tachycardia. Permanent pacemakers are typically placed transvenously in the older child and adults utilizing local anesthesia to access the cephalic or subclavian veins. A pacer generator is then placed into a subcutaneous pocket in the infraclavicular region. Size limitations prevent the use of this technique in infants and smaller children who therefore require surgically placed epicardial wires and subcostal generator placement. Full operative sternotomy may be indicated for more complex placements. Correct pacemaker operation is assured intraoperatively with full electronic interrogation of the device's sensing and pacing functionality. Data supports the use of antibiotic prophylaxis for 24 hours surrounding permanent pacer implantation using an anti-staphy-

Class I recommendations for congenital complete heart block include a ventricular escape rhythm of less than 50 bpm, symptomatic infants, infants with long pauses, or infants with wide complex QRS escape patterns.

Permanent pacemakers are typically placed in infants and children with congenital or acquired heart block. Modern devices are complex and require electronic interrogation if a malfunction is suspected.

lococcal agent. Once implanted, modern pacemaker function can be examined by direct telemetry or by indirect, trans-telephonic, monitoring. Pacer telemetry allows the clinician to examine the patient's innate rhythm, see a record of arrhythmic events, test sensing and pacing thresholds, and determine remaining battery strength and lifespan.

Placement of temporary atrial and ventricular epicardial pacing wires is standard procedure after complex cardiac repairs. Postoperative inflammation, edema, electrolyte abnormalities, and direct injury to the conducting system place the postoperative child at significant risk for arrhythmia. Interventions to control postoperative arrhythmias include maintenance of physiologic and metabolic parameters, antiarrhythmic agents, and at times temporary cardiac pacing.

A complete review of cardiac pacing is covered elsewhere in the text. However, critical care practitioners should be familiar with temporary cardiac pacemaker functionality. Modern pacemakers are becoming increasingly sophisticated as to their ability to sense the intrinsic heart rhythm, pace multiple cardiac chambers, and respond to a patient's variable cardiac demand. The North American Society of Pacing and Electrophysiology endorsed a uniform code to delineate pacer functions. There are five coded positions, of which the first three are most important in postoperative temporary cardiac pacing (see ► Box 18.2).

Pacemaker functionality is described using a 5-letter pacing code system where the first letter designates the chamber that is paced (A, atrial; V, ventricular; or D, dual chamber). The second letter designates whether or not a chamber's activity is sensed (0, no sensing; A, atrially sensed; V, ventricular sensing; D, dual chamber sensing). The third letter designates the response to a sensed beat (0, no response; I, pacing is inhibited; T, pacing is triggered; or D, dual response based upon programmed characteristics). The fourth and fifth letters are less commonly used in the PICU and designate programmable rate functions and the presence of anti-tachycardia/arrhythmia settings.

The generic 5-letter pacing code is ordered as follows: chamber paced, chamber sensed, response to sensing, rate modulation, and multisite pacing.

Box 18.2 Pacer Terminology[a]

I. *Chamber(s) paced*
   - 0 – None
   - A – Atria is paced
   - V – Ventricle is paced (right ventricle)
   - D – Dual, both the atria and the ventricle are paced

II. *Chamber(s) sensed*
   - 0 – None
   - A – Atrial
   - V – Ventricular
   - D – Dual chamber sensing

III. *Response to sensing*
   - 0 – None
   - I – Pacing is inhibited (i.e., pacing is not necessary due to spontaneous chamber activity)
   - T – Triggered (e.g., atrial sensing triggers ventricular pacing)
   - D – Dual (e.g., atrial sensing triggers ventricular pacing, unless there is an appropriately timed, conducted ventricular response)

IV. *Fourth letter designates programmable functions, such as rate responsiveness*

V. *Fifth letter designates anti-tachycardia functionality (e.g., burst pacing, defibrillation, etc.)*

[a]Pacemaker settings are designated by a lettered system. Typically used settings include AAI (atrial demand pacing), VVI (ventricular demand), or DDD (dual chamber demand) settings

Temporary pacemaker settings are typically described using the first three of the five standard categories; letters IV and V describe additional features used in more sophisticated, permanently implanted devices. For example, V00 describes asynchronous ventricular pacing. In this mode, the ventricle is paced at a set, predetermined rate regardless of innate ventricular activity. With V00 pacing, th ventricle is paced (V), and no sensing of ventricular activity is performed (0), so there is no response to sensing (0). Asynchronous ventricular pacing is rarely used outside of an emergency setting as it is inefficient and carries the theoretical risk of inducing dangerous ventricular arrhythmias should a pacer spike occur during repolarization (an "R on T" phenomenon). Ventricular demand pacing (VVI) represents a better option to assure a minimal ventricular rate. In VVI pacing, the ventricle is paced (V), ventricular activity is monitored (V), and, if the patient's intrinsic rate is equal to or higher than the set rate, pacer activity is inhibited (I). Ventricular demand (VVI) pacing safely assures a minimal ventricular rate and avoids pacing the patient unnecessarily. Dual chamber demand pacing (DDD) is typically used with transvenously placed permanent devices. DDD pacing requires the presence of bipolar (sensing and pacing) leads in both the atria and the ventricle. DDD pacing assures a minimum heart rate, allows for sequential AV pacing, and, by sensing intrinsic chamber activity, avoids unnecessary pacing. Intensivists should remember to consult their cardiology colleagues for pacemaker interrogation if device malfunction or arrhythmic problems are suspected.

18.4 Common Atrial Tachyarrhythmias

18.4.1 Sinus Tachycardia

Sinus tachycardia is most commonly confirmed in children identified with a narrow complex tachyarrhythmia. Clinicians must remember to define a tachycardia considering age-appropriate heart rate norms and the clinical context of the patient. Published "normal" heart rate ranges are often based on data from healthy resting children, which is not relevant in the child with acute pain, anxiety, or fever. Sinus rates of 150 bpm are relatively unremarkable in the agitated infant but are likely significant in the older child or adolescent. Sinus node and other "automatic" tissues increase their rate of phase 4 depolarization in response to stimuli such as endogenous or administered catecholamines, elevated temperature, decreased vagal nerve activity (vagolysis), and thyroid hormone excess (thyrotoxicosis). Sinus tachycardia is most commonly a secondary manifestation of some other clinical stressor, as opposed to a primary pathology. Endogenous catecholamine stimuli are nearly universal in the intensive care setting where hypotension, fever, anemia, heart failure, anxiety, and pain are frequently encountered. When confronted with a narrow complex tachycardia, the intensivist must confirm a sinus origin and then treat the underlying condition producing the adrenergic stress. Differentiating a sinus tachycardia from other forms of narrow complex tachycardia is not always an easy task. The degree of heart rate elevation is the first clue. Maximal sinus rates decline with age and can be *approximated* by the simple formula of 220 – patient age (in years).

18.4.2 Supraventricular Tachycardias

A. Automatic mechanisms.
   - Sinus tachycardia.
   - Ectopic atrial tachycardias.

B. Atrial reentry.
   - Atrial fibrillation.
   - Atrial flutter.

C. Atrioventricular reciprocating tachycardias (atrioventricular reentry).
   - Atrioventricular reciprocating tachycardia (AVRT).
     (a) Concealed pathways (normal baseline ECG).
     (b) WPW (preexcitation on baseline ECG).
     (c) Orthodromic SVT – ventricular activation via the His-Purkinje system (typical narrow complex SVT).
     (d) Antidromic SVT – ventricular activation via accessory pathway during SVT (often produces a wide complex SVT).
   - Atrioventricular nodal reciprocating reentrant tachycardia (AVNRT).

D. Atrial triggered activity.
   - Chaotic atrial tachycardia.
   - Digoxin toxicity.

The lower limit for sinus tachycardia is age dependent and therefore should be considered in the context of the child's age. Maximal sinus rates decline with age and are approximately 220 bpm minus the patient's age in years. Rates higher than this are suggestive, but not diagnostic, of a non-sinus tachycardia. For example, sinus rates may be higher than this estimate in infants with high fever, but this is not common. Unusually fast heart rates should trigger an analysis of the ECG to rule out the presence of a tachyarrhythmia.

The catecholamine stress response in combination with a high fever can lead to high sinus rates in severely ill infants and young children (sinus rates as high as 240 bpm have been documented, although this is rare). A heart rate >200 bpm in an infant (perhaps >160 bpm in the older child) should generally be suspected to arise from a non-sinus mechanism and prompt the clinician to exam an ECG. Children with a variety of atrial and reentrant tachycardias often have heart rates in the 200–300 bpm range, or higher. Clinical characteristics differentiating a sinus tachycardia from other rhythms are summarized in Table 18.2.

18.4.3 Paroxysmal SVT

Paroxysmal SVT occurs when an accessory pathway is present and allows for abnormal atrioventricular conduction.

As previously mentioned, most supraventricular tachycardias in children originate from reentrant mechanisms involving *accessory pathways*. In large part, the electrophysiologic properties of specific reentrant tachycardias are determined by the location and conductive properties of the specific pathway involved. In infants and young children, accessory tissues commonly bridge the fibrous skeleton of the heart, electrically connecting the atria and ventricles at an additional site separate from the AV node. Atrioventricular conduction normally occurs *only* at the AV node/His bundle, as depicted in Fig. 18.3. Accessory pathways often do not support anterograde (forward) conduction during normal sinus beats. These pathways produce no abnormalities on the baseline surface electrocardiogram and are therefore said to be *concealed*. Alternatively, some accessory tissues can conduct in an anterograde (forward) manner during a baseline sinus rhythm, leading to delta waves on the baseline electrocardiogram (delta waves are diagnostic of Wolff-Parkinson-White (WPW) syndrome; see below).

Paroxysmal supraventricular tachycardia is seen in all age groups. SVT in infants and small children typically results from an accessory atrioventricular pathway in the reentrant circuit. This form of SVT is referred to as an atrioventricular reciprocating tachycardia (AVRT). AVRTs typically show a narrow QRS complex with rates of 200–300 bpm (or faster). Figure 18.4 is an example of an AVRT in an infant. Note the R-P interval with downward ori-

Table 18.2 Differentiating sinus tachycardia from other arrhythmias

Sinus tachycardia	Non-sinus rhythms
Rates less than age appropriate max (often <200 bpm)	Often >200 bpm
Clear P-waves present, 1:1 relationship with subsequent QRS complex (regular P-R relationship)	P-waves may be absent, have multiple morphologies, or occur after the QRS complex (retrograde R-P relationship)
Normal P-wave axis (0–90°)	Often inferior oriented or variable P-wave axis
Gradual onset, rate warms and slows with clinical interventions (volume expansion, sedation, etc.)	Reentrant SVT has an abrupt onset and termination (paroxysmal)
Typically demonstrates some rate variability. Often phasic, undulating rate changes	Reentrant SVT demonstrates little or no rate variability Ectopic tachycardias may show highly irregular, chaotic rates
Narrow complex QRS	VT or SVT with aberrant conduction typically shows a wide complex QRS. Ventricular origin is confirmed if atrioventricular disassociation can be demonstrated. A wide complex tachycardia should be assumed to be of ventricular origin until proven otherwise
Normal central venous waveform	Cannon A-waves or irregular CVP waveform

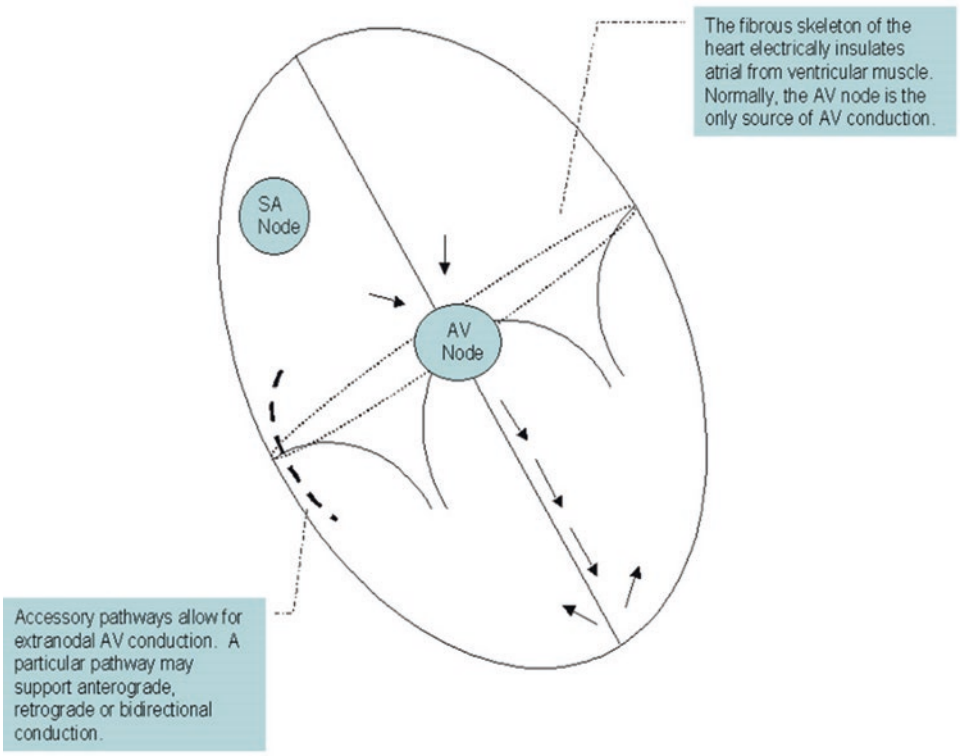

Fig. 18.3 Normal AV conduction (arrows) and accessory pathway (dashed line) that has the potential to allow extranodal AV conduction

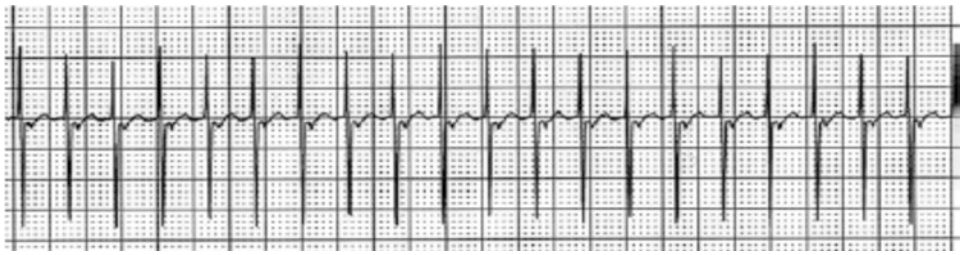

Fig. 18.4 Rhythm strip demonstrating AV reciprocating tachycardia (AVRT). SVT in infants frequently utilizes congenital accessory pathways that electrically connect the atria and ventricles distant from the AV node. These accessory pathways act as one limb of a reentrant circuit during AVRT. Accessory tissue often regresses during infancy, with many infants "outgrowing" their tachycardia. Conversely, some children develop accessory pathways in or near the AV node during late childhood and adolescence and develop episodes of AVNRT

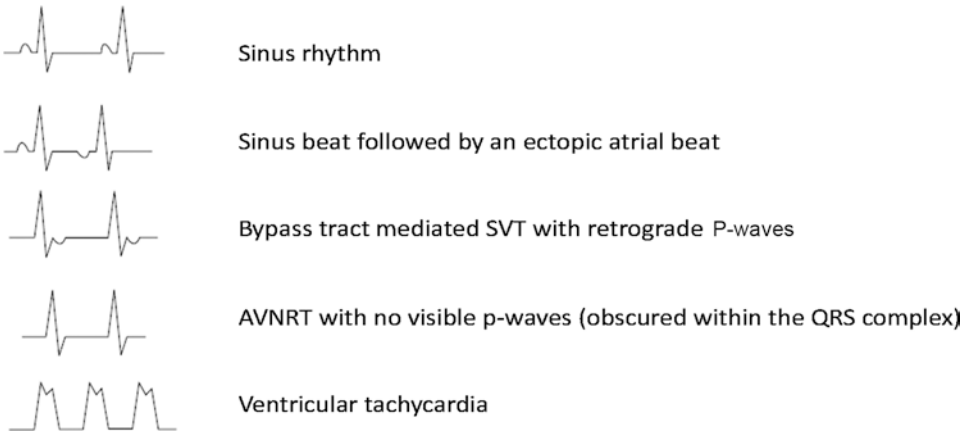

Fig. 18.5 Idealized P-wave morphology in selected arrhythmias

ented P-waves produced in lead II by retrograde activation of the atria. This is an example of an *orthodromic* tachycardia, defined when the reentrant circuit conducts in the normal direction through the AV node and His bundle. The atria are then activated in a retrograde manner with V-A conduction through the accessory pathway, producing the negative P-wave orientation. Since the ventricles are activated through the normal conduction pathways, a narrow QRS complex results.

Paroxysmal SVT occurs when an accessory pathway is present and allows for abnormal atrioventricular conduction. The most common form of paroxysmal SVT in infants and young children involves an accessory pathway outside of the AV node, whereas in older children and adolescents, it involves a recurrent pathway near or within the AV node itself.

SVT occurring in older children or adolescents is more likely to arise from a reentrant pathway near or within the AV node itself – an atrioventricular nodal reentrant tachycardia (AVNRT). The 12-lead surface ECG can often give some clue as to the type of SVT in a particular patient; in a hemodynamically stable patient, this should be carefully reviewed prior to administering any treatment. P-wave identification is often a crucial step for diagnosis. AVRT often produces clear retrograde P-waves with a 1:1 ventricular-atrial relationship and a consistent R-P interval. In contrast, multiple P-wave morphologies with inconsistent P-R relationships will be seen with ectopic atrial tachycardias, which do not utilize a reentrant circuit. P-waves may not be visible during an AVNRT, since they are often simultaneous with, and obscured by, the QRS complex. Figure 18.5 demonstrates idealized ECG appearances for several different tachyarrhythmias.

18.4.4 Wolff-Parkinson-White Syndrome (WPW)

WPW is an example of an *antidromic* AVRT where depolarization moves from the ventricle to the atria through the AV node. Children with WPW have an accessory pathway that supports forward (anterograde) conduction from the

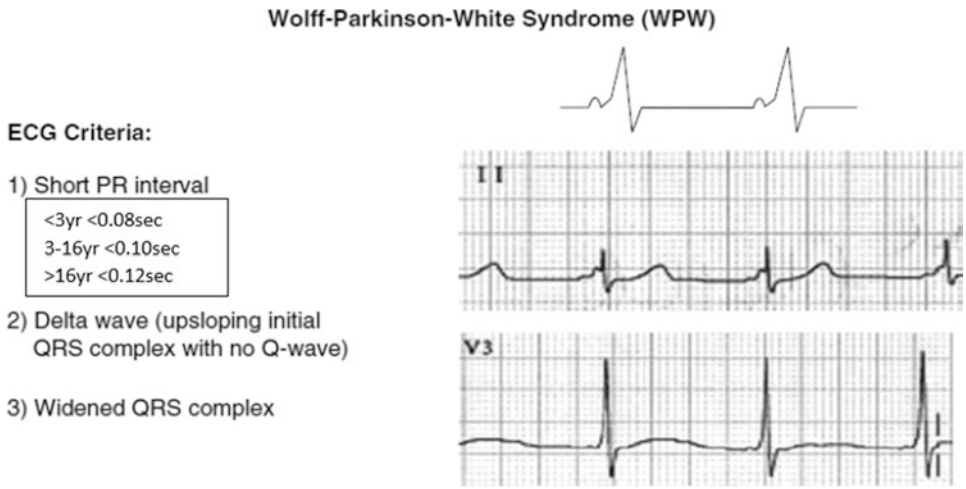
atria to the ventricle during a normal sinus rhythm. Unlike normal conduction via the AV node, there is *no* pause of atrial to ventricular conduction along the accessory pathway. This leads to early activation of the ventricle, thereby shortening the P-R interval and producing the delta wave and widened QRS complex characteristic of the WPW syndrome. Note that the absence of a q-wave is also characteristic of preexcitation. In some patients, accessory tissue can support very fast conduction velocities. These patients are potentially at risk for sudden cardiac death should they develop fast atrial rhythms such as atrial fibrillation or atrial flutter. Normally, AV nodal conduction delay protects the ventricle from excessively fast atrial stimulation. However, if an accessory pathway is present, and it is capable of fast conduction, very high atrial rates may be transmitted directly through to the ventricle and potentially induce lethal ventricular fibrillation. This mechanism is thought to be responsible for a low, but not negligible, risk of sudden cardiac death in some patients with WPW. Children with preexcitation (WPW) should be referred to a pediatric cardiologist for risk assessment and a complete cardiovascular evaluation. ECG criteria for WPW are seen in ◘ Fig. 18.6.

WPW occurs when there is early activation of the ventricles (seen as a delta wave or shortened P-R interval on ECG). Some accessory pathways may allow fast atrial to ventricular conduction, thereby putting the child at risk for ventricular fibrillation and sudden cardiac death should they develop an atrial tachyarrhythmia. Therefore, all children with preexcitation (WPW) should be evaluated by a pediatric cardiologist.

18.4.5 Wide Complex SVTs

Most SVTs produce narrow QRS complexes, but this is not absolute. Forward (antidromic) conduction along accessory pathways, the presence of multiple accessory pathways, and rate-dependent conduction blocks are some of the mechanisms that can lead to wide QRS complex reentrant SVTs. In these settings, it can be very difficult to differentiate an SVT from a ventricular tachycardia. In the stable patient, debate over the specific diagnosis can often be prolonged and esoteric. However, when confronted with a hemodynamically unstable patient, clinicians should assume a wide complex rhythm is of ventricular origin. Per standard resuscitation protocols, *a hemodynamically unstable patient with an organized tachycardia thought to be of cardiac origin (of either narrow or wide complex morphology) should be promptly treated with synchronized cardioversion using 0.5–1 J/kg*. If the patient is pulseless, then asynchronous settings should be used and the patient should be defibrillated using 2 J/kg.

While some wide complex SVTs may be hemodynamically stable, an unstable patient should be promptly treated with 0.5–1 J/kg of synchronized cardioversion.



◘ **Fig. 18.6** Wolff-Parkinson-White syndrome (WPW)

18.4.6 SVT Treatment

Paroxysmal SVT is typically well tolerated in otherwise normal children. This is important to remember when evaluating a child for a newly identified tachycardia. In the outpatient setting, children often have vague complaints of palpitations for years prior to suffering a sustained episode that is captured on an electrocardiogram. In most cases, patients should be taught to think of SVT as a nuisance, rather than a danger. SVT can, however, be life-threatening in specific situations. For example, infants lack the ability to fully communicate and may suffer an unrecognized tachycardia for many hours or even days prior to developing recognized signs of illness. These infants come to medical attention when they develop an acute rate-related cardiomyopathy and congestive heart failure. Immediate and long-term rate control is essential in these infants in order to maintain and improve their cardiac function.

Children with congenital heart disease, underlying cardiomyopathy, or an excessively fast tachycardia may also develop rapid hemodynamic collapse during an SVT event and require emergent care. Note that infants with otherwise normal cardiac structure and concealed or WPW pathways have a high incidence of spontaneous resolution during the first year of life. Thus, it is common for infants to "outgrow" their tachycardia. Conversely, adolescents may "grow into" their AVNRT with increasing episodes or medication dependence during late childhood and the teenage years. Treatment options for SVT are relatively vast with the tenor of clinical intervention based upon the severity of a child's symptoms.

Vagal maneuvers can be very effective in terminating reentrant SVT by altering conduction properties of the AV node. In infants, applying a bag of iced saline induces a diving reflex. Older children can be taught to perform the Valsalva maneuver.

Most types of reentrant SVT in children utilize AV nodal tissue as part of the reentry circuit. Since reentry requires precise timing to sustain itself, any alteration of AV nodal conduction properties or refractoriness can render the circuit unsustainable and prevent or abort an SVT event. *Vagal maneuvers* can be very effective in terminating reentrant SVT; these maneuvers lead to AV nodal cell hyperpolarization, thereby slowing conduction in that arm of the reentrant circuit. Beta-adrenergic blockade and digoxin are thought to act similarly in terms of altering AV node function. The Valsalva maneuver, when performed in the supine position and held for 20s, has been shown to break over half (53%) of AVRT and one-third of AVNRT-associated tachycardia in adult patients undergoing electrophysiologic study. A school-age child can be taught to perform the Valsalva maneuver by blowing on a clamped straw or the tip of their thumb, continuing for the required 15–20 seconds. Other common vagal maneuvers include holding iced water to a child's face (thereby inducing a diving reflex). The ice bag technique, where an ice water-containing bag is held over the entire forehead and face, while avoiding obstructing the nose and mouth, for up to 15 s is recommended as especially effective for infants and children when performed appropriately. Due to their simplicity, safety, and relative efficacy, vagal maneuvers should be attempted as initial therapy for most children presenting with paroxysmal SVT.

Vagal maneuvers fail to break SVT roughly 50% of the time. Adenosine administration is generally recommended as the next intervention of choice for most children with SVT. Adenosine is a naturally occurring nucleoside that binds to specific G-protein-coupled receptors located in the atria, AV node, and ventricular tissue. Adenosine receptor activation secondarily opens potassium channels, leading to cellular hyperpolarization. Furthermore, by inhibiting adenylate cyclase, adenosine inhibits L-type calcium channels, which reduces conduction velocity. Reduced cAMP also reduces the slope of phase 4 in pacemaker cells, reducing their pacemaker rate. Bolus adenosine administration in most individuals produces a short period of complete heart block

and transient (<5 sec) asystole. This brief interruption is sufficient to abort most types of reentrant SVT that rely on the AV node as a component of their circuit. In vascular smooth muscle, adenosine administration stimulates G-protein activation of adenylate cyclase, which causes systemic vasodilation with a resultant baroreceptor-mediated sympathetic response. Many patients feel transient chest pain, likely secondary to the profound bradycardia/brief asystole leading to myocardial ischemia. Sympathetic activation can be quite marked and may speed or otherwise alter conduction properties of a reentrant circuit or automatic tissue. Thus, adenosine administration poses at least a theoretical risk of inducing ventricular fibrillation in some patients, thereby mandating continuous ECG monitoring and a bedside defibrillator whenever adenosine is used.

Adenosine is administered as a starting dose of 0.1 mg/kg (maximum, 6 mg) and is best given by a two-syringe, rapid bolus technique. This is performed by rapidly pushing the drug through the largest, most central vein possible, followed immediately with a large volume flush of normal saline. Adenosine may be administered via the intraosseous route. A continuous, multi-lead ECG recording should be obtained surrounding adenosine injection in order to obtain maximal diagnostic information. If ineffective, the dose of adenosine can be doubled to 0.2 mg/kg (maximum, 12 mg) and repeated. Adenosine has a half-life of seconds, thus drug accumulation does not occur.

Adenosine, when given by rapid intravenous bolus, interrupts AV nodal conduction, thereby interrupting reentrant SVT and restoring sinus rhythm. Adenosine administration is the treatment of choice for the hemodynamically stable patient with SVT not responsive to vagal maneuvers. If adenosine is used to attempt to terminate an SVT rhythm, it should be done in bolus form, given quickly as close to the heart as possible, and monitored with a continuous ECG rhythm strip during administration since adenosine administration can be diagnostic by examining the cardiac rhythm during the pause of AV nodal conduction.

Successful sinus conversion of a narrow complex SVT essentially confirms the diagnosis of either an AVRT or AVNRT. When unsuccessful, careful review of the electrocardiogram often provides clues as to the mechanism of the tachycardia. Junctional ectopic tachycardia or some ventricular tachycardias may continue unchanged following bolus adenosine dosing. Alternatively, adenosine-induced complete heart block may allow for a clear ECG tracing of atrial activity and prove the presence of ectopic atrial activity, flutter waves, or other similar mechanisms (Fig. 18.7).

Clinicians must remember to continually monitor hemodynamic status during SVT by following mental status, palpation of pulses, and blood pressure measurements. Patients may be placed supine or in Trendelenburg position to augment venous return and maximize their cardiac output. As stated previously, synchronized cardioversion with 0.5–1 J/kg should be used in any unstable patient with an organized narrow or wide complex tachycardia, especially when immediate pharmacologic intervention is not possible.

Recurrent evaluation of the patient with stable SVT is crucial, as they may become hemodynamically unstable with a more prolonged episode.

Suppressive pharmacologic therapy is indicated for most children who have frequent or prolonged bouts of SVT. Digoxin and beta-adrenergic blockade are most commonly employed for SVT control in children. Calcium channel blockers, such as verapamil, can also be very effective but can have profound (**even lethal!**) negative inotropic effects in infants and young children. For this reason, calcium channel blockers are generally contraindicated for treatment of SVT in this age group. Many pediatric cardiologists choose to treat infants and young children with digoxin, a digitalis glycoside that produces a variety of electrophysiologic effects. Digoxin inhibits a sodium-potassium ATPase,

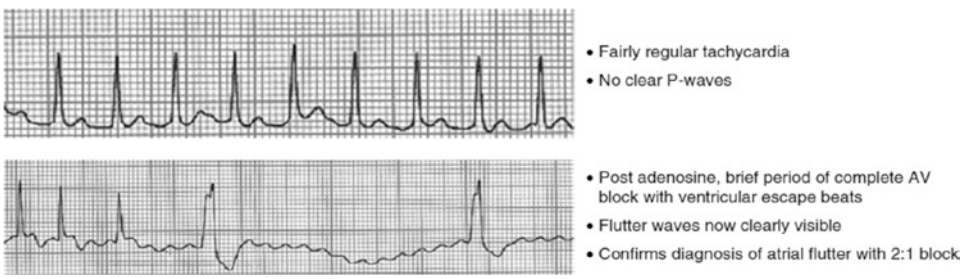


Fig. 18.7 Diagnostic use of adenosine revealing atrial flutter

leading to an increase in the intracellular sodium concentration. This, in turn, stimulates a sodium-calcium exchange mechanism that raises the intracellular calcium concentration. Increased intramyocardial Ca^{++} produces a positive inotropic effect, which is beneficial in low cardiac output states. As an antiarrhythmic agent, digoxin has potent effects at the AV node, where it leads to nodal cell hyperpolarization and slowed conduction. This vagomimetic effect directly alters the timing in a reentrant circuit, which may render it nonfunctional. It should be noted that digoxin and verapamil are *contraindicated* in the setting of WPW syndrome due to the risk of accelerating anterograde conduction along the accessory pathway. Accelerated conduction over an accessory connection may increase the risk of a rapid ventricular response during atrial fibrillation and potentiate the risk for inducing lethal ventricular fibrillation. For this reason, a beta-blocker is the initial drug of choice for treatment of WPW-associated SVT.

Digoxin is frequently used for the chronic treatment of SVT in infants and small children, but it is contraindicated with WPW, as it may accelerate conduction along accessory pathways. Digoxin has complex pharmacology with a narrow therapeutic index and a high degree of tissue binding as well as important drug interactions requiring careful monitoring of drug concentrations.

Digoxin has a long history of safe and effective use in the pediatric age group. Toxicity is rare but can be lethal. Oral digoxin has a slow initial rate of distribution, with peak serum levels achieved after 30–90 min during chronic administration. Digoxin is widely distributed, especially into skeletal and cardiac muscle, which results in a high volume of distribution. Most digoxin is eliminated unchanged in the urine with an elimination half-life that varies with age, ranging from 20 to 40 h; the long half-life is due to the high degree of tissue binding. Dosing should be adjusted in patients with impaired or immature renal function and in those receiving a variety of other commonly used drugs (e.g., amiodarone, erythromycin). Loading (digitalizing) doses are often employed in the first 12–24 h of therapy to overcome the large volume of distribution and more quickly achieve therapeutic levels. Alternatively, maintenance dosing can be initiated with the expectation of achieving steady-state concentrations after approximately 5 days of therapy. Digoxin may be administered once or twice daily. The drug has a narrow therapeutic window, with goal serum values generally between 1 and 2 ng/mL. Signs of toxicity include anorexia, vomiting, visual disturbances (blurred or yellow vision), atrioventricular block, and other atrial and ventricular arrhythmias. Hypokalemia, hypomagnesemia, and hypercalcemia can potentiate the arrhythmic potential during digoxin toxicity; these electrolytes should be measured and corrected as needed. Serious intoxications can be treated with anti-digoxin Fab antibodies.

β-Adrenergic antagonists are considered first-line therapy for a variety of atrial and ventricular arrhythmias. β-Blockade reduces the sinus node rate, decreases automaticity of ectopic pacemakers, slows conduction in the atria and AV node, and increases the functional refractory period of the AV node. Cardiac β_1-adrenergic receptors mediate inotropic and conduction effects. β_2 receptors are also located to a lesser extent in the atria and ventricles but primarily reduce tone in bronchial and vascular smooth muscle. A variety of β-adrenergic antagonists are currently available for clinical use. These vary in their receptor specificity, lipid solubility, and receptor agonist potential. Nonselective agents block both β_1 and β_2 receptors, whereas cardioselective agents have proportionately higher β_1 receptor specificity, with little or no β_2 effect. Nonselective β-blockers may precipitate bronchospasm in asthmatic individuals and are relatively contraindicated in this group. Importantly, vast data supports the safe use of cardioselective β_1-adrenergic antagonists (e.g., atenolol, metoprolol, esmolol) in adults with asthma and COPD, where they were shown to be safe and not associated with worsening of pulmonary function. Lipid solubility and volume of distribution also vary between agents.

These pharmacologic properties alter the side effect profile of each drug. Agents with increased lipid solubility have relatively greater CNS penetration and may be more likely to induce fatigue or other CNS effects (antianxiety, depression, etc.).

Propranolol had widespread clinical use since the 1970s. Propranolol is a non-cardioselective agent available in a liquid form suitable for infant administration. It is generally administered at a dose of 2–6 mg/kg/day divided every 6–8 h. It is a highly effective antiarrhythmic agent with an additional quinidine-like membrane-stabilizing action. Propranolol is often a first-line agent for infants and young children with WPW, AVRT, or ectopic tachycardias. Individual responses vary, making dose titration necessary, guided by heart rate response and antiarrhythmic efficacy. Nonselective β-blockers have metabolic effects that can be significant in children. Endogenous epinephrine stimulates hepatic glycogenolysis and glucose mobilization in response to hypoglycemia. Nonselective β-blockade can blunt this response, leading to symptomatic hypoglycemia, such as in infants during gastrointestinal illness with impaired oral intake, or in diabetics with insulin shock.

Atenolol is often used in the older child or adolescent, typically at doses of 25–50 mg daily. Atenolol is a cardioselective agent with the added benefit of little CNS penetration. Esmolol is a parenteral cardioselective agent with a brief half-life (~8 min) and a peak onset of action within 10 min. Esmolol is a useful drug in the intensive care setting where rapid onset, short half-life, and titratability are desirable. Esmolol is typically administered using a loading dose of 100–500 mcg/kg, with subsequent infusion rates of 25–500 mcg/kg/min. Longer term esmolol administration can be associated with CNS symptoms (confusion, personality change, lethargy). Esmolol remains a good choice for control of adenosine-resistant SVT, with the infusion either leading to sinus conversion on its own or by altering conduction sufficiently to allow successful adenosine use. A number of other drugs can be used to treat SVT in specific situations (e.g., amiodarone, calcium channel blockers, sotalol, propafenone, etc.). These agents are best used in concert with cardiology consultation.

β-Adrenergic blockade is very effective and is commonly used for suppression of SVT in older children. β-Adrenergic blockade can be associated with hypoglycemia in younger patients, especially during a gastrointestinal illness. A cardiologist should be consulted regarding the selection and dose of the best agent to use in the management of SVT.

During cardiac catheterization, detailed electrophysiologic studies (EPS) can be performed to localize most accessory tissue and, once found, destroy it using radio frequency energy (RF ablation). This procedure is considered an effective, routine standard of care for the older patient with WPW, difficult to treat SVT, or for individuals who simply prefer to stop taking a daily medication. With increasing experience, RF ablation is becoming more of a routine therapy for older infants and children. EP studies are performed using several multielectrode catheters inserted transvenously into the heart to precisely map the location of ectopic foci or accessory conduction tissue. There is some risk of valve, myocardial, or conduction system injury, although such complications are fairly rare. Patient age, size, rhythm severity, and ease of pharmacologic control all weigh into the decision to undergo RF ablation. Catheter ablation can be offered to any age patient, although there is likely increased risk of complications for infants and small children. RF ablation is often not deemed to be necessary in children who may outgrow their rhythm disorder or in those who can be easily controlled with medication. Several successful case series have been reported involving infants and toddlers with life-threatening or pharmacologically resistant arrhythmias, and this should always be considered as a therapeutic option in an experienced center. Multicenter studies showed that RF ablation is ultimately curative for the vast majority of children, with success rates as high as 97% and few reported complications (AV block in 1.2% among nearly 3000 study participants).

Electrophysiology studies are becoming more routine in the pediatric population and can provide valuable diagnostic details as well as definitive treatment for the vast majority of reentrant SVT and WPW dysrhythmias, but cannot be performed in young infants.

18.4.7 Atrial Flutter

While more common in adults, atrial flutter can be seen postoperatively after repair of certain congenital heart defects, most notably repair of anomalous pulmonary venous return.

Atrial flutter is a relatively uncommon rhythm disorder in children. It is most often encountered in children following surgical correction of congenital heart disease, especially following repair of anomalous pulmonary venous return or other similar left-sided surgery. Late atrial arrhythmias are also common following the Fontan procedure. Atrial flutter results from a reentrant circuit that is confined to the atria. Classic ECG findings include rapid flutter waves (typical rates of 300–400 bpm) with a negative P-wave axis (downward P-waves in leads II, III and AVF). AV node conduction slows the ventricular response, often with every second or third flutter wave conducting through to the ventricle (◘ Fig. 18.7 atrial flutter with 2:1 block). It is often difficult to maintain good pharmacologic control of atrial flutter in children. Digoxin is often used to slow AV nodal conduction and limit the ventricular response. Cardioversion is often required to terminate atrial flutter or atrial fibrillation, with several important considerations. First, atrial thrombi need to be ruled out by echocardiogram to prevent systemic emboli following conversion to sinus rhythm. In the adult-sized patient, this usually requires the use of transesophageal echocardiography (TEE) to obtain images of sufficient quality. In small or thin children, transthoracic (routine) echocardiograms often provide adequate imaging and a TEE can be avoided. The second important consideration with reference to elective cardioversion is the potential for sinus arrest post conversion since chronic atrial flutter often produces transient sinus node dysfunction. This requires the ability to externally pace a child following successful electrical cardioversion pending sinus node recovery. This is easily accomplished with the use of adhesive pacing/defibrillation pads available with modern defibrillators.

18.4.8 Junctional Ectopic Tachycardia (JET)

JET is primarily a postoperative dysrhythmia resulting from increased automaticity within the His-Purkinje complex leading to gradual increase in heart rate with atrioventricular dissociation.

Almost exclusively a postoperative tachycardia, JET is caused by enhanced and abnormal automaticity of cells within the His-Purkinje complex. This automaticity arises from some perioperative insult and is a transient process, with JET beginning within a few hours of surgery that typically resolves within a week postoperatively. JET is often identified when the heart rate approaches 170 bpm and may gradually accelerate toward 250 bpm or higher. Treatment is typically necessary when rates are sustained at or above 180 bpm. JET is most commonly a narrow complex tachycardia but may widen in the presence of a bundle branch block. In this setting, it may be difficult to differentiate JET from a ventricular tachycardia. As JET is an automatic dysrhythmia, the rate typically accelerates in a gradual fashion and becomes evident as the JET focus begins to compete with the sinus mechanism. When JET and sinus rates are similar, the heart rate may appear to be irregular as the two mechanisms compete for heart rate control. As JET speeds up and supersedes the sinus rate, the HR often becomes regular again. JET arises below the level of the AV node and may or may not consistently conduct in a retrograde manner. If no P-waves are seen in the setting of postoperative tachycardia, an atrial electrogram can be obtained using temporary pacing wires, if present. To confirm JET with an atrial electrogram, one looks to confirm that ventricular activation (the QRS complex) precedes the onset of P-waves. As JET is an automatic arrhythmia, rates tend to "warm up and cool down" over time and can be influenced by the

patient's temperature, endogenous and exogenous catecholamines, and sedation administration in a similar manner to that of a sinus mechanism. The central venous pressure waveform can provide clear evidence as to the presence of JET by the demonstration of prominent "cannon A-waves."

Cannon A-waves occur when the atria contract against a closed tricuspid valve. During JET the heart rate originates below the level of the AV node, not in the SA node. As a result, there is a loss of the normal atrial-ventricular contraction sequence and a loss of the normal "atrial kick." In the normal heart, atrial contraction prior to ventricular systole helps fill the ventricle; this may account for 10–15% of ventricular filling and thus stroke volume. In the postoperative setting, diastolic dysfunction is often present with a requirement for higher ventricular filling pressures to support ventricular preload and cardiac output, which makes ventricular preload more dependent on the "atrial kick." For this reason, the loss of sequential AV conduction caused by a JET rhythm can be particularly hazardous in a postoperative patient already struggling with a low cardiac output state.

A warming-up period is seen with JET, with the heart rate slowly increasing. Cannon A-waves may be seen on the monitor as the atria contract against a closed tricuspid valve. Diagnosis can be definitively made via an atrial electrogram if atrial wires are present.

JET results from some perioperative insult and to some extent seems to be preventable by optimizing intraoperative anesthetic, bypass, and operative techniques. The perioperative use of magnesium sulfate, amiodarone and dexmedetomine have all been shown to decrease the postoperative incidence of JET. All of these agents have a role in the postoperative treatment of this tachyarrhythmia.

Treatment is twofold as attempts should be made to slow the JET rate and to restore AV synchrony (see box).

Treatment of JET

1. Slow automaticity
   - Correct metabolic and electrolyte abnormalities with particular attention to Mg+, Ca+, and K+.
   - Reduce excessive inotrope administration (hemodynamic instability often mandates continued use of some vasoactive agents).
   - Mild hypothermia to 35 °C aimed to slow automaticity.
   - Provide adequate sedation to minimize endogenous sympathetic drive. There is some evidence that dexmedetomidine may be a useful agent since it reduces centrally mediated sympathetic nervous system activation.
   - Antiarrhythmics: Amiodarone is the preferred antiarrhythmic, typically administered by continuous infusion. Bolus administration can cause acute hypotension; pacing may be required if drug-induced bradycardia occurs.
2. Restore AV synchrony (atrial kick) with temporary atrial pacing

Mainstays of JET treatment include decreasing catecholamine stimulation as much as possible, minimizing metabolic/electrolyte abnormalities, and overdrive pacing (if atrial leads are available). Amiodarone is the preferred antiarrhythmic treatment but should be given slowly to avoid hypotension.

Overdrive pacing – once the rate has been slowed sufficiently (often using an amiodarone infusion), atrial or AV sequential pacing above the JET rate should be attempted to restore AV synchrony.

A variety of other supraventricular tachycardias are seen in the intensive care setting. Ectopic atrial tachycardia, multifocal atrial tachycardia, and atrial fibrillation are relatively rare disorders that may be seen in children with underlying heart disease, rate-related cardiomyopathy, or following congenital heart surgery. Care should focus on basic resuscitation principles when caring for these children, maintaining appropriate hemodynamic and respiratory support.

18.4.9 Ventricular Ectopy and Tachycardia

Ventricular ectopy originates from specific foci. Unifocal ventricular ectopy is typically a benign finding in *otherwise healthy children with normal cardiac structure and function* and is not a harbinger of higher-grade arrhythmia. Premature contractions can arise in either the atria or ventricles. In general, wide complex beats (>0.14 s) are ventricular in origin but can be confused with atrial beats when there is aberrant conduction across forward conducting accessory pathways. Several criteria can help differentiate atrial from ventricular ectopy. PVCs are typically not conducted in a retrograde manner through the AV node into the atria. This leads to two potential phenomena – (i) a compensatory pause of the ventricular response following a PVC and (ii) the potential for fusion beats. Figure 18.8 shows frequent unifocal ventricular ectopic beats in a child with a normal heart; note the "compensatory pause" after each PVC. Ventricular premature contractions depolarize infra-nodal tissue, often rendering it refractory to the next sinus beat. Sinus atrial beats continue rhythmically and unabated (in the example below, approximately every 960 msec). Close examination of the T-waves may identify the presence of a superimposed P-wave.

Sinus P-waves occurring during the ventricular refractory period are not propagated through ventricular tissue, producing the classic "compensatory pause" seen in association with ventricular ectopy. The combination of the SA node maintaining its original pace and the compensatory pause causes the length of two cycles including the PVC to be equal to twice the length of the previous cycle (2 × RR). In contrast, atrial depolarizations resulting from a conducted atrial ectopic beat typically depolarize sinus nodal tissue. Once a premature atrial contraction is conducted through the sinus node, sinus nodal tissue immediately repolarizes and continues with its undisturbed intrinsic rate. Thus, premature atrial contractions generally produce an early beat immediately followed by a continuation of the background sinus rate and do not produce the compensatory pause seen in association with ventricular ectopy.

Ventricular rhythm disorders are uncommon in pediatrics, and a thorough work-up should be performed if suspected, along with cardiology consultation. Unifocal ventricular ectopy (PVC) is typically a benign finding in *otherwise healthy children with normal cardiac structure and function* and is not a harbinger of higher-grade arrhythmia.

Ventricular rhythm disorders are relatively rare in the pediatric population. Ventricular ectopy in the presence of myocarditis, structural heart disease, inherited channelopathy, postoperatively, or in association with a critical systemic illness (e.g., shock, CNS injury, inotropic infusion) often warrants a complete cardiovascular evaluation with subsequent pharmacologic or device intervention. Table 18.3 lists selected, relatively common causes of ventricular rhythm disorders in children. Chronic VT occurs mainly with inherited channelopathies, postoperatively or from a relatively short list of idiopathic ventricular rhythm disorders. Secondary causes of VT occur in children with otherwise normal hearts undergoing the acute stresses of critical illness. In this setting, therapy is based on treating the underlying condition while addressing such issues as electrolyte disturbances or limiting potential arrhythmogenic medications. Increasing frequency or multifocal ventricular ectopy may force the clinician to wean catecholamine support and may serve as a marker of unfavorable myocardial energetics. The onset of hemodynamically compromising acute ventricular tachycardia (VT) demands prompt resuscitative interventions, whereas slower forms of chronic

Hemodynamically significant ventricular tachycardia should be promptly treated with attempted defibrillation using 2 J/kg and increasing to 4 J/kg for subsequent attempts.

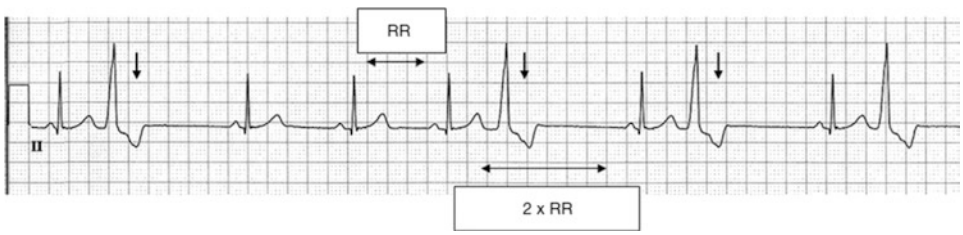

Fig. 18.8 Unifocal PVC with compensatory pause after each ventricular ectopic beat

Table 18.3 Common causes of ventricular ectopy/tachycardia

A. *Ventricular ectopic foci (automatic mechanism)*	
Benign ventricular ectopy	
Automatic ventricular tachycardia	
B. *Ventricular reentry*	
Postsurgical (circuit around a surgical scar)	
Postinfarction (chronic phase)	
C. *Ventricular triggered activity*	
Long QT-induced torsades de pointes	
Other inherited ion channelopathies (e.g., Brugada syndrome, catecholaminergic polymorphic ventricular tachycardia, others)	
Right ventricular outflow tract ventricular tachycardia (RVOT VT)	
Arrhythmogenic right ventricular dysplasia (ARVD)	
Adenosine-sensitive ventricular tachycardia	
Verapamil-sensitive ventricular tachycardia	
D. *Presence of an intracardiac catheter*	
Percutaneous intravenous catheters, PICC lines, dialysis catheters, etc., can migrate across the tricuspid valve and induce ventricular ectopy or sustained VT. This should be identified and corrected if present	
E. *Acute/secondary ventricular tachycardia (selected causes)*	
Acidosis	Anesthetics
Antiarrhythmic medications	Caffeine
Cardiac contusions	Cardiomyopathy (dilated, hypertrophic)
Catecholamines	Catheter irritation
Cocaine	Congenital heart surgery
Hyper- or hypokalemia	Hypocalcemia
Hypomagnesemia	Hypoxemia
Ischemia	Myocarditis
Pericarditis	Tricyclic antidepressants
Toxin exposures	Tumors (rhabdomyomas)

ventricular tachycardia may be hemodynamically tolerated. Once again, the clinician must perform a rapid patient assessment to decide on the appropriate tenor of intervention. Hemodynamically compromised or pulseless VT should always be treated with prompt defibrillation, per standard resuscitation protocols. For children, defibrillation energy is recommended to begin at 2 J/kg, increasing to 4 J/kg for subsequent shock attempts. Bolus epinephrine administration is recommended as an initial pharmacologic intervention for pulseless children unresponsive to three defibrillation attempts. Patients with VT and less severe hemodynamic compromise can be treated pharmacologically or with *synchronized* cardioversion using 0.5–1 J/kg. Current recommendations are to use the same energy dose with either a monophasic or biphasic defibrillator in the pediatric population since no outcome difference has been identified. Current defibrillators and AED devices use biphasic energy. In the pediatric critical care setting, three medications predominate for the treatment of ventricular tachy-

Monomorphic ventricular ectopy in a child with a normal heart may be a normal variant, caused by a benign ventricular ectopic focus. Conversely, ventricular ectopy in a child undergoing intensive care may be a marker of diseased myocardium at risk for ventricular arrhythmia. In the PICU, normal electrolytes should be assured, a transvalvular central venous catheter should be identified, and a complete cardiovascular assessment should be performed.

cardia. These include lidocaine, amiodarone, and magnesium sulfate. A wide variety of other agents may be encountered following electrophysiology consultation; for the purposes of this discussion, we will focus on these three medications.

18.4.10 Lidocaine

Lidocaine is a class IB antiarrhythmic primarily used for acute suppression/conversion of ventricular tachyarrhythmias.

Lidocaine is the classic agent widely used for decades for acute suppression/conversion of ventricular tachyarrhythmias. As a class IB drug, lidocaine blocks sodium channels leading to decreased membrane excitability, decreased conduction velocity, and slowed automaticity of ventricular tissue. Lidocaine has little effect on the QRS duration or QT interval. With these conduction effects, lidocaine is an effective treatment for ventricular tachycardia arising from a variety of origins. It may have a mild negative inotropic effect that should be kept in mind when used in the setting of left ventricular dysfunction. Lidocaine, when administered by rapid intravenous infusion, can cause seizure activity. Excessive plasma concentrations during prolonged intravenous infusion can produce tremor, speech changes, and CNS toxicity. Nystagmus is a typically described early marker of lidocaine toxicity. Lidocaine must be administered parenterally, as it undergoes extensive first-pass hepatic metabolism. It rapidly redistributes from the central compartment after bolus administration with a half-life of less than 10 min, thereby necessitating administration via a continuous infusion when used for continuous arrhythmia management. Pediatric dosing recommendations include a 1 mg/kg loading dose (may be repeated) followed by a continuous infusion of 20–50 mcg/kg/min. Lidocaine has a variable terminal elimination half-life (1.5–3 h); lower infusion rates are recommended for children with hepatic insufficiency or congestive heart failure. Lidocaine is a relatively safe drug with a vast history that remains part of routine resuscitation protocols. Other agents may be more effective in specific situations.

18.4.11 Amiodarone

Amiodarone is an antiarrhythmic acting at multiple ion channels useful for treating supraventricular and ventricular arrhythmias. Care should be taken when giving amiodarone due to its multiple mechanisms of action and large side effect profile.

Amiodarone is a drug with multiple class effects, useful for a variety of supraventricular and ventricular arrhythmias. Amiodarone is more effective than lidocaine when used in the setting of adult cardiac arrest. Amiodarone is an alternative to lidocaine during the resuscitation of children with pulseless VT/VF. Amiodarone has prominent class III (as well as class IB, II, and IV) effects that prolong the action potential, lengthen refractory periods, and slow AV node conduction and sinus node function. These multiple conduction changes combine to make amiodarone effective against most ventricular and supraventricular arrhythmias. It has an unusual pharmacokinetic profile with a high degree of tissue uptake (volume of distribution is approximately 66 L/kg) leading to a prolonged elimination half-life upward of 30–60 days with chronic oral therapy. This prolonged half-life limits the utility of electrophysiology studies until the drug has been eliminated. Side effects are relatively common (4–44%) and range from mild to severe reactions. These include slate blue skin discoloration, corneal deposits, hypothyroidism, and a potentially severe interstitial pneumonitis. Cardiovascular effects include bradycardia, heart block, QT prolongation with torsades de pointes, and hypotension. Side effects occur less frequently in children but mandate chronic amiodarone use only when potentially less toxic agents are ineffective. Limiting the dose and duration of amiodarone treatment can minimize side effects. In the pediatric critical care setting,

amiodarone is generally administered IV as a loading dose of 5 mg/kg, infused over 30 min or longer to avoid hypotension. Repeat doses are titrated to effect with a maintenance dose of 10–15 mg/kg daily. Amiodarone is commonly administered as a continuous infusion in the perioperative period when treating junctional ectopic tachycardia; a dosage range of 7 to 10 mcg/kg/min approximates standard daily mg dosing totals. Fluid for volume support and calcium chloride should be readily available if clinically significant hypotension ensues. Hypotension is more common with rapid IV administration; this can often be avoided using slower infusion rates or with oral administration.

18.5 Miscellaneous Antiarrhythmic Agents and Arrhythmias

18.5.1 Sotalol

Sotalol is a class III antiarrhythmic with class II properties useful for atrial tachyarrhythmias.

Sotalol is classified as a class III antiarrhythmic, as the primary mechanism of action is to block potassium channels. This results in a prolonged period of repolarization (and, subsequently, prolongation of the QTc interval). However, sotalol differs from other class III antiarrhythmics in that it also has beta-adrenergic blocking properties. This allows the drug to be used for the treatment of both atrial and ventricular dysrhythmias. The drug is most commonly used in children for the treatment of difficult-to-control atrial tachyarrhythmias and was first included in the 2010 American Heart Association's guidelines for the treatment of atrial fibrillation. While it was previously available as an oral medication, in 2015 it became available in the United States for intravenous use. Since that time, sotalol has been administered by both intermittent bolus dosing and continuous infusion. Limited pediatric experience reports that sotalol is safe and effective in the treatment of difficult-to-control atrial tachyarrhythmias such as atrial flutter and ectopic atrial tachycardias. Sotalol is renally excreted and should be used very carefully in patients with renal failure. Due to sotalol's ability to significantly increase the QTc, periodic ECG monitoring is mandated, and it carries a black box warning recommending patients only be started or stopped on this medication as an inpatient with monitoring of both cardiovascular status and creatinine clearance.

18.5.2 Magnesium for Torsades De Pointes/Long QT Syndrome

TdP is a specific polymorphic ventricular tachycardia seen in patients with prolonged QT intervals. It can be acute in onset and lead to syncope or sudden death.

Torsades de pointes (TdP) is a polymorphic ventricular tachycardia associated with a prolonged QT interval. This arrhythmia is encountered in individuals with the congenital long QT syndrome (LQTS) and in those with drug induced (or other secondary cause) for QT prolongation. Patients may suddenly develop TdP, often in response to an acute adrenergic stress. Precipitating stressors may include cold-water immersion (swimming), startling events, or strong emotions. Patients are often diagnosed with inherited LQTS during an evaluation of recurrent syncope or seizures, and this should be considered when evaluating patients after unexplained near drowning or syncope. The corrected QT interval calculated using Bazett's formula (QTc = QT/(square root of the preceding RR interval)) remains the standard screening tool for the LQTS. In general, the corrected QT interval should be less than 450 msec, with some normal females reaching as high as 460 msec. This is an inexact screening tool, as individuals with genetically proven and clinically significant LQTS have been doc-

umented to have QTc in the normal range. Syncopal events in patients with LQTS result from self-terminating bouts of torsades de pointes, any of which could ultimately degrade to ventricular fibrillation and result in sudden cardiac death. A number of inherited ion channel mutations have been identified as causative, with some individuals presenting with spontaneous mutations and a negative family history. An increasing number of gene mutations have been described, with growing knowledge as to their clinical significance. For example, specific potassium channel mutations (KvLQT1, *minK*, *HERG*, *MiRP1*) have been shown to interfere with potassium ion flow and prolong cell repolarization. Conversely, mutations in sodium channels (SCN5A) produce a "gain of function" that prolongs sodium flow and, with it, action potential duration.

Figure 18.9 shows an ECG from an adolescent female who presented with recurrent syncopal events. Her corrected QT interval was prolonged at 492 msec. This degree of QT prolongation is diagnostic but is not nearly as dramatic as is often seen in many families where the corrected QT interval can reach 550–600 msec or greater.

TdP first-line treatment is basic resuscitation principles with the addition of magnesium sulfate.

Torsades de pointes can be identified as a particular type of ventricular tachycardia with undulating, phasic changes in the QRS axis (Fig. 18.10). Basic resuscitation principles take precedence: the unstable patient with pulseless VT should be immediately defibrillated using 2 J/kg of energy. Epinephrine is recommended for the pulseless patient if defibrillation is unsuccessful. When TdP is identified, magnesium sulfate (25–50 mg/kg, maximum 2 g) should be administered. This has been shown experimentally to decrease triggered activity and, clinically, to effectively and safely suppress TdP in patients of all ages. Some data suggest that lower magnesium doses (5–10 mg/kg bolus followed by a continuous infusion of 0.5–1 mg/kg/h) may be effective to suppress bursts of TdP in children with inherited or acquired QT prolongation. Serum magnesium levels should be followed in children treated with magnesium sulfate to assure correction of hypomagnesemia and to limit the risk of side effects (somnolence, muscular weakness, respiratory suppression) that can be observed with high serum concentrations (>5 mg/dL).

18.5.3 Other Treatment/General Principles

Full cardiac evaluation is indicated for children with ventricular rhythm disorders. The cardiologist will attempt to assess the risk for recurrent arrhythmia and sudden death, balancing treatment recommendations accordingly. Similar

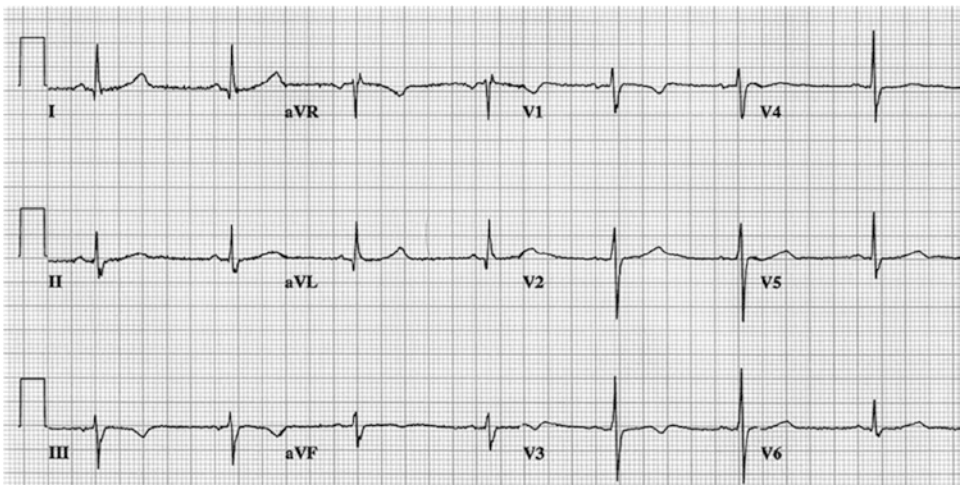

Fig. 18.9 12-lead ECG displaying long QT interval in an adolescent female with a history of recurrent syncope. Long QT syndrome is caused by cardiac ion channel mutations. Patients have a corrected QT interval >450 msec and are at risk for sudden death due to the onset of torsades de pointes and ventricular fibrillation. Episodes are typically precipitated by adrenergic stress and can present as recurrent seizures or syncope. Screening ECGs should be performed when caring for patients with unexplained syncope, seizures, or accidental events

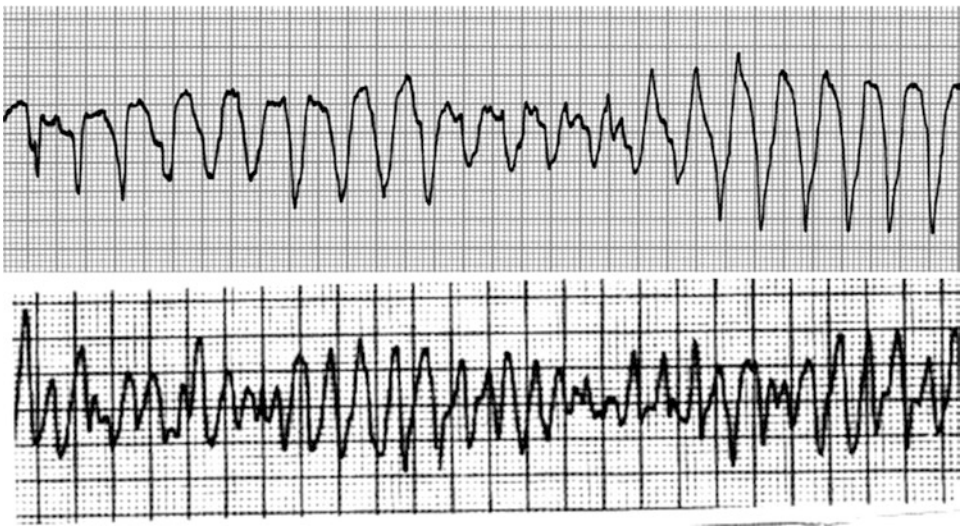

Fig. 18.10 Undulating pattern of a wide complex ventricular tachycardia characteristic of torsades de pointes

to the strategy used when treating supraventricular tachycardias, a wide variety of interventions are possible, titrated to risk and patient choice. Children with normal cardiac structure and function may not require any treatment for non-sustained periods of an accelerated idioventricular rhythm, which is a slow ventricular tachycardia typically at rates of 100–120 bpm. Patients with LQTS may be treated with ß-adrenergic blockade. Automatic implanted cardiac defibrillators (AICDs) are being increasingly placed in children with LQTS, hypertrophic cardiomyopathy, and similar disorders where defined risks of sudden cardiac death are possible. Catheter ablation is also effective for some conditions, such as RVOT ventricular tachycardia and some ectopic tachycardias.

18.6 Summary

A basic understanding of the normal cardiac conduction pathways is important in order to understand and distinguish between the various types of rhythm disturbances seen in the critical care setting. An overview of the rapid identification of rhythm abnormalities along with a basic understanding of the available antiarrhythmic agents and their mechanism of actions has been covered. Utilization of membrane-stabilizing mechanisms, such as calcium or magnesium administration, may be lifesaving in an acute situation, but consultation with a cardiologist regarding the management of nonurgent rhythm disturbances is always advised.

Review Questions

1. Which of the following statements is true regarding the cardiac action potential?
   - A. During hyperkalemia, calcium administration may be harmful by augmenting the calcium component of the resting potential.
   - B. The high potassium concentration within the cardiac myocyte contributes to the resting action potential.
   - C. The spreading wave of myocardial depolarization causes a negative deflection as it moves toward a surface ECG lead.
   - D. Sodium channel blockade with class IB agents (e.g., lidocaine) results in prolongation of the action potential duration.
   - E. Sympathetic augmentation decreases the inward calcium current and the slope of phase 4 depolarization.

2. Which one of the following mechanisms accounts for the most tachyarrhythmias (other than sinus tachycardia) in children?
   A. Ectopic foci.
   B. Nodal block.
   C. Reentry.
   D. Triggered activity.
   E. Vagal stimuli.

3. Which one of the following represents a class II antiarrhythmic medication?
   A. Amiodarone.
   B. Atenolol.
   C. Diltiazem.
   D. Lidocaine.
   E. Procainamide.

4. A 2-month-old female infant is being cared for in the pediatric intensive care unit for resolving viral bronchiolitis. You are called to the bedside to evaluate her for the sudden onset of a narrow complex tachycardia at a rate of 280 bpm. The infant is awake and interactive, although fussy and crying intermittently. Her blood pressure is 82/50 mmHg, her femoral pulses are readily palpable, and her capillary refill time is less than 2 s. Prior to the event, she had a documented normal sinus rhythm with no evidence of a delta wave. Which of the following interventions is *contraindicated*?
   A. Application of a bag of ice to the infant's face without establishing peripheral intravenous catheter.
   B. Placement of a peripheral intravenous catheter and administration of adenosine.
   C. Placement of a peripheral intravenous catheter and administration of digoxin.
   D. Placement of a peripheral intravenous catheter and administration of verapamil.
   E. Placement of a peripheral intravenous catheter and await input from a cardiology consult.

5. A 1-year-old male is admitted to the pediatric intensive care unit following closure of a large, unrestricted ventricular septal defect. The infant is receiving mechanical ventilation with his pulse oximeter consistently reading 98–100% breathing an inspired FiO_2 of 0.25. He is receiving heavy sedation to maintain synchrony with the ventilator. Several minutes following endotracheal suctioning, he suddenly became cyanotic and bradycardic. Evaluation of his cardiopulmonary monitor reveals a narrow complex junctional rhythm with a heart rate of 45 bpm and a blood pressure of 62/30 mmHg. The pulse oximeter is reading in the 50s and the patient is clearly cyanotic. Of the following choices, which is the most likely explanation for his bradycardia?
   A. Acute respiratory compromise with hypoxemia resulting in bradycardia.
   B. Atrioventricular dissociation from the surgical procedure.
   C. Sinus node dysfunction secondary to his surgical procedure.
   D. Sinus node suppression from required sedation.
   E. Vagally induced bradycardia from the suctioning.

6. Which of the following children is at **LEAST** risk for a sudden cardiac event?
   A. A 15-year-old, previously healthy female with scoliosis admitted following spinal fusion procedure having unifocal premature ventricular contractions.
   B. A 5-year-old male with preexcitation (Wolff-Parkinson-White syndrome) noted on his baseline electrocardiogram.

C. A 13-year-old female with syncope and a family history of long QT syndrome.
D. A 12-year-old male with a known cardiomyopathy having multifocal premature ventricular contractions.
E. An 8-year-old female with known long QT syndrome being started on methadone for chronic pain.

7. Which of the following medications used in the treatment of supraventricular tachycardia is contraindicated in the setting of Wolff-Parkinson-White syndrome due to the risk of accelerating anterograde conduction along the accessory pathway?
A. Adenosine.
B. Flecainide.
C. Digoxin.
D. Propranolol.
E. Sotalol.

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_19

Learning Objectives

- Discuss the epidemiology of congenital heart diseases and the multidisciplinary approach to management.
- Describe the pathophysiologic aftereffects of cardiopulmonary bypass relevant to postoperative care and organ dysfunction.
- Describe the principles and use of hemodynamic monitoring tools in postoperative cardiac patients.
- Describe the principles of mechanical ventilation in the postoperative management of cardiac patients.
- Describe low cardiac output syndrome and discuss postoperative management principles.
- Describe the physiologic effects of pulmonary arterial hypertension and discuss postoperative management principles.
- Discuss the diagnosis and management of postoperative arrhythmias.
- Describe acute kidney injury and management options in postoperative cardiac patients.
- Describe important clinical elements of the immediate postoperative encounter.
- Discuss critical issues in postoperative management of congenital heart defects including:
  - Left-to-right shunting lesions.
    - Patent ductus arteriosus (PDA).
    - Atrial septal defect (ASD).
    - Ventricular septal defect (VSD).
    - Atrioventricular septal defect (AVSD).
  - Left-sided obstructive lesions.
    - Critical aortic stenosis (AS).
    - Coarctation of aorta (CoA).
    - Interrupted aortic arch (IAA).
  - Ductal-independent mixing lesions.
    - D-transposition of great arteries (D-TGA) and arterial switch operation.
    - Total anomalous pulmonary venous return (TAPVR).
    - Truncus arteriosus.
  - Lesions with ductal-dependent pulmonary blood flow.
    - Tetralogy of Fallot (TOF).
  - Single ventricle lesions.
    - Stage 1: Norwood procedure.
    - Stage 2: Bidirectional Glenn operation.
    - Stage 3: Fontan operation.
- Discuss management of postoperative heart transplant patients.
- Discuss the importance and principles of nutrition support in postoperative cardiac patients.
- Discuss the causes, diagnosis, and treatment of chylothorax in postoperative cardiac patients.
- Discuss the causes, diagnosis, and treatment of diaphragmatic paresis in postoperative cardiac patients.
- Discuss the causes, diagnosis, and treatment of vocal cord paresis and paralysis in postoperative cardiac patients.

19.1 Introduction

Successful management of the postoperative pediatric cardiac surgical patient requires a thorough understanding of the pre- and postoperative anatomy and physiology of the patient, the impact of the surgical intervention, and the potential postoperative complications for each patient. This chapter intends to provide a clear and concise review of the most common and the most critical issues in the immediate postoperative care of congenital heart disease patients in the pediatric intensive care unit. The following text is written from the perspective of the pediatric intensive care specialist, and not all aspects of all congenital heart diseases are reviewed. Detailed anatomical description and classification, initial clinical presentation, physical examination findings, various diagnostic modalities, and long-term outcomes of each congenital heart defect are beyond the scope of this chapter. Therefore, readers should refer to separate pediatric cardiology or pediatric cardiothoracic surgery resources for this information.

19.2 Epidemiology of Congenital Heart Disease

Epidemiology: With improved surgical and medical care, about 85% of children with CHD are expected to live into adulthood.

Congenital heart disease (CHD) affects a large, ever-growing population of infants, children, adolescents, and adults. It accounts for 0.8–1.2% of all birth defects with a prevalence of 5.8–7.8 per 1000 people. About 40,000 babies are born with CHD every year in the United States. The disease burden for CHD is substantial. Cardiac defects are associated with lifelong comorbidity and significantly increase health services use during infancy and childhood. The surgical management of CHD is a cornerstone of comprehensive therapy. Development of cardiopulmonary bypass (CPB) made possible definitive repair of more complex defects, especially those with an intracardiac component. Many subsequent modifications in CPB, anesthesia management, surgical interventions and techniques, and patient selection led to increasingly successful interventions. With improved surgical and medical care, about 85% of children with CHD are expected to live into adulthood. Achieving this outcome necessitates the commitment of a diverse team of clinicians who specialize in the care of patients with complex CHD including pediatric intensive care specialists, cardiovascular surgeons, cardiac anesthesiologists, cardiologists, critical care nurses, respiratory therapists, pharmacists, and nutritionists.

19.3 Cardiopulmonary Bypass

Cardiopulmonary Bypass: CPB is a distinctly non-physiological state characterized by non-pulsatile blood flow, hypothermia, ischemia/reperfusion injury, inflammation, alterations in coagulation status, hemodilution, acid-base alterations, microembolization and oxidative stress.

Cardiopulmonary bypass (CPB) is used to divert the blood from the heart in order to perform complex congenital heart surgeries in a bloodless surgical field (See ◘ Fig. 19.1). Cardioplegia is also required to keep the heart still during the surgical repair. Cardioplegia is achieved by solutions with a high potassium concentration that inhibits myocardial cell repolarization and stops myocardial contraction. Cardioplegia solution can be administered into the aortic root during aortic cross clamp (antegrade infusion), or it can be administered into the coronary sinus (retrograde infusion) depending on the heart defect and the surgical repair.

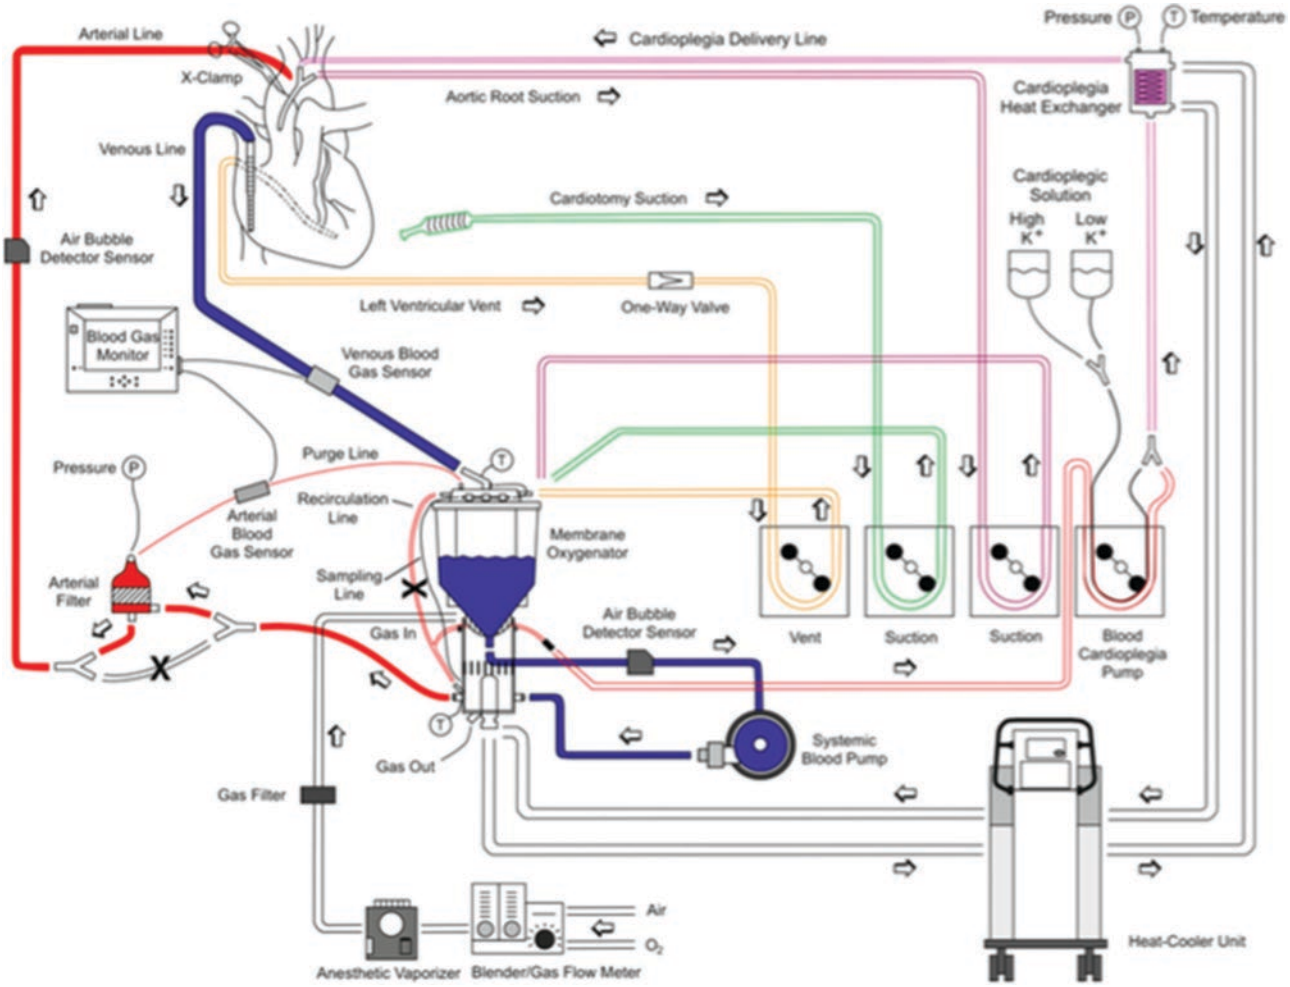

Fig. 19.1 Schematic diagram of typical cardiopulmonary bypass circuit. Illustrated are the systemic blood pump (*lower right*), oxygenator and venous reservoir (incorporated as a single hard-shell unit which also includes the heat-exchanger, depicted in the *lower center* of this diagram), cardiotomy suction (*upper center*), and arterial line filter/bubble trap (*lower left*). Also displayed are multiple safety devices and monitors, cardioplegia delivery, field suction and vent systems, gas and water delivery systems for the oxygenator and heat-exchangers. Not displayed is the central data processing and monitoring console

19.3.1 Cardiopulmonary Bypass-Induced Inflammation and Organ Dysfunction

Cardiopulmonary bypass–induced inflammation is triggered by multiple factors, including exposure of patient's blood to the artificial surface of the CPB circuit, ischemia/reperfusion, and hypothermia. Complex interactions between the complement system, coagulation system, fibrinolytic system, leukocytes, cytokines, platelets, and endothelium result from this exposure, eventually resulting in capillary leak and organ dysfunction. This CPB-induced postsurgical acute inflammatory response is the primary underlying pathophysiological process in the development of organ dysfunction by causing increased permeability of the blood-brain barrier, damage to the alveolar-endothelial barrier, decreased shortening of cardiac muscle cells, dysfunction of the systemic vascular endothelium, altered hypothalamic pituitary adrenal axis, injury to renal glomerular and tubular cells, and increased intestinal mucosal permeability.

Cytokines are the key molecules of acute inflammation following cardiac surgery. Individual cytokines may exert either proinflammatory or anti-inflammatory effects. Proinflammatory cytokine response to cardiac surgery includes tumor necrosis factor alpha (TNF-α), interleukin-1β (IL-1β), IL-6, and IL-8. Conversely, there is increased production of IL-10, a well-known anti-inflammatory cytokine. Cellular elements of the immune system also play a critical role in organ dysfunction in the setting of acute inflammation. Recent evidence highlights the importance of neutrophils in producing organ dysfunction in infants after CBP (Fig. 19.2).

Achieving immunological balance between pro- and anti-inflammatory responses is essential for healthy recovery following cardiac surgery. The counter-regulatory system to balance the pro-inflammatory response is called the compensatory anti-inflammatory response syndrome (CARS). Immunoparalysis is another term to describe the immunological state where the anti-inflammatory response dominates the pro-inflammatory response. Immunoparalysis is also described as a specific pathophysiological subcategory of pediatric multiple organ dysfunction syndrome that may occur in pediatric patients after CPB exposure. Laboratory findings of immunoparalysis following CBP include reduced levels of human leukocyte antigen-D–related (HLA-DR) expression (< 30%) on monocytes, reduced TNF-α production capacity (<200 pg/mL) in response to ex vivo stimulation with lipopolysaccharide, and increased levels of IL-10. Immunoparalysis following CBP in children is associated with a higher risk of postoperative infections and longer hospital stay.

Postoperative organ dysfunction is an important cause of mortality and morbidity in infants and children following cardiac surgery. As high as 81.8% of early postoperative mortality after cardiac surgery in children was attributed to multiple organ dysfunction. Infants and children undergoing cardiac surgery with CPB are particularly at high risk of developing postoperative organ dysfunction, specifically cardiac dysfunction/low cardiac output state requiring inotropic support, respiratory failure requiring prolonged mechanical ventilation, clinical/subclinical seizures, and acute kidney injury.

CPB-induced endothelial damage is responsible for capillary leak and generalized edema. The interaction between neutrophils and endothelium is a well-studied CPB-related mechanism of endothelial damage and organ dysfunction. As part of the inflammatory response, activated neutrophils bind to

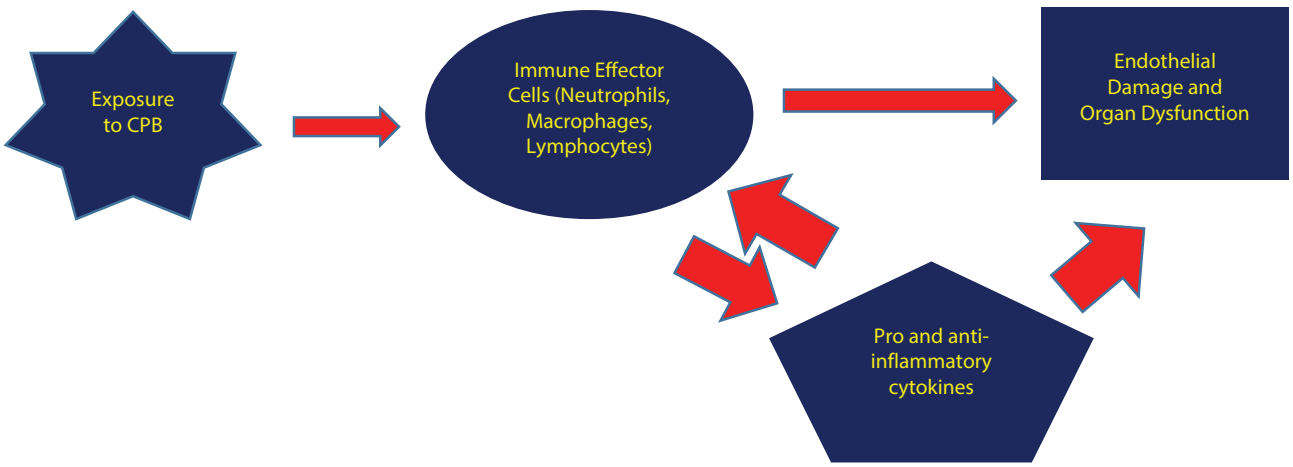

Fig. 19.2 Simplified schematic representation of the pathway to organ dysfunction induced by cardiopulmonary bypass (CPB)

endothelium via adhesion molecules such as selectins and integrins, eventually transmigrating out of the blood vessel and entering into the interstitial tissue of organs where inflammatory damage continues. Neutrophils also play an important role in lung inflammation, resulting in alveolar edema and inactivation of surfactant leading to increased alveolar-arterial oxygen gradient and decreased lung compliance. Reperfusion injury to the pulmonary vasculature and decreased nitric oxide production from injured endothelium are considered to be contributing factors to altered pulmonary vasculature reactivity and pulmonary hypertension that can be seen after CPB.

Effects of CPB on the myocardium are mainly due to ischemia-reperfusion injury. It is also suggested that inflammatory mediators may cause direct negative effects on the myocardium. Overall, CBP results in decreased cardiac contractility and myocardial edema causing decreased myocardial compliance. These myocardial changes significantly contribute to the postoperative low cardiac output state seen in some patients. The central nervous system, kidneys, and splanchnic circulation are also vulnerable to CBP-induced inflammation and ischemia-reperfusion injury. Furthermore, the CBP-induced inflammatory response causes increased intestinal permeability and bacterial translocation from intestines to the blood.

To attenuate the negative effects of CPB-induced inflammation and minimize organ dysfunction, systemic steroids have been studied extensively. Studies employed a wide variation in dosing and timing of steroids and reported conflicting results. However, preoperative steroid administration is still a common practice in many congenital heart disease centers. Heparin-coated CPB circuits decrease CPB-induced inflammation by decreasing complement and contact system activation. Removal of water by ultrafiltration during CPB is also thought to be effective in eliminating inflammatory cytokines and may improve postoperative cardiopulmonary function.

Cardiopulmonary Bypass-Induced Inflammation and Organ Dysfunction:

- Complex interactions between the complement system cascade, coagulation system, fibrinolytic system, leukocytes, cytokines, platelets and endothelium result from exposure to the CPB circuit, eventually resulting in capillary leak and organ dysfunction.
- Proinflammatory cytokines in the immune response to cardiac surgery include tumor necrosis factor alpha (TNF-α), interleukin-1β (IL-1β), IL-6 and IL-8. Conversely, IL-10 is the most well-known anti-inflammatory cytokine.
- Achieving immunological balance between the pro and anti-inflammatory response is essential for healthy recovery following cardiac surgery.

19.4 Perioperative Monitoring

Perioperative Monitoring:

Electrocardiogram (ECG), pulse oximetry, arterial blood pressure (invasive and/or non-invasive), and central venous pressure (CVP) are standard monitoring tools in postoperative cardiac patients. CVP monitoring is used to indirectly assess preload, but it is influenced by the compliance of the right ventricle. Depending on the heart defect and the surgical operation, left atrial pressure (LAP) monitoring is also used. LAP measurement is particularly useful in postoperative management of lesions with small left sided structures, (e.g., Shone's complex patients). For endotracheally intubated patients, end-tidal carbon dioxide ($ETCO_2$), peak inspiratory pressure, end-expiratory pressure, tidal volume, and other respiratory mechanics data should be monitored and recorded. Hourly urine output and strict fluid balance documentation provide essential data in the immediate postoperative period.

19.4.1 Near-Infrared Spectroscopy (NIRS) Monitoring

Near-Infrared Spectroscopy:
NIRS is a non-invasive technology that provides continuous venous weighted oxygen saturation of tissue beds of interest: renal, splanchnic, and brain.

Data on oxygenation status of the venous side of the systemic circulation provides valuable information to guide goal-directed interventions in shock states. NIRS provides continuous venous-weighted oxygen saturation of tissues. Unlike pulse oximetry, NIRS measures oxygen saturation of vascular beds with non-pulsatile blood flow. NIRS sensor uses light at two wavelengths (730 and 805 nm) emitted into the tissues, and two detectors in the NIRS sensor

measure the intensity of the reflected light. The change in the intensity of the reflected light at each wavelength is used to calculate oxyhemoglobin saturation of the tissue under the NIRS sensor. The depth of sampling beneath the NIRS sensor is about 2–3 cm, which is half of the source-detector distance in the NIRS sensor. While central venous oxygen saturation ($ScvO_2$) monitoring provides information about the global balance of oxygen supply and demand, NIRS allows clinicians to assess regional tissue oxygenation. Multi-site monitoring allows the assessment of regional tissue oxygenation, typically placing NIRS sensors on the forehead, flank, and abdominal wall.

NIRS is used in pediatric cardiac surgery patients most commonly to assess the adequacy of brain perfusion, and thus, to improve neurological outcomes in CHD surgery. Clinical studies demonstrated significant association of long-term neurodevelopmental outcomes with early postoperative cerebral oxygenation measured by NIRS. Experience in pediatric cardiac ICUs and recent publications support the use of NIRS measurement as part of goal-directed interventions in the perioperative management of congenital heart surgery patients. In a recent study by Hoffman et al., NIRS data predicted mortality and need for extracorporeal membrane oxygenation in the early postoperative period after stage 1 palliation of hypoplastic left heart syndrome patients.

19.5 Mechanical Ventilation

Mechanical ventilation is frequently necessary in the postoperative period after cardiac surgery. Positive pressure ventilation significantly impacts hemodynamics, especially in patients with myocardial dysfunction where it may reduce LV afterload and oxygen demand by reducing the work of breathing.

Pulmonary compliance decreases with increasing lung water content after CPB, which results from inflammation, reperfusion injury, and capillary leak. Decreased lung and chest wall compliance then lead to impaired pulmonary mechanics, which may manifest as increased work of breathing to the point of respiratory failure in neonates and infants with low baseline reserve. A considerable proportion of the total body oxygen (up to 20-25%) is consumed by respiratory muscles in severe respiratory distress, especially in the presence of concomitant LV dysfunction. Therefore, positive pressure ventilation to reduce the work of breathing can be beneficial. On the other hand, in children who undergo single ventricle palliation leading to passive pulmonary blood flow, for example, positive pressure ventilation may significantly impair pulmonary circulation; such patients benefit from early extubation.

As a general principle, increased mean intrathoracic pressure leads to a decrease in venous return and thus RV preload, although this effect may be temporized by augmenting intravascular volume immediately after the initiation of positive pressure ventilation. Pulmonary vascular resistance (PVR) and RV afterload are also affected by mechanical ventilation, as increased intra-airway pressure may overdistend alveoli, leading to increased resistance of intra-alveolar pulmonary vessels. However, low lung volumes and associated atelectasis may likewise increase resistance in extra-alveolar pulmonary vessels; in this instance using PEEP and positive pressure ventilation may reduce PVR and RV afterload.

Early extubation after cardiopulmonary bypass is increasing and is generally safe. Advantages of this approach include the reduction of the amount of postoperative sedation and length of stay in the ICU. Careful selection of patients for early extubation is necessary and should be discussed among car-

Mechanical Ventilation:
Pulmonary compliance decreases with increasing lung water content after CPB and may manifest as increased work of breathing to the point of respiratory failure in neonates and infants with low baseline reserve, especially in the presence of concomitant LV dysfunction. Therefore, positive pressure ventilation in this context can be beneficial. Conversely, in those infants or children who undergo single ventricle palliation leading to passive pulmonary blood flow, positive pressure ventilation may significantly impair pulmonary circulation; thus, such patients benefit from early extubation.

diac anesthesia, the cardiac surgeon, and the ICU team. Patients with high inotropic support, preoperative pulmonary hypertension, younger age, and long CPB times are at risk for extubation failure and need thorough evaluation before deciding upon extubation. If these patients fail extubation, both morbidity and ICU length of stay substantially increase. Protocolized assessment of patients for extubation readiness should also be considered in order to reduce the length of mechanical ventilation and decrease the risk of extubation failure. Diaphragmatic or vocal cord paresis/paralysis should specifically be considered in postoperative congenital heart disease patients who fail extubation (see Diaphragmatic Paresis and Vocal Cord Paresis or Paralysis sections of this chapter).

19.6 Low Cardiac Output Syndrome

Low cardiac output syndrome (LCOS), defined as a postoperative decline in cardiac output within the first 24 hours, was described in 1995 by Wernovsky et al. and occurs in up to 25% of neonates undergoing the arterial switch operation, with hemodynamic data indicating low cardiac index (<2.0 L/min per m^2) and high systemic and pulmonary vascular resistances. An oft-cited predisposing factor for LCOS includes the inflammatory effects of CPB (see CPB section and ◘ Fig. 19.2) on ventricular-vascular interactions, which may manifest as significant capillary-leak, systolic and/or diastolic dysfunction, and peripheral vasoplegia or vasoconstriction. Which vascular physiology predominates, however, likely depends on several factors, including patient age (post-CPB vasoplegia syndrome may develop in up to 25% of adult patients) and changes in lesion-specific perioperative pressure and volume loading conditions. As such, while still anticipating patient-specific perioperative risks (e.g., diastolic dysfunction in tetralogy of Fallot [TOF] or pulmonary hypertension status post repair of obstructed total anomalous pulmonary venous return [TAPVR]), a bedside-driven empiric approach using close hemodynamic monitoring and frequent reassessment remains the best way to ensure appropriate management for given changes in physiology. This should involve a systematic assessment of heart rate, rhythm, and stroke volume (preload, afterload, contractility) along with estimates of adequacy of tissue perfusion using NIRS and/or central venous oxygen saturation monitoring.

Included in therapies to maximize oxygen delivery are a variety of vasoactive agents (see ▶ Chap. 20). Their use should be tailored to the child's physiology, while also recognizing their potentially deleterious effects on increasing oxygen demand. Catecholamine-sparing agents, including milrinone, vasopressin, or calcium infusions in neonates, may be preferred as first-line agents under states of high metabolic stress depending on the neonate's clinical manifestations. Changes in cardiopulmonary interactions induced by adjusting mean airway pressure, lung volumes, and gas exchange may also significantly affect loading conditions on the postoperative heart. Reducing oxygen consumption through adequate sedation, treating hyperthermia, and minimizing work of breathing may help restore the balance between oxygen delivery and consumption. The use of stress-dose steroids in severe LCOS, while common (94% use based on a recent survey), continues to lack a strong evidence base, and is in need of further studies. Lastly, early use of extracorporeal life support should be considered in patients not responding favorably to medical management, and multidisciplinary discussions regarding candidacy and cannulation strategy should occur upon PICU admission.

LCOS: A systematic approach to LCOS management includes assessing heart rate, rhythm, and components of stroke volume (i.e., preload, afterload, contractility) to help ensure that appropriate therapies are utilized.

19.7 Pulmonary Arterial Hypertension

Pulmonary vascular pathology seen in patients with congenital heart disease includes both pulmonary arterial hypertension (PAH) (defined by mean pulmonary arterial pressure mPAP ≥25 mm Hg, pulmonary artery wedge pressure (PAWP) < 15 mm Hg, and pulmonary vascular resistance index (PVRI) > 3 Wood units/m^2) and pulmonary venous hypertension. While both can be associated with increased perioperative pulmonary vasoreactivity and over time precipitate fixed pulmonary arterial disease, management strategies sometimes vary markedly between the two pathologies. Perioperative management of PAH will be focused upon here.

Predisposing factors for PAH exacerbations include the already normally increased neonatal pulmonary vasculature tone, genetic predisposition (e.g., trisomy 21), lesions associated with increased pulmonary blood flow or high sustained pulmonary venous pressures (see ▶ Box 19.1), and the effects of cardiopulmonary bypass (CPB). While the exact mechanism of CPB-induced pulmonary vascular reactivity is still not well understood, it may be related to effects on the endothelium, which inhibit nitric oxide production, and the endogenous dysregulation of other vasoactive substances.

Pulmonary Hypertension:

- Hypoxemia with initial maintenance of hemodynamics often occurs during a PHTN exacerbation with an intracardiac shunt, whereas a low output state +/– significant oxygen desaturation often first presents in the absence of an intracardiac shunt.
- Management of PHTN crisis includes two global and interrelated strategies: (1) decreasing pulmonary vascular resistance (e.g., increased FiO_2, respiratory or metabolic alkalosis and/or using a pulmonary vasodilator) and (2) supporting right ventricular function.

Box 19.1 Congenital Heart Disease Categories Associated with Increased Risk of Pulmonary Vascular Disease

(a) Large left-to-right shunts.
- Large VSDs, AVSD, aortopulmonary window.

(b) Pulmonary venous hypertension/obstructive lesions.
- Cardiomyopathies, pulmonary vein stenosis, TAPVR, LV outflow tract obstruction, Shone's complex, isolated mitral valve obstructive disease.

(c) Cyanotic heart disease with increased pulmonary blood flow.
- Transposition of the great arteries (especially with VSD), truncus arteriosus, pulmonary atresia with VSD, univentricular heart (high pulmonary blood flow with or without a restrictive atrial septum).

VSD ventricular septal defect, *AVSD*: atrioventricular septal defect, *TAPVR* total anomalous pulmonary venous return, *LV* left ventricle

19.7.1 Pathophysiology of PAH

Clinical manifestations of pulmonary hypertensive crises result from two interrelated factors: (1) acute increase of the pulmonary vascular resistance and (2) the effect of the increased vascular resistance on ventricular performance and cardiac output. Triggers of increased pulmonary vascular resistance include: hypoxemia, acidemia, hyperthermia, and sympathetic stimulation related to pain/agitation. Hypoxemia in patients without intracardiac shunts, while not occurring in all patients, can be related to small airway obstruction from distended pulmonary arteries and perivascular edema, and may in severe cases lead to significant increases in airflow resistance and decline in lung compliance. Regarding acidemia, there is some evidence to suggest systemic pH may play a bigger role in affecting vascular resistance than pCO2 in the absence of acidemia, although both acidemia and hypercarbia should be avoided. Of note, excessively inflated or under-inflated lungs may exacerbate PVR through effects on the intra- and extra-alveolar vasculature, respectively.

Increased right ventricle (RV) afterload may lead to clinical signs of LCOS secondary to RV ischemia and failure, which reduces preload to the LV and thus low systemic blood flow. Furthermore, increased RV end-diastolic volume and

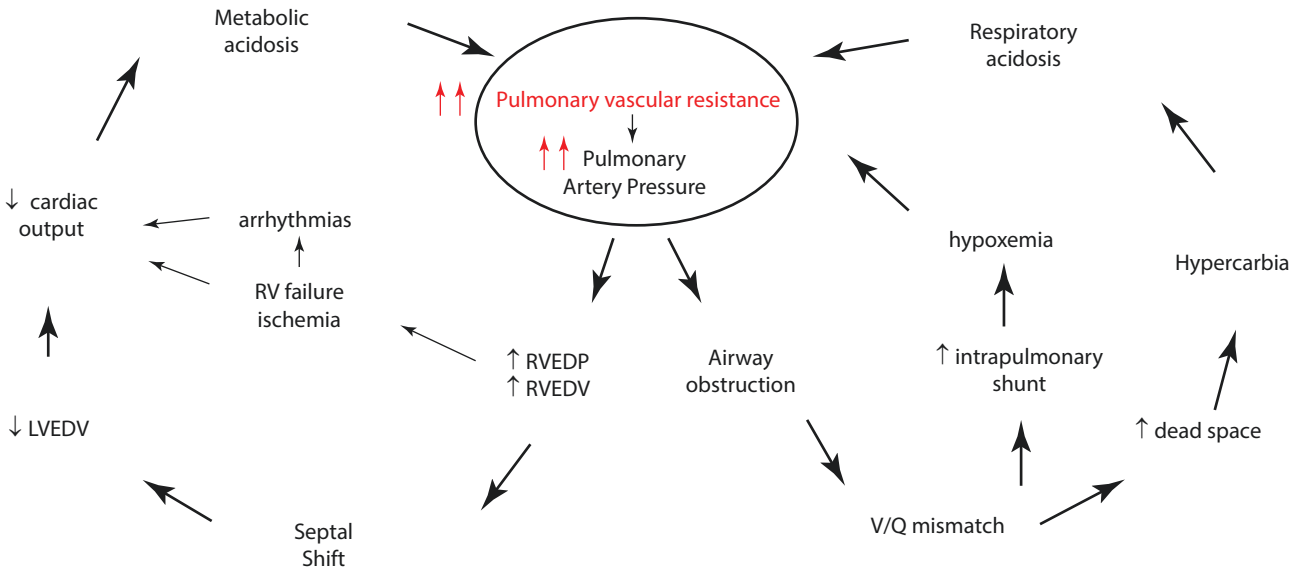

Fig. 19.3 Pathophysiology of PAH. LVEDV: left ventricular end-diastolic volume, RV: right ventricle, RVEDP: right ventricular end-diastolic pressure, RVEDV: right ventricular end-diastolic volume, V/Q: ventilation/perfusion ratio. (Reprinted from Shah and Szmuszkovicz 2017)

pressure shifts the interventricular septum toward the left ventricle (LV), leading functionally to LV diastolic dysfunction and compromised filling, which further reduces systemic output. Low systemic blood flow and pressure combined with increased RV end-diastolic pressure reduces RV coronary perfusion pressure (RV CPP = diastolic aortic root pressure – right ventricle end-diastolic pressure), which leads to RV ischemia and worse function, leading to a rapid downward spiral. This low output state also worsens acidemia that further increases PVR and decreases CPP, leading to a downward spiral (see Fig. 19.3).

19.7.2 Diagnosis

In addition to clinical recognition of LCOS, PAH exacerbation is characterized by high right-sided ventricular diastolic filling pressures documented by increased central venous pressure (CVP), and evidence of elevated right ventricular systolic pressures (>50% systemic) along with interventricular septal flattening and RV dilation on echocardiogram. Continuous direct measurement of pulmonary artery pressure remains the gold standard and should be considered in selected perioperative high-risk patients. Knowledge of the presence of a preexisting shunting or mixing lesion is paramount to interpreting bedside data, as in those patients who may shunt right to left. With PAH in this setting, hypoxemia is a first and early sign with an associated decrease in end-tidal CO_2, and the patient may not have signs of an immediate low output state unless hypoxemia persists. Those without a shunting lesion often present first with signs of a low output state, and although not common, may later develop hypoxemia through the mechanism described above.

19.7.3 Management of PAH

Two interrelated factors must be targeted for effective management of exacerbations: (1) decreasing pulmonary vascular resistance and (2) ensuring adequate RV function. Effective early interventions to decrease pulmonary

vascular resistance include increasing FIO_2 to 1.0, reversing acidemia through increasing minute ventilation and/or administration of sodium bicarbonate or tris-hydroxymethyl aminomethane (THAM), and sedation/muscle relaxation. Safely intubating such patients poses one of the biggest challenges in pediatric critical care and while doing so may allow for optimization of gas exchange and lung volumes; all precautions must be carefully considered including ECMO candidacy and standby. Inhaled nitric oxide (iNO), a fast-acting selective pulmonary vasodilator acting through a cGMP-dependent pathway, is considered first-line pharmacotherapy in perioperative exacerbations, and has the advantage of having minimal direct effect on the systemic vasculature. Often initiated at 20 PPM during a pulmonary hypertensive crisis, weaning iNO is often subsequently performed in a stepwise fashion given the association of rebound PAH with abrupt discontinuation. Nitrogen dioxide and methemoglobin levels should be monitored to avoid potential toxicities.

Sildenafil, a phosphodiesterase type 5 inhibitor, is sometimes used to facilitate weaning of iNO and is also used independently as primary therapy for PAH, although it has been associated with reduced systemic blood pressure and increased intrapulmonary shunting, especially when administered intravenously. Milrinone, also in the phosphodiesterase inhibitor family, acts as a nonspecific systemic and pulmonary vasodilator in addition to having modest inotropic properties and may be helpful during PAH exacerbations while keeping in mind the risk of systemic hypotension. Prostacyclin analogs, another class of agents used during exacerbations, are often used in cases refractory to the above agents and exist in both inhaled (inhaled iloprost and epoprostenol) and systemically administered forms. In choosing management strategies, anatomic causes of pulmonary venous obstruction and patients with left atrial hypertension should be investigated, as pulmonary vasodilation in these patients may exacerbate pulmonary edema by facilitating increased pulmonary blood flow and/or increased pulmonary capillary hydrostatic pressure.

RV failure may persist despite attempts to reduce RV afterload, and vasoactive agents should be strongly considered to support the RV, including inotropic agents to aid RV contractility and systemic vasoconstrictors to augment RV coronary perfusion pressure in the presence of preserved LV systolic function. For the latter, vasopressin is a promising therapy, given its unique action as both a systemic vasoconstrictor and pulmonary vasodilator. Management of RV preload can be difficult and should be based on close observation and reassessment as RV overdistension from fluid boluses can exacerbate RV failure.

19.8 Postoperative Arrhythmias

Preservation of an appropriate heart rate and AV synchrony is paramount to maintaining adequate cardiac output in the immediate postoperative period, as arrhythmias are common during this time. Several factors predispose cardiac surgical patients to develop arrhythmias, including myocardial dysfunction and edema following surgical resection, manipulation of cardiac tissue that may adversely affect the conduction system, electrolyte abnormalities, and finally the presence of a hyperadrenergic state resulting from both intrinsic and extrinsic catecholamine stimulation. Postoperative arrhythmias may cause significant hemodynamic instability and lead to a prolonged demand for mechanical ventilation, increasing need for inotropic support, and increased morbidity and ICU length of stay. Prompt and accurate diagnosis of arrhythmias is crucial for treatment; for example, ventricular tachycardia, which presents as a wide QRS complex tachycardia, can lead to rapid decline in cardiac output and should be quickly differentiated from SVT with aberrant conduction.

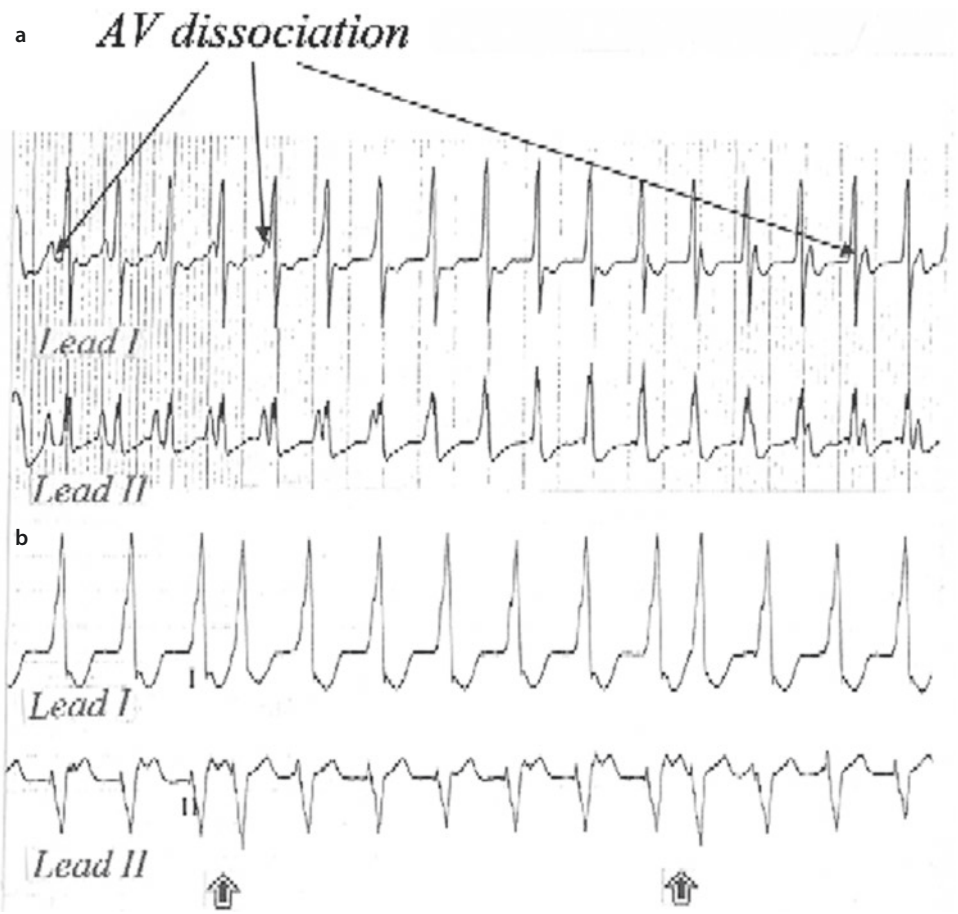
Most often, postoperative arrhythmias are attributed to one of the following mechanisms: enhanced automaticity (junctional ectopic tachycardia [JET], atrial ectopic tachycardia [AET]), reentrant excitation (reentrant SVT), conduction block (varying degrees of AV node block), or failure of impulse formation (bradycardia from sinus node dysfunction).

19.8.1 Sinus Tachycardia

Sinus tachycardia is a commonly encountered arrhythmia in the postoperative period as it is by triggered by fever, pain, agitation, anemia, hypovolemia, or a low cardiac output state. Heart rates that are extremely fast shorten diastolic filling time, which can compromise cardiac output, especially in patients with hypertrophied and non-compliant ventricles. Therefore, it is prudent to determine the underlying etiology to treat this rhythm.

19.8.2 Junctional Ectopic Tachycardia (JET)

JET results from enhanced automaticity within the atrioventricular node (AVN) or His bundle. JET most commonly occurs following VSD, AVSD, or tetralogy of Fallot repair. The rhythm is usually incessant, at a junction rate generally between 110 and 250 beats/min, and presents with AV dissociation or retrograde atrial conduction (◘ Fig. 19.4). A sudden change in heart rate with concurrent changes in the CVP tracing or blood pressure should alert caregiv-



◘ **Fig. 19.4** **a**, **b** Junctional ectopic tachycardia (JET). **a** Rhythm strip demonstrates JET with AV dissociation (*arrows* identify P waves), **b** rhythm strip of JET with intermittent short RR intervals (*double arrows*) due to sinus capture beats. (Reprinted by permission from: Springer, Critical Care of Children with Heart Disease Basic Medical and Surgical Concepts by Lee Beerman, Gaurav Arora, Sang C Par, 2009)

ers at the bedside. The diagnosis is made by examining the 12-lead ECG with a rhythm strip, and in some instances, the use of epicardial pacing wires to obtain an atrial electrogram is necessary to localize the P-waves and define the ventriculo-atrial relationships. Although it is a self-limited phenomenon, cardiac output can be significantly compromised in JET by reducing diastolic filling from the rapid heart rate and by the loss of coordinated atrial systole.

JET:
- Endogenous or exogenous catecholamines, fever and electrolyte disturbances usually exaggerate JET.
- Initial treatment is tailored toward minimizing both intrinsic and extrinsic catecholamines, repleting electrolytes, cooling to 35–36 degrees and atrial pacing at a rate slightly faster than the JET rate to restore AV synchrony and augment cardiac output.

JET is frequently unresponsive to pharmacologic therapy and is usually exacerbated by catecholamines and electrolyte disturbances. Therefore, initial treatment should be tailored toward minimizing both intrinsic and extrinsic catecholamines; this is achieved with aggressively treating fever and pain/agitation, reducing adrenergic drugs, and sometimes deepening sedation and neuromuscular blockade. In addition, repleting electrolytes and cooling to 35–36° centigrade should be implemented. Dexmedetomidine, an α_2-adrenoreceptor agonist, has been successfully used in cardiac intensive care units to treat JET, partly because of its sedative and analgesic effects and direct suppression of central nervous system–mediated adrenergic stimulation. In addition, dexmedetomidine can reduce the JET rate and may facilitate overdrive atrial pacing using a rate slightly faster than the JET rate to restore AV synchrony and augment cardiac output. Other therapies include the administration of either amiodarone or procainamide, both of which have been used successfully to treat JET. Both drugs have negative inotropic effects, so smaller doses and more prolonged administration times may help reduce the risk of sudden hemodynamic compromise.

19.8.3 Atrial Ectopic Tachycardia (AET)

This rhythm is a result of enhanced automaticity within an ectopic focus in the atrium. It presents as a narrow complex tachycardia, with P-wave morphology that is distinct from sinus P-waves and with a different P-wave axis on EKG. The tachycardia pattern typically presents with a gradual warming phase of increasing heart rate and a slow cooling down phase. Persistent AET may lead to arrhythmia-induced cardiomyopathy; therefore, treatment is necessary and should initially focus on correcting electrolyte abnormalities. Specific therapies should follow recommendations from an electrophysiology consultant and usually includes either procainamide or amiodarone. Digoxin may be used transiently to slow ventricular rate if hemodynamics are compromised because of the rapid ventricular rate. Cardioversion and atrial overdrive pacing may only transiently suppress this arrhythmia because the majority of the time this is not a reentrant tachycardia. Cardiac catheterization with ablation is usually used if the arrhythmia is unresponsive to maximal medical therapy.

19.8.4 Reentrant Supraventricular Tachycardia (SVT)

The term "SVT" is an imprecise term and often refers to an atrioventricular reentry tachycardia (AVRT) or AV nodal reentry tachycardia (AVNRT). These two are the primary substrates of reentrant SVT, manifesting as a reciprocating tachycardia with distinct antegrade and retrograde limbs in the reentry circuit. The main features of this arrhythmia are the sudden onset and termination, fixed cycle length, narrow QRS complexes, and either the absence of clear P-waves or the presence of retrograde P-waves. Management of this arrhythmia includes the termination of SVT and prevention of its recurrence. For termination of the tachycardia, vagal maneuvers, intravenous adenosine,

esmolol, or amiodarone can be considered. In the context of unstable hemodynamics, however, synchronized cardioversion should be used. Following the resolution of the SVT, an EKG should be performed to identify if the rhythm is now sinus and to assess if ventricular preexcitation is present, which indicates the presence of an accessory pathway as in WPW syndrome. The second part of management is the prevention of recurrence (e.g., correcting electrolyte abnormalities). If SVT is recurrent, consultation with an electrophysiology specialist and initiation of medical therapy such as beta-blockers or digoxin could be warranted.

19.8.5 Bradyarrhythmias

Bradyarrhythmias in the postoperative period include sinus bradycardia (e.g., sick sinus syndrome) and varying degrees of AV node block (Fig. 19.5). In the infant, cardiac output is heart rate dependent, especially in the postoperative period. Thus, bradyarrhythmias may be associated with low cardiac output states. Postoperatively, a complete atrioventricular block may occur after operations performed near the atrioventricular node as in VSD, AVSD and TOF repair. Bradyarrhythmias respond well to pacing using temporary pacing wires placed at the time of surgery. In isolated sick sinus syndrome, atrial pacing alone is adequate, while the AV node block often requires atrial sensing and ventricular pacing. Daily assessment of atrial and ventricular sensing and pacing thresholds is necessary; thresholds begin to rise with the development of

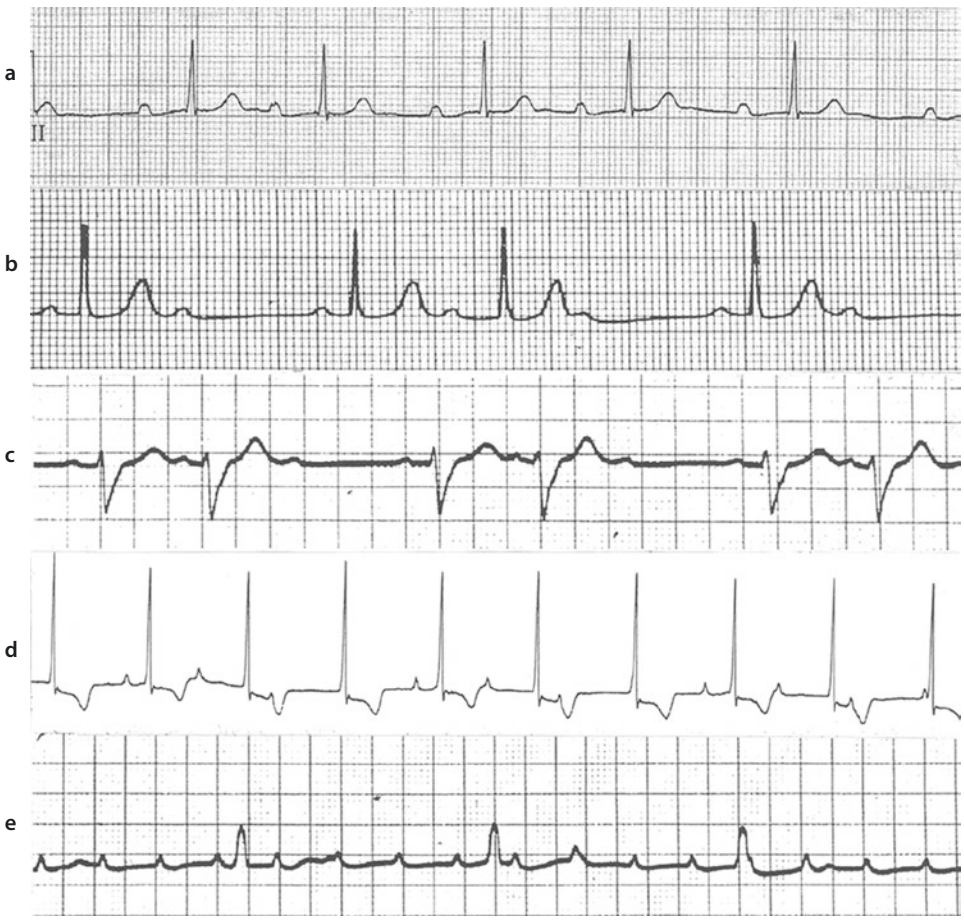


Fig. 19.5 **a**–**e** Types of AV block. **a** First-degree, PR interval is prolonged, but every P wave is conducted, **b** second-degree, Mobitz Type I (Wenckebach) block shows progressive prolongation of PR interval before a blocked P wave, **c** Second-degree, Mobitz Type II block shows no change in PR interval before the blocked P wave. Note wide QRS which is frequently associated with more distal AV block, **d** third-degree or complete AV block characterized by complete dissociation of atrial and ventricular activity. Narrow complex junctional escape rhythm suggests block is above the His bundle, **e** third-degree AV block with slow wide QRS escape rhythm indicates block is below His bundle and is an indication for urgent intervention. (Reprinted by permission from: Springer, Critical Care of Children with Heart Disease Basic Medical and Surgical Concepts by Lee Beerman, Gaurav Arora, Sang C Par, 2009)

fibrosis around the leads. Advanced second- or third-degree atrioventricular block that persists for at least seven days and that is not expected to resolve after cardiac surgery is considered a class I indication for pacemaker implantation.

19.9 Acute Kidney Injury Following Congenital Heart Surgery

Acute kidney injury (AKI) after congenital heart surgery is a significant problem that is associated with worse clinical outcomes. Identification of patients at risk for AKI, preventative measures, and early diagnosis and treatment are essential components of successful management of postoperative AKI. There are three diagnostic criteria used to identify acute kidney injury in children: (1) pediatric RIFLE (Risk, Injury, Failure, Loss, ESRD) developed by the Acute Dialysis Quality Initiative Group, (2) Acute Kidney Injury Network (AKIN) criteria, and (3) the Kidney Disease Improving Global Outcomes (KDIGO) classification system. Depending on the diagnostic criteria used, AKI has been reported in 30–60% of pediatric patients undergoing cardiac surgery. While serum creatinine has been the classical biomarker used in AKI diagnosis and monitoring, new biomarkers are being investigated to improve diagnostic sensitivity and prognostication. Among several other molecules, cystatin C and neutrophil gelatinase-associated lipocalin (NGAL) seem to be the most promising new biomarkers of AKI.

In a study by Aydin et al., 458 pediatric patients (median age of 7.6 months) undergoing cardiac surgery were analyzed. Using RIFLE criteria, AKI was diagnosed in 51% of the entire cohort and in 60.9% of the patients younger than 1 month of age. Of those developing AKI, roughly 6% went on to require renal replacement therapy. Younger age, higher RACHS-1 (risk-adjusted classification for congenital heart surgery) category, and longer CPB time (>55 minutes for the cohort and >90 minutes for patients younger than 1 month of age) were identified as risk factors for developing postoperative AKI. Furthermore, AKI was found to be associated with longer duration of mechanical ventilation and length of PICU and hospital stay.

The pathophysiology of AKI following congenital heart surgery is not entirely understood, but literature supports that AKI is a multifactorial process in cardiac surgery patients. Alterations in renal perfusion, low cardiac output state, ischemic-reperfusion injury, oxidative injury, injury from nephrotoxic agents, hemolysis-induced free hemoglobin, and the inflammatory response induced by CPB are all thought to be contributing factors to AKI pathophysiology. Aminophylline, dexmedetomidine, fenoldopam, steroids, and intravenous acetaminophen have been investigated as potential agents to reduce the risk of AKI in cardiac surgery patients; however, there is no reliable evidence to support the use of those agents in the prevention of AKI following cardiac surgery in children.

Fluid overload in critically ill pediatric patients is associated with increased mortality and morbidity. Early postoperative fluid overload is also independently associated with worse outcomes in pediatric cardiac surgery patients. Therefore, prevention of fluid overload in postoperative cardiac surgery patients has become an important clinical goal. In a 2015 retrospective study by Kwiatkowski et al., early initiation of peritoneal dialysis (PD) in high-risk infants resulted in a higher percentage of negative fluid balance on postoperative days 1 and 2, shorter time to negative fluid balance, earlier extubation, improved inotrope scores, and fewer electrolyte imbalances requiring correc-

tion. A more recent study in 2017 prospectively comparing PD with diuretics in high-risk infants showed that PD was superior to diuretics in achieving negative fluid balance and shorter duration of mechanical ventilation.

PD is relatively easy to initiate and perform and is usually well tolerated (compared to hemodialysis) in hemodynamically unstable children. Similar to any foreign body, the PD catheter can be a source of infection (insertion site infection and peritonitis), and thus, protocols for its maintenance and timely removal should be routinely used.

Continuous renal replacement therapy (CRRT), unlike PD, allows for more rapid correction of serum electrolyte abnormalities and fluid overload. Commercially available circuits with small priming volumes, together with algorithms that allow maintenance of more exact fluid balance, have rendered CRRT feasible in infants after cardiac surgery. CRRT can be used in conjunction with ECMO. Such combined therapy can simultaneously address low cardiac output, severe respiratory failure, and symptomatic AKI, all of which may prove refractory to less-invasive treatments.

Acute Kidney Injury Following Congenital Heart Surgery:

- Younger age, higher RACHS-1 (risk-adjusted classification for congenital heart surgery) category, and longer CPB time are identified as risk factors for developing postoperative AKI.
- Early postoperative fluid overload is also independently associated with worse outcomes in pediatric cardiac surgery patients.

19.10 Immediate Postoperative Encounter

Postoperative care of the cardiac patient starts with the transfer of care from the operating room to the PICU personnel. The pediatric intensive care physician, bedside nurse, respiratory therapist and pediatric cardiologist who will be taking care of the patient should be present at the bedside during transfer of care to ensure that all team members receive consistent information from the operating room team and understand specific goals of care for the patient in the immediate postoperative period.

The cardiovascular surgeon should relate the details of the procedure performed, articulating the pre- and postoperative anatomy, echocardiography findings, and anticipated physiologic outcomes. This should include describing complications, if any, and identifying potential problems that require notification of the surgical team.

The cardiac anesthesiologist is expected to document and communicate the following important patient information as relevant for the case:

- Relevant non-cardiac problems and home medications.
- Baseline preoperative vital signs.
- Issues during the induction of anesthesia.
- Details of airway management.
- The number and location of venous and arterial catheters.
- Pre- and post-CPB inotropic support and trend of hemodynamic parameters.
- Dysrhythmias, presence of pacing wires.
- Duration of CPB, aortic cross-clamp, and circulatory arrest times; the degree of hypothermia achieved.
- The amount of intraoperative fluid and blood products administered.
- Intraoperative urine output amount and diuretics administered.
- Intraoperative ventilation/oxygenation issues, lung compliance, and current mechanical ventilator settings and last blood gas if available.
- Current sedative and analgesic medications as well as the timing of the last dose of neuromuscular blocker agent given.

Initial assessment of the postoperative patient should include heart rate, rhythm, arterial blood pressure, central venous pressure, arterial oxygen saturations, near-infrared spectroscopy (NIRS) values, level of sedation, ausculta-

tion of heart and lungs, quality of proximal and distal pulses, capillary refill time, and respiratory mechanics. Obtaining blood gas analysis (arterial and/or venous), lactate level, electrolyte concentrations including ionized calcium concentration, hemoglobin/hematocrit levels, platelet count, and coagulation tests should be considered in the immediate postoperative period. A chest radiograph should be obtained to evaluate the position of the endotracheal tube, vascular catheters, chest tubes, and lung fields to rule out the presence of pneumothorax, effusion, etc. An ECG should also be performed to document the cardiac rhythm in the immediate postoperative state.

19.11 Postoperative Management of Selected Congenital Heart Defects

All patients after cardiac surgery are at risk of a low cardiac output state, rhythm abnormalities, and post-surgical bleeding; and patients require adequate sedation and postoperative pain control. The following sections focus on selected lesion/surgery-specific pre- and postoperative issues relevant to the immediate postoperative intensive care unit management.

19.11.1 Left-to-Right Shunting Defects

Patent ductus arteriosus (PDA), atrial septal defect (ASD), ventricular septal defect (VSD), and atrioventricular septal defect (AVSD) are the typical heart defects causing left-to-right shunting of blood that results in increased pulmonary blood flow. If these heart defects are left untreated, they can cause pulmonary vascular obstructive disease. As the pulmonary vascular disease worsens over time, pulmonary vascular resistance increases and, if unchecked, may result in right-to-left shunting of blood flow, causing cyanosis that is called Eisenmenger syndrome.

19.11.1.1 Patent Ductus Arteriosus (PDA)

PDA results from a failure to close the vascular structure connecting the descending aorta to the pulmonary artery after birth. It classically results in left-to-right shunting from the aorta to the pulmonary artery, as the direction of blood flow depends on the relative resistances of pulmonary and systemic arterial vasculature. In premature infants, pharmacotherapy with ibuprofen or indomethacin can be attempted to induce PDA closure. If unsuccessful and clinically indicated, however, surgical ligation and division via thoracotomy may be performed. Postoperatively, such patients are at risk of recurrent laryngeal nerve injury and thoracic duct injury; therefore, these patients should be monitored for vocal cord paresis/paralysis and chylothorax in the postoperative period. Transcatheter closure techniques are an alternative to surgical closure in selected patients.

19.11.1.2 Atrial Septal Defect (ASD)

ASD is a defect in the interatrial septum. ASDs are classified into different categories: (1) primum ASD (associated with atrioventricular valvular abnormalities), (2) secundum ASD (most common type of ASD), (3) sinus venosus defect (associated with abnormal pulmonary vein connections), and (4) coro-

nary sinus defect (unroofing of the tissue separating the coronary sinus from left atrium). The magnitude and direction of the shunted blood flow at the atrial level depend both on the size of the defect and left and right atrial pressures, which reflect the relative diastolic compliances of the left and right ventricles. A systemic to pulmonary blood flow ratio greater than 1.5 is considered hemodynamically significant, leading over time to progressive volume loading of the right ventricle and may, if unaddressed, result in changes in the myocardium and pulmonary vasculature leading to pulmonary arterial hypertension in adulthood. Volume overload–induced right atrial enlargement may also result in atrial arrhythmias (e.g., atrial flutter or atrial fibrillation).

Hemodynamically significant ASDs require closure. Primum ASD, sinus venosus defects and coronary sinus defects are surgically closed. There are two options for closure of secundum ASDs: (1) percutaneously placed occluding devices and (2) surgical repair. Large secundum ASDs without adequate tissue margins to anchor occluding devices are considered poor candidates for device closure. Device embolization, pericardial tamponade, erosion through the atrial wall, atrial arrhythmias, and transient heart block are some of the postprocedural complications of this approach. Surgical closure is performed by either direct suture repair or patch closure. Short- and long-term outcomes of surgical closure are excellent. Almost all the patients are extubated in the operating room with minimal or no inotropic support. Postoperative patients should be monitored for dysrhythmias – specifically atrial arrhythmias – and pericardial effusion. Postpericardiotomy syndrome can complicate the postoperative course of any child undergoing open heart surgery. It presents with chest pain, fever, cough, fatigue, and emesis about a week or later after cardiac surgery; and it may, in rare cases, progress into cardiac tamponade that may require pericardiocentesis.

Atrial Septal Defect: Postpericardiotomy syndrome presents with chest pain, fever, cough, fatigue and emesis. It occurs about a week or later after cardiac surgery.

19.11.1.3 Ventricular Septal Defect (VSD)

VSD is a defect in the interventricular septum causing communication between the two ventricles. VSDs are one of the most common congenital heart defects (CHD) and can be found in isolation or as part of more complex CHDs. VSDs are classified as (1) muscular, (2) perimembranous, (3) subarterial, and (4) inlet-type defects. The amount of shunted blood through the VSD depends on the size of the defect and the relative resistances of the pulmonary and systemic vasculature. Left-to-right shunted blood flow through the VSD causes increased blood flow through the pulmonary vascular bed and results in increased pulmonary venous return, leading to increased volume load of the left heart. If the VSD is small and has an intrinsic flow limitation, then these are called restrictive VSDs.

VSDs are closed surgically using CPB. Access to the defect is usually achieved through either the atrioventricular or semilunar valves to avoid the need to perform a ventriculotomy. Selected VSDs can be closed by transcatheter methods, but it is not a routine practice due to high risk of heart block. Older patients without signs of heart failure preoperatively are typically extubated in the operating room. Others may benefit from staying intubated for the first postoperative night while hemodynamics stabilize. Patients may require inotropic support for a short period of time. Patients with longstanding excessive pulmonary blood flow in the preoperative period are at risk of postoperative pulmonary hypertensive crisis. Complete heart block is a known complication of VSD closure. If the complete heart block does not recover in 7–10 days following surgery, those patients require permanent pacemaker placement.

19.11.1.4 Atrioventricular Septal Defect (AVSD)

AVSD consists of atrioventricular valvar (AV valve) abnormalities along with interatrial and interventricular septum defects. AVSD is also referred to as atrioventricular canal defect. AVSD is especially known to be associated with trisomy 21. If the defect only involves the interatrial septum, then it is called a partial AVSD or primum ASD. When both interatrial and interventricular septums have defects, then it is known as a complete AVSD. Left-to-right shunt occurs via the atrial and ventricular septal defect(s) with high shunt flow likely from flow from the high-pressure LV to the atria through incompetence of the common AV valve. AVSD is treated surgically by patch repair of the atrial and ventricular septum and suture repair of AV valves. The surgical goal is to establish an intact atrial and ventricular septum and competent AV valves. Similar to other left–to-right shunting lesions, excessive pulmonary blood flow in the preoperative period puts patients at higher risk of pulmonary hypertensive crisis during the postoperative period. AVSD patients also have a higher risk of acquiring heart block following surgical repair.

19.11.2 Left-Sided Obstructive Lesions

This section focuses on critical aortic stenosis (AS), coarctation of the aorta (CoA), and interrupted aortic arch (IAA). Hypoplastic left heart syndrome (HLHS) is discussed separately in detail in another section of this chapter. Maintenance of systemic blood flow requires a PDA in these lesions. Therefore, these patients typically present with cardiogenic shock in the postnatal period as the PDA closes. Usually, these patients require prostaglandin E_1 infusion to keep the ductus open in the preoperative period.

19.11.2.1 Critical Aortic Stenosis (AS)

Congenital AS includes aortic annular hypoplasia and various forms of bicuspid or unicuspid aortic valves. If systemic blood flow depends on a PDA, this is usually referred to as critical AS, and these neonates/infants often present in shock at birth and often can have associated small left-sided structures. Critical AS can be addressed by transcatheter balloon valvuloplasty or surgical valvotomy; the latter is performed under CPB with aortic cross-clamping. Aortic valve regurgitation can be seen after transcatheter balloon valvuloplasty and surgical valvotomy. Neonatal Ross-Konno operation is performed in selected cases with a very small aortic annulus. In the setting of fixed postoperative residual aortic obstruction that limits the cardiac output, systemic afterload reduction is used cautiously due to a risk of decreased coronary artery perfusion pressure and flow postoperatively. The risk of postoperative pulmonary hypertension should be remembered if there is a history of preoperative left atrial hypertension.

19.11.2.2 Coarctation of Aorta (CoA)

There are a few different surgical techniques for CoA repair (i.e., end-to-end aortic anastomosis, patch augmentation, subclavian flap aortoplasty, and extended resection with primary anastomosis). If no other intracardiac lesions need to be surgically addressed and the transverse arch is of adequate size, CoA repair is typically performed through a lateral thoracotomy. During the repair, the PDA is also ligated and divided. Postoperative management is usually uncomplicated, but a lateral thoracotomy incision is considered more painful compared with sternotomy so that special attention to postoperative

pain management is indicated. Pre- and post-ductal invasive or non-invasive BP measurements, along with echocardiography, can be used to assess the degree of postoperative residual CoA. Recurrent laryngeal nerve injury, thoracic duct damage, and spinal cord ischemia due to aortic cross-clamping are potential complications and respectively may lead to postoperative vocal cord dysfunction, chylothorax, and neurological deficits in the lower extremities. Postoperative paradoxical hypertension is a known phenomenon after CoA repair and can be managed by nitroprusside and/or esmolol infusions. Postcoarctectomy syndrome is defined by systemic hypertension, abdominal distention/tenderness, feeding intolerance, and gastrointestinal bleeding, which requires bowel rest and aggressive management of systemic hypertension.

Coarctation of Aorta: Postcoarctectomy syndrome is defined by systemic hypertension, abdominal distention/tenderness, feeding intolerance and gastrointestinal bleeding, which requires bowel rest and aggressive management of systemic hypertension.

19.11.2.3 Interrupted Aortic Arch (IAA)

IAA repair is performed through a median sternotomy with VSD closure if present. IAA, especially type B, is associated with DiGeorge syndrome (22q11.2 deletion), and those patients should be monitored for hypocalcemia during the postoperative period. Similar to postoperative CoA repair, IAA repair patients have extensive suture lines in the aorta, which increases the risk of postoperative aortic bleeding if hypertension is not aggressively managed.

19.11.3 Ductal-Independent Mixing Lesions

19.11.3.1 Transposition of the Great Arteries and the Arterial Switch Operation (D-TGA, ASO)

Transposition of the great arteries with concordant atrioventricular and discordant ventriculoarterial connections (D-TGA) and no significant outflow tract obstruction is very commonly fully repaired with the arterial switch operation (ASO). Two keys to anticipating postoperative problems include (1) the recognition of possible LV deconditioning due to prolonged preoperative exposure of the LV to the lower resistance pulmonary circulation and (2) the risk of coronary ischemia resulting from intraoperative coronary artery manipulation and relocation via coronary buttons into the neoaorta.

Postoperatively these neonates generally do well and can be safely extubated within the first 12–24 hours, but they may present in the first 4–12 hours with LCOS, partly related to the effects of CPB and long perioperative ischemic times on the fragile neonatal heart. If LCOS occurs, the following must *always* be considered as well: (1) mechanical compromise of coronary blood flow and (2) "deconditioning" of the left ventricle. Mechanical compromise of coronary blood flow should be considered when LCOS does not respond to standard management. Any hemodynamically significant arrhythmia or ECG findings suggesting myocardial ischemia in a coronary distribution may exist as well. There should be a low threshold for repeat echocardiographic or cath imaging to assess for regional wall motion abnormalities and compromised coronary blood flow. Regarding the "deconditioning" of the LV following ASO, which is primarily observed in repairs done at an older age, the LV is exposed to the higher systemic vascular resistance and may need some time to adapt. Inotropic infusions and afterload reduction, such as low-dose epinephrine and milrinone, may be needed to support the ventricle in the immediate postoperative period. Hypertension should be avoided since it increases afterload on the potentially dysfunctional LV and puts stress on the fresh postoperative aortic suture lines, which increases the risk of bleeding.

19.11.3.2 Total Anomalous Pulmonary Venous Return (TAPVR)

In managing patients with TAPVR, the most critical postoperative management question is the presence and extent of preoperative obstruction of pulmonary venous flow. Patients with TAPVR and obstruction often enter the operating room with significant pulmonary venous hypertension, leading to acute pulmonary edema with poor lung compliance, along with significant concern of reactive pulmonary vasculature. Postoperative management can be challenging, and paroxysmal PAH crises should be anticipated and managed accordingly (see pulmonary hypertension section). The value of inhaled nitric oxide (iNO) has been clearly demonstrated in these patients. However, if persistent, or if clinical deterioration occurs during iNO initiation, the possibility of residual pulmonary venous obstruction should be actively investigated.

19.11.3.3 Truncus Arteriosus

Truncus arteriosus (TA), representing a single arterial trunk and semilunar valve from which pulmonary, systemic, and coronary circulations arise, is now very commonly repaired in the neonatal period. Although the neonatal myocardium adapts less well postoperatively to perioperative stressors, significant congestive heart failure and coronary malperfusion often arise from neonatal pulmonary circulation runoff and truncal valve insufficiency. Furthermore, if not corrected early, this lesion can result in irreversible pulmonary vascular disease. The surgery, essentially involving patch closure of the VSD and separation of the pulmonary circulation with placement of an RV-PA conduit, requires a right ventriculotomy and may necessitate truncal valve repair as well.

Postoperatively, other than LCOS from exposure of the neonatal myocardium to surgery, the following additional problems should be anticipated: pulmonary vasoreactivity, isolated RV dysfunction, and postoperative arrhythmias. Given often torrential pulmonary blood flow preoperatively in addition to the effects of CPB on the pulmonary vasculature, a high concern of pulmonary hypertension should exist, with close monitoring and early if not prophylactic initiation of iNO (see pulmonary hypertension section). Independent of this, the right ventricle in this lesion is often hypertrophied with evidence of diastolic dysfunction and, having undergone ventriculotomy, may exhibit signs of postoperative failure. Higher filling pressures may be needed to maintain adequate cardiac output. Lastly, postoperative arrhythmias associated with surgical repair to the interventricular septum may include junctional arrhythmias and heart block. Not infrequently, delayed sternal closure is employed in these patients to allow tissue edema to subside, given the above-stated concerns.

19.11.4 Lesions with Ductal-Dependent Pulmonary Blood Flow

19.11.4.1 Tetralogy of Fallot (TOF)

TOF is a complex disease with many variations (e.g., absent pulmonary valve, pulmonary atresia, major aortopulmonary collateral arteries). This section focuses upon the "classic" tetralogy of Fallot: A constellation of problems caused by anterior malalignment of the conal septum results in an unrestrictive anterior VSD with overriding aorta, multilevel obstruction to the right ventricular outflow tract (RVOT), and right ventricular hypertrophy. Although palliative shunts and RVOT stents are sometimes still performed as a bridge to full repair, almost all patients undergo full repair in early infancy and even

neonatally as the primary intervention, which includes VSD closure and various methods to relieve RVOT obstruction.

Postoperatively, these patients generally have an uncomplicated course, and early extubation (6–24 hours) is safe and effective in improving hemodynamics in patients with a favorable trajectory. However, when specific concerns of LCOS exist in the immediate postoperative phase, the following should be considered: (1) postoperative arrhythmias and (2) restrictive RV physiology. Postoperative irritation of the area surrounding the AV node can cause a range of arrhythmias from junctional ectopy to high-grade heart block; recent reports suggest a postoperative incidence of JET as high as 30%. Postoperative arrhythmias often resolve within the first 24–72 hours but can lead to significant hemodynamic compromise. See the arrhythmia section for more details on diagnosis and management. "Restrictive RV physiology," defined in prior studies as diastolic antegrade flow of blood across the pulmonary valve, which reflects a stiff RV with diastolic dysfunction in the context of usually preserved biventricular function, may be encountered in the immediate postoperative phase. This physiology may need higher right-sided filling pressures to maintain preload for adequate cardiac output, although side effects of sustained higher central venous pressures may include pleural effusions and ascites. Small fluid challenges, even in the context of a "normal" CVP, may be indicated with close assessment of response in indices or clinical signs of cardiac output. Milrinone may be of some benefit given its lusitropic effect. Positive pressure ventilation may impede venous return to an already preload sensitive right ventricle and increase the afterload against which it must pump; hence considering early extubation is very reasonable.

19.11.5 Single Ventricle Lesions

Atresia of an atrioventricular and/or semilunar valve results in single ventricle physiology, where complete mixing of systemic and pulmonary venous return typically occurs at the atrial and/or ventricular levels, leading to equal oxygen saturations in the pulmonary artery and the aorta. Ventricular output is divided between the competing pulmonary and systemic circulations; the amount of blood flowing to either the pulmonary circulation (Qp) or systemic circulation (Qs) is determined by the respective vascular resistances in these parallel circuits. A variety of congenital heart diseases fall into this physiology.

In general, these neonates are divided into two main categories: those with pulmonary blood flow obstruction with a single left ventricle (e.g., tricuspid atresia, double inlet left ventricle, pulmonary atresia with intact ventricular septum) and those with systemic blood flow obstruction with a single right ventricle (e.g., hypoplastic left heart syndrome (◘ Fig. 19.6) with variations of mitral valve and aortic valve atresia or severe stenosis). Other cardiac lesions with two ventricles may also present with single ventricle physiology (e.g., TOF with pulmonary atresia and truncus arteriosus). The cornerstone of preoperative management of these neonates involves balancing blood flow into the parallel circulations, providing adequate oxygen delivery without excessive volume load on the single ventricle, minimizing acidosis, and ensuring optimal end-organ perfusion.

Prostaglandin E_1 at a low dose (0.01 mcg/kg/min) is usually initiated immediately after birth to maintain ductal patency, and to avoid other dose-dependent side effects (i.e., apnea, fever, increased secretions, and capillary leak). Echocardiography is performed in the first few hours after birth to confirm the diagnosis.

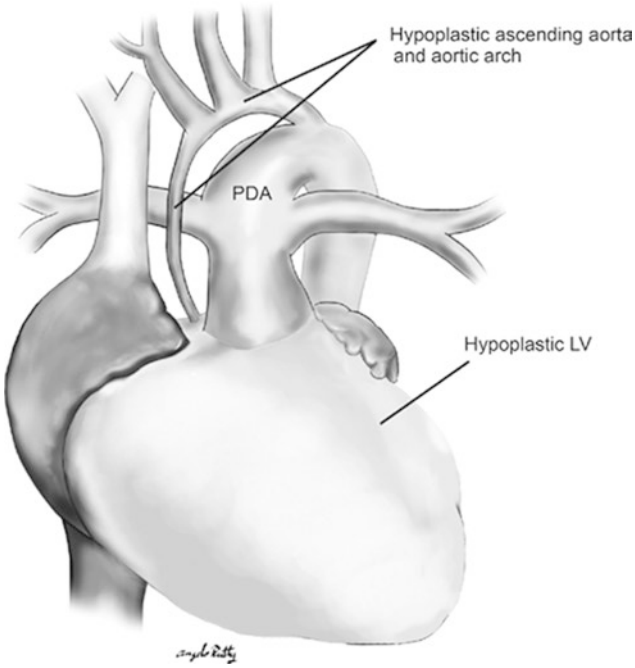

Fig. 19.6 Hypoplastic left heart syndrome. (Reprinted by permission from: Springer, Critical Care of Children with Heart Disease Basic Medical and Surgical Concepts by Yuliya A. Domnina, Ricardo Muñoz, Traci M. Kazmerski et al., 2009)

Based on the Fick principle: Qp:Qs = (SaO_2–SvO_2) / ($SpvO_2$–$SpaO_2$).

SaO_2: Arterial oxygen saturation, SvO_2: Venous oxygen saturation. $SpvO_2$: Pulmonary vein oxygen saturation, $SpaO_2$: Pulmonary artery oxygen saturation.

The ultimate goal is to have adequate systemic cardiac output with a Qp:Qs of ~1:1, manifesting as an arterial oxygen saturation of 75–80% and a systemic venous oxygen saturation of ~60%, assuming pulmonary venous saturation of 95%. This would result in mild ventricular volume load, and adequate systemic blood flow and systemic oxygen delivery. Do not rely on arterial oxygen saturation alone to estimate Qp:Qs as this could be deceptive. Indeed, an increasing oxygen saturation implies excessive pulmonary blood flow and potentially inadequate systemic flow.

Optimal clinical management relies upon understanding the role of pulmonary and systemic vascular resistance in determining systemic blood flow and in recognizing signs of inadequate systemic oxygen delivery. Clinical examination to assess peripheral perfusion, close monitoring of urine output, laboratory data including blood gas pH, lactate, mixed venous oxygen saturation levels, and other biomarkers of end-organ injury should be monitored closely. Measurements of regional venous-weighted oxygen saturations in both cerebral and somatic or renal regions using NIRS have become a standard of care in pediatric cardiac intensive care, as previously discussed.

A decrease in pulmonary vascular resistance occurs in almost all neonates after birth, and as this evolves over the first several days of life in an infant with single ventricle physiology, Qp:Qs increases, manifesting with higher arterial oxygen saturation, tachypnea, and respiratory distress. Often, the systemic output is still preserved, and if symptoms of congestive heart failure become apparent, cautious use of diuretics may be helpful.

If systemic perfusion becomes compromised, controlled mechanical ventilation, sedation, and paralysis may become necessary to improve the Qp:Qs ratio and minimize oxygen consumption. PVR may be increased by adopting a strategy to minimize the FiO_2, as necessary, to limit the vasodilatory effects of oxygen, permit a slight respiratory acidosis if on mechanical ventilation and/or supplement inspired carbon dioxide into the ventilator circuit. Maintaining a

hematocrit at ≥40% improves oxygen-carrying capacity and increases viscosity, which may increase PVR. In neonates with severe hypoxemia, ductal patency and the presence of an adequately sized atrial shunt should be confirmed; if an intact or restrictive atrial septum is present, transcatheter intervention with balloon or blade-mediated enlargement of the atrial septum should be considered.

The goal of staged surgical palliation for patients with single ventricle anatomy is to separate the systemic and pulmonary circuits, diverting systemic venous return directly to the pulmonary vascular bed, resulting in normal oxygen saturation and reducing the volume load on the single ventricle. This results in passive blood flow into the pulmonary vascular bed, which is improved with spontaneous breathing and may be impaired with positive pressure ventilation. The current sequence of single ventricle palliation in HLHS includes stage 1 reconstruction in the neonatal period, stage 2 bidirectional Glenn shunt between 4 and 6 months of age, and stage 3 modified Fontan between 2 and 3 years of age.

Single Ventricle Physiology:

Single ventricular output is divided between the pulmonary and systemic circulations. The common ventricle leads to equal oxygen saturations in the pulmonary artery and the aorta. The amount of blood flowing to either the pulmonary circulation (Qp) or systemic circulation (Qs) is determined by the resistance to flow into these parallel circuits.

19.11.5.1 Stage 1: Norwood Procedure

The goals of stage 1 palliation involve: (1) ensuring complete mixing of both pulmonary and systemic venous return at the atrial level, (2) securing unobstructed systemic blood flow from the right single ventricle, and (3) providing an adequate but controlled source of pulmonary blood flow. To achieve these goals, the classic Norwood procedure entails, respectively: (1) atrial septum resection, (2) aortic arch reconstruction (transection of the main PA, constructing a neoaorta using the main PA to augment the aortic arch and resected area of coarctation), and (3) insertion of modified Blalock-Taussig (mBT) shunt, which directs blood from the innominate artery to the pulmonary arteries via a polytetrafluoroethylene tube (◘ Fig. 19.7a), the size and length of which control the amount of pulmonary blood flow.

PVR is low compared to systemic vascular resistance; thus there is continuous forward flow into the mBT shunt throughout both systole and diastole. This results in lower systemic diastolic blood pressure and may lead to coronary hypoperfusion, which is referred to as "coronary steal." Hence, modification of the classic Norwood procedure, using a right ventricle → pulmonary artery conduit, was proposed by Sano and colleagues (◘ Fig. 19.7b). Advantages of RV-PA shunt modification include the elimination of diastolic runoff and "coronary steal," and fewer patients needing cardiopulmonary resuscitation during the Norwood hospitalization. These advantages must be weighed against the adverse effects from performing a ventriculotomy on the right (systemic) ventricle. In a large randomized controlled study (Single ventricle reconstruction trial) comparing the mBT shunt to the RV-PA conduit, there was a significantly higher risk of mortality in the mBT shunt group at the 12-month endpoint, but at longer follow-up this was no longer significant. In addition, in the RV-PA conduit group, stenosis at the distal anastomosis site was common and required multiple catheter interventions.

Postoperative management of patients after the Norwood procedure can be very challenging. Restoration of hemostasis early in the immediate postoperative period is essential, as bleeding is common given the substantial suture lines placed in the creation of the neoaorta. Attention is focused on balancing systemic and pulmonary blood flow and sustaining adequate perfusion to various organ systems. Measuring systemic venous oxygen saturation and/or NIRS (near infrared spectroscopy) is essential in the immediate postoperative period. Targeting a goal arterial oxygen saturation of 75–80% and maintaining arteriovenous oxygen saturation difference of 20–25% are important. Preferentially

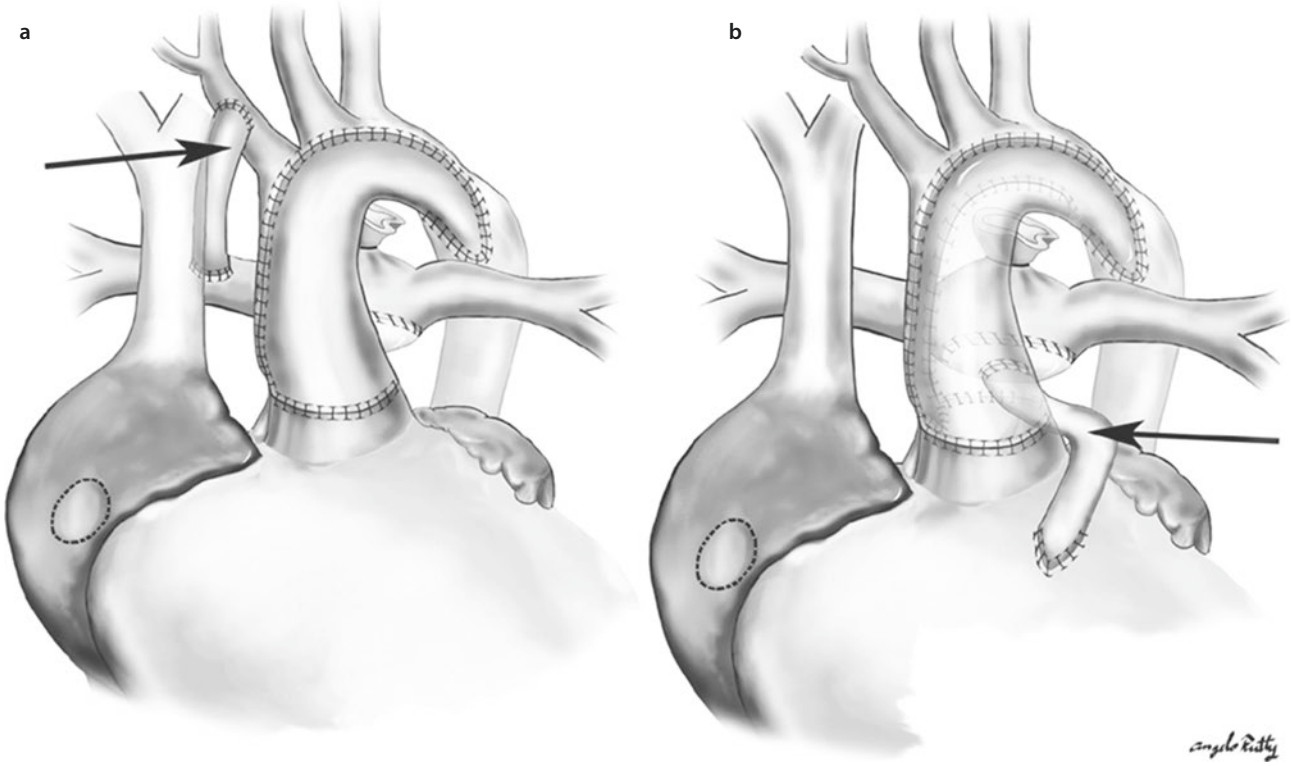

Fig. 19.7 **a** Right modified BT shunt; **b** Sano shunt. (Reprinted by permission from: Springer, Critical Care of Children with Heart Disease Basic Medical and Surgical Concepts by Yuliya A. Domnina, Ricardo Muñoz, Traci M. Kazmerski et al., 2009)

lowering systemic vascular resistance to divert blood flow from the lungs into the systemic circuit using systemic vasodilators can be effective. Conservation of systemic oxygen delivery is reliant on optimizing cardiac output and arterial oxygen content. Optimizing cardiac output requires attention to myocardial contractility, intravascular volume status (preload), systemic vascular resistance (afterload), heart rate, and rhythm. Therefore, inotropic agents, fluid boluses, vasodilators and/or vasoactive medications, and pacing could be necessary, especially in the immediate postoperative period. Arterial oxygen content depends on the hemoglobin concentration and arterial oxygen saturation. Therefore, maintaining adequate oxygen-carrying capacity is crucial. If shock develops, use strategies to minimize metabolic demand and allow for better matching of oxygen consumption to oxygen delivery. Sedative-analgesic medications and temperature regulation could be necessary to reduce metabolic demand. Use a ventilator management strategy that prevents atelectasis and avoids excessive work of breathing and hypocarbia; the latter lowers PVR and therefore can worsen systemic blood flow. Delayed sternal closure is a common strategy to reduce the risk of tamponade physiology in the immediate postoperative period. Outcomes after Norwood have improved significantly over the last two decades, likely due to broad improvements in perioperative care arising from a better understanding of single ventricle physiology and greater reliance on various monitoring devices.

19.11.5.2 Stage II Palliation: Bidirectional Glenn Shunt (BDG)

Bidirectional Glenn shunt procedure is the first step in separating the pulmonary and systemic circuits and entails conversion of pulmonary blood flow from a high pressure system (RV or aorta) to a low pressure venous source through anastomosis of the superior vena cava to the pulmonary arteries. The

Table 19.1 Causes of hypoxemia after superior cavopulmonary anastomosis

Pulmonary venous oxygen desaturation	Pleural effusion, chylothorax, pulmonary edema, atelectasis, pneumonia, or arteriovenous malformation
Systemic venous oxygen desaturation	Anemia, low cardiac output state, ventricular dysfunction, atrioventricular valve regurgitation, or veno-venous collateral
Decreased pulmonary blood flow	Increased pulmonary vascular resistance, pulmonary venous hypertension or obstruction of the pulmonary artery, or SVC-pulmonary artery anastomosis

preexisting mBT shunt or RV-PA conduit is removed during this stage. Advantages of BDG shunt include volume unloading of the single ventricle, thereby preserving its function and minimizing the risk of AV valve regurgitation, in addition to promoting more effective circulation by decreasing intercirculatory mixing while maintaining a Qp:Qs of typically 0.6–0.7.

The immediate postoperative management for the BDG emphasizes the maintenance of preload and early extubation to sustain normal cardiac output. If the patient remains intubated, then achieving normocapnia or mild hypercarbia may improve SVC → PA blood flow and improve oxygen saturation. Elevation of PVR after CPB may be minimized by using pulmonary vasodilators. In order to maintain adequate oxygen-carrying capacity anemia should be corrected in this admixture lesion.

Persistent hypoxemia after BDG could be due to any of the following (also see Table 19.1):

1. Systemic venous oxygen desaturation (anemia and/or low cardiac output, or the presence of a decompressing vein (i.e., veno-venous collateral from superior cavopulmonary circuit to the systemic ventricle)).
2. Pulmonary venous oxygen desaturations (e.g., from pleural effusions, atelectasis, pneumonia, pneumothorax, or pulmonary arteriovenous malformations).
3. Low pulmonary blood flow due to increased PVR, pulmonary venous hypertension or obstruction of the pulmonary artery, or SVC-pulmonary artery anastomosis.

Other common postoperative problems include pleural effusion, which is usually managed with diuretics and fluid restriction. High systemic venous pressures or perioperative lymphatic injury may precipitate chylous effusions as well (see chylothorax section). Systemic hypertension is also a very common phenomenon after stage 2, and may be related to pain and probably headache from the sudden rise in SVC pressure immediately following surgery. This is usually a transient phenomenon and often resolves in the first 24–72 hours after surgery. If SVC syndrome develops, further workup should be done to rule out thrombosis in the BDG shunt.

19.11.5.3 Stage 3: Fontan Operation

Francois Fontan was the first surgeon to separate the pulmonary and systemic circulation into a series circuit in the single ventricle patient. While the initial surgery was performed in a patient with tricuspid atresia, the concept is now applied to all patients with single ventricle anatomy.

The criteria for candidacy of Fontan completion include normal ventricular function, low pulmonary vascular resistance, absence of AV valve regurgitation, and the absence of pulmonary artery distortion. In this final palliative reconstructive surgery, blood flow from the IVC is routed to the pulmonary

artery using an extracardiac PTFE conduit of 18–22 mm diameter or through a lateral tunnel that is created within the right atrium. Some surgeons may create a small fenestration between the systemic venous pathway and the atrium, reducing pressure within the central venous system and pulmonary circuit and minimizing the risk of immediate postoperative low cardiac output, pleural effusions, and ascites at the expense of arterial desaturation and the risk of systemic embolization.

Postoperatively, patients ideally will have a Fontan pressure of 10–15 mmHg and a left atrial pressure of 5–8 mmHg with a transpulmonary gradient of 5–10 mmHg. Often, such patients are sensitive to changes in intravascular volume, given that the extrathoracic systemic venous pressure must be adequate to maintain blood flow across the pulmonary circuit. Treat hypovolemia if it occurs and maintain intravascular volume. Typically, these patients are extubated immediately after the procedure, as venous return to the heart and thus pulmonary blood flow occur mainly during inspiration in spontaneously breathing patients and positive pressure ventilation raises intrathoracic pressure and limits systemic venous return and pulmonary blood flow. If the patient returns from the OR intubated, extubation should be considered once hemodynamic stability with no active bleeding and adequate gas exchange have been achieved on modest support.

To differentiate the causes of low cardiac output after the Fontan procedure, using fontan pressure and LA pressure monitoring in conjunction can be helpful (see ◘ Table 19.2). If both pressures are low, this may be due to intravascular volume depletion. If the Fontan pressure is elevated and LA pressure is low, the differential diagnosis includes an increase in PVR, Fontan baffle obstruction, or pulmonary artery stenosis. Both elevated Fontan and LA pressures could be related to the following: ventricular dysfunction, AV valve regurgitation or stenosis, cardiac tamponade, or arrhythmias. Evaluation of persistent hypoxemia after Fontan completion with fenestration is similar to the prior discussion regarding BDG shunt; if a fenestration is present, the amount of blood shunting through the fenestration affects the arterial oxygen saturation.

Arrhythmias are not uncommon in the immediate postoperative period, and if associated with the loss of AV synchrony, these tend to be poorly tolerated. Prompt diagnosis and therapy are warranted. Other post-Fontan complications include pleural effusion, protein-losing enteropathy, hepatic fibrosis, and finally plastic bronchitis, which is rare but could be potentially fatal.

◘ **Table 19.2** Causes of low cardiac output state after Fontan operation

Fontan pressure low and LA pressure low	Fontan pressure high and LA pressure low	Fontan pressure high and LA pressure high
Hypovolemia	High pulmonary vascular resistance	Ventricular dysfunction
	Baffle obstruction or thrombosis	Atrioventricular valve stenosis or regurgitation
	Pulmonary artery stenosis	Arrhythmia, cardiac tamponade

LA left atrium

19.12 Postoperative Heart Transplantation Patient

Heart transplantation, now the standard of care in pediatric end-stage heart failure, requires both early recognition of potential candidacy and knowledge of perioperative complications by the pediatric cardiac intensivist. In the first 30 days postoperatively, primary graft failure, defined as compromised ventricular function requiring significant vasoactive and/or mechanical support in the absence of hyperacute rejection, remains the leading cause of mortality. Recipient preoperative risk factors that anticipate postoperative difficulties include liver/kidney dysfunction, ventilator dependence, diagnosis of congenital heart disease (vs. an acquired lesion), multiple reoperations, allosensitization, and pulmonary vascular disease. An indexed PVRi >6 Woods units/m^2 that is not responsive to vasodilator therapy is a common contraindication for transplantation; however, some newer data suggest no strong correlation between PVRi and postoperative mortality.

Postoperatively, in addition to standard medical approaches, early temporary use of mechanical circulatory support has been successful, although initiation of support in the context of a severe low cardiac output state has been associated with poor outcome. Special considerations should be made to support the right ventricle in the context of preoperative pulmonary vascular disease. Inhaled nitric oxide is commonly used in this circumstance, in addition to inodilators such as milrinone and low-dose epinephrine to support ventricular function. The loss of cardiac innervation should also be recognized as a unique postoperative issue, as normal stress-response induced chronotropy and inotropy can be blunted and inconsistent. Commonly used strategies to address this include the use of temporary pacing wires or pharmacological agents such as the nonspecific beta-adrenergic agonist isoproterenol. Any concerns about postoperative low cardiac output within the first 30 days should also lead to consideration of acute rejection as well as sepsis, given the high-dose immunosuppression administered in the immediate postoperative phase. Ultimately, a multidisciplinary approach to postoperative management is critical to ensure optimal outcomes.

19.13 Other Postoperative Issues

19.13.1 Nutrition

Infants with complex congenital heart disease are known to exhibit impaired weight gain during the first several months of life, and the ICU and postoperative course can significantly negatively impact growth. Within the ICU, lower caloric intake has been associated with longer need for mechanical ventilation and longer length of stay. Existing evidence suggests that 93% of postoperative children do not reach 90% of basic metabolic requirements by postoperative day 4, and that a 1 standard deviation weight-for-age Z-score decrease occurs in infants with single ventricle physiology between the time of shunt palliation and hospital discharge. Perioperative metabolic dysregulation and associated failure to recognize energy needs likely contribute to this, as most published predictive equations are inaccurate when compared to caloric requirements determined by indirect calorimetry (IC), which is difficult to perform. Moreover, other contributing factors include caloric restriction due to fluid restriction, frequent feed interruptions, inability to absorb nutrients, and large variations in practice regarding timing and mode of feeding initiation.

Controversies regarding the risk of perioperative enteral feeding while on vasoactive infusions, during umbilical artery catheter use, and with ductal-dependent lesions all remain, which reflects the lack of definitive data addressing such issues in this patient population. Strategies to optimize nutrition can include: using IC when possible to better estimate caloric needs, initiation of parenteral nutrition within the first week if tolerance of higher volumes of enteral nutrition during that time is not anticipated, using early gastric and transpyloric feeds in those at risk of dysphagia, early calorie concentration of feedings in fluid-restricted patients, and the use of feeding protocols to achieve consistency and minimize interruptions. The use of breastmilk in infants with a perceived risk of necrotizing enterocolitis (NEC) is reasonable, given its association with decreased NEC incidence in premature infants.

19.13.2 Chylothorax

The postoperative leakage of lymphatic fluid into the pleural space may result from surgical disruption of the thoracic duct or one of its main tributaries, and/or from increased pressure within the intrathoracic lymph system, e.g., secondary to central vein thrombosis or venous hypertension. Bidirectional Glenn (BDG) operation, Fontan-type procedure, TOF-repair associated with right ventricular diastolic dysfunction are all associated with a higher incidence of chylothorax due to central venous hypertension. Surgical operations in the vicinity of the thoracic duct, including systemic-to-pulmonary arterial shunt insertion, repair of aortic coarctation, and patent ductus arteriosus ligation may also predispose to the development of chylothorax. The development of chylothorax soon after the operation suggests traumatic laceration, while a later onset suggests central venous thrombosis or hypertension. The diagnosis of chylothorax cannot be based on appearance alone. It is established when the pleural fluid contains a triglyceride level of more than 1.24 mmol/L (110 mg/dL) or an absolute cell count >1000 cells/ mL with a lymphocyte fraction >80%. The most consistent diagnostic marker is the predominance of lymphocytes. Conservative treatment should begin with medium-chain triglyceride (MCT)-enriched diets, after ruling out venous thrombosis and/or hypertension. If the chylothorax persists, treatment with somatostatin, or the somatostatin analogue, octreotide, may be considered. Regular monitoring of liver function, blood glucose, and thyroid function tests is recommended during the administration of either somatostatin or octreotide; and necrotizing enterocolitis was reported in association with octreotide treatment. In children with chylothorax, intravenous albumin 25% and immunoglobulin supplementation may be necessary to maintain adequate serum albumin and immunoglobulin G levels. Antithrombin loss in chyle has been associated with the development of thrombosis after CPB operations. The role and impact of thoracic duct ligation in the management of persistent chylothorax are not clear. Other surgical procedures are described, including chemical pleurodesis and placement of a pleuroperitoneal shunt.

19.13.3 Diaphragmatic Paresis

Diaphragmatic paresis or paralysis may occur if injury to the phrenic nerve occurs. Neonates and small infants rely on a functioning diaphragm to maintain vital capacity; in this population the compliant chest wall combined with immature accessory and intercostal muscles lead to a reduced ability to compensate for a dysfunctional diaphragm. Transient palsy or permanent injury to the phrenic nerve, usually the left phrenic nerve, occurs during operations that

involve dissection of branch pulmonary arteries (TOF repair and Arterial switch operation) or during aortic arch reconstruction as in the Norwood operation or interrupted aortic arch repair.

Clinical suspicion is important to diagnose this condition. Clinical signs include increased work of breathing during ventilator weaning, hypercapnia, low lung volumes on the affected side, and an elevated hemidiaphragm on chest x-ray. Ultrasonography or fluoroscopy confirm the diagnosis with findings of diaphragm dysfunction and classical paradoxical motion. Recovery of the phrenic nerve may occur if it is a temporary paresis. Attempt to extubate after optimizing nutrition and cardiovascular status. If lung volume loss and failed extubation recur, then surgical plication of the diaphragm should be considered.

19.13.4 Vocal Cord Paresis or Paralysis

Post-extubation stridor presents as raspy and noisy breathing and is most likely due to mucosal swelling of the glottis or the trachea. If the stridor is persistent, or if the patient required reintubation, the clinician should rule out unilateral vocal cord paresis or paralysis, which is characterized by a weak, sometimes hoarse cry, weak cough and biphasic stridor. Direct laryngoscopy to evaluate vocal cord mobility is necessary to confirm the diagnosis, especially in patients with surgery near the recurrent laryngeal nerve (e.g., aortic arch reconstruction or aortic coarctation repair). Nerve function may return after a few days if the recurrent laryngeal nerve was traumatized but not transected.

19.14 Summary

The immediate postoperative management of congenital heart disease patients in the intensive care unit can be challenging and requires not only a thorough understanding of cardiovascular pathophysiology but also depends on a multidisciplinary team approach to provide the best care for these patients.

Review Questions

1. A 4-month-old infant is admitted to the PICU following complete repair of tetralogy of Fallot. Upon arrival, he is intubated and pharmacologically sedated. He is noted to have a regular, narrow complex, progressive tachycardia with a heart rate of 174 bpm and CVP of 15–20 mmHg. There are no discernible p-waves. He has adequate peripheral pulses and a blood pressure of 75/45 mm Hg. He is receiving a continuous infusion of milrinone (0.5 mcg/kg/min). The most appropriate initial treatment for this infant is which of the following?
   A. Administer a dose of adenosine (0.1 mg/kg).
   B. Administer a dose of furosemide (1 mg/kg).
   C. Avoid fever and stimulation, and assess and correct any electrolyte abnormalities.
   D. Decrease his sedation and allow him to become more awake.
   E. Initiate a low-dose epinephrine infusion (0.05 mcg/kg/min).

2. A 6-month-old female patient with Down syndrome is admitted postoperatively following successful two-patch repair of complete AV septal defect with no postoperative residual defects. Soon after arrival during endotracheal tube suctioning, she is noticed to have increased mottling with associated narrow complex tachycardia ranging around 180 bpm, arterial BP 60s/40s, and arterial oxygen saturations ~91%. CVP tracing appears to have normal morphol-

ogy, but was previously 8–10 mm Hg and is now trending in the low 20s with downward trending brain and splanchnic near-infrared spectroscopy (NIRS) readings. The next appropriate step should include:

A. Increase FiO_2 to 100% and hand ventilate.
B. Administer 2 mcg/kg fentanyl bolus.
C. 5 ml/kg 5% albumin bolus.
D. Amiodarone 5 mg/kg bolus.
E. Preparation for cardioversion.
F. A and B.

3. A 2-month-old male patient who is postoperative day 4 after the repair of aortic coarctation is in the PICU. The patient was extubated 3 days ago and oral feeding was started 2 days ago. His cry has been noted to be very weak and coarse in addition to mild biphasic stridor since extubation. The infant is also noted to be coughing frequently during oral feeding. An anterior-posterior view chest X-ray film was reported to be normal except for right upper lobe opacity. The arterial oxygen saturations are >95% in room air despite being mildly tachypneic. What would be the most appropriate next step in evaluation of this patient?
   A. Upper GI study.
   B. Perform bedside direct flexible laryngoscopy and speech therapy consult.
   C. Infectious diseases consult for initiation of systemic antibiotics.
   D. Obtain Computed tomography (CT) of chest.
   E. Ultrasonographic evaluation of diaphragm mobility.

4. A 7-day-old 2.6 kg neonate with hypoplastic left heart syndrome is admitted to the pediatric intensive care unit following stage I palliation (Norwood, 3.5 mm mBT shunt). The patient is receiving fentanyl (2 mcg/kg per hour), milrinone (0.5 mcg/kg per min) and epinephrine (0.08 mcg/kg per min). Initial ventilator settings include a tidal volume of 8 mL/kg, 28 breaths/min, PEEP of 5 cm H_2O, and FiO_2 of 0.4. The patient has delayed capillary refill time with cold extremities. The arterial blood pressure is 52/32 mm Hg (mean 38 mm Hg) and the atrial pressure is 14 mm Hg. An arterial blood gas sample shows a pH of 7.14, $PaCO_2$ of 38 mm Hg, PaO_2 of 70 mm Hg, HCO_3– of 15 mEq/L, SaO_2 of 93%, and lactate is 7 mmol/L with SVC oxygen saturation of 40%. Of the following, the BEST next step in the management of this patient is:
   A. Administer a fluid bolus of 5% albumin.
   B. Reduce the FiO_2 to 0.21.
   C. Decrease the epinephrine dose to 0.05 μg/kg per min.
   D. Administer an intravenous bolus of sodium bicarbonate.
   E. Increase the ventilator rate.

5. A 3-year-old child with tricuspid atresia who had a bidirectional Glenn shunt at 6 months of age now is admitted to the PICU after fenestrated lateral tunnel Fontan procedure. The patient is hypotensive with decreased urine output and delayed capillary refill. His vital signs are as follows: Heart rate 140 bpm with a sinus rhythm, BP 55/38, left atrial pressure is 5 mm Hg, venous pressure (Fontan pressure) is 6 mmHg and arterial saturations is 92%. Patient is receiving milrinone at 0.5 mcg/kg per minute and epinephrine at 0.05 mcg/kg per minute. What is the most likely diagnosis?
   A. Pulmonary hypertension.
   B. Ventricular dysfunction.
   C. Severe AV valve regurgitation.
   D. Hypovolemia.
   E. Fontan baffle obstruction.

Answers

1. C.
   Explanation: This scenario depicts a common postoperative problem following tetralogy of Fallot repair: Junctional ectopic tachycardia (JET). Commonly occurring in the first 1–3 days postoperatively, clues to the diagnosis include a narrow complex tachycardia driven by the junctional ectopic focus with AV dissociation or retrograde atrial conduction. Often, it is difficult to discern P waves on bedside telemetry; the use of epicardial atrial wires to perform an atrial electrocardiogram may be helpful to better discern the AV relationship. The CVP waveform tracing should be examined for the presence of "cannon" A waves resulting from atrial contraction against a closed tricuspid valve. Although one may expect higher CVP values in TOF given postoperative restrictive RV physiology, higher values should also lead to consideration of AV dissociation. Management of JET in the relatively stable patient first includes supportive measures, but may then include both pharmacotherapy and/or atrial overdrive pacing if incessant. Exogenous catecholamines such as epinephrine may stimulate and exacerbate this rhythm and should be minimized if possible.

2. F.
   Explanation: The above patient has several risk factors for postoperative reactive pulmonary vasculature, including Trisomy 21, young age, exposure to CPB, and having a defect (AV septal defect) commonly associated with this condition. Often with noxious stimuli such as endotracheal tube suctioning, this may manifest as evidence of LCOS with acute elevation in CVP due to acute right heart failure. Although arrhythmias such as JET may exist in such patients, normal CVP morphologic tracing would argue against this. Desaturation, although possible, is not consistently present during a pulmonary hypertension exacerbation unless a residual intracardiac shunt exists. Initial management includes increasing FiO_2 and inducing alkalemia with hyperventilation/sodium bicarbonate/THAM and ensuring adequate sedation/muscle relaxation. See PHTN section for ongoing management if not resolving.

3. B.
   Explanation: This patient's presentation is consistent with vocal cord paresis and aspiration. Recurrent laryngeal nerve damage is a known complication of aortic coarctation repair resulting in vocal cord dysfunction. These patients are at high risk of aspiration and feeding difficulties. To evaluate the vocal cords, a direct flexible laryngoscopy should be performed. Due to the strong suspicion of aspiration, the infant should also be evaluated by a speech therapist and a swallowing study may be needed to document the extent of aspiration and if thickened feeds can be provided safely.

4. B.
   Explanation: In this scenario, the infant with single ventricle physiology is presenting with signs of systemic hypoperfusion and low cardiac output syndrome. Remember that the single ventricular output is divided between the pulmonary and systemic circulations, leading to equal oxygen saturations in the pulmonary artery and the aorta. The amount of blood flowing to either the pulmonary circulation (Qp) or systemic circulation (Qs) is determined by the resistance to flow into these parallel circuits. In this case, the patient has pulmonary overcirculation with systemic hypoperfusion. Therefore, decreasing the FiO2 to 0.21 to raise the PVR is the best next step. Increasing the ventilator rate may further lower the PVR; thus allowing the pCO_2 to rise by lowering the ventilator rate may also be helpful. Pulmonary overcirculation is

commonly seen in patients with a low pulmonary vascular resistance and a low resistance Blalock–Taussig shunt (relatively large diameter and short length), as is the case with the infant in this scenario.

5. D.
Explanation: The patient has low cardiac output syndrome, associated with both low LAP and low Fontan circuit pressure; hypovolemia best explains these findings. If the systemic venous pressure is elevated and LA pressure is low, the differential diagnosis includes an increase in PVR, Fontan baffle obstruction or pulmonary artery stenosis. If both the systemic venous pressure and LA pressures are elevated, it could be related to one of the following causes: ventricular dysfunction, AV valve regurgitation or stenosis, cardiac tamponade, or arrhythmias.

Cardiovascular Agents

Frank A. Maffei, Jennifer E. L. Diep, and Arno L. Zaritsky

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_20

Learning Objectives

- Review the physiology of autonomic nervous system receptors.
- Describe the various adrenergic receptors, their agonists, and their receptor relationship with G proteins.
- Summarize the clinical effects of specific adrenergic receptor-agonist interactions.
- Describe non-adrenergic mechanisms important in cardiovascular pharmacology.
- Summarize common factors that affect the pharmacokinetics of vasoactive infusions.
- Describe the physiology of vasodilators in the treatment of heart failure.
- Describe the mechanism of action, clinical uses, metabolism, and potential adverse effects of the following vasoactive agents:
  - Norepinephrine (NE)
  - Epinephrine (Epi)
  - Dopamine
  - Dobutamine
  - Phenylephrine
  - Isoproterenol (ISO)
  - Vasopressin
  - Milrinone
  - Nitroprusside
  - Nitroglycerine (NTG)
  - Novel cardiovascular agents
- Describe the mechanism of action, clinical uses, metabolism, and potential adverse effects of the following antihypertensive agents:
  - Nicardipine
  - Esmolol
  - Labetalol
  - Enalapril/enalaprilat
  - Fenoldopam
  - Phentolamine and phenoxybenzamine

20.1 Introduction

Cardiovascular agents are utilized when myocardial and/or circulatory dysfunction persists despite optimization of volume status. They have activity on the biochemical and neurochemical pathways that maintain and regulate vascular tone, cardiac contractility, and heart rate. Although these drugs may have multiple dose-dependent effects, they are often categorized by their primary cardiovascular activity. Terms used to describe the primary cardiovascular effect of these drugs are listed in Table 20.1.

Effective use of vasoactive agents requires understanding their mechanism of action and pharmacology in addition to the effects of the patient's endogenous response to their critical illness, which can modify the patient's response to the vasoactive agent. The observed action may differ from what is expected because of a host of factors that affect agonist-receptor interactions and post-receptor messaging within the cell. In addition, critical illness may affect drug clearance so that textbook effects associated with a specified infusion rate may not be observed at the bedside. Because of the variation in pharmacokinetics and pharmacodynamics of these agents, administration of vasoactive agents *should always be targeted to effect and not based on a fixed dose* (although for safety reasons a maximal dose may be considered for some agents, e.g., vasopressin).

Due to variation in pharmacokinetics, the patient's endogenous stress response and complex effects on secondary messenger systems within cells, vasoactive agents should be titrated to effect rather than based on a fixed dose.

Table 20.1 Primary cardiovascular effects, characteristics, and associated vasoactive agents

Primary cardiovascular effect	Characteristics	Example
Inotrope	Improves myocardial contractility and thus stroke volume	Dobutamine, epinephrine (Epi), norepinephrine (NE)
Vasopressor	Increases systemic and often pulmonary vascular resistance and blood pressure	NE, phenylephrine, vasopressin
Chronotrope	Increases heart rate	Epi, isoproterenol
Lusitrope	Improves rate and extent of diastolic relaxation which may decrease end-diastolic pressure	Milrinone, dobutamine, Epi
Vasodilator	Decreases systemic and/or pulmonary vascular resistance (afterload) and often decreases venous tone in capacitance vessels and thus end-diastolic pressure	Nitroprusside sodium, nitroglycerine, nitric oxide
Inodilator	Improves myocardial contractility while decreasing systemic and pulmonary afterload and often dilates venous capacitance vessels	Milrinone, levosimendan

In addition to agents used to support the cardiovascular system, various agents may be used in the PICU to manage severe, symptomatic hypertension. These agents typically block α- and/or β-adrenoceptors, calcium channels, and activation of the renin-angiotensin-aldosterone system (RAAS) or relax vascular smooth muscle by increasing intracellular cGMP. The pharmacology of several antihypertensive agents used to treat hypertensive emergencies will be reviewed in this chapter.

20.2 Physiologic Considerations of Vasoactive Agents

Cardiovascular agents often act at receptor sites within the autonomic nervous system; some agents affect intracellular metabolism of secondary message systems (e.g., milrinone and nitric oxide). When using vasoactive agents, it is often helpful to understand the autonomic receptor systems and subsequent receptor-induced biochemical pathways that affect myocardial function and vascular tone.

20.2.1 Overview of Adrenergic Receptor-Cell Interactions

In 1948, Alquist identified and classified adrenergic receptors, α and β, based on their differing response to pharmacologic agents. Since then, adrenergic receptor physiology has been the subject of extensive study. Techniques in molecular pharmacology lead to the classification of adrenergic and dopaminergic sub-subtypes (Fig. 20.1). The following section concentrates on adrenergic (α_1, α_2, β_1, β_2) and dopaminergic (DA_1, DA_2) receptor physiology.

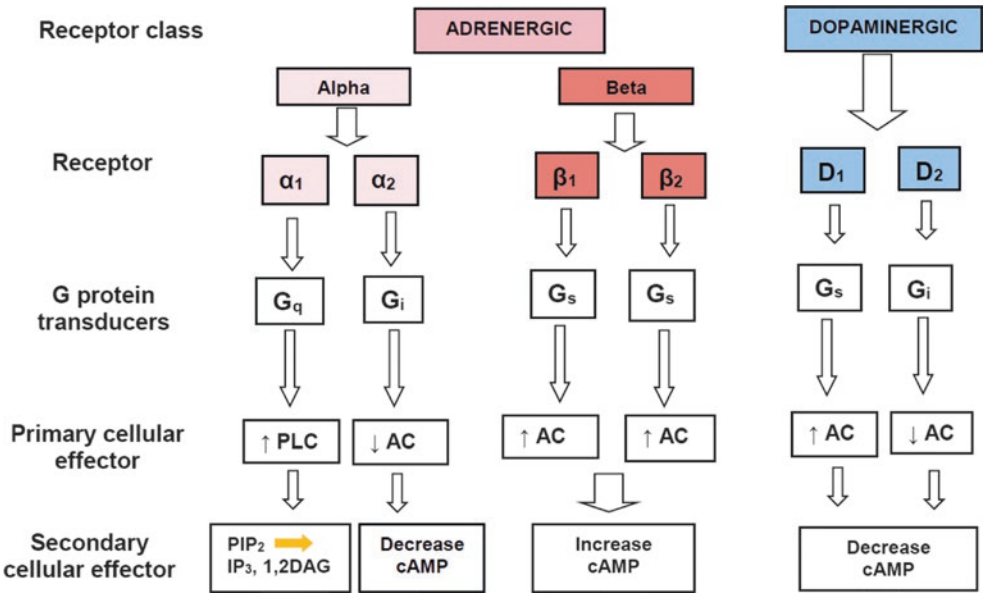

Fig. 20.1 Adrenergic and dopaminergic subtypes with respective G proteins and cellular effectors. *PLC* phospholipase C, *PIP2* phosphatidylinositol bisphosphate, *IP3* inositol triphosphate, *1,2 DAG* 1,2 diacylglycerol, *AC* adenylate cyclase, *cAMP* cyclic adenosine monophosphate

The α_1- and β_1-adrenoceptors are innervated by sympathetic nerves, whereas the α_2- and β_2-adrenoceptors are "hormonal" (or, in the case of presynaptic α_2-adrenoceptors, "autocrine") receptors. The hormonal adrenoceptor agonist is epinephrine (Epi), which is released by the adrenal gland, whereas norepinephrine (NE) is the neurotransmitter of the sympathetic nervous system (SNS) and acts as the principal physiologic agonist at α_1- and β_1-adrenoceptors.

The binding affinity of NE and Epi at the β_1-adrenoceptor is the same, but Epi has a significantly higher affinity than NE at the β_2-adrenoceptor. These differences in binding affinity and site of action explain why epinephrine has effects on heart rate and vascular resistance at plasma concentrations of 75–125 pg/mL, whereas the NE concentration required to observe a hemodynamic effect is approximately 1800 pg/mL. The difference in the plasma threshold concentration is explained by Epi acting at the hormonal β_2-adrenoceptor causing an increase in heart rate and fall in vascular resistance. Higher NE concentrations are needed for the agent to diffuse from the vascular space through the tissue to reach the innervated α_1- and β_1-adrenoceptors. Furthermore, there are two tissue uptake mechanisms designed to limit the effect of neuronally released NE from reaching the circulation that eliminate a portion of the exogenously administered catecholamines. These uptake systems reduce the quantity of infused catecholamines reaching the innervated receptors. These differences in receptor location have clinical implications with respect to the pharmacologic actions of vasoactive agents. For example, it explains why "low-dose" epinephrine infusions increase heart rate and vasodilate vascular beds, especially in the skeletal musculature; higher infusions are needed to subsequently raise vascular resistance when sufficient epinephrine reaches the vasoconstricting innervated α_1-adrenoceptors.

Adrenergic receptors (and various other vasoactive receptors) are tightly coupled to one of several different membrane-bound G proteins, which facilitate different actions within the cell depending on the receptor system. G proteins are composed of three subunits (α, β, γ) and are named for their association with guanosine diphosphate (GDP) and guanosine triphosphate (GTP). The inactive G-protein α subunit is bound to GDP; agonist binding to the adrenoceptor causes GTP to replace GDP on the α subunit. The activated GTP α subunit then separates from the $\beta\gamma$ subunit and acts on the target enzyme in either a stimulatory (Gs) or inhibitory (Gi) fashion. Depending on the cell, the

enzymes targeted by the activated G-protein α subunit include adenylate cyclase, phospholipase C, and phosphodiesterases. The activated α subunit may also directly act on potassium ion channels in vascular smooth muscle to cause hyperpolarization. Activation of the target enzyme also results in conversion of GTP back to the inactive GDP by GTPase coupled to the G α subunit.

Adenylate cyclase is the key enzyme involved in α_2, β_1, and β_2 signal transduction. When stimulated by the GTP α subunit, adenylate cyclase hydrolyzes ATP to the cytosolic second messenger 3,5-cyclic adenosine monophosphate (cAMP). A rise in intracellular cAMP concentration activates protein kinases that in turn phosphorylate biologically active proteins such as calcium channels. Increased intracellular cAMP and the subsequent phosphorylation of key proteins result in clinical effects depending upon the effector cell.

Adrenergic receptors (α_2, β_1, and β_2) are tightly coupled to membrane-bound G proteins that are composed of three subunits (α, β, γ). Depending on the structure of the α subunit, G proteins can stimulate (Gs) or inhibit (Gi) the membrane-bound adenylate cyclase.

At the α_1-adrenoceptor, Gq protein coupling stimulates the enzyme phospholipase C to hydrolyze phosphatidylinositol bisphosphate to intracellular second messengers: inositol triphosphate (IP_3) and diacylglycerol (DAG). The specific molecular mechanisms summarized below are based on the adrenoceptor-G protein relationships.

α_1 adrenoceptors are bound to a Gq protein that stimulates increased production of IP_3 and DAG as secondary messengers to increase vascular smooth muscle tone.

20.2.1.1 Adrenergic Receptor Density

The density of adrenoceptors on the cell surface may undergo regulation in response to agonist interactions with the receptor and may further be regulated by other mediators that are endogenously activated or exogenously given to treat critically ill children. Agonist stimulation of adrenoceptors causes receptor internalization and ultimately destruction; this reduces the response to agonists over time. Conversely, blocking agonist interaction with the receptor (e.g., with the use of beta-blockers) causes increased receptor density on the cell surface which explains why these blocking agents should generally be discontinued slowly to limit the risk of an excessive catecholamine response.

β-adrenoceptor expression on the cell surface is increased by corticosteroids, which may partly explain this agent's utility in children with asthma, especially if albuterol use reduced cell surface β-adrenoceptor density in the airways. Thyroid hormone increases the secondary messenger responsiveness to β-adrenoceptor stimulation, which explains the clinical symptoms observed in hyperthyroid patients. Conversely, inadequate thyroid hormone reduces the responsiveness to β-adrenoceptor agonists.

The density of adrenoceptors on the cell surface may undergo regulation in response to agonist interactions with the receptor and may further be regulated by other mediators that are endogenously activated or exogenously given to treat critically ill children.

Patients with chronic heart failure or other chronic stress states have increased endogenous SNS activity acting on adrenoceptors, which downregulates receptor expression. As expected, cardiac adrenergic receptor density is reduced in studies of explanted hearts in transplant recipients and cardiac biopsies during repair of acyanotic cardiac lesions.

20.2.1.2 Alpha- and Beta-Adrenoceptors

Alpha$_1$ (α_1)-Adrenoceptors

Key sites – α_1-adrenoceptors are innervated receptors primarily on vascular smooth muscle, but they are also found in the heart where activation increases contractility and stimulates cardiac muscle hypertrophy, although the effects on cardiac contractility are thought to be a minor effect. As noted in ► Chap. 15, Regional Circulation, the distribution of these receptors is not uniform; α_1-adrenoceptors are prominent in the skeletal muscle and renovascular and splanchnic circulation and less so in the cerebral and coronary circulation.

Binding – Ligand binding to α_1-adrenoceptors activates the Gα q subunit protein, which stimulates phospholipase C to hydrolyze phosphatidylinositol bisphosphate (PIP_2) to the intracellular second messengers: inositol triphosphate (IP_3) and 1,2 diacylglycerol (1,2 DAG). In vascular smooth muscle, IP_3 via a receptor-mediated process promotes the release of Ca^+ from the sarcoplasmic reticulum. 1,2 DAG activates protein kinase C, which causes an increased influx of extracellular calcium (Fig. 20.2). The net increase in cytosolic Ca^{+2} concentration ultimately causes vascular smooth muscle contraction.

α_1 vascular smooth muscle receptor binding acts on Gq protein, which releases GDP and binds GTP; the activated subunit then activates phospholipase C.

Phospholipase C hydrolyzes PIP_2 to IP_3 and 1,2 DAG, which produces IP_3 and 1,2 DAG, both mediators that promote increased intracellular Ca^+ which leads to vasoconstriction.

Alpha$_2$ (α_2)-Adrenoceptors

Key sites – α_2-adrenoceptors are present on presynaptic adrenergic and cholinergic nerve terminals. Peripheral α_2-adrenoceptors on vascular smooth muscle have also been identified and cause vasoconstriction when stimulated by agonists like epinephrine, but they are less prevalent than α_1-adrenoceptors. They are present in the central nervous system (CNS) vasomotor center of the medulla, the locus coeruleus, and the dorsal spinal column.

Binding – Binding of presynaptic α_2-adrenoceptors by synaptically released NE starts an autocrine negative feedback loop that decreases NE release (Fig. 20.3). Presynaptic receptor binding activates G_i protein that inhibits adenylate cyclase and thus decreases cAMP formation. Reduced intracellular cAMP reduces protein kinase A activity, which decreases downstream phosphorylation of proteins important in NE release. Although exogenous Epi and NE binds at the presynaptic α_2-adrenoceptor, the direct effect of these agents on vascular smooth muscle adrenoceptors dominate the pharmacologic response.

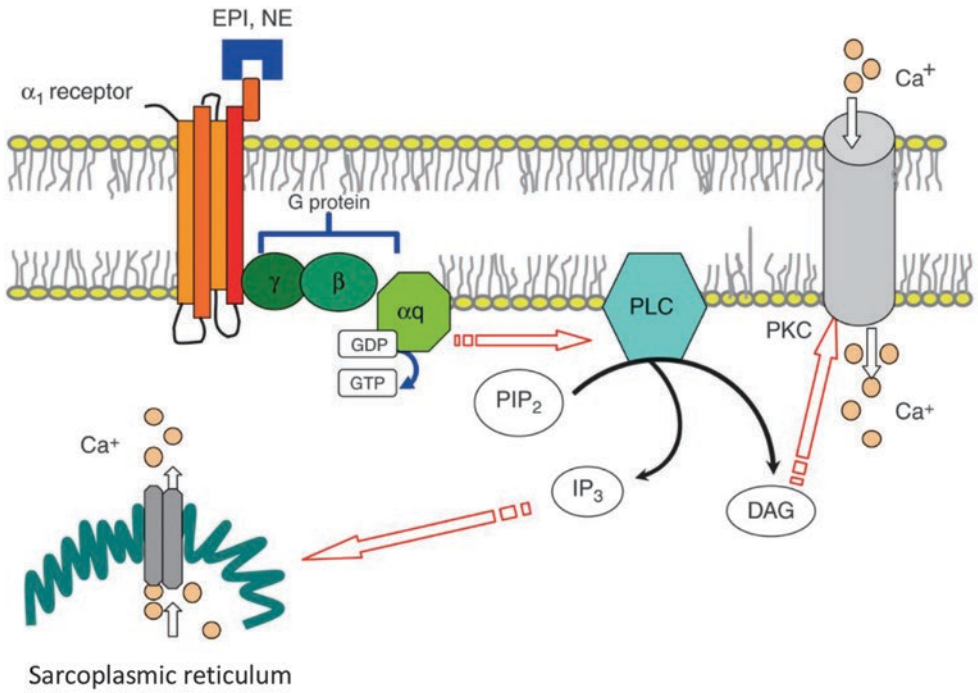

Fig. 20.2 Vascular α_1-adrenoceptor binding by agonists such as epinephrine (EPI) and norepinephrine (NE) results in a G-protein conformational change that releases GDP and binds GTP. The activated α q subunit of the G protein stimulates phospholipase C (PLC) to hydrolyze phosphatidylinositol bisphosphate (PIP2) to the second messengers: inositol triphosphate (IP3) and 1,2 diacylglycerol (DAG). These second messengers promote an increase in cytosolic calcium concentration which results in vascular smooth muscle contraction. IP3 promotes the release of Ca^+ from the sarcoplasmic reticulum, and 1,2 DAG activated protein kinase C (PKC) causes influx of extracellular calcium

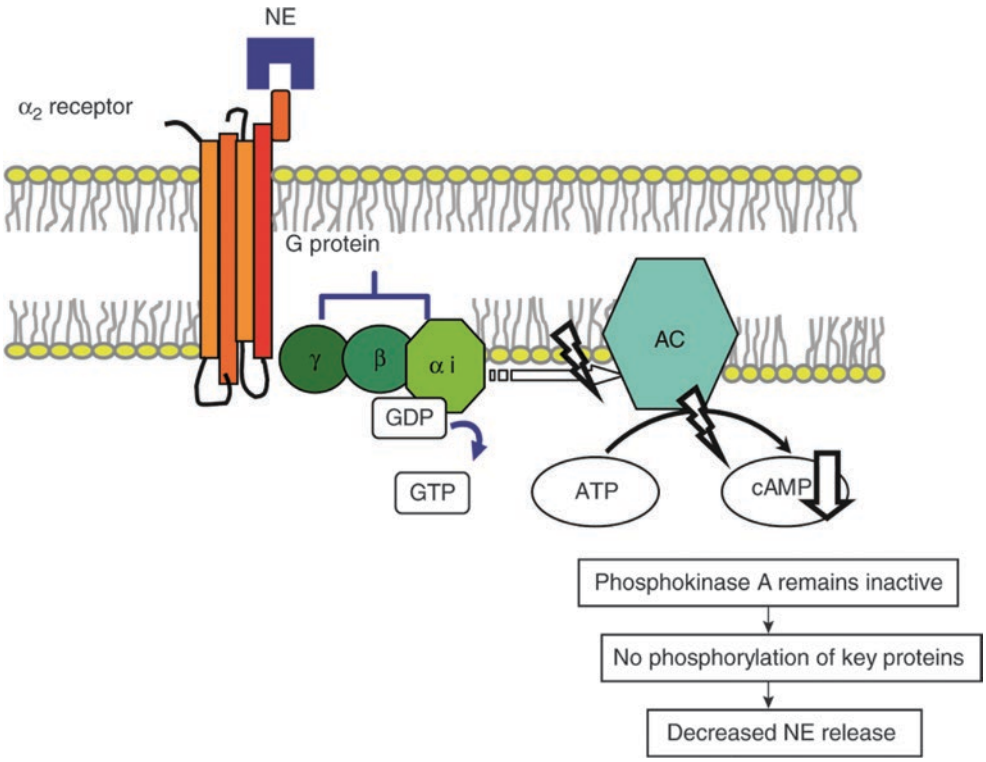

Fig. 20.3 α_2 presynaptic adrenoceptor binding inhibits adenylate cyclase activity, which decreases the intracellular cAMP concentration and ultimately decreases NE release

Presynaptic α_2-adrenoceptor nerve terminal binding acts on the Gi protein, which releases GDP and binds GTP ⇒ inhibition of adenylate cyclase ⇒ decreased cAMP ⇒ decreased protein kinase activity ⇒ inhibition of NE release.

In the CNS, α_2-adrenoceptor agonists, such as clonidine and dexmedetomidine, reduce sympathetic nervous system (SNS) activity, which leads to vasodilation and reduced heart rate and contractility (if increased from baseline). Binding of α_2-adrenoceptors located in the dorsal column of the spinal cord and the locus coeruleus of the brainstem also has sedative and analgesic effects.

Beta$_1$ (β_1)-Adrenoceptors

Key sites – β_1-adrenoceptors are located in the myocardium and kidney. Within the heart, β_1-adrenoceptors are found in the atria and ventricles and throughout the conduction system.

Binding – Ligand binding to β_1-adrenoceptors activates Gs protein which stimulates adenylate cyclase. Increased adenylate cyclase activity increases cytosolic cAMP. Increased cAMP levels activate protein kinase A, which increases the phosphorylation of target proteins. These targets include myocardial myofilament proteins and Ca^+ channel proteins. Ca^+ influx through membrane-bound channels ensues and results in a *net increase* in cytosolic calcium. Clinically, this leads to increased actin-myosin coupling and ultimately increased inotropy (Fig. 20.4).

It is important to appreciate that the net increase in cytosolic calcium not only increases myocardial inotropy during systole but also has implications on muscle relaxation during diastole. Lusitropy, which is the rate at which myocardial relaxation occurs, is also affected by cytosolic Ca^+ gradient changes. Increased cytosolic Ca^+ increases the rate of Ca^+ reuptake into the sarcoplasmic reticulum, which potentiates diastolic relaxation. In addition, protein kinase A phosphorylation of myofilament proteins enhances the lusitropic response by promoting a reduction in myofilament tension.

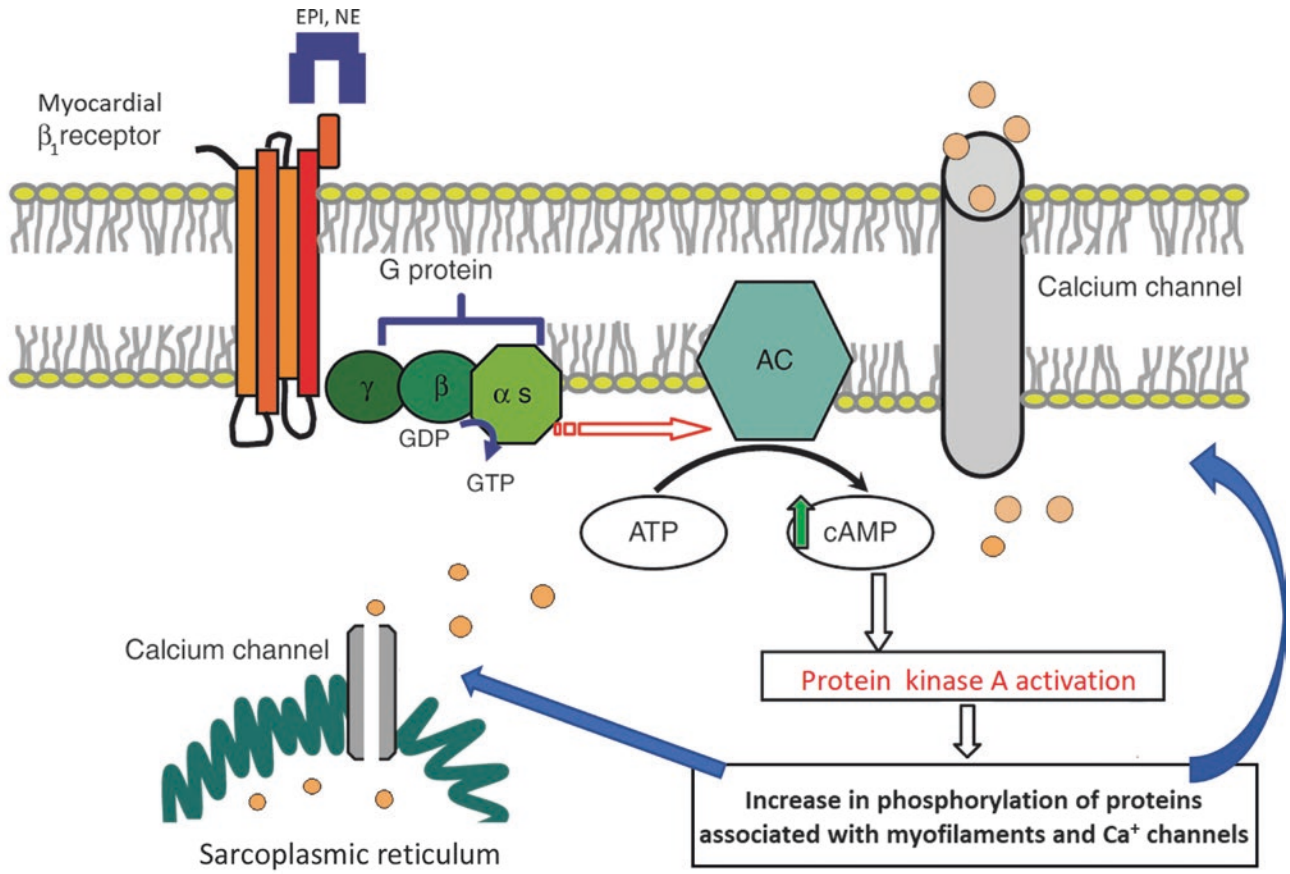

Fig. 20.4 Myocardial β_1-adrenergic G-protein signal transduction. Ligand binding (e.g., *EPI*, *NE*) to β_1 adrenoceptors on myocardium results in adenylate cyclase (*AC*) activation via Gs-protein activation. Increased AC activity increases cAMP, which increases protein kinase A activity, which increases phosphorylation of proteins associated with myofilaments and Ca^+ channels. Membrane calcium channel stimulation results in Ca^+ influx into the cytosol and increases reuptake of Ca^+ into the sarcoplasmic reticulum (SR). Clinically, increased cytosol Ca^+ concentration results in increased inotropy, lusitropy, and chronotropy

Increased lusitropy also facilitates an increased heart rate as less time is required for passive filling by increasing the rate of calcium reuptake, and it makes more calcium available in the sarcoplasmic reticulum, which facilitates increased contractility by providing a pool for rapid release of calcium into the cytoplasm. In cardiac pacemaker cells, increased cAMP also increases their activation rate (i.e., chronotropy).

Beta$_2$ (β_2)-Adrenoceptors

Key sites – β_2-adrenoceptors are located on the surface of vascular smooth muscle (skeletal, coronary, gastrointestinal), ciliary muscle, bronchial smooth muscle, lymphocytes, and mast cells. They also are located in both the atria and ventricles in a ratio of β_1- to β_2-adrenoceptors of approximately 70:30 in the atria and 80:20 in the ventricle.

Binding – Ligand binding to β_2-adrenoceptors activates Gs protein, which stimulates adenylate cyclase leading to increased cAMP and increased protein kinase A activity. However, unlike cardiac myocyte β_1-adrenoceptor stimulation, increased cAMP in vascular smooth muscle increases the uptake of cytosolic calcium by the sarcoplasmic reticulum and increases efflux of calcium out of the cell resulting in a net decrease in cytosolic calcium. Increased cAMP in

Myocardial β_1-adrenoceptor binding ⇒ activation of Gs protein ⇒ adenylate cyclase stimulated ⇒ increased cAMP ⇒ increased protein kinase A activity ⇒ increases phosphorylation of proteins associated with Ca+ channels and cardiac contractile proteins ⇒ increased inotropy, lusitropy, and chronotropy.

vascular smooth muscle also inhibits myosin light-chain kinase activity, which is responsible for phosphorylating smooth muscle myosin. Therefore, β_2 agonists inhibit smooth muscle contraction and promote smooth muscle relaxation (vasodilation, bronchodilation).

In the heart, atrial β_2-adrenoceptors, which are hormonal receptors, increases the pacemaker rate, which partly explains why a selective β_2 agonist such as albuterol causes tachycardia. Similarly, low-dose infusions of epinephrine cause tachycardia with less effect on contractility, which requires higher epinephrine concentrations to activate cardiac β_1 adrenoceptors.

Ligand binding (e.g., Epi, ISO) to β_2-adrenoceptors on vascular or bronchial smooth muscle results in activation of adenylate cyclase via Gs protein. Adenylate cyclase activity results in increased cAMP, increased protein kinase activity, and increased phosphorylation of proteins associated with Ca+ channels. Unlike β_1 receptor stimulation on the myocyte, β_2 receptor stimulation on vascular and bronchial smooth muscle increases the uptake of cytosolic calcium by the sarcoplasmic reticulum and pumps calcium out of the cell leading to a net decrease in cytosolic calcium. Clinically, the decreased cytosolic calcium results in vascular and bronchial smooth muscle relaxation.

20.2.1.3 Dopamine Receptors

Dopamine is a neurotransmitter that is generally more important in the central versus the peripheral nervous system. Dopamine is an intermediary in the pathway for NE and Epi synthesis and is only released as a neurotransmitter by select sympathetic nerves located in the kidney and splanchnic vascular bed as well as the anterior pituitary gland and hypothalamus (◘ Fig. 20.5). Although dopamine receptors are in the renal and splanchnic vascular beds, their clinical significance is uncertain since the anticipated beneficial effects of infusing dopamine or dopamine receptor agonists have had limited clinical utility.

Exogenous dopamine can interact with adrenergic receptors in a dose-dependent fashion but has a lower binding affinity than Epi or NE. Instead, studies show that much of dopamine's cardiovascular action is mediated by stimulating NE release from sympathetic nerves. Since NE stored in sympathetic nerve terminals is depleted in chronic heart failure and other chronic stress states, dopamine has limited inotropic effects in these settings. In the peripheral vascular system, dopamine interacts with a group of distinct dopaminergic receptors, most importantly dopamine$_1$ (DA_1) and dopamine$_2$ (DA_2) receptors.

Dopamine$_1$ (DA_1)

DA1 receptor binding results in Gs protein activation of adenylate cyclase, which increases cAMP production and protein kinase activity causing vasodilation of selective vascular beds.

Key sites – Like α_1- and β_1-adrenoceptors, DA_1 adrenoceptors are innervated receptors present in renal, mesenteric, and coronary vascular smooth muscle. Non-innervated DA_1 receptors are on the surface of proximal renal tubule cells.

Binding – Ligand binding activates Gs protein, causing vasodilation of selective vascular beds. Locally produced dopamine acts as an autocrine/paracrine natriuretic hormone by inhibiting the activity of both apical (e.g., Na^+/H^+ exchange, Cl^-/HCO_3^- exchange, and Na^+/Pi cotransport) and basolateral (e.g., Na^+, K^+-ATPase, and Na^+/HCO_3^- cotransport) tubule transporters. These actions facilitate increased salt and water excretion.

Dopamine$_2$ (DA_2)

Key sites – Like α_2- and β_2-adrenoceptors, DA_2 receptors are found on presynaptic nerve terminals and in the adrenal cortex. They are also found in the anterior pituitary gland and other CNS locations.

Binding – Similar to presynaptic α_2-adrenoceptors, presynaptic DA_2-receptor stimulation inhibits NE release from the sympathetic nerve terminus. Similar effects are observed at DA_2 receptors in the CNS; the effect is mediated by activation of Gi protein, which decreases cAMP. DA_2 receptor activation of cells in the anterior pituitary inhibits release of TSH and prolactin. In the adrenal cortex, DA_2-adrenoceptor stimulation inhibits aldosterone synthesis and release.

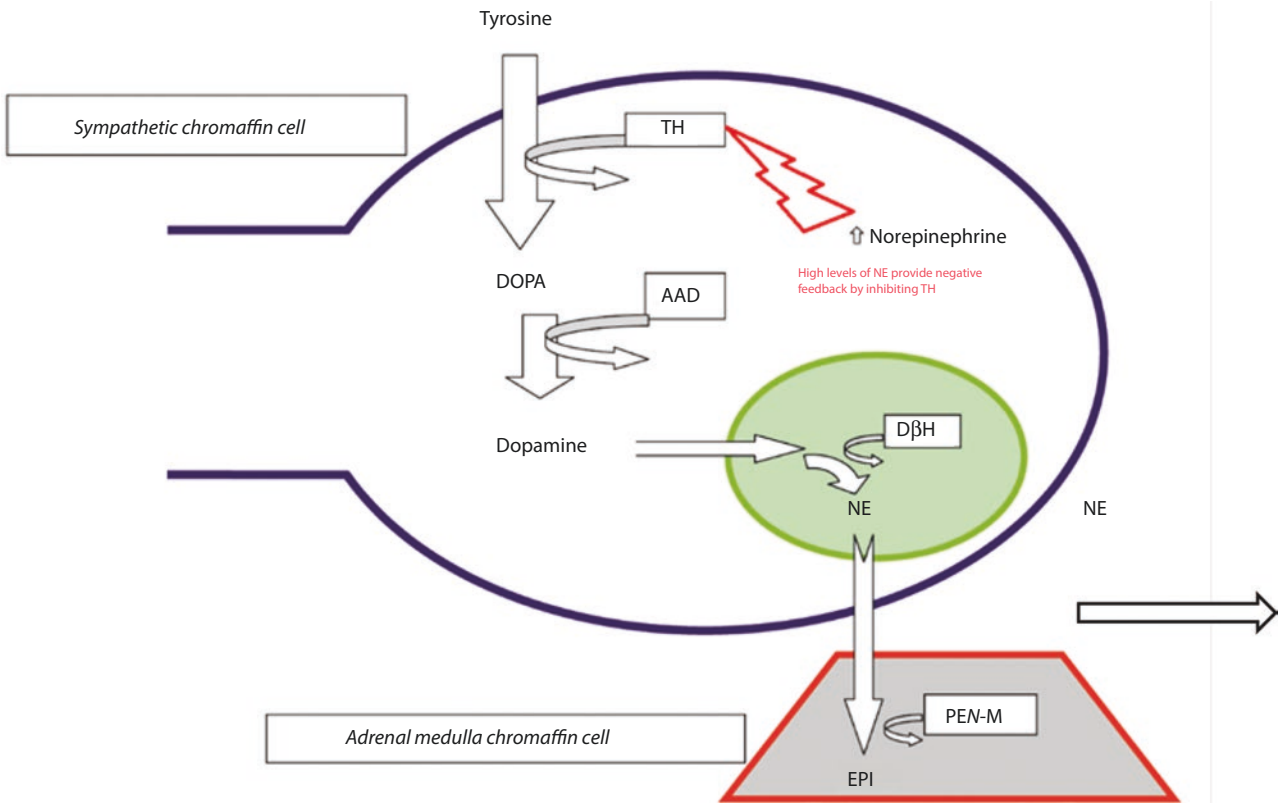

Fig. 20.5 Dopamine is an intermediary in norepinephrine (NE) and epinephrine (EPI) biosynthesis. Tyrosine is converted to dihydroxyphenylalanine (DOPA) by the rate-limiting enzyme, tyrosine hydroxylase (TH). High levels of NE inhibit TH. DOPA is decarboxylated by aromatic amino acid decarboxylase (AAD) to produce dopamine. Dopamine enters the storage vesicle and is β-hydroxylated by dopamine β-hydroxylase (DβH) to produce NE. Approximately 85% of NE synthesized in the adrenal medulla is converted to EPI by phenylethanolamine *N*-methyltransferase (PE *N*-M)

The relationship between sympathomimetic agents and adrenoceptors including dopamine receptors are summarized in Table 20.2.

20.2.1.4 Genetics of Adrenoceptors

Another source of variation in clinical response to adrenergic agonists was identified after receptor sequencing became available. Single-nucleotide polymorphisms (SNP) have been mostly studied for the β_2-adrenoceptors, which explains some of the variation in response to β_2 agonists observed in asthmatic patients. For example, one SNP is associated with a threefold to fourfold reduction in the maximal stimulation of adenyl cyclase activity. This SNP is associated with a smaller increase in heart rate, contractility, and plasma renin activity in response to dobutamine infusion in healthy young subjects and was associated with the need for a higher dose and longer inotrope support after CABG in patients who were treated with metoprolol preoperatively. Another SNP is associated with rapid β_2-adrenoceptor internalization reducing responsiveness to ongoing agonist stimulation.

Single-nucleotide polymorphisms of adrenergic receptors likely explain some of the variation in response to adrenergic agonists observed in clinical use.

20.2.1.5 Complexity of Adrenoceptor Activation

Adrenergic signal transduction results in a myriad of physiologic responses including highly complex metabolic processes. Adrenergic receptor-mediated cellular and hemodynamic effects in response to endogenous and exogenous agonists are summarized in (Table 20.3).

Table 20.2 Relative receptor stimulation by sympathomimetic agents

Sympathetic agent	Relative receptor action[a]	Quantitative receptor action
Sympathomimetics:		
Norepinephrine	$\alpha_1 = \beta_1 >> \beta_2$	++++ α_1, ++++ β_1
Epinephrine	$\beta_2 > \beta_1 = \alpha_1$	++ α_1, ++++ β_1, ++++ β_2
Phenylephrine	α_1 selectively	++++ α_1
Isoproterenol	$\beta_1 = \beta_2$	++++ β_1, ++++ β_2
Dopamine		
Low dose[b]	$DA_1 > \beta_1 > \alpha_1$	+++DA_1
Intermediate dose	$\beta_1 > \alpha_1 > DA_1$	++ α_1, ++ β_1
High dose	$\alpha_1 >> \beta_1 > DA_1$	++++ α_1, ++ β_1
Dobutamine: (+) isomer (−) isomer	 $\beta_1 \cong \beta_2$, α_1 *antagonist* Weak β_1 and β_2 agonist, α_1 *agonist*	 ++++ β_1, ++ β_2 Variable effect on α_1 depending on balance of agonist/antagonist actions
Alpha-blockers:		
Phenoxybenzamine	α_1, α_2	Irreversible receptor inhibition
Phentolamine	α_1, α_2	
Prazosin	α_1	
Beta-blockers:		
Propranolol	β_1, β_2	Equal effects at β_1, and β_2
Esmolol, Atenolol, Metoprolol	β_1	
Labetalol	β_1, α_1	β_1 inhibition is 7 times greater than α_1 blockade

[a]Relative receptor action accounts for the differences in adrenoceptor location such that the hormonal adrenoceptors (β_2 and α_2) are activated at lower drug concentrations than the innervated receptors (β_1 and α_1)
[b]"Low-dose" assumes normal pharmacokinetics. Dopamine is a weak direct agonist at α_1- and β_1-adrenoceptors; much of its action is mediated by facilitating the release of NE from sympathetic nerves

20.2.1.6 Phosphodiesterase Inhibition

Inhibition of phosphodiesterase III causes a sustained increase in the cAMP levels, leading to increased protein kinase A activity and ultimately increased myocardial cytosolic calcium and decreased vascular smooth muscle cytosolic calcium. The net clinical effect is increased inotropy combined with vasodilation in both the systemic and pulmonary circulations as well as reduced tone in the venous capacitance system.

Since cAMP is an essential mediator in the sympathetic response, inhibition of its breakdown has important clinical implications. Phosphodiesterase III is responsible for the breakdown of cAMP; thus, phosphodiesterase III inhibition in the myocardium and vascular smooth muscle leads to sustained cAMP levels and increased protein kinase A activity. The ultimate effect on cytosolic calcium concentration is cell type-dependent; calcium release is increased in myocardial cells and decreased in vascular smooth muscle (Fig. 20.6). In smooth muscle, phosphorylation of myosin light-chain kinase by protein kinase A inhibits its activity, which is essential for smooth muscle contraction. Milrinone (see below) is the most commonly utilized phosphodiesterase III inhibitor. The net clinical effect of milrinone is increased inotropy with vasodilation, often referred to as inodilation.

Table 20.3 Relationship of agonists to adrenergic receptors, intracellular messengers, cellular response, and hemodynamic response

Agonists	Receptor	G protein	Second messenger	Cellular response	Hemodynamic result
Epinephrine Norepinephrine Phenylephrine Dobutamine[a]	α_1	Gq	IP_3, 1,2DG ⇧	Smooth muscle: Increased cytosolic Ca^+	Vasoconstriction
Norepinephrine Epinephrine Dobutamine Clonidine, Dexmedetomidine	α_2	Gi	cAMP ⇩	Central and peripheral presynaptic adrenergic nerve terminals: Decreased norepinephrine release from sympathetic nerves (negative feedback)	Any action of exogenous NE, Epi, and Dob at presynaptic α_2- adrenoceptors is overwhelmed by the vasoconstriction effect of these agents at the α_1 receptor Central α_2 agonists lead to sympatholytic effects
Epinephrine Isoproterenol Dobutamine Norepinephrine Dopamine	β_1	Gs	cAMP ⇧	Myocardium: Increased influx of Ca^+ through membrane channels, increased Ca^+ release from sarcoplasmic reticulum, and increased Ca+ reuptake into the sarcoplasmic reticulum Kidney: Increased renin production	Increased inotropy, lusitropy, and chronotropy Increased renin-angiotensin-aldosterone activity
Isoproterenol Epinephrine Dobutamine	β_2	Gs	cAMP ⇧	Smooth muscle: Increased removal of cytosolic Ca^+ from cytoplasm and into sarcoplasmic reticulum	Vasodilation Bronchodilation
Dopamine Fenoldopam	DA_1	Gs	cAMP ⇧	Renovascular, splanchnic, and coronary smooth muscle: Increased PKA activity Increased Ca^+ mobilization	Selective vasodilation

[a]Dobutamine has a unique pharmacologic action due to opposing actions of the two isomers on α_1-adrenoceptor resulting in mainly β-adrenoceptor stimulation. In addition, a long-lasting active metabolite has α_1 antagonist activity. PKA is protein kinase A

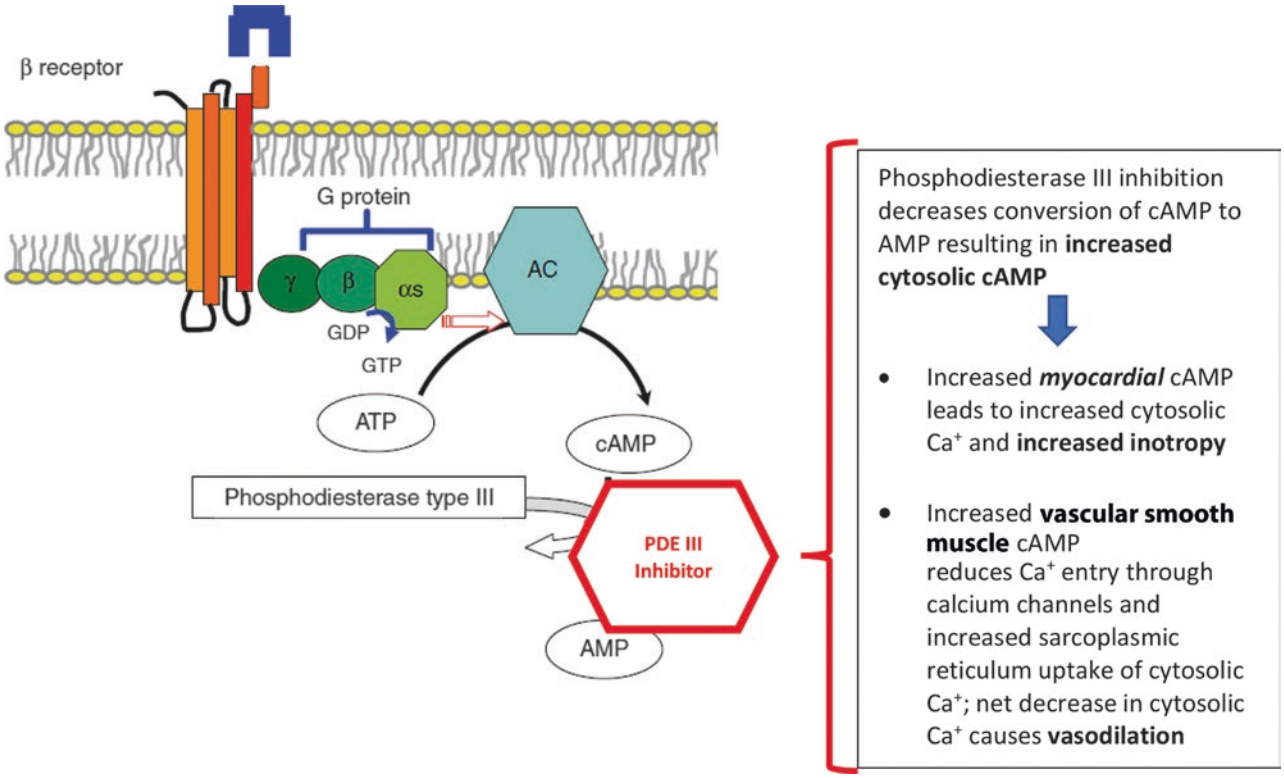

Fig. 20.6 Inhibition of phosphodiesterase III (e.g., milrinone) causes a sustained increase in cAMP levels, protein kinase A activity, and ultimately increased myocardial cytosolic calcium concentration but decreased vascular smooth muscle cytosolic calcium. The net clinical effect is inodilation

20.2.2 Pharmacokinetics of Vasoactive Infusions

Because of the short half-life for most of the vasoactive agents, they are administered as a continuous infusion. One implication is that changes in infusion rate will rapidly achieve a new steady-state concentration; 90% of the steady-state concentration is achieved in three half-lives, which is on the order of 6–9 minutes for the sympathomimetic drugs.

Pharmacokinetic studies of sympathomimetic agents identified both age-based and disease-based variations in clearance. In general, younger children clear these agents more rapidly than older children and adolescents; neonates tend to clear these agents more slowly, especially premature infants. More importantly, wide interindividual variation in clearance is observed in critically ill infants and children based on studies using dopamine, dobutamine, norepinephrine, or epinephrine. Low clearance is associated with renal and/or hepatic dysfunction and low cardiac output states; the latter likely impairs clearance due to reduced blood flow to the kidney and liver, which are the main sites for metabolic elimination. Clearance may vary up to 10- to 20-fold so that an infusion of dopamine or dobutamine at 2 mcg/kg/min in one child may achieve the same steady-state concentration seen in another child receiving an infusion at 20 mcg/kg/min!

The pharmacokinetics of nitroprusside and nitroglycerine do not exhibit the same variations in clearance since their clearance is not dependent on liver or renal function. Milrinone, however, is renally cleared and has a long half-life in normal individuals (~1.5–2.5 hour). Thus, a change in infusion rate will not achieve 90% of the new steady-state concentration for at least 3–4.5 hours and may be much longer in an infant or child with reduced renal function. Thus, the onset of the beneficial or adverse effect of the drug may be quite delayed after a change in infusion rate.

There are wide variations in the clearance of sympathomimetic agents observed in infants and children. Reduced renal and/or liver function and low cardiac output states reduce clearance. Thus, a given infusion rate may produce markedly different effects in individual patients.

20.2.3 Pharmacodynamics of Vasoactive Infusions

The preceding discussions regarding changes in receptor density, expression, genetic variation, and secondary messenger activation are several factors that affect the clinical manifestation observed from a vasoactive drug infusion. Innate physiologic stress responses are also very important to consider when understanding the effects of vasoactive infusions.

Critically ill or injured children typically mount an endogenous stress response with increased SNS activation and elevated endogenous Epi concentrations. Corticosteroid concentrations are often increased along with vasopressin levels. In addition, multiple other mediator signals are either stimulating or inhibiting endothelial signaling with the release of NO, endothelial-derived hyperpolarizing factor, or other mediators. Vascular smooth muscle cells have multiple surface receptors that either increase or decrease secondary messengers (see ◘ Fig. 20.7), which then either stimulate or inhibit the action of various enzymes and channels within the cell. The balance between these conflicting signals ultimately leads to the net vascular tone. All forms of shock, but especially septic shock, may be characterized by vasoplegia where factors that reduce actin-myosin coupling overwhelm the vasoconstricting mediators. Similar conflicting intracellular signals are present in the cardiomyocytes of critically ill children.

Nitroprusside and nitroglycerine exhibit much less variation in pharmacokinetics, whereas milrinone is renally excreted with a relatively long half-life meaning that changes in the infusion rate do not reach a new steady-state concentration for many hours.

There are complex mechanisms that regulate vascular smooth muscle tone. Multiple mediators act on receptors or enzyme systems generating secondary and tertiary intracellular messengers that affect vascular smooth muscle tone, making it unlikely that a given vasoactive agent will produce a consistent response in different patients.

The physiologic effects from vasoactive infusions also depend on the target organ. As reviewed in ▶ Chap. 15, Regional Circulation, the density and type of adrenergic receptor varies by organ system. For example, cutaneous blood vessels physiologically express mainly α_1-adrenoceptors; thus, NE and Epi cause cutaneous vasoconstriction. Conversely, the cerebral and coronary vasculatures have a low density of adrenoceptors and are not prone to the vasoconstrictive effects of α_1 stimulation. Skeletal muscular vasculature has a high concentration of β_2-adrenoceptors, so epinephrine markedly increases skeletal muscle blood flow, whereas NE has little effect at these receptors. This may explain the observation in animal and clinical studies that Epi tends to increase cardiac output but may compromise splanchnic perfusion by "stealing" blood flow to skeletal muscles, whereas NE tends to maintain splanchnic perfusion in septic shock.

In addition to the polymorphisms in β-adrenoceptors, a recent review identified 24 genes associated with significant differences in outcome in sepsis and/or cardiovascular disease. These genes regulate various inflammatory mediators, signaling pathways and channels. This adds further complexity to the pharmacodynamics of vasoactive infusions.

Ultimately, the net effect of a vasoactive agent on a target cell depends on the balance of conflicting messages being received by the cell. When combined with the variations in pharmacokinetics noted above, it should not be surprising that there may be wide variation in the hemodynamic response to a vasoac-

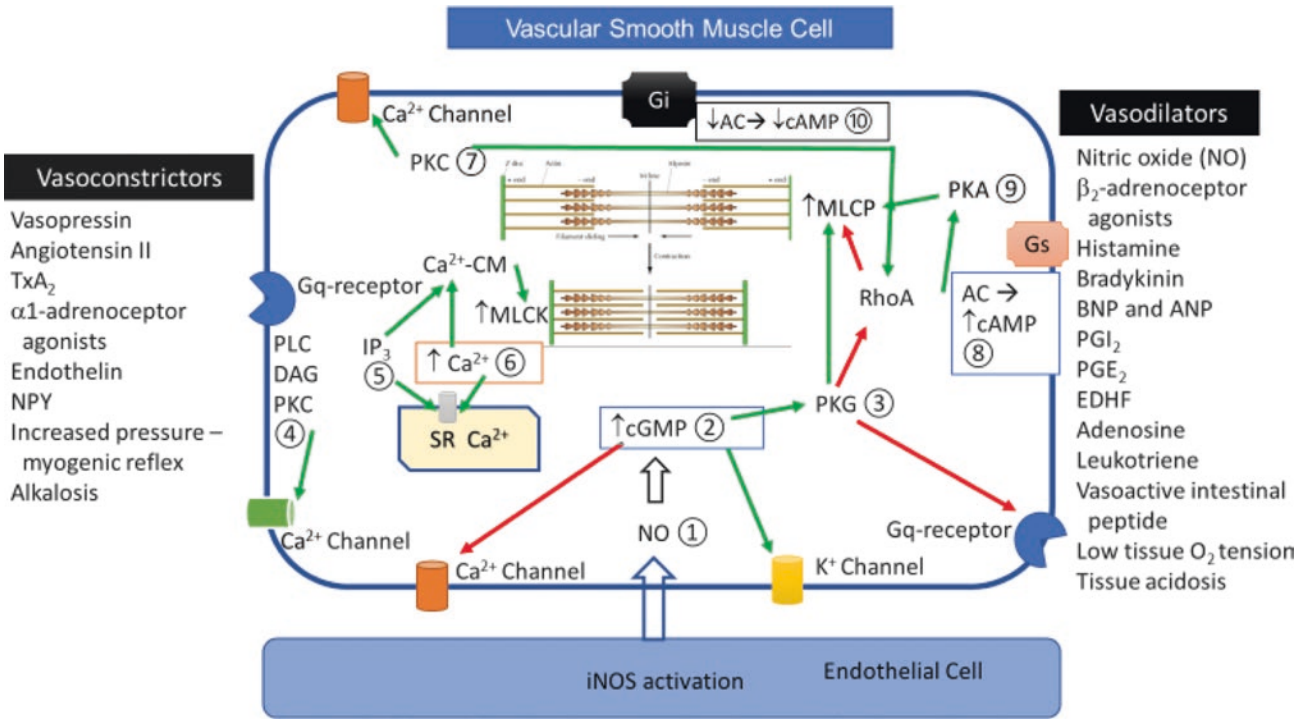

Fig. 20.7 A portion of the complex factors affecting vascular tone are illustrated. A host of mediators stimulate either smooth muscle contraction or relaxation through action at specific G-protein-coupled receptors. ① Nitric oxide (NO) is derived from endothelial cells under a variety of stimuli. Inducible nitric oxide synthase (iNOS) is an important source of increased NO production; in sepsis models, NO production increases more than 1000-fold. NO activates soluble guanylate cyclase to increase cGMP production. ② cGMP inhibits (red arrow) the opening of voltage-gated Ca^{2+} channels and opens a specific K+ channel leading to hyperpolarization, which reduces intracellular Ca^{2+}. ③ cGMP activates protein kinase G (PKG), which phosphorylates RhoA and other proteins (not shown); RhoA phosphorylation inhibits RhoA's inhibitory effect on myosin light-chain phosphatase (MLCP). PKG also phosphorylates and thus activates MLCP, which reduces actin-myosin coupling. ④ When a vasoconstricting agonist binds to the Gq-coupled G-protein receptor complex, phospholipase C (PLC) is activated, which generates 1,2-diacylglycerol (DAG) and 1,4,5-inositol triphosphate (IP_3). DAG activates protein kinase C (PKC), which phosphorylates a number of kinases (not shown) with the net effect of increasing actin-myosin interaction and thus smooth muscle contraction; IP_3 also increases the activity of the Ca^{2+}-calmodulin complex. The α_1-Gq adrenoceptor complex opens a receptor-operated calcium channel increasing intracellular Ca^{2+} concentration. ⑤ IP_3 opens a channel on the sarcoplasmic reticulum (SR) to release stored Ca^{2+} into the cytoplasm. ⑥ Increased intracellular Ca^{2+} concentration increases the interaction with calmodulin (CM); the Ca^{2+}-CM complex activates myosin light-chain kinase (MLCK), an important enzyme that increases actin-myosin coupling. ⑦ PKC also opens voltage-gated Ca^{2+} channels increasing the intracellular Ca^{2+} concentration. ⑧ When a vasodilating agonist binds to its Gs-coupled receptor, adenylate cyclase (AC) is activated, which increases cAMP production. ⑨ cAMP activates protein kinase A (PKA); among its actions, PKA activates MLCP, which reduces actin-myosin coupling. In addition, PKA phosphorylates MLCK, which inhibits its activity (not shown). ⑩ Agonist binding to α_2-Gi-coupled adrenoceptors inhibits adenylate cyclase, reducing cAMP production. Red arrows show inhibitory pathways; green arrows activate the target. There are several different Ca^{2+} and K^+ channels which are regulated by kinases and phosphatases (not shown). EDHF is endothelial-derived hyperpolarizing factor; TxA_2 is thromboxane; NPY is neuropeptide Y; BNP and ANP are B-type and atrial natriuretic peptides, respectively; PGI_2 is prostacyclin; PGE_2 is prostaglandin E_2

tive infusion. In addition, clinicians should be aware of how other therapeutic interventions may modulate the patient's response. For example, using sedative agents reduces the patient's SNS response, which may result in the need for a higher vasoactive infusion rate; conversely, as sedation is withdrawn, the patient often needs less vasoactive support. Giving corticosteroids increases the expression and responsiveness at β-adrenoceptors; thus, a lower inotrope infusion may be required. Finally, it is important to recognize that critical illness is a dynamic process; thus, the patient's endogenous response and local mediator production in addition to changes in organ function and blood flow (i.e., changes in drug pharmacokinetics) will impact the pharmacodynamics observed. Textbook infusion rates are helpful starting points for an infusion, but clinicians need to be aware of how alterations in organ function and the

patient's stress response may modulate the response; ultimately the patient's response is the most important determinant of either beneficial or harmful effects.

20.3 Specific Agents and Clinical Indications

20.3.1 Norepinephrine

20.3.1.1 Pharmacology

Norepinephrine (NE) is the principle neurotransmitter of the SNS. Like other catecholamines, NE is degraded in the liver and kidney by methylation via catechol-O-methyltransferase (COMT) or by deamination via monoamine oxidase (MAO). NE is also cleared from the circulation by reuptake at nerve terminals (uptake-1) and in nonneuronal tissues by uptake-2. It has a short half-life of 2–2.5 minutes. The usual dosage range for NE is 0.01–1 mcg/kg/min.

20.3.1.2 Clinical Effects

NE is a potent adrenergic agonist acting primarily on the α_1- and β_1-adrenoceptors with little effect at β_2-adrenoceptors, so it increases systemic vascular resistance, mean arterial pressure, and myocardial oxygen consumption (MVO_2) while stimulating increased inotropy. Many reviews and textbooks state that NE is a weak inotrope. This is based on studies showing that it may not increase cardiac output when blood pressure is increased. However, these actions on cardiac output are due to the effect of NE to increase blood pressure, which activates the baroreceptor reflex resulting in a reduced heart rate. The increased afterload from its peripheral vascular effects also limit the increased stroke volume expected from its inotropic effect. Recall that NE is the neurotransmitter released at the myocardial innervated β_1-adrenoceptors, and thus it is expected to have significant inotropic effects. In patients with hypotension or low blood pressure and cardiac output, especially patients with evidence of vasoplegia, the baroreceptor reflex is not stimulated by an NE-induced increase in systemic vascular resistance; thus, NE-mediated inotropic effects increase stroke volume and cardiac output.

NE has a reduced chronotropic effect compared with Epi since it has weak action at the atrial β_2-adrenoceptors. It also increases venous tone, which may increase end-diastolic pressure and MVO_2. NE may increase PVR, especially in patients with increased pulmonary vascular muscularization. Historically its use was limited by fear of mesenteric and renal ischemia; however, recent evidence suggests its use in septic patients after volume resuscitation may restore perfusion to susceptible vascular beds by reestablishing mean arterial pressure. In addition, norepinephrine may promote synthesis of prostaglandins that attenuate renal afferent arteriolar vasoconstriction.

In cardiogenic shock, NE is considered the drug of choice. A recent multicenter clinical trial comparing NE to Epi in adults with postinfarction cardiogenic shock was stopped prematurely because of a significant increase in mortality and refractory shock in the Epi arm.

Norepinephrine is an excellent pressor choice for shock states characterized by excessive vasodilation. Although often considered only a vasoconstrictor, NE possesses potent inotropic activity at the myocardial β_1-adrenoceptor.

Low binding affinity for β_2-adrenoceptors limits the chronotropic effects of NE.

20.3.1.3 Clinical Indications

NE like all other vasoactive agents should be used only when intravascular volume is adequate. Clinical conditions appropriate for its use include:

- Hyperdynamic (i.e., vasodilated) septic shock
- Neurogenic shock
- Cardiogenic shock
- Tricyclic antidepressant toxicity producing shock

20.3.1.4 Adverse Effects

NE increases MVO_2 by increasing contractility, afterload, and ventricular end-diastolic pressure. Since NE does not act at atrial β_2-adrenoceptors, it has little effect on heart rate, which also may be suppressed if the increase in SVR increases the blood pressure and reflexively increases vagal activity. Improper use of NE (i.e., without adequate volume loading) decreases end-organ perfusion leading to ischemia, especially in the kidney and gut. Like other α-adrenergic agonists, NE increases tone in the venous system, which increases mean systemic pressure that facilitates increased venous return. Since the normal pulmonary vasculature has limited muscularization (see ▶ Chap. 15: Regional Circulation), NE often has little effect on PVR, but in a patient with pulmonary hypertension and/or increased muscularization of the pulmonary vasculature, NE will increase pulmonary vascular resistance and thus increase right ventricular afterload. Due to the sparsity of cerebral vascular and coronary adrenoceptors, these circulations are at reduced risk from the vasoconstrictor effects of NE.

Although NE is often considered a vasoconstrictor, it is the neurotransmitter released from sympathetic nerves and thus has high affinity for cardiac β_1-adrenoceptors. Therefore, it produces inotropic actions in addition to increasing vascular resistance. NE has little effect at β_2-adrenoceptors so there is little effect on the atrial pacemaker. In cardiogenic shock, adult studies show that NE is superior to Epi.

Extravasation can lead to severe tissue necrosis; therefore, infusion should be limited to central venous sites. Local extravasation can be treated by infiltrating the α-adrenergic antagonist phentolamine into the affected area.

20.3.2 Epinephrine

20.3.2.1 Pharmacology

Epinephrine (EPI) is an endogenous catecholamine synthesized mainly in the adrenal medulla. It has a very short half-life (2–3 minutes) and is degraded by COMT and MAO.

20.3.2.2 Clinical Effects

EPI acts on the α_1-, α_2-, β_1-, and β_2-adrenoceptors in a dose-dependent fashion. As noted previously, at low infusion doses, the hormonal β_2-adrenoceptors are first affected; higher epinephrine concentrations are required to reach the innervated α_1- and β_1-receptors. Thus, at low infusion doses, the prominent action is vasodilation, especially in the skeletal muscle vascular bed, combined with an increase in heart rate and some increase in contractility mediated by β_2-adrenoceptor stimulation. These actions help redirect blood flow to the muscles to help either fight or flee a predator. Clinically, the reduced SVR is manifested by a fall in the diastolic blood pressure with an increased pulse pressure due to improved stroke volume and often an increased systolic blood pressure. As the infusion rate is increased further (>~0.1 mcg/kg/min), action at the α_1-adrenoceptor counteracts the vasodilating action and begins to dominate with a rise in both the systolic and diastolic blood pressure. Contractility and heart rate increase further due to β_1 effects with increased infusion dose. In addition, at higher infusion doses, Epi increases tone in the veins through α_1-adrenoceptor activation, which decreases their compliance and increases venous return, further supporting the increase in cardiac output. Increased cardiac output likely increases pulmonary artery pressures rather than the pressure being increased by pulmonary artery vasoconstriction. In patients with preexisting pulmonary hypertension, Epi can significantly increase PVR, but in normal patients, this is not an important hemodynamic effect. Epi also relaxes smooth muscle in the airways and GI tract and EPI has a variety of metabolic effects such as increasing ketogenesis, glycolysis, and gluconeogenesis.

20.3.2.3 Clinical Indications

Epi is the vasoactive agent of choice in cardiac arrest (0.01 mg/kg/dose IV/IO or 0.1 mg/kg/dose intratracheally) and many postarrest situations. It is also the drug of choice to treat anaphylaxis. At cardiac arrest doses, EPI dramatically increases SVR, which leads to improved coronary and cerebral perfusion pressures even though global cardiac output is reduced. High-dose epinephrine in arrest situations is not beneficial and may be harmful; therefore, it should not be routinely used.

Historically, in children with low cardiac output and hypotension seen in cardiogenic shock, hypodynamic septic shock, and postarrest situations, Epi was used as a continuous infusion (usual dosage ranges from 0.01 to 1 mcg/kg/min). Studies in adults, however, showed that NE is preferred in cardiogenic and hypodynamic septic shock. Epi may also be used in cases of anaphylaxis where a degree of myocardial dysfunction exists. In addition, Epi may benefit patients with anaphylaxis since it is a bronchodilator and inhibits mast cell degranulation. Epi in conjunction with a vasodilator such as nitroprusside may improve distal perfusion in low cardiac output and high SVR states.

Epinephrine may be used initially in the postarrest setting; however, transition to a more appropriate cardiovascular regimen such as norepinephrine with or without dobutamine is recommended.

Epinephrine acts at all adrenergic receptors; at low infusion doses, the action at the β_2-adrenoceptors is responsible for much of its hemodynamic effect.

20.3.2.4 Adverse Effects

Although EPI increases coronary perfusion due to its effects on increasing perfusion pressure at higher infusion doses, at lower infusion doses, diastolic blood pressure falls secondary to reduced systemic vascular tone by its β_2-adrenergic effect; pulse pressure increases since systolic blood pressure is also increased by its positive inotropic effect. However, increased contractility and heart rate increase MVO_2 which increases coronary blood flow. At higher infusion doses that increase SVR, Epi increases afterload. When combined with the increase in heart rate, MVO_2 is markedly increased, which is not favorable in the patient with cardiogenic shock. Its potential to cause myocardial ischemia is of importance in adults with coronary disease.

EPI increases automaticity and may be arrhythmogenic causing ventricular tachyarrhythmias. Metabolic effects of EPI (◘ Table 20.4) include hypokalemia (β_2-adrenoceptor-mediated K^+ influx into muscle cells) and hyperglycemia (increased glycolysis, gluconeogenesis, and suppressed insulin release). To support gluconeogenesis, EPI increases the release of lactate from skeletal muscle that is used by the liver for glucose synthesis (Cori cycle). Thus, an increased lactate concentration is commonly observed when using an epinephrine infusion, limiting lactate's use as a marker of tissue perfusion. Of note, when lactate rises due to Cori cycle activation, there is *no* metabolic acidosis as compared with increased lactate concentrations associated with inadequate tissue perfusion. Extravasation injury is also a potential complication.

A recent randomized controlled trial comparing NE to Epi in cardiogenic shock due to an acute MI documented a significantly higher incidence of refractory cardiogenic shock and lactic acidosis associated with Epi despite similar increases in cardiac output. The heart rate was significantly higher in the Epi group, and the trial was stopped by the safety board because of the adverse effects associated with Epi. This is consistent with the different actions of these catecholamines; endogenous Epi likely helped a species survive in a world with predators by increasing cardiac output, glucose, and blood flow to skeletal muscles. Unfortunately, these actions redirect blood flow from the splanchnic and renal circulation in sepsis models. Thus, Epi often increases global cardiac output, but renal and splanchnic perfusion and thus function may be compromised.

Epinephrine has important hemodynamic and metabolic effects that may limit its effectiveness as a vasoactive agent. Low to moderate doses tend to redirect the increased cardiac output to skeletal muscles and away from the splanchnic and renal circulations. Glucose and lactate concentrations increase, and potassium concentration falls during an Epi infusion.

Table 20.4 Noncardiovascular effects of vasoactive agents

Noncardiovascular effect	Mechanism	Receptor (agent)
Metabolic		
Increased glucose concentration	↑ Skeletal muscle and liver glycogenolysis ↑ Hepatic gluconeogenesis ↑ Glucagon release ↓ Pancreatic insulin release	β_2-adrenoceptors (Epi) β_2-adrenoceptors (Epi) β_2-adrenoceptors (Epi) α_2-adrenoceptor (Epi)
Increased lactate concentration	↑ Skeletal muscle release (Cori cycle)	β_2-adrenoceptors (Epi)
Decreased K^+ concentration	Movement into muscle cells	β_2-adrenoceptors (Epi, albuterol)
Endocrine		
↓ TRH, prolactin, LH, growth hormone	Decreased release of hormones from anterior pituitary	DA_2 receptor (dopamine)
↓ TSH	Inhibits TRH-stimulated release of TSH from thyroid	DA_2 receptor (dopamine)
↓ Renin release from juxtaglomerular cells	Indirect effect of receptor activation	DA_1 receptor (dopamine)
↑ ACTH release from pituitary gland	Acts synergistically with corticotropin releasing factor	V_{1b} receptors (vasopressin and oxytocin)
Immune, hematologic		
Transient T-cell hyporesponsiveness	Secondary to lower prolactin levels	DA_2 receptor (dopamine)
Increased PMN concentration	Demargination of PMNs	β_2-adrenoceptor (Epi)
Decreased mast cell response	Inhibit release of histamine and leukotrienes from mast cells	β_2-adrenoceptor (Epi)
Decreased endotoxin-induced release of proinflammatory mediators	Inhibition of lymphocyte, macrophage activation, mediated by increased intracellular cAMP	β_2-adrenoceptor (Epi) Milrinone
Decreased levels of circulating proinflammatory mediators		Levosimendan, vasopressin
Increased platelet aggregation response	Appears to increase platelet sensitivity to aggregating agents such as fibrin	α_2-adrenoceptor (Epi)
Increased coagulation	Vasopressin stimulates the release of von Willebrand factor	V_2 receptors

K+ potassium, *TRH* thyroid releasing hormone, *TSH* thyroid-stimulating hormone, *LH* luteinizing hormone, *PMN* polymorphonuclear leukocyte

20.3.3 Phenylephrine

20.3.3.1 Pharmacology

Phenylephrine is a selective α_1-adrenergic agonist. It is structurally similar to epinephrine, only lacking a hydroxyl group. It has a rapid onset and short duration of action (5–10 min) and can be given as a bolus (5–20 mcg/kg/dose) or continuous infusion (0.1–0.5 mcg/kg/min).

20.3.3.2 Clinical Effects

Phenylephrine causes significant arterial vasoconstriction and thus elevates SVR and PVR. It has no inotropic properties; therefore, if cardiac function is impaired, cardiac output may be reduced by the increase in afterload even though the blood pressure increases.

20.3.3.3 Clinical Indications

Phenylephrine has limited clinical uses. It may be helpful in cases of hypotension due to spinal shock or during spinal anesthesia. It may also be used to elevate SVR and promote pulmonary blood flow (by reversing shunt) in cases of hypercyanotic spells associated with tetralogy of Fallot.

20.3.3.4 Adverse Effects

Adverse effects are primarily due to decreased end-organ perfusion. Renal and splanchnic ischemia are of particular concern. Phenylephrine should be avoided in patients with pulmonary artery hypertension.

20.3.4 Dobutamine

20.3.4.1 Pharmacology

Dobutamine was developed by systematic modification of the catecholamine molecule in a search for a selective inotropic agent with limited peripheral vascular effects. Unlike other commonly infused catecholamines, dobutamine consists of two isomers having different adrenergic activity, which achieves its desired hemodynamic effect:

(+) Isomer	Strong β_1, β_2 agonist and α_1 *antagonist*
(−) Isomer	Weak β_1, β_2 agonist and α_1 *agonist*

Dobutamine has a unique pharmacologic action due to opposing actions of the two isomers on α_1 adrenoceptors resulting in mainly β-adrenoceptor stimulation. In addition, a long-lasting active metabolite has α_1 antagonist activity.

The pharmacokinetics of dobutamine are unclear with both linear and nonlinear kinetics reported. The half-life is ~2 minutes and it is metabolized by COMT. The 3-O-methyldobutamine metabolite is also a potent α-adrenergic antagonist and may add to the vasodilating action seen with dobutamine, especially if terminal renal elimination of the metabolite is impaired. The usual dosage range for a continuous infusion of dobutamine is 2.5–20 mcg/kg/min, although as with other vasoactive agents wide interindividual variation was observed in children with clearance varying over a 40-fold range.

20.3.4.2 Clinical Effects

Excess vasodilation and hypotension may be seen in some patients receiving dobutamine secondary to its intrinsic α_1-adrenoceptor blocking activity.

The net effect of the combined isomers is significant inotropy with trivial, if any, α_1-mediated vasoconstriction. Dobutamine's β_2 effects and intrinsic α-adrenergic antagonist activity counter its α_1-adrenergic vascular effects, with net vasodilation in most patients. Dobutamine's β_2 effects are thought to decrease SVR and PVR; however, endogenous sympathetic withdrawal once cardiac function is improved likely contributes to the reduction in SVR. In

addition, the intrinsic α-adrenergic antagonist activity of the (+)-isomer and metabolite contributes to reduced SVR and PVR. Dobutamine's intrinsic α-adrenergic antagonist activity suggests that it should be used cautiously in vasoplegic shock since it may further lower SVR. The combination of dobutamine and NE has been recommended in adults to selectively adjust SVR and improve cardiac contractility.

Dobutamine is less likely to produce tachycardia and arrhythmias than Epi or dopamine. Like other β-adrenergic agonists, dobutamine also improves diastolic relaxation (lusitropy). With its limited α_1 effects, dobutamine may be safer for peripheral venous administration while central access is being obtained.

20.3.4.3 Clinical Indications

Dobutamine can improve cardiac function in the failing heart. Its cardiovascular profile and short half-life make it a good initial choice for the child in congestive heart failure (e.g., myocarditis, cardiomyopathy). Transition to a phosphodiesterase inhibitor can be made later in the child's course if necessary. Dobutamine can be used in conjunction with other agents (e.g., NE or Epi) in the child with low CO and hypotension and may be useful combined with NE in children with vasoplegic septic shock. Adult studies observed that combination treatment with dobutamine and NE is superior to Epi or dopamine in patients with postarrest cardiac dysfunction.

20.3.4.4 Adverse Effects

Although dobutamine can improve myocardial performance, often without significant tachycardia, it still increases MVO_2. Ischemia with high dosing or prolonged use may rarely occur. Tachydysrhythmias are a risk, but less so than with epinephrine or dopamine. As noted above, hypotension may be worsened when used in vasoplegic shock. Dobutamine often has no metabolic side effects, but increased glucose and decreased potassium concentration may be observed.

20.3.5 Dopamine

20.3.5.1 Pharmacology

Dopamine is an intermediary compound in the production of EPI and NE. The half-life is approximately 2 minutes. Exogenous dopamine interacts with dopaminergic and adrenergic receptors in a dose-related fashion; however, the latter action is mediated largely by dopamine-stimulating NE release from sympathetic nerve terminals. Thus, dopamine is categorized as an indirect-acting catecholamine. This has clinical implications, since, as noted previously, chronically stressed patients deplete their sympathetic nerve NE stores; thus, dopamine's cardiac effects are attenuated in this setting.

Dopamine has a direct effect through dopamine receptors on renal tubules enhancing natriuresis.

Dopamine clearance appears to be age-related. In general, children under 2 years of age have a significantly greater rate of clearance and may require higher infusion rates to produce desired clinical effects, although wide interindividual variation (up to 10- to 20-fold) in clearance is observed. Concomitant administration of dobutamine causes dopamine clearance to increase linearly, perhaps due to improved renal and hepatic perfusion.

20.3.5.2 Clinical Effects

When dopamine is administered, its effects are dose-related, with the caveats regarding variation in pharmacokinetics noted previously:

Low dose (1–5 mcg/kg/min)	$DA_1 > \beta > \alpha_1$	Renal/splanchnic vasodilation, natriuresis
Intermediate dose (5–8 mcg/kg/min)	$\beta > \alpha_1 > DA_1$	Increased inotropy/chronotropy
High dose (> 10 mcg/kg/min)	$\alpha_1 > \beta > DA_1$	Increased SVR, PVR

20.3.5.3 Clinical Indications

Historically, low-dose dopamine was thought to improve renal perfusion and prevent progressive renal dysfunction. However, any improvement in renal perfusion and urine output is likely primarily due to maintaining an appropriate mean arterial pressure and cardiac output. Multiple clinical studies showed no benefit of low-dose dopamine in preventing renal dysfunction in normotensive patients. Based on the lack of clinical evidence and the potential for adverse endocrinologic and immunologic effects, infusing low-dose dopamine as a therapeutic option in the prevention or treatment of acute renal failure should be abandoned.

For children with poor cardiac function, a direct-acting vasoactive agent is preferred to an indirect-acting agent such as dopamine. A recent study randomized 120 children with fluid-refractory septic shock to dopamine or epinephrine; mortality was significantly increased in the dopamine group. In addition, healthcare-associated infections were significantly more common in the dopamine group, whereas hyperglycemia was more common in the epinephrine group. Thus, the role of dopamine in the management of shock remains limited.

There is little to no evidence to support the use of renal low-dose dopamine in children with shock; direct-acting vasoactive agents are preferred.

20.3.5.4 Adverse Effects

At high doses, α_1-adrenergic effects may cause clinically significant impairment of end-organ perfusion. Extravasation injury and dysrhythmias (especially supraventricular) may occur. There also is concern that dopamine may compromise immune function by decreasing serum prolactin concentration, therefore increasing susceptibility to infection. In addition, dopamine suppresses TSH release from the anterior pituitary gland prolonging recovery from euthyroid sick syndrome and raising the concern that dopamine may suppress thyroid function. The thyroid axis cannot be tested if the patient is on a dopamine infusion since dopamine potently suppresses TRH-stimulated TSH release. Because of these concerns, the use of dopamine as a primary cardiovascular agent is decreasing.

Dopamine has potentially important effects on endocrine function, which is a further reason to limit its use.

20.3.6 Isoproterenol

20.3.6.1 Pharmacology

Isoproterenol (ISO) is a synthetic derivative of NE where an isopropyl group is added to the N-terminal. The isopropyl addition changes the receptor affinity such that there is potent β-adrenergic activity but no α_1 activity. ISO has a half-life of ~2 minutes. The usual dosage range for ISO is 0.01–1 mcg/kg/min.

20.3.6.2 Clinical Effects

As a pure β_1 and β_2 agonist, ISO increases inotropy and chronotropy while decreasing SVR and PVR and relaxing venous tone. Due to its strong β_2 activity, ISO also causes bronchodilation, and it antagonizes hypoxic pulmonary vasoconstriction, which can increase intrapulmonary shunt.

By increasing both heart rate and contractility, ISO increases MVO_2, but its potent effects on SVR may decrease coronary diastolic blood flow due to lowering diastolic blood pressure; marked tachycardia further adds to the risk of myocardial ischemia by decreasing the time for diastolic coronary blood flow. Therefore, ISO should be avoided in children with specific heart conditions (see below).

20.3.6.3 Clinical Indications

With its potential to cause myocardial ischemia and the advent of newer vasoactive agents, ISO has limited clinical utility. It is most often used in cases of refractory bradycardia (especially in the transplanted heart). It may be useful in severe asthma when no underlying heart disease exists, although selective β_2-adrenergic agonists are preferred.

20.3.6.4 Adverse Effects

Isoproterenol is a potent β-adrenoceptor agonist, but its potent vasodilating effects and marked tachycardia increase the risk of myocardial ischemia. It is mainly indicated in patients with refractory bradycardia. Isoproterenol should be avoided in children with left ventricular outflow tract obstruction, shunt lesions with low diastolic blood pressure, ischemic heart disease, and arrhythmias.

ISO is contraindicated in children with obstruction of the left ventricular outflow tract (e.g., subaortic stenosis, hypertrophic cardiomyopathy), as it increases the outflow pressure gradient. It also should be avoided in children with lesions associated with low diastolic pressures (e.g., systemic-pulmonary shunts and aortic regurgitation), as it will further decrease diastolic pressure and coronary filling. ISO is contraindicated in any child with ischemic heart disease and it may cause tachydysrhythmias. Although ISO is a potent bronchodilator, its nonselective β-adrenergic effects results in excessive tachycardia compared with β_2-adrenoceptor selective agents; thus, myocardial ischemia has occurred in children with status asthmaticus treated with ISO. Finally, like other potent β_2-adrenergic agonists, ISO causes potassium to move into cells, reducing the plasma concentration and perhaps increasing the risk for arrhythmias, especially in the patient who is already hypokalemic.

20.3.7 Vasopressin

20.3.7.1 Pharmacology

Arginine vasopressin is produced in the paraventricular nucleus of the hypothalamus and transported via neuronal axons to the posterior pituitary for secretion. Also known as antidiuretic hormone (ADH), vasopressin is released in response to hemodynamic, osmotic, and nonosmotic stimuli.

When the peripheral and central osmoreceptors sense an increased plasma osmolality, vasopressin is released from the posterior pituitary. Multiple nonosmotic stimuli such as pain, nausea, hypercarbia, hypoxia, and stress associated with catecholamine release all can stimulate vasopressin release. This may result in excessive free water conservation and the syndrome of inappropriate ADH release. Decreased effective circulating volume is a potent stimulus for the *appropriate* release of ADH. During hypovolemia, baroreceptors and stretch receptors located in the left atrium, aortic arch, and carotid sinus respond to reduced pressure and volume by stimulating the release of vasopressin from the posterior pituitary.

Vasopressin has multiple hemodynamic effects including V_1 receptor-mediated vascular smooth muscle contraction and endothelial NO-mediated selective vasodilation of the cerebral and pulmonary circulations.

Vasopressin has multiple physiologic effects dependent upon specific receptor interaction. Three G-protein-coupled vasopressin receptors, termed V_{1a}, V_{1b}, and V_2, have been characterized. V_{1a} receptors are widely distributed and occur mainly on vascular smooth muscle; receptor binding activates the phospholipase C-phosphatidylinositol pathway increasing cytosolic Ca^{++} that mediates vascular smooth muscle contraction. Vasopressin may also restore vascular tone by blocking potassium-sensitive adenosine triphosphate (K^+-ATP) channels; inhibition of these channels increases Ca^{++} entry into the cytosol, ultimately causing vasoconstriction. Vasodilation of cerebral and

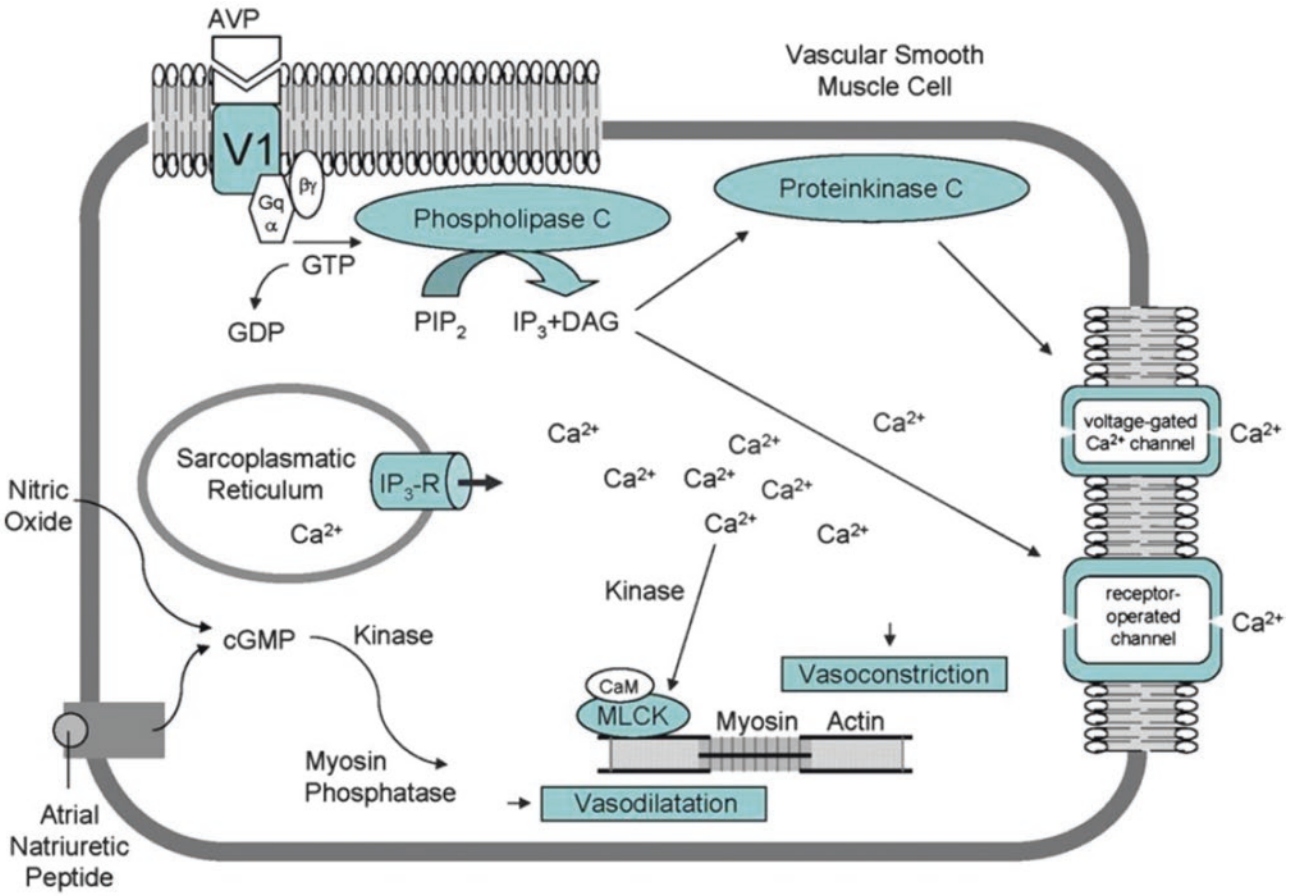

Fig. 20.8 Signal transduction of vasopressin (VP) analogues on V1 receptor (V1R) in vascular smooth muscle cells. Abbreviations: CaM, calcium-calmodulin complex; GDP, guanosyl diphosphate; Gq α, β, γ, G-protein subunits; GTP, guanosine triphosphate; MLCK, myosin light-chain kinase; black arrows, activation of pathways. (Figure used with express permission from Maybauer MO, Maybauer DM, Enkhbaatar P, Traber DL. Physiology of the vasopressin receptors. Best Practice and Research Clinical Anesthesiology. 2008;22(2):253–263)

pulmonary circulations by a low-dose vasopressin infusion is likely secondary to the induction of endothelial nitric oxide (Fig. 20.8).

V_{1b} receptors are expressed in the anterior pituitary; receptor stimulation increases adrenocorticotrophic hormone (ACTH) and endorphin release. V_2 receptors are expressed predominantly in the renal collecting duct system; vasopressin receptor binding mediates an antidiuretic effect in the renal collecting ducts conserving free water during hypertonic and/or hypovolemic states. Vasopressin also acts at oxytocin and purinergic receptors, which stimulate endothelial nitric oxide production. In the pulmonary vascular bed, vasopressin action at oxytocin receptors reduces PVR; thus, vasopressin may be useful in a deteriorating patient with severe pulmonary hypertension by increasing SVR and coronary perfusion pressure while not worsening PVR.

Whereas concentrations of ADH necessary to regulate water reabsorption are extremely low (1–7 pg/mL), higher concentrations are needed to produce vasoconstriction (10–200 pg/mL). Despite high levels of ADH during states of decreased effective circulating volume, osmoregulation often is kept intact. This is due to alterations in the relationship between plasma osmolality and vasopressin such that higher vasopressin levels are required to maintain normal osmolality in the setting of hypovolemia.

The half-life of vasopressin is 6–20 min. It is metabolized by a variety of peptidases in the liver and kidney. The usual dosage range used for hemody-

namic effects is 0.00017–0.008 U/kg/min (equivalent to 0.17 mU/kg/min–8 mU/kg/min). Studies in adults have used doses of 0.04–0.06 U/min to produce peripheral vasoconstriction. Terlipressin (tricyl-lysine-vasopressin, not FDA-approved) is a synthetic prodrug form of vasopressin that has comparable pharmacodynamics; vasopressin is slowly released by enzymatic action on the prodrug. The half-life of terlipressin is ~6 h, and its duration of action is 2–10 h, as opposed to the short half-life and duration of action (30–60 min) of vasopressin.

20.3.7.2 Clinical Effects

Vasopressin has important vasoconstrictor activity during states of hypotension due to excessive vasodilation. Vasopressin levels are acutely elevated during hemorrhagic and septic shock. However, if hemodynamic instability continues (particularly in cases of vasodilatory septic shock), vasopressin levels fall dramatically. Decreased vasopressin levels may be secondary to depletion of pituitary stores and due to nitric oxide inhibition of vasopressin release.

Vasopressin potentiates the vasoconstrictor effects of catecholamines and in septic shock can reduce the need for NE to support the blood pressure; however, these effects are diminished or absent in certain regional circulations; specifically, the cerebral, coronary, and pulmonary circulations are not as sensitive to vasopressin-induced vasoconstriction. As noted previously, these regional effects are likely due to V_1 and oxytocin receptor-mediated release of endothelial-derived nitric oxide in those vascular beds. Vasopressin selectively constricts the glomerular efferent arteriole raising glomerular filtration pressure; clinical studies in septic patients show improved creatinine compared with NE use. In a large randomized trial (VASST trial) of vasopressin + NE vs. NE alone in septic shock, patients with less severe renal injury had improved survival with the combination therapy. One limitation of this study is that fixed doses of both drugs were used, ignoring the likely variation in pharmacokinetics and pharmacodynamics discussed above.

Vasopressin may have negative inotropic effects mediated by NO. In normal subjects, it decreases cardiac output by stimulating the baroreflex (increased SVR and blood pressure causing reflexive bradycardia).

In patients hypotensive due to vasoplegia, vasopressin administration does not produce an antidiuretic effect; instead, urine output often increases, which is thought to be secondary to improved hemodynamics and glomerular filtration pressure.

20.3.7.3 Clinical Indications

The clinical pharmacology of vasopressin suggests it may be of value in refractory vasodilatory shock. Its action is not dependent on the adrenergic system and thus may be used in settings where NE or Epi are not effective. However, adult and limited pediatric data failed to demonstrate improved outcomes when using low-dose vasopressin versus norepinephrine in septic shock. A multicenter randomized controlled trial of low-dose vasopressin in vasodilated pediatric shock observed a worrisome, but not significant, increase in overall mortality (69 total patients, 30% mortality in vasopressin arm vs. 15% mortality in placebo arm). A meta-analysis supports the use of vasopressin or terlipressin for renal insufficiency in hepatorenal syndrome.

During adult CPR, vasopressin alone or combined with epinephrine had no beneficial effects on outcome. Therefore, the 2015 American Heart Association treatment recommendations for cardiac arrest removed vasopressin from the ACLS guidelines for out-of-hospital cardiac arrest. However, based on the results from two randomized controlled trials, vasopressin combined with corticosteroids (methylprednisolone) and epinephrine may be con-

sidered for in-hospital adult arrests. Due to the lack of any trial data, vasopressin has no current role during pediatric CPR.

Unlike other vasoconstricting agents, animal studies and limited clinical data show that vasopressin can reduce pulmonary vascular tone, especially if it is increased at baseline. Studies in isolated human pulmonary arteries did not show that vasopressin induced vasoconstriction. Several case series reported that unlike other vasopressors, vasopressin may be helpful in the management of refractory pulmonary hypertensive crisis by increasing SVR to improve coronary perfusion pressure while not worsening and indeed potentially reducing PVR. Similarly, in patients with chronic hepatic dysfunction, pulmonary hypertension may develop. Case reports suggest that vasopressin/terlipressin may have favorable effects in this setting by increasing SVR while improving PVR.

20.3.7.4 Adverse Effects

Adverse effects are mainly secondary to its vasoconstrictor effects. Though vasoconstriction is less pronounced in the coronary circulation, myocardial ischemia can occur especially with underlying heart disease.

Unlike all other vasoconstricting agents, vasopressin may reduce PVR through stimulation of NO release mediated by action at pulmonary endothelial oxytocin receptors. Thus, it may be useful in unstable patients with pulmonary hypertension and in patients with portopulmonary hypertension. Since it acts through a non-adrenergic mechanism, vasopressin may be useful in vasoplegic shock that is adrenergic-unresponsive.

20.4 Vasodilators for Circulatory Support

20.4.1 Physiologic Effects

There are several common misconceptions regarding the action of vasodilators when used to support the circulatory system. For example, publications often state that vasodilators are used to improve cardiac output and reduce venous return, but this statement is physiologically impossible since at steady state cardiac output must equal venous return. The misperception results from the effect of vasodilators on venous and atrial compliance; a decrease in CVP or left atrial/pulmonary wedge pressure (LAP/PWP) is perceived to represent a decline in venous return. Instead, by reducing tone in the venous capacitance system, where ~70% of blood volume is normally located (see ▶ Chap. 15, Regional Circulation), venous compliance is increased so that a given volume in the atria is associated with a lower filling pressure (◘ Fig. 20.9).

As seen in ◘ Fig. 20.9, vasodilators shift the ventricular pressure-volume curve (i.e., compliance). If the patient receives fluid to increase the venous filling pressure back toward the previous level, preload (i.e., end-diastolic volume) is increased since a higher volume is now in the heart at a lower pressure.

At steady state, cardiac output must equal venous return. Thus, vasodilator-induced improvement in cardiac output is associated with a concomitant increase in venous return as the increased venous compliance allows a higher volume in the venous system at a lower filling pressure.

Vasodilators are also assumed to routinely decrease blood pressure secondary to the reduction in SVR. If the patient has inadequate intravascular volume, blood pressure will fall, but in patients with poor cardiac function, regulatory mechanism such as increased SNS activity, renin-angiotensin-aldosterone activation and increased vasopressin release all increase peripheral vascular resistance to maintain perfusion pressure as stroke volume (SV) falls. As seen in ◘ Fig. 20.10, a series of curves illustrate the relationship between SVR and SV; as cardiac pumping function declines, stroke volume declines as SVR rises. Recall that cardiac output (CO) = (MAP – CVP)/SVR, where MAP is mean arterial pressure and CVP is central venous pressure. If HR is kept constant, then SV ∝ (MAP – CVP)/SVR. In a patient with normal contractility, as seen in the top curve, increasing SVR from point A to B has little effect on SV; instead, the blood pressure increases. This relationship continues until the increased afterload reaches a point where the ventricle is no longer able to overcome the vascular resistance and then SV begins to fall.

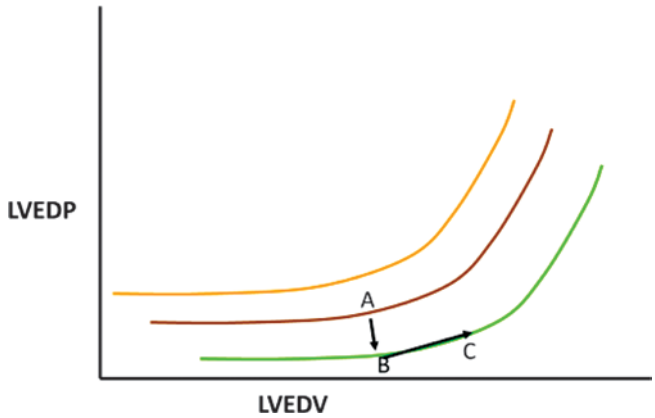

Fig. 20.9 Left ventricular compliance curves are illustrated, where LVEDP is left ventricular end-diastolic pressure and LVEDV is left ventricular end-diastolic volume. The middle curve illustrates a patient with increased LVEDP and moderate ventricular filling. Adding a vasodilator shifts the curve down so that a slightly higher LVEDV (point B) is associated with a lower LVEDP illustrating that filling pressures often do not reflect the end-diastolic volume. If fluid is given after the vasodilator to increase filling pressure, note at point C that a much higher preload is achieved without raising the LVEDP to the same extent as seen before the vasodilator was added (point A). Factors that may shift the curve up and to the left (orange curve) include right ventricular volume overload, increased PEEP, and adding a vasoconstrictor that increases afterload and reduces ventricular emptying

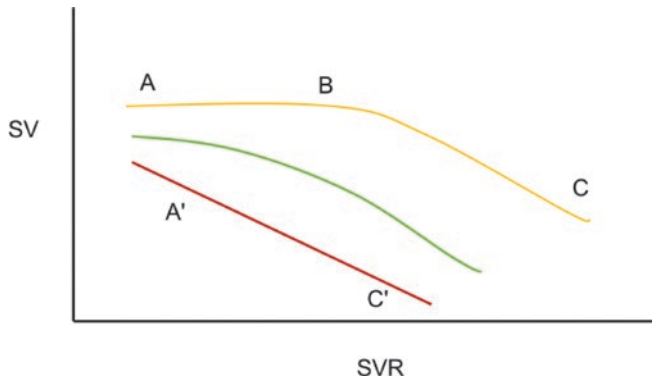

Fig. 20.10 Relationship between stroke volume (SV) and SVR in patients with different degrees of ventricular pumping function. The top curve illustrates a normal ventricle. The middle curve illustrates a patient with worsening pump function. The bottom curve illustrates a patient with severe ventricular dysfunction. As explained in the text, in the normal ventricle as SVR is increased from point A to B, SV is maintained so that blood pressure must increase. In the bottom curve as SVR increases, SV falls proportionally resulting in little change in systemic pressure

In a child with poor cardiac contractility, as illustrated by the bottom curve in Fig. 20.10, the SV declines linearly as SVR increases; the driving pressure (MAP – CVP) changes very little as you move along the curve from A′ to C′. This illustrates a significant limitation of assuming that an increase in MAP reliably reflects an improvement in cardiac output in a patient with poor pump function. Indeed, in the patient whose endogenous systems have increased their SVR, using a vasodilator to reduce SVR from C′ to A′ often improves SV with little change in blood pressure!

Furthermore, unlike vasoactive agents that improve cardiac output by adrenergic stimulation, vasodilators often improve cardiac output while reducing myocardial oxygen demand. Adrenergic agonists increase myocardial oxygen demand by increasing both heart rate and contractility. If the vasoactive

agent also increases SVR, myocardial wall stress is increased, which further increases myocardial oxygen demand. In contrast, if cardiac output improves in response to a vasodilator, the patient's endogenous catecholamine stress response is reduced, with further beneficial effects on myocardial energetics.

Myocardial oxygen demand (MVO_2) is determined by the heart rate and ventricular stroke work; the latter is determined by the volume pumped times the pressure generated to perform that volume work. The left ventricular stroke work index (LVSWI) = (MAP – LAP) * SVI * 0.0144 dyne-sec-cm^{-5}; SVI is stroke volume index (ml per beat/m^2). For a given LVSWI, volume work requires less oxygen demand than pressure work. You can appreciate this difference by using your respiratory muscles to exhale while your lips are tightly pursed. This clearly requires more effort and energy than exhaling a large volume of air with your mouth wide open. The same is true for the heart, which is much happier doing volume rather than pressure work. Thus, when the heart muscle is weak, reducing resistance reduces the effort to move the stroke volume into the arterial circulation and has the added advantage of reducing myocardial oxygen demand while cardiac output is increased.

Volume work requires less energy than pressure work, so vasodilators increase cardiac output while decreasing myocardial oxygen demand.

In summary, vasodilators have the following effects when used to support the failing circulation, such as seen following cardiopulmonary bypass (CPB), which is typically associated with increased SVR:

- Vasodilators increase cardiac output while reducing MVO_2.
- Blood pressure changes are a poor indicator of a change in CO; blood pressure will fall with vasodilator use if the intravascular volume is depleted. In patients with adequate intravascular volume, reducing SVR increases pulse pressure as recognized by a fall in the diastolic blood pressure; an improved SV also may increase the systolic BP so that the effect on pulse pressure is further augmented.
- In patients with poor cardiac function, heart rate may decline with vasodilators as an indirect indicator of reduced endogenous SNS stimulation in response to an improved cardiac output.
- Vasodilators typically reduce tone in the venous capacitance system; this increases diastolic compliance so that a fall in filling pressure does *not* reliably indicate a fall in venous return.
- If a vasodilator improves cardiac output, then venous return increases even though filling pressure often falls as noted above.
- Restoring filling pressure after adding a vasodilator reliably increases preload.
- Infants with functional univentricular hearts and systemic-to-pulmonary artery shunts often have excessive pulmonary blood flow that is exacerbated if SVR is increased. Thus, in this setting, systemic vasodilators can improve systemic perfusion and reduce pulmonary overcirculation.
- Vasodilators should *not* be used in patients with low cardiac output due to a fixed obstruction that limits cardiac output.

20.5 Specific Vasodilators

20.5.1 Milrinone

20.5.1.1 Pharmacology

Milrinone is a bipyridine phosphodiesterase (PDE) III inhibitor; inhibition of PDE III reduces cAMP breakdown and thus increases cytosolic cAMP concentrations in vascular smooth muscle and cardiac cells. Since cAMP is the

secondary messenger for β-adrenergic agonists, the cellular effects are like those produced by β agonists: increased cardiac contractility, lusitropy, and chronotropy combined with systemic and venous vasodilation.

Milrinone has a half-life of approximately 2–3 hours and is ~70% protein-bound. It is mainly excreted unchanged by the kidney and therefore requires dose adjustment in renal insufficiency. A small percentage is hepatically metabolized. Usual dosages include a loading dose of 50 mcg/kg (may be omitted due to the risk of hypotension) and a continuous infusion range of 0.1–1 mcg/kg/min. Sometimes the loading dose is divided into five 10 mcg/kg boluses with fluid given after a mini-bolus if there is evidence for a vasodilation-induced fall in blood pressure.

20.5.1.2 Clinical Effects

Vasodilation occurs in both the systemic and pulmonary vascular beds, reducing both SVR and PVR. In addition, milrinone relaxes tone in the capacitance venous system, which helps reduce end-diastolic filling pressure. If intravascular volume is adequate, milrinone increases cardiac output and venous return (i.e., preload) in children with myocardial dysfunction, illustrating the limitation of following filling pressures as an indicator of preload in this clinical setting. MAP is usually maintained due to improved contractility and lower SVR which increase stroke volume, but if intravascular volume is low, milrinone causes hypotension from both systemic vasodilation and pooling of blood in the capacitance venous system, which reduces venous return.

Although tachycardia may be expected, milrinone usually does not significantly elevate heart rate, perhaps secondary to reduced endogenous SNS stimulation as cardiac output improves.

Milrinone can increase both the beneficial and adverse effects of β-adrenoceptor agonists by augmenting the increase in intracellular cAMP.

Since milrinone inhibits the degradation of cAMP and adrenergic agonists increase cAMP production, the combination of milrinone with a β-adrenoceptor agonist may increase both the beneficial and adverse effects on the heart and vascular systems. Like other phosphodiesterase inhibitors, milrinone has some anti-inflammatory effects.

20.5.1.3 Clinical Indications

Milrinone is an excellent choice for children with primary myocardial dysfunction (e.g., cardiomyopathy or postoperative myocardial dysfunction). Its favorable cardiovascular profile has led to its increased use in the PICU. However, due to its relatively long half-life, it should be instituted only after careful delineation of myocardial function and volume status. Based on results from a multicenter clinical trial, it is commonly used in infants and children at risk of low cardiac output syndrome after cardiopulmonary bypass.

Although milrinone is given as a continuous infusion, it is important to recognize that changes in the infusion rate will not reach a new steady-state concentration for 6 to 9 hours (i.e., about three times the half-life to reach 90% of the steady-state concentration). Therefore, if a higher concentration is desired more rapidly, a small bolus (e.g., 5–10 mcg/kg) can be given along with an increase in the infusion rate. Similarly, if excess milrinone-induced vasodilation occurs, it will take many hours for the concentration to fall after reducing the infusion rate.

20.5.1.4 Adverse Effects

Rapid infusion of the loading dose can produce hypotension. Similarly, hypotension may occur from excessive systemic and venous dilation hours after starting an infusion in a patient with impaired renal function due to the slow

accumulation of milrinone. Supraventricular and ventricular arrhythmias have been reported. Thrombocytopenia is far less common than was previously reported with amrinone.

Milrinone is a useful vasoactive agent providing afterload reduction, reduced preload pressure, and improved contractility, but its long half-life may lead to slow accumulation, especially if renal function is impaired.

20.5.2 Sodium Nitroprusside

20.5.2.1 Pharmacology

Nitroprusside acts as an NO donor to produce relaxation of both venous and arterial smooth muscles. NO stimulates guanylate cyclase in vascular smooth muscle to increase intracellular cGMP. This in turn increases cGMP-dependent protein kinase activity, which ultimately decreases Ca^{2+} influx into smooth muscle cells resulting in vasodilation.

Nitroprusside has a very rapid onset of action (less than 30 seconds) and a half-life of ~2 minutes. Its effects dissipate within 2 to 3 minutes of discontinuation. Usual dosage range for nitroprusside is 0.1–6 mcg/kg/minute.

Metabolism of nitroprusside to certain by-products may lead to toxicity. Upon contact with hemoglobin, nitroprusside rapidly forms cyanide and methemoglobin. Cyanide is slowly released into the plasma and is converted to thiocyanate by the hepatic enzyme rhodanase. Thiosulfate and vitamin B_{12} (cyanocobalamin) are important cofactors in this reaction. Thiocyanate subsequently undergoes renal excretion with a half-life of 3 days that may be increased to 9 days with renal impairment.

Unlike adrenergic agents, milrinone does not result in rapid hemodynamic effects with changes in the infusion rate (i.e., within minutes). Infusion rate changes will not reach a new steady-state concentration for 6 to 9 hours (i.e., about three times the half-life to reach 90% of the steady-state concentration). Therefore, if a higher concentration is desired, a small bolus (e.g., 5–10 mcg/kg) can be given along with an increase in the infusion rate.

Unlike nitroglycerin, nitroprusside infusion does not result in resistance or tachyphylaxis to its pharmacologic action.

20.5.2.2 Clinical Effects

Nitroprusside effectively lowers SVR and PVR; venodilation increases compliance, which decreases the filling pressures. Improved ventricular emptying secondary to afterload reduction and improved venous compliance typically reduces ventricular end-diastolic pressure (EDP), which may also reduce end-diastolic volume (EDV). The combination of reduced EDP and EDV reduces ventricular wall stress and therefore MVO_2.

Nitroprusside has no direct inotropic activity. Its effect on cardiac output is variable and depends on the presence or absence of cardiovascular pathology and the intravascular volume status. In healthy hearts with normal intravascular volume, venodilation causes blood to pool in the venous capacitance system, which reduces venous return and thus CO. In patients with left ventricular dysfunction and typically increased intravascular volume and pressure, the reduction in afterload improves ventricular ejection and thus increases CO. If there is excessive vasodilation that reduces systemic pressure, reflex activation of the SNS may increase the heart rate.

When used to control blood pressure, such as following coarctation repair, the drug-induced reduction in SVR may be counterbalanced by increased activation of the SNS. In this setting, combining nitroprusside with a β-blocker such as esmolol is often useful to achieve blood pressure control and limit reflex tachycardia.

20.5.2.3 Clinical Indications

The rapid onset and short half-life of nitroprusside helps to rapidly assess a patient's response to afterload reduction, especially when pumping function is poor and filling pressures are elevated. Its short duration of action also makes it an effective agent in the treatment of hypertensive emergencies by allowing for gradual and controlled reduction of dangerous elevations in blood pressure.

The rapid onset and short half-life of nitroprusside helps to rapidly assess a patient's response to afterload reduction, especially when pumping function is poor and filling pressures are elevated.

Its short duration of action also makes it a very effective agent in the treatment of hypertensive emergencies and for afterload reduction following certain cardiac surgeries.

When used for afterload reduction, nitroprusside is often infused in combination with an inotrope in the setting of acute myocardial dysfunction such as seen in postoperative cardiac surgery and dilated cardiomyopathy, although a similar effect may be achieved with milrinone.

20.5.2.4 Adverse Effects

Nitroprusside adverse effects are usually related to excessive vasodilation and venodilation with resultant hypotension; therefore, its use requires continuous monitoring of arterial pressure. Nitroprusside can cause progressive hypoxemia in patients with parenchymal pulmonary disease by uncoupling hypoxic pulmonary vasoconstriction, thereby increasing intrapulmonary shunting. It should be use with caution and close monitoring in patients with elevated intracranial pressure (ICP) since it may cause cerebral vasodilation leading to increased cerebral blood volume and ultimately increased ICP. Additionally, administration in patients with elevated ICP may reduce cerebral perfusion pressure if blood pressure falls resulting in cerebral ischemia. Like other systemic vasodilators, nitroprusside is contraindicated in patients with conditions that obstruct ventricular emptying such as aortic or pulmonary stenosis.

Less commonly, toxicity may result from the accumulation of metabolic by-products (see ► Boxes 20.1 and 20.2). These toxicities are more often seen in patients with hepatic (cyanide) or renal (thiocyanate) insufficiency. Serial acid-base and methemoglobin determinations should be obtained on all patients on high-dose and/or prolonged infusions.

Box 20.1 Overview of Cyanide Toxicity

- Hepatic insufficiency is a significant risk factor
- Usually seen in children with prolonged high-dose infusions (>3 days at ≥4 mcg/kg/min)
- Toxicity is due to mitochondrial poisoning by inhibiting cytochrome oxidase and oxidative phosphorylation

Signs/symptoms:

- Giddiness, confusion, headache, coma, seizures
- Metabolic acidosis
- Increased central or mixed venous O_2 saturation due to disruption of oxidative phosphorylation

Treatment:

- Discontinuation
- Increase rhodanase activity by providing thiosulfate and hydroxocobalamin
- Induce conversion to methemoglobin with amyl nitrite inhalation followed by IV sodium nitrite. Methemoglobin (MtHgb) preferentially binds cyanide and thus induces cyanide release from mitochondrial cytochrome oxidase
- Methylene blue should *not* be used to decrease MtHgb levels, as it will liberate large amounts of cyanide from the cyanomethemoglobin complex; exchange transfusion is the preferred treatment for significant methemoglobinemia caused by cyanide toxicity

Box 20.2 Overview of Thiocyanate Toxicity

- Renal insufficiency is the risk factor
- Usually seen in children with prolonged high-dose infusions (>3 days at ≥4 mcg/kg/min)

Signs/symptoms:
- Abdominal pain, nausea
- Tinnitus
- Blurred vision
- Psychosis, confusion, hyperreflexia, seizures

Treatment:
- Thiocyanate is 100 times less toxic than cyanide and generally only requires discontinuation of nitroprusside and supportive care
- Dialysis may be considered in severe cases

20.5.3 Nitroglycerine (NTG)

20.5.3.1 Pharmacology

NTG (glycerol trinitrate) is one of several organic nitrates that are metabolized within vascular smooth muscle cells to release NO, which activates the soluble form of guanylyl cyclase increasing intracellular cGMP. Besides its effects on vascular smooth muscle, NO-mediated cGMP inhibits platelet aggregation and relaxes smooth muscle in the bronchi and GI tract. Despite more than 140 years since its introduction, the precise mechanisms of NO release from NTG are still not clear; a nonenzymatic interaction with cysteine groups is one mechanism that releases NO.

The onset of action is within 1–2 minutes. The duration of action after the infusion is stopped is 2–5 minutes with an elimination half-life of 1–3 minutes.

A major limitation of long-term NTG use is the development of tolerance, which attenuates its effects. The onset and magnitude of tolerance is related to the duration and dose used. Tolerance appears to represent a reduced capacity of vascular smooth muscle to convert NTG to NO, although other mechanisms may play a role, such as increased endogenous SNS activity and/or depletion of intracellular sufhydryl groups. To limit tolerance, infusions are often used for <24 hours. If used topically, therapy is often interrupted for 8–12 hours per day.

20.5.3.2 Clinical Effects

For reasons that are not understood, NTG dilates large blood vessels (>200 μm diameter) more potently than smaller vessels, explaining why low doses of NTG preferentially dilate veins and conductance arteries and has little effect on medium and small arterioles, which are the main source of systemic vascular resistance. Thus, NTG's main action is to increase venous compliance; filling pressures (CVP and LAP) decrease, and EDV may also decrease. Heart rate may be unchanged or may increase secondary to SNS activation if cardiac output declines. The latter typically results from reduced venous return secondary to pooling in the capacitance venous system if intravascular volume is low or venodilation is excessive. SVR declines modestly; a greater decrease in PVR may be seen, especially if PVR is increased in association with an increased LAP.

NTG has a short-half life and produces relatively selective dilation of large blood vessels, especially in the venous circulation. This reduces end-diastolic pressure and may reduce end-diastolic volume if intravascular volume is low or if there is excessive venorelaxation.

Tolerance develops with prolonged infusions (>24 hours), limiting the use of NTG for long-term management.

20.5.3.3 Clinical Indications

NTG may be used to reduce high filling pressures in patients with reduced ventricular pumping function. Although NTG can dilate coronary vessels, studies during cardiac catheterization show that direct injection does not resolve angina; instead the beneficial effects are related to NTG's action on

venous pressures, which reduces ventricular wall stress and thus MVO_2. This is especially helpful in improving subendocardial perfusion. If there is coronary vasospasm, NTG's effect on the coronary vessels may be important. NTG may be helpful to more selectively reduce elevated PVR since a relatively higher proportion of resistance is on the venous side in the pulmonary circulation compared with the systemic circulation.

When used, infusions are typically started at 0.5 mcg/kg/min and titrated to the desired effect with upper infusion dose of ~5 mcg/kg/min.

20.5.3.4 Adverse Effects

Excessive venodilation may pool blood in the capacitance venous system leading to a fall in venous return and thus cardiac output and blood pressure. Facial flushing and vasodilation of meningeal arteries may occur with the latter causing headache. High doses or inadvertent bolus administration may cause profound hypotension and bradycardia secondary to high myocardial NO concentrations. A major potentially lethal side effect results from NTG's interaction with PDE type V inhibitors (e.g., sildenafil), which can markedly increase intracellular cGMP concentrations leading to profound vasodilation and life-threatening hypotension.

20.5.4 Phentolamine and Phenoxybenzamine

20.5.4.1 Pharmacology

Both phentolamine and phenoxybenzamine are nonselective inhibitors of α-adrenoceptors with no effect at β-adrenoceptors. The onset of action following phentolamine administration is 1–2 minutes with a half-life of ~19 minutes. Phenoxybenzamine has unique pharmacology since it covalently binds to the receptor, producing complete inhibition until new α-adrenoceptors are synthesized and expressed on the cell surface.

20.5.4.2 Clinical Effects

Rapid reduction in SVR along with reduced venous tone results in reduced blood pressure. Cardiac output may be maintained if intravascular volume is adequate; if ventricular pumping function is impaired, CO often improves, in part due to reflex sympathetic tachycardia. Normally, PVR is not affected by increased SNS activity unless there is increased muscularization of the pulmonary vasculature (see ► Chap. 15, Regional Circulation), so phentolamine tends to reduce SVR more than PVR.

20.5.4.3 Clinical Indications

Both agents have been used as part of a strategy to lower SVR in the perioperative management of infants following stage I palliation of hypoplastic left heart syndrome. The objective is to improve systemic blood flow, which can be monitored by a reduced oxygen saturation difference between central venous and arterial oxygen saturation.

Phenoxybenzamine is also used in the management of children with pheochromocytoma to limit the risk of severe hypertension.

20.5.4.4 Adverse Effects

Hypotension and reflex tachycardia are the major adverse effects. Clinicians should be prepared to manage excessive vasodilation with volume administration.

20.6 Novel Agents

20.6.1 Levosimendan

20.6.1.1 Pharmacology

Levosimendan is a calcium-sensitizing agent that produces inodilator effects. Its mechanisms of action include calcium sensitization of contractile proteins in the myocardium and the opening of ATP-dependent potassium channels in vascular smooth muscle. The latter action leads to hyperpolarization and reduced calcium entry into the smooth muscle cell, resulting in vasodilation. These vasodilatory effects are seen throughout vascular beds, including the coronary, pulmonary, and cerebral circulations as well as the capacitance venous system. The latter leads to increased venous compliance and reduced end-diastolic pressure.

Although levosimendan is also an inhibitor of PDE III, this action, at low doses, does not contribute to its clinical effects. Levosimendan increases myofilament calcium sensitivity by binding to cardiac troponin C in a calcium-dependent manner. This stabilizes the calcium-induced conformational change of troponin C, thereby sensitizing the cardiac myofilaments to calcium. Since levosimendan increases contractility without increasing intracellular Ca^{++} concentration, there is less cellular work and associated oxygen consumption related to the transport of increased cytoplasmic Ca^{++} back into the sarcoplasmic reticulum compared with adrenergic inotropic agents.

Levosimendan is extensively protein-bound. Although it is administered intravenously, it is excreted into the small intestine and reduced by intestinal bacteria to an amino phenolpyridazinone metabolite (OR-1855) which is further hepatically metabolized to an N-acetylated metabolite (OR-1896); this final metabolite is active and has a far longer half-life than the parent drug (70–80 hours vs. ~1 hour). This likely explains the prolonged hemodynamic effects seen after discontinuation of an infusion, but also is undesirable since, if hypotension develops secondary to drug effect, it is not readily reversed. Doses should be adjusted in patients with severe renal or hepatic insufficiency.

20.6.1.2 Clinical Effects

Levosimendan increases cardiac output with little effect on MVO_2. Vasodilation results in decreased systemic and pulmonary afterload, reduced LAP and RAP, and improved coronary perfusion. Although not a direct chronotrope, levosimendan may increase heart rate by vasodilation-induced activation of baroreceptor reflexes.

20.6.1.3 Clinical Indications

Levosimendan was shown to improve cardiac function and hemodynamic performance in adults with severe heart failure; however, several recent trials in medical and surgical patients with cardiac dysfunction failed to show a benefit over conventional therapy. The effects of levosimendan in children with myocardial dysfunction (both congenital and acquired) have not been fully investigated, but small studies to date appear promising, with initial studies showing improved cardiac output, appropriate heart rate, and an encouraging safety profile. However, a recent double-blind, randomized clinical trial assessing levosimendan in adults with sepsis found that treatment with levosimendan did not decrease severity of organ dysfunction or mortality and increased the likelihood of arrhythmias. Thus, larger and more rigorous studies in pediatrics are required to further elucidate the efficacy and safety of levosimendan therapy in

pediatrics. A meta-analysis of 40 clinical trials of perioperative levosimendan in adults found a higher risk of hypotension and arrhythmias when including just the five trials with low risk of bias; when including all trials, there was a mortality benefit associated with the use of levosimendan, but the quality of data was judged to be low, so no conclusions could be drawn. A recent review suggests that levosimendan may be specifically useful in patients with heart failure on β-adrenergic blockers since its action bypasses the adrenergic receptor system.

At this time, the drug is not FDA-approved, but it is approved for use in adults in ~60 countries and is currently undergoing study in the treatment of pulmonary artery hypertension.

20.6.1.4 Adverse Effects

The most common adverse reactions are related to dose-dependent vasodilation and include syncope, headache, and overt hypotension, emphasizing the need for adequate intravascular volume when initiating this agent. Electrophysiologic side effects include prolongation of the QT interval. Despite prolonging the QT interval, early studies have not demonstrated a significant proarrhythmic effect of levosimendan. Because of its vasodilating effects, levosimendan is contraindicated in patients with obstruction to ventricular filling or ventricular outflow.

20.6.2 Tolvaptan

The vaptans are arginine vasopressin receptor antagonists. Tolvaptan is a selective V_2 receptor antagonist that acts on the distal nephron to increase free water excretion (aquaresis) by blocking water reabsorption; this action helps correct heart failure-induced hyponatremia from excess ADH activity. In adults, tolvaptan was shown to improve symptoms of chronic heart failure and normalize serum sodium. Potential adverse effects include hypernatremia, dehydration, elevated aminotransferases, and elevated bilirubin. Unfortunately, an international phase 3 randomized trial evaluating the use of tolvaptan in pediatric patients with hyponatremia was terminated due to inadequate patient enrollment. A smaller pediatric study showed adverse events including thirst, dry mouth, and increased aminotransferases. A large adult study evaluating the use of tolvaptan in autosomal dominant polycystic kidney disease identified potential adverse effects including a transient increase in aminotransferases and bilirubin. Tolvaptan is not currently approved for pediatric use, but in several small investigational studies, it showed promise for the treatment of chronic heart failure in a select subset of patients.

20.6.3 Istaroxime

Istaroxime is a novel cardiovascular agent with both inotropic and lusitropic properties, at present studied only in adults and investigational in the United States (FDA granted fast-track designation in August 2019). The drug acts by improving cellular calcium cycling. Like digoxin, inotropic effects are achieved via Na^+/K^+ ATPase inhibition, which leads to cytosolic calcium accumulation in systole. Unlike digoxin, however, lusitropic effects are achieved via stimulating the enzyme responsible for sarcoplasmic reticulum sequestration of Ca^{2+} in diastole. In a study of adults with heart failure, istaroxime reduced pulmonary capillary wedge pressure, increased systolic blood pressure, decreased heart

rate, and decreased left ventricular end-diastolic volume. At higher doses, istaroxime improved cardiac index and stroke work index. Istaroxime had relatively few side effects and demonstrated a half-life of less than 1 hour. These preliminary findings suggest istaroxime may have efficacy, safety, and a pharmacokinetic profile amenable to its application in the pediatric population, though it has not yet been studied in children.

20.7 Use of Cardiovascular Agents in Septic Shock

The use of cardiovascular agents in septic shock has been studied extensively in adults, and recommendations were recently updated in the literature. An in-depth discussion regarding cardiovascular agent therapy in the context of septic shock can be found elsewhere in this text. (See ► Chap. 34, Sepsis, and ► Chap. 17, Circulatory Failure/Shock).

20.8 Control of Severe Hypertension

At times, the pediatric intensivist must obtain hemodynamic stability by controlling excessive arterial blood pressure. *Hypertensive urgency* is defined as severe hypertension without evidence of end-organ damage. *Hypertensive emergency* or crisis occurs when severe hypertension is associated with evidence of progressive end-organ dysfunction. Clinically, end-organ dysfunction may manifest as encephalopathy, retinal changes (hemorrhage, exudates, or papilledema), renal insufficiency (proteinuria and/or hematuria), microangiopathic hemolytic anemia, thrombocytopenia, and/or myocardial dysfunction. Without treatment, severe hypertension can produce catastrophic results such as intracerebral hemorrhage and/or left ventricular failure with pulmonary edema. Hypertensive emergencies require rapid but controlled reduction in blood pressure. This should occur in the intensive care unit, ideally with intra-arterial pressure monitoring since both oscillometric and manual blood pressure measurements are not reliable in this setting. Lowering the blood pressure by <25% in the first 8 h followed by a slower reduction over the next 24–48 h is generally recommended since more rapid reductions may result in ischemic stroke or ischemia in other organ systems that have adjusted their autoregulation to a higher blood pressure. Hypertensive urgencies should have blood pressure control achieved more gradually over 24–48 h.

A complete discussion of the epidemiology, clinical presentation, pathophysiology, and causes is beyond the scope of this section, which is focused on pharmacologic agents used to treat hypertensive emergencies. Regardless of the hypertensive state, a complete history and physical examination (including fundoscopic examination) combined with targeted laboratory tests and imaging is required to ascertain the etiology and end-organ effects of severe hypertension. This is of paramount importance as identifying the etiology allows appropriate tailoring of the therapeutic options. Primary hypertension is more common in older children, whereas secondary hypertension is more common in children <7 years of age. Common etiologies for severe hypertension in children are renovascular, intrinsic renal disease, drug effect (e.g., sympathomimetics, corticosteroids, or calcineurin inhibitors), and endocrine causes (e.g., pheochromocytoma, hyperadrenal states and hyperthyroidism).

There are no pediatric studies comparing antihypertensive agents in hypertensive emergencies, and drug and dosing recommendations are largely based on studies in adults.

Classes of antihypertensives include:

- Direct vasodilators (sodium nitroprusside, hydralazine)
- Calcium channel blockers (nicardipine, nifedipine, isradipine)
- Cardioselective β_1-adrenergic blockers (esmolol)
- Mixed adrenergic α-, β_1-blockers (labetalol)
- Selective α-adrenergic antagonists (phentolamine, phenoxybenzamine)
- Angiotensin-converting enzyme inhibitors (enalaprilat, enalapril, captopril)
- Angiotensin receptor antagonists (losartan, valsartan, olmesartan)
- Selective dopamine agonists (fenoldopam)
- Central α_2-adrenergic agonist (clonidine, dexmedetomidine)

Table 20.7 summarizes important properties of selected antihypertensives. A more detailed discussion of selected parenteral agents follows.

20.8.1 Nicardipine

20.8.1.1 Pharmacology

Nicardipine is a dihydropyridine calcium channel blocker that blocks a specific L-type Ca^{2+} channel that has a greater action on vascular smooth muscle instead of the heart. This channel blockade reduces movement of calcium into the cytoplasm of vascular smooth muscle producing selective arteriolar vasodilation (i.e., it has little effect on venous smooth muscle tone). The cerebral and coronary circulations are particularly sensitive to its effects. There is little effect on the heart.

Nicardipine has a rapid onset of action of approximately 5 minutes. Although its half-life is 40 minutes, its duration of action after discontinuation of a prolonged infusion may be 6 hours or more. Infusion rates range from 0.5 to 5 mcg/kg/min. Metabolism is hepatic with renal excretion.

20.8.1.2 Clinical Effects

Nicardipine promotes arteriolar vasodilation, thus reducing systemic vascular resistance with less reflex tachycardia than direct vasodilators. It also improves coronary blood flow and oxygen delivery and does not affect cardiac contractility.

20.8.1.3 Clinical Indications

Nicardipine's effectiveness, rapid onset, titratability, and safe therapeutic profile have made it an appropriate initial choice in a variety of hypertensive emergencies. It has been successfully used in children with hypertension secondary to renovascular disease, acute renal failure, post-coarctectomy, and hypertension secondary to calcineurin inhibitors or extracorporeal membrane oxygenation.

20.8.1.4 Adverse Effects

Nicardipine has become the preferred alternative to nitroprusside for the control of multiple types of pediatric hypertensive emergencies. The risk of thrombophlebitis with peripheral administration generally requires a large peripheral vein or central venous access for administration.

Thrombophlebitis has been reported with peripheral administration; therefore, large peripheral vein or central venous access is preferred. Like other nonspecific vasodilators, increased intrapulmonary shunt in children with preexisting parenchymal lung disease may occur due to uncoupling of hypoxemic pulmonary vasoconstriction. Nicardipine should be used with caution in children with conditions associated with raised ICP as cerebral vascular dilation may further increase intracranial pressure. It should be avoided in children with severe left ventricular outflow obstruction. Nicardipine-induced hypotension can be reversed with the administration of calcium and intravascular volume expansion.

Table 20.7 Parenteral agents for hypertensive emergencies

Agent	Mechanism of action	Usual dose	Onset/duration of action	Comments/cautions
Sodium nitroprusside	Nitric oxide donor – relaxes both venous and arterial smooth muscle	Infusion: 0.5–6 mcg/kg/min	30 seconds/2–3 min	May cause nausea, vomiting, reflex tachycardia and increased cardiac contractility, methemoglobinemia,
				Thiocyanate intoxication, lactic acidosis due to cyanide poisoning
				May increase intrapulmonary shunt or ICP
				Bags, bottles, and delivery sets must be light resistant
Nicardipine	Arteriolar vasodilator via calcium channel blockade in vascular smooth muscle	Infusion: 0.5–5 mcg/kg/min	2–5 min/40 min, but may be longer after prolonged infusion	May cause nausea, vomiting, or headache Phlebitis with peripheral administration so need central access
				Less reflex tachycardia than other vasodilators
				May increase intrapulmonary shunt or ICP
Esmolol	Cardioselective β_1 blockade	Initial 100–500 mcg/kg bolus	1–5 min/10–30 min	Rapid hydrolysis by RBC esterases
				Useful in post-coarctation repair
		Infusion: 25–300 mcg/kg/min		Use with caution with first-degree heart block, congestive heart failure, asthma
Labetalol	Mixed adrenergic blockade ($\beta_1 > \alpha_1$ blockade in ratio of 7:1)	Initial: 0.2–1 mg/kg, max. single dose 20 mg	5–15 min/2–6 hr	Hepatic metabolism allows use in children with renal insufficiency Use with caution with first-degree heart block, congestive heart failure, asthma, hepatic dysfunction
		Infusion: 0.25–3 mg/kg/hr		
Hydralazine	Direct arteriolar vasodilator	0.1–0.6 mg/kg/dose every 4-6 h prn Max single dose = 20 mg	10 min/2–6 hr after IV	Limited clinical usefulness due to unpredictable pharmacokinetics and risk of excessive drop in blood pressure. Useful in eclampsia – improves uterine blood flow
				May cause reflex tachycardia, headache, vomiting, increased ICP
Enalaprilat	Angiotensin-converting enzyme inhibitor	5–10 mcg/kg/dose every 8–24 hr up to 1.25 mg/dose	15–60 min/6 hr	Limited usefulness in hypertensive emergencies, second-line agent
				Useful in hyper-renin states
				Contraindicated in pregnancy, bilateral renal artery stenosis, chronic kidney disease and in states of decreased effective circulating volume
				Hyperkalemia possible with reduced GFR or with K^+ sparing diuretic
Fenoldopam mesylate	Selective dopamine (DA_1) agonist causing vasodilation of renal and splanchnic arterioles	Infusion: 0.05–0.3 mcg/kg/min	15 min/30 min	Useful in hypertension associated with renal insufficiency
				May cause headache, tachycardia, flushing, local phlebitis, increased intraocular pressure
Phentolamine	Selective α-adrenergic antagonist	0.05–0.1 mg/kg/dose, max 5 mg	1–2 min/30–60 min	Use limited to states characterized by catecholamine excess – specifically pheochromocytoma
				May cause reflex tachycardia, hypotension

20.8.2 Esmolol

20.8.2.1 Pharmacology

Esmolol is a highly selective β_1-adrenergic blocker that has a rapid onset (1–5 minutes) and short duration of action (15–30 minutes) making it an easily titratable antihypertensive. It is rapidly metabolized by red blood cell esterases allowing its use in children with renal and hepatic dysfunction.

Esmolol is a selective β_1 adrenergic blocker that has a rapid onset and short duration of action due to metabolism by RBC esterases, making it an easily titrated antihypertensive that can be used in children with renal and/or hepatic dysfunction.

Important drug-drug interactions include digoxin and morphine; digoxin levels should be followed closely as esmolol may increase digoxin levels by 20%. Morphine may increase esmolol effects; therefore, a decrease in esmolol dosing may be required. A starting dose of 50 mcg/kg/min can be titrated up to 300 mcg/kg/min.

20.8.2.2 Clinical Effects

By competitively blocking β_1 adrenoceptors, esmolol exerts negative inotropic and chronotropic effects. Its antihypertensive effects are due to a reduction in cardiac output; therefore, it should be used with caution and close monitoring in patients with preexisting myocardial insufficiency.

20.8.2.3 Clinical Indications

Esmolol has been used for the management of hypertension after pediatric cardiac operations, specifically coarctation of the aorta. It also may be effective in controlling hypertension and tachycardia in other situations characterized by excess sympathetic activity such as thyrotoxicosis and sympathomimetic overdose. It may be combined with a direct-acting vasodilator such as nitroprusside to blunt the peripheral vascular effects of reflex SNS activation as the blood pressure is reduced.

20.8.2.4 Adverse Effects

Like all β-blockers, esmolol should be used with extreme caution in children with a history of congestive heart failure, asthma, or conduction disturbances. Nausea, vomiting, dizziness, and confusion have been reported with prolonged or high-dose use.

20.8.3 Labetalol

A mixed adrenergic blocker, labetalol's antihypertensive effects are primarily from β_1 blockade causing a reduction in cardiac output and to a lesser extent α_1 blockade causing a reduction in systemic vascular resistance (β_1-to α_1-blocking activity is 7:1). In addition, labetalol has partial agonism for vascular β_2 receptors adding to its effect to lower systemic vascular resistance. Labetalol's β_1 blockade inhibits reflex tachycardia from a reduction in blood pressure. Labetalol has a rapid onset of action within 15 minutes of intravenous administration. Its prolonged duration of action up to 8 hours limits its titratability. Metabolism is hepatic, primarily via glucuronide conjugation with extensive first-pass effect.

An initial intravenous loading dose of 0.2–1 mg/kg can be followed by a carefully titrated infusion at 0.25–3 mg/kg/h, remembering that changes in the infusion rate will slowly reach a new steady-state concentration. Its hepatic metabolism allows for its use in children with renal dysfunction. Unlike direct vasodilators and calcium channel blockers, it does not appear to cause an increase in intracranial pressure, and thus, it is useful in patients with increased intracranial pressure. It should be used with caution in patients with first-degree heart block, congestive heart failure, asthma, and hepatic dysfunction.

20.8.4 Enalaprilat

The ACE inhibitor, enalapril, is converted in the liver to its active form, enalaprilat, which can be given intravenously. Unlike enalapril, enalaprilat has a rapid onset of action with a duration of 4–6 hours after a bolus. It is a second-line antihypertensive generally reserved for children suspected or known to have renin-mediated hypertension. Adult studies suggest this agent may be helpful in patients with hypertensive heart failure.

Since it lowers glomerular pressure and thus filtration by blocking the formation of angiotensin II, enalaprilat should not be used in children with bilateral renovascular hypertension or chronic kidney disease since it may cause acute kidney injury in these settings. Inhibition of angiotensin II reduces stimulation of aldosterone formation, so hyperkalemia may develop, especially in patients receiving potassium supplements. In patients whose blood pressure is highly dependent on activation of the renin-angiotensin system, an initial small dose should be infused and titrated upward since a large dose may cause profound hypotension. The usual dose is 5–10 mcg/kg/dose every 8–24 hr up to 1.25 mg/dose.

20.8.5 Fenoldopam

Fenoldopam is a selective postsynaptic dopamine DA_1 receptor agonist on vascular smooth muscle causing peripheral arteriolar vasodilation that is most pronounced in the renal and splanchnic vasculatures, but also increases coronary and cerebral blood flow. It promotes urine flow via improved renal perfusion and natriuresis. These characteristics make it of particular use in children with hypertensive emergencies associated with renal insufficiency. It is FDA-approved for short-term use in children with severe hypertension.

It has a rapid onset (~4 min) and short half-life (~5 min), but full extinction of effect may take up to 60 minutes. An initial infusion of 0.2 mcg/kg/min can be increased by 0.3–0.5 mcg/kg/min every 20–30 minutes (maximum dose: 0.8 mcg/kg/min). Tolerance develops rapidly; therefore, its use is limited to short-term (48 hours) control of blood pressure. Metabolism is hepatic via methylation, glucuronidation, and sulfation. Adverse effects include hypotension, hypokalemia, headache, nausea, dose-related tachycardia, flushing, local phlebitis, and increased intraocular pressure. To date, there are no large randomized controlled studies for the use of fenoldopam for pediatric hypertension.

Review Questions

1. *Dobutamine is started in a 16-year-old patient who presents with poor perfusion secondary to a previously unrecognized dilated cardiomyopathy. Which of the following statements is true regarding dobutamine?*
   A. Dobutamine selectively activates both β_1- and β_2-adrenoceptors with no effect at α-adrenoceptors.
   B. Dobutamine has important effects inhibiting thyroid and prolactin hormone release.
   C. Dobutamine is unlikely to cause tachyarrhythmias.
   D. Dobutamine's hemodynamic effects on vascular smooth muscle tone are difficult to predict since one isomer is an α_1-adrenergic agonist and the other is an α_1-adrenergic antagonist.
   E. Dobutamine is the drug of choice for treatment of cardiogenic shock.

2. *A 2-year-old near-drowning victim is brought to the PICU with poor perfusion, a low blood pressure, and a significant metabolic acidosis with a lactate concen-*

tration of 4.5 mmol/L. Which of the following statements is not true regarding the use of an epinephrine infusion in this setting?

A. An epinephrine infusion decreases plasma potassium concentrations through stimulation of β2-adrenoceptors.
B. An epinephrine infusion can complicate the interpretation of lactate concentrations since lactate levels often rise secondary to increased gluconeogenesis (Cori cycle).
C. Epinephrine is the drug of choice in postarrest cardiogenic shock because it better preserves myocardial blood flow and reduces myocardial metabolic demand.
D. When compared with norepinephrine, epinephrine is more likely to cause death or refractory cardiogenic shock with lactic acidosis in post-myocardial infarction shock.
E. An epinephrine infusion may redirect blood from the splanchnic circulation to the skeletal muscular vascular bed.

3. *To improve cardiac function in a child admitted with heart failure, an infusion of dobutamine is started. Dobutamine demonstrates high β_1 agonism. Which of the following statements accurately describes the effect of stimulation of myocardial β_1 adrenoceptors?*

A. Myocardial β_1 receptor binding results in the activation of a Gs protein which activates adenylate cyclase resulting in an increase in cytosolic cAMP.
B. Myocardial β_1 receptor binding results in the activation of a Gi protein which activates adenylate cyclase leading to increased cAMP.
C. Myocardial β_1 receptor binding results in the activation of a Gs protein that inhibits adenylate cyclase and, thus, cAMP formation.
D. Myocardial β_1 receptor binding results in the activation of a Gq protein which stimulates phospholipase C resulting in the formation of inositol triphosphate (IP_3).
E. Myocardial β1 receptor binding results in the activation of a Gs protein and the inhibition of adenylate cyclase leading to decreased cAMP.

4. *A child is admitted in status asthmaticus and started on continuous albuterol. Which of the following statements accurately describes the effect of stimulation of vascular and bronchial smooth muscle β_2-adrenoceptors?*

A. Vascular and bronchial smooth muscle β_2-adrenoceptor binding results in the activation of a Gs protein which activates adenylate cyclase leading to increased cAMP and increased protein kinase activity.
B. Vascular and bronchial smooth muscle β_2-adrenoceptor binding results in the activation of a G_i protein which activates adenylate cyclase leading to increased cAMP and increased protein kinase activity.
C. Vascular and bronchial smooth muscle β_2-adrenoceptor binding results in the activation of a Gi protein that inhibits adenylate cyclase, and thus, cAMP formation.
D. Vascular and bronchial smooth muscle β_2-adrenoceptor binding results in the activation of a Gq protein which stimulates phospholipase C resulting in the formation of inositol triphosphate (IP_3).
E. Vascular and bronchial smooth muscle β_2-adrenoceptor binding results in the activation of a Gs protein which stimulates phospholipase C resulting in the formation of inositol triphosphate (IP_3).

5. *Vasopressin is ordered for a child with renal insufficiency and low systemic blood pressure in the context of hepatorenal syndrome. Which of the following*

most accurately characterizes the effect of endogenous secretion of vasopressin?

A. It produces a vasopressin receptor-mediated improvement in cardiac contractility.
B. It results in a slowing of cardiac conduction via its effect on the atrioventricular node.
C. It results in adrenergic-mediated smooth muscle contraction.
D. It results in a receptor-mediated increase in chronotropy
E. Secretion may occur in response to either osmotic or nonosmotic stimuli.

6. *A 14-year-old presents with toxic shock syndrome due to osteomyelitis and Staphylococcus aureus bacteremia. His vital signs reveal a heart rate of 133 bpm, a blood pressure of 82/25 mmHg, and a respiratory rate of 30 breaths/min. Clinical exam reveals diffuse erythema, bounding pulses, and flash capillary refill. He receives aggressive fluid resuscitation with 0.9% normal saline (80 mL/kg) and has a central venous catheter placed. His plasma lactate concentration is 4.4 mmol/L with base deficit of 5.2 mmol/L, and his repeat blood pressure is 90/21. Which of the following is the most appropriate vasoactive infusion to initiate?*

A. Dobutamine
B. Dopamine
C. Norepinephrine
D. Epinephrine
E. Milrinone

7. *A 2-month-old infant is admitted to the PICU following patch closure of a large ventricular septal defect. She remains cool with poor distal pulses despite adequate volume resuscitation and an epinephrine infusion of 0.3 mcg/kg/min. Her current blood pressure is 98/64, her pulse is 168 bpm, and her pulmonary artery oxygen saturation is 53% with normal pulmonary artery pressure. An infusion of nitroprusside is initiated to decrease afterload. Which of the following is a characteristic of nitroprusside that would support its use in this setting, and what is a potential side effect of this medication?*

A. It has a rapid onset and short duration of effect; increased intracranial pressure
B. It has a direct effect on the distal collecting tubules promoting natriuresis; reflex bradycardia
C. It has a direct positive inotropic effect on the heart; increased intracranial pressure
D. It is metabolized by Hoffman degradation; methemoglobinemia
E. It slows atrioventricular cardiac conduction; thiocyanate intoxication

8. *A child is admitted to the PICU postoperatively status post-coarctation repair. An infusion of esmolol is administered. Esmolol is characterized by which of the following statements?*

A. It is a highly selective α_1-adrenoceptor antagonist with a rapid onset and short duration of effect and metabolism by hepatic glucuronide conjugation.
B. It is a highly selective β_1-adrenoceptor antagonist with a rapid onset and short duration of action and metabolism by hepatic glucuronide conjugation.
C. It is a mixed α_1-β_1-adrenoceptor antagonist with a rapid onset of effect, relatively long duration of effect, and metabolism by hepatic glucuronide conjugation.

D. It is a highly selective β_1-adrenoceptor antagonist with a rapid onset of effect, short duration of action, and metabolism by red blood cell esterases.
E. It is a nonselective β-adrenoceptor antagonist with a rapid onset of effect, short duration of action, and metabolism by red blood cell esterases.

9. *Nicardipine is considered for the treatment of a hypertensive emergency. Which of the following is a contraindication to the use of nicardipine?*
   A. Acute renal failure
   B. Left ventricular outflow tract obstruction
   C. Post-coarctectomy state
   D. Status post-extracorporeal membrane oxygenation
   E. Renovascular disease

10. *A 10-year-old boy is admitted to the PICU with severe hypertension. He is asymptomatic but was found to have a blood pressure of 212/100 mmHg and pulse of 100 bpm this morning when he presented to his pediatrician today for a school physical. Laboratory evaluation is unremarkable. A cardiac echocardiogram reveals a shortening fraction of 40%. A renal ultrasound is pending, and four extremity blood pressures are all elevated. Which of the following is the most appropriate treatment option while delineating the etiology of his hypertension?*
   A. Enalapril
   B. Esmolol
   C. Labetalol
   D. Nifedipine
   E. Nicardipine

11. *A 15-year-old male lacrosse player presents to the PICU with a thyrotoxicosis crisis following significant trauma to his anterior neck. His temperature is 104.8 °F, his heart rate is 190 bpm, and his blood pressure is 170/90 mmHg. He is very agitated and confused. Which of the following would be most indicated to control his symptoms, and which diagnosis in his past medical history would be concerning if prescribing this drug?*
   A. Clonidine, dry mouth
   B. Esmolol, asthma
   C. Enalaprilat, asthma
   D. Nicardipine, intrapulmonary shunt
   E. Nitroprusside, ventriculoperitoneal shunt

12. *A 5-year-old girl is admitted to the PICU with primary myocardial dysfunction due to cardiomyopathy. She is to be started on a milrinone infusion. Which of the following is an important consideration prior to initiating her infusion?*
   A. Intravascular volume status
   B. Relatively short half-life
   C. Mechanism of action as a β-adrenergic antagonist
   D. Its extensive hepatic metabolism
   E. Its negative lusitropic effects

13. *A 3-month-old baby boy is status post-cardiac catheterization during which he was diagnosed with anomalous origin of the left coronary artery arising from the pulmonary artery. He is noted to have severe left ventricular dysfunction. His pulse is 170 beats per minute and blood pressure is 80/65 mm Hg. He*

is cool to touch and has poor pulses. His central venous pressure measured at the superior cava – right atrial junction is 13 mm Hg. His hemoglobin is 10.5 gm/dL. He had been given furosemide earlier in the day. The most appropriate next step in the management of this infant is:

A. Administer a 20 ml/kg normal saline bolus
B. Administer a 10 ml/kg transfusion of packed red blood cells
C. Begin an epinephrine infusion at 0.2 mcg/kg/min
D. Begin a norepinephrine infusion at 0.1 mcg/kg/min
E. Begin a dobutamine infusion at 5 mcg/kg/min

14. *Which of the following statements best describe the overall hemodynamic results of isoproterenol?*
A. Decreased systemic vascular resistance
B. Increased inotropy and chronotropy with decreased systemic vascular resistance
C. Increased inotropy and chronotropy with increased systemic vascular resistance
D. Increased chronotropy
E. Increased inotropy

15. *What are two potential side effects of phentolamine?*
A. Tachycardia, hypotension
B. Tachycardia, hypertension
C. Bradycardia, hypotension
D. Hypertension, bronchoconstriction
E. Bradycardia, increased intracranial presssure

16. *Which of the following statements regarding vasodilators is true?*
A. Vasodilators routinely increase myocardial oxygen demand.
B. Nitroprusside selectively relaxes arteriole vascular tone with no effect on venous vascular tone.
C. Nitroglycerine is a useful vasodilator for long-term administration.
D. A vasodilator-induced increase in cardiac output is accompanied by an increase in venous return, even if the filling pressures (CVP, LAP) decrease.
E. Milrinone is a useful inodilator that has a short half-life making it useful for rapid titration to the desired hemodynamic effect.

Learning Objectives

CPR

- Describe the physiologic basis of CPR.
- Explain the rationale underlying the selection of pharmacologic agents and doses.
- Explain why inpatient and out-of-hospital outcomes may differ.
- Describe the components of quality CPR.
- State the scientific reasoning behind the American Heart Association's most recent guidelines for the performance of pediatric basic and advanced life support.

ECMO

- Describe the difference between VV and VA ECMO.
- List three components of an ECMO circuit.
- Describe contraindications to the use of ECMO.
- Describe the outcomes after ECMO support.

Mechanical Assist Devices

- Describe the mechanics of mechanical assist devices: VADs and balloon pumps.
- Describe the indications for the use of a VAD.
- Describe complications associated with the use of a VAD.
- Discuss outcomes data of patients who require VADs.

Temporary Cardiac Pacing

- Describe the indication for using a temporary pacemaker.
- Describe the basic operations of a temporary pacemaker.
- Describe how to measure thresholds.

21.1 Cardiopulmonary Resuscitation

Cardiopulmonary resuscitation (CPR) and resuscitation medicine has progressed significantly in the past century. An explosion of interest in resuscitation in the mid-1900s led to important advancements in chest compressions and artificial respirations. The goal of CPR is to maximize coronary and cerebral blood flow and restore spontaneous circulation as soon as possible. The general principles of CPR remain the same; however, further investigations emphasized the importance of providing timely, high-quality CPR with limited hands-off time to improve patient outcomes. In this summary, we review the physiologic basis of CPR, detail the rationale for pharmacotherapy, discuss the outcomes for victims of pediatric cardiac arrest, and review the most recent American Heart Association guidelines.

21.1.1 Physiologic Basis of CPR and Patterns of Blood Flow

Three potential mechanisms are thought to support circulation during CPR: the cardiac pump, the thoracic pump, and the abdominal pump. The cardiac pump concept involves direct squeezing of the heart between the sternum and the spine leading to forward circulation via an open aortic valve and closed mitral valve, mimicking normal anatomic blood flow. This mechanism is thought to predominate in very young children due to their compliant thoracic wall, and in patients of all ages during open chest cardiac massage. The thoracic pump is a more likely mechanism in adults and older children during standard closed chest CPR. Increased intrathoracic pressure during chest com-

pression creates a pressure gradient between blood contained in structures within the thorax compared with extra thoracic blood vessels, which results in blood flow into the periphery. With the thoracic pump mechanism, the heart acts like a conduit with both the mitral and aortic valves open during chest compression. Releasing pressure on the chest in between compressions creates a negative subatmospheric intrathoracic pressure, which is lower than the pressure in the extrathoracic capacitance venous circulation so that the right heart fills prior to the next compression. The abdominal pump mechanism (i.e., abdominal compressions) is not invoked during standard chest compression CPR but is used in some CPR models to compress the abdominal aorta and inferior vena cava to respectively increase diastolic aortic pressure and venous return. There is insufficient evidence to recommend abdominal compressions in children.

21.1.2 Rationale of Pharmacotherapy for Patients with Cardiac Arrest

The initial study of the effect of epinephrine on cardiac output occurred in the 1870s when Pellacani administered adrenal extract to animals and observed increased arterial tone, ventricular contractions, and blood pressure. Since then, subsequent studies have demonstrated the importance of supporting diastolic blood pressure in the successful resuscitation of cardiac arrest. The heart is perfused through the coronaries only during diastole; thus, coronary perfusion is dependent on adequate diastolic blood pressure. Support of diastolic blood pressure, therefore, underlies the selection of pharmacologic agents during cardiac arrest. Standard code-dose epinephrine (0.01 mg/kg or 10 mcg/kg) remains the mainstay of cardiac arrest pharmacotherapy, with epinephrine's alpha-adrenergic vasopressor effects working primarily to augment aortic diastolic blood pressure. In a large analysis of in-hospital pediatric cardiac arrest, delays in epinephrine administration were associated with decreased chance of ROSC and decreased chance of survival. Randomized controlled trials of higher doses of epinephrine have not demonstrated any benefit, with a potential that high-dose (0.1 mg/kg) therapy worsens patient outcomes.

Epinephrine also augments inotropy and chronotropy via beta-adrenergic effects, which risks increasing myocardial oxygen consumption. To reduce this risk, efforts to identify an alternative agent with primary vasopressor properties without the potentially deleterious beta-adrenergic effects led to studies of vasopressin. Vasopressin acts on V1 receptors located on vascular smooth muscle, causing vasoconstriction via phospholipase C-phosphoinositide-mediated calcium release from intracellular stores. Low-dose vasopressin also causes vasodilation of cerebral and pulmonary circulations, potentially via the induction of nitric oxide release. A number of trials in adults failed to show a clear benefit of vasopressin over epinephrine, with a large pediatric cohort study associating vasopressin use with lower ROSC and a trend toward lower survival. There is insufficient evidence to make a recommendation for or against the routine use of vasopressin during pediatric cardiac arrest.

21.1.3 Outcomes After Cardiac Arrest

Pediatric cardiac arrest is a rare event, especially when compared to cardiac arrest in adults. The incidence of out-of-hospital cardiac arrest ranges from 2.6 to 19.7 annual cases per 100,000 children. ROSC is achieved in about 30% of

patients; however, only 24% of patients survive to be admitted to the hospital. Survival to discharge occurs in 8–12% of patients, with intact neurologic survival in only about 4% of patients. Survival differences exist between witnessed arrests (13% survival) compared to unwitnessed arrests (4.6% survival), indicating that earlier interventions may have important effects on long-term outcomes.

Outcomes from in-hospital pediatric cardiac arrest are better, with recent studies indicating 36–50% survival to hospital discharge. In one retrospective cohort multicenter study of inpatient pediatric cardiac arrest, 77% of cardiac arrest survivors were deemed to have a favorable neurologic outcome by the time of discharge, indicating that overall 37% of children who had suffered an in-hospital cardiac arrest had a good neurologic outcome. While differences likely exist in the baseline characteristics of children who suffer out-of-hospital versus those who suffer in-hospital arrests, the presence and availability of skilled providers capable of providing resuscitative efforts likely also contributes to the differences in outcomes. Nonetheless, even with expert resuscitation, cardiac arrest is a life-threatening event, with less than half of children surviving in-hospital cardiac arrest.

As with many aspects of pediatric medicine, efforts have shifted toward prevention and identification of hospitalized children who are clinically deteriorating. Rapid response teams have prevented cardiac and respiratory arrest, improved survival, reduced the need for ICU-level treatments following transfer, and decreased the time between patient deterioration and treatment.

Arrests are often preceded by several warning signs and symptoms. Studies are underway to evaluate the effectiveness of early warning systems such as the Pediatric Early Warning Scores (PEWS). Currently, there is limited evidence to suggest that the implementation of PEWS significantly reduces hospital mortality.

21.1.4 2015 AHA Pediatric Guidelines for Basic and Advanced Life Support for Healthcare Providers

The 2015 AHA guidelines for pediatric resuscitation transitioned from A–B–C (airway, breathing, circulation) to C–A–B sequences for all ages. The guidelines focus on calling for help, starting compressions early, and efficient treatment of dysrhythmias. For infants, the two-finger chest compression technique is recommended for single rescuer CPR, and the two-thumb chest-encircling technique recommended for two rescuer CPR. Compression-only CPR was studied in out-of-hospital pediatric cardiac arrest, with some studies indicating that it may be equally effective in children with a primary cardiac cause of arrest. However, considering most pediatric cardiac arrests are respiratory in origin, conventional CPR is recommended over compression-only CPR in the hospital environment. However, compression-only CPR may be a reasonable alternative in out-of-hospital cardiac arrest if it leads to increased bystander CPR, as lack of any bystander CPR is associated with worse outcomes.

The five components of high-quality CPR are (1) ensuring chest compressions at an adequate rate of 100–120 per minute; (2) compression depth of at least one-third the anterior-posterior diameter of the chest; (3) allowing full recoil between compressions; (4) minimizing interruptions in chest compressions; and (5) avoiding excessive ventilation. Unfortunately, CPR quality for in-hospital pediatric cardiac arrest often does not adhere to guidelines. Interruptions in compressions, including for rescue breaths, rhythm checks, and defibrillation attempts, lead to significantly decreased coronary perfusion

pressures and should be minimized. Leaning on the chest during CPR is common, even during in-hospital pediatric CPR, and was shown to decrease coronary perfusion pressure. Ensuring regular switches (approximately every 2 min) in chest compressors is recommended to decrease fatigue-associated leaning during CPR. Care should also be taken to avoid excessive ventilation, as this increases intrathoracic pressure, which impedes venous return and decreases cardiac output, as well as increasing the risk of stomach inflation leading to emesis and aspiration. An increase in end-tidal carbon dioxide ($ETCO_2$) during CPR reflects an increase in effective pulmonary blood flow, assuming that ventilation is held constant. Thus, monitoring $ETCO_2$ may be used to evaluate the quality of chest compressions. Since ROSC is characterized by a sudden increase in cardiac output, a sudden rise in $ETCO_2$ was shown to be a sensitive marker of ROSC. $ETCO_2$ during CPR may also offer limited prognostic information; however, specific target values have not been established in children.

The ratio of compression-to-ventilation for pediatric patients is 30:2 when a single health care provider (HCP) is present and 15:2 when two HCPs are present. Adult BLS guidelines apply for children at or beyond puberty, with a compression-to-ventilation ratio of 30:2 for one or two HCPs. If an advanced airway is placed, synchronized compression/ventilation cycles are no longer needed. Instead compressions are maintained at a rate of 100–120/min while ventilations are delivered at a rate of 8–10 breaths/min. CPR should continue until an AED or defibrillator arrives to check for the presence of a shockable rhythm. If a pulseless rhythm is found to be shockable (ventricular fibrillation or pulseless ventricular tachycardia), a first shock of 2 J/kg should be delivered, and CPR resumed immediately. After 2 min of CPR, the pulse and rhythm should be rechecked to determine the need for a subsequent shock of 4 J/kg, epinephrine, and continued CPR. The 2015 guidelines were updated to include lidocaine as an alternative to amiodarone for the treatment of ventricular tachycardia and ventricular fibrillation.

If bradycardia (<60 bpm) results in significant cardiopulmonary compromise (i.e., hypotension, signs of shock or acutely altered mental status) despite adequate oxygenation and ventilation, CPR should be initiated. Epinephrine remains the primary drug to treat pediatric bradycardia with compromised circulation; atropine is only reserved for cases when the bradycardia is believed to be secondary to excessive vagal tone or a primary AV conduction block. Persistent bradycardia unresponsive to ventilation, oxygenation, and medications is a potential indication for transcutaneous cardiac pacing (see Temporary Cardiac Pacing section).

Advanced airway placement during CPR allows continuous chest compressions; however, there is no clear benefit of endotracheal intubation over bag-valve-mask ventilation in out-of-hospital cardiac arrest. A laryngotracheal airway may provide a feasible alternative to endotracheal intubation, with some evidence that laryngotracheal airways confer a survival benefit in adult out-of-hospital arrest. Airway management ultimately depends on provider expertise and resources, with an emphasis remaining on avoiding interruptions in compressions.

Extracorporeal CPR (ECPR) may be considered for refractory cardiac arrest; however, studies found no overall benefit to ECPR compared with conventional CPR. However, compared with children with non-cardiac disease, children with underlying cardiac disease appear to have improved outcomes when ECPR is initiated in a critical care setting. Therefore, ECPR may be considered for pediatric patients with underlying cardiac disease suffering an in-hospital cardiac arrest.

Post-arrest care is focused on reversing the underlying disease process, optimizing end-organ perfusion, and avoiding secondary injury. While studies have

CPR most likely provides support during standard closed chest CPR by a "thoracic pump" mechanism in children and adolescents, whereas direct cardiac compression is likely important in infants and young children. The thoracic pump mechanism increases intrathoracic pressure during compression, which creates a pressure gradient that moves blood from the intrathoracic to extrathoracic compartments; releasing pressure in between compressions creates a subatmospheric intrathoracic pressure that helps refill the heart from blood in the higher pressure extrathoracic veins.

Supporting diastolic blood pressure is important during cardiac arrest, likely because coronary perfusion is dependent on diastolic blood pressure. At standard code-dose (0.01 mg/kg or 10 mcg/kg), epinephrine's predominant alpha-adrenergic vasoconstrictor effects augment aortic diastolic blood pressure.

The five components of high-quality CPR are (1) ensuring chest compressions at an adequate rate of 100–120 per minute; (2) depth of at least one-third the anterior-posterior diameter of the chest; (3) allowing full recoil between compressions; (4) minimizing interruptions in chest compressions; and (5) avoiding excessive ventilation.

Post-arrest care focuses on reversing the underlying disease process, optimizing end-organ perfusion, and avoiding secondary injury. There is no clear benefit to induced hypothermia following cardiac arrest, but fever (>38 °C) should be aggressively avoided.

Post-arrest, inspired oxygen concentration should be adjusted to achieve a pulse oximeter saturation between 94% and 99%.

not demonstrated a clear benefit to induced hypothermia following either in-hospital or out-of-hospital pediatric cardiac arrest, AHA guidelines recommend either maintaining 5 days of continuous normothermia (36 °C to 37.5 °C) or 2 days of initial continuous hypothermia (32–34 °C) followed by 3 days of continuous normothermia in comatose children following cardiac arrest. Fever (temperature > 38 °C) should be aggressively avoided. Given the potential oxidative stress of hyperoxia, inspired oxygen concentration should be weaned to maintain an oxyhemoglobin saturation of less than 100% but greater than 94%.

21.2 Extracorporeal Life Support

Veno-arterial extracorporeal membrane oxygenation (ECMO) is a form of prolonged cardiopulmonary bypass (CPB) that provides complete respiratory and cardiac support for critically ill patients with refractory cardiac and/or respiratory failure. Since 1990, over 60,000 patients have required ECMO for severe cardiopulmonary failure. Of those pediatric patients who received ECMO, greater than 70% survive to decannulation.

21.2.1 Mechanics of ECMO

A detailed physiologic description of ECMO is beyond the scope of this review. However, it is important conceptually to understand the means by which ECMO supports those with severe cardiac and/or respiratory failure. During ECMO, blood is removed from the venous circulation, oxygenated, and then returned to either a venous or arterial circuit. Veno-venous ECMO returns oxygenated blood to the venous circulation that is subsequently delivered to the pulmonary bed; systemic cardiac output depends on intact cardiac function and low pulmonary vascular resistance. Veno-arterial ECMO returns oxygenated blood to the systemic arterial circulation. ECMO flow can be supported through the use of either a roller or centrifugal pump. Data from the extracorporeal life support organization (ELSO) indicates that many institutions have converted to the use of centrifugal pumps for pediatric cardiac and respiratory ECMO, pediatric ECPR, and neonatal cardiac and ECPR. However, in neonatal respiratory failure, roller pumps are more commonly used. In comparison to roller pumps, centrifugal pumps are associated with increased hemolysis, hyperbilirubinemia, need for inotropic support, acute renal failure, and non-surgical bleeding. Contact of blood with the bioactive materials of the ECMO circuit is associated with an inflammatory response. Although controversial, pulsatile flow has been shown to better preserve the microvasculature, which may attenuate the systemic inflammatory response associated with EMCO.

21.2.1.1 Veno-Venous (VV) ECMO

VV ECMO has become the preferred mode of ECMO for respiratory support and should not be used for primary severe cardiac dysfunction. In VV ECMO the circuit is connected in series to the heart and lungs. Blood is removed from the venous circulation via a large catheter placed into the internal jugular vein, femoral vein, or the right atrial appendage for centrally cannulated patients. Blood is then pumped via a centrifugal or roller head pump through a membrane oxygenator, becomes highly oxygenated, and then is returned back to the venous circulation.

Systemic delivery of oxygenated blood is dependent upon adequate right-ventricular function, low pulmonary vascular resistance and left-atrial pres-

sure, and adequate left-ventricular function. Cannula placement and size must allow simultaneous venous drainage from and return to the patient's central venous circulation at sufficient flows to replace enough of the compromised lung function and maintain adequate oxygenation and ventilation. The efficacy of VV-ECMO can be affected by malpositioned cannulae that limit flow or increase recirculation of blood in the ECMO circuit. In contrast to VA ECMO, VV ECMO may result in recirculation, which occurs when oxygenated blood returning from the ECMO circuit is captured by the venous drainage port of the cannula without passing through the systemic circulation. Recirculation results in an increased monitored venous oxygen saturation noted in the venous drainage port and less than optimal tissue oxygenation. Determinants of recirculation include the cannula type and position along with the extracorporeal flow rate relative to the patient's cardiac output. Recirculation can be minimized by assuring optimal positioning of the bi-caval lumen catheter and avoidance of excessive ECMO flow rates. Specifically, with the bi-caval lumens, oxygenated venous return to the patient should be directed toward the tricuspid valve and the drainage holes should be oriented toward the lateral portion of the right atrium. The use of echocardiography and/or fluoroscopy can aid in optimizing catheter placement. High flow rates may increase streaming of oxygenated blood from the oxygen delivery port of the catheter to the venous drainage port.

21.2.1.2 Veno-Arterial (VA) ECMO

VA ECMO supports both the cardiac and respiratory systems. During VA ECMO, blood is removed from the venous circulation as seen with VV ECMO. However, after oxygenation the blood is returned to the aortic arch either through the common carotid artery, femoral artery, or directly to the aortic arch via central cannulation. With VA ECMO the circuit is connected in parallel to the heart and lungs. In comparison to VV ECMO, VA ECMO bypasses the pulmonary circulation in a flow-dependent manner resulting in a much higher arterial partial pressure of oxygen and oxygen delivery.

VA ECMO, especially pediatric peripheral VA ECMO, which most commonly uses the femoral vessels, may significantly increase left ventricular (LV) afterload through retrograde infusion of arterialized blood into the descending aorta. This increased afterload results in LV dilation and increased left ventricular and atrial pressures, which may cause hydrostatic pulmonary edema. To minimize LV overload and support recovery of the failing heart during VA ECMO, the failing LV may be unloaded by performing an atrial septostomy, which allows for left-to-right atrial flow, or by percutaneous or direct surgical venting of the LV.

21.2.2 Indications for ECMO

Indications for ECMO include hypoxemic or hypercapnic respiratory failure, circulatory failure, or a combination of both cardiac and respiratory failure. The use of ECMO for patients with cardiorespiratory failure should be deployed while recognizing that it does not treat the underlying illness. ECMO can be a bridge to recovery, a bridge to transplant, or a bridge to a ventricular assist device. Most contraindications are relative and patient specific. Relative contraindications may include the following: irreversible conditions; preexisting conditions which affect the quality of life; age and size of patient; and futility. Prolonged intubation and mechanical ventilation greater than 2 weeks also may be considered a potential contraindication. Caution should be taken

to employ ECMO in those with severe coagulopathy, concern for cognitive compromise prior to initiation of ECMO, or if the use of a ventricular assist device would be superior for the patient. With improvement in care and ECMO management, underlying illnesses such as malignancy and recent hematopoietic stem cell transplantation are not categorically seen as contraindications in the presence of a reversible illness such as acute respiratory distress syndrome.

21.2.3 Outcomes

Survival outcomes stratified by age and indication from 1989 to 2017 obtained from the Registry of the Extracorporeal Life Support Organization (ELSO) are summarized in ◘ Table 21.1.

21.2.3.1 Outcomes for ECMO Used for Respiratory Indications

Refractory neonatal respiratory failure is the largest single population in the ELSO registry and has the highest rate of survival. Since 1992, the rate of ECMO use for neonatal respiratory support has decreased by approximately 50%. This decline may be the result of improved technologies such as high-frequency ventilation, surfactant, and inhaled nitric oxide. The most common neonatal diagnosis requiring respiratory ECMO is congenital diaphragmatic hernia followed by meconium aspiration and persistent pulmonary hypertension. VA ECMO, through the internal jugular vein and carotid artery, remains the most common form of ECMO for neonatal respiratory failure. The most common complications for neonatal respiratory ECMO are cannula-related and intra-cerebellar hemorrhage.

The number of ECMO cases for pediatric respiratory extracorporeal life support continues to increase. Despite the increase in respiratory ECMO cases and complexity of patients supported, survival remains between 55–60%. The most common indication for pediatric ECMO is infectious pneumonias. Pediatric VA ECMO remains the predominate mode of cannulation. However, over the past decade VV ECMO is increasingly used. The mean duration of respiratory ECMO is longer than ECMO used for myocardial support. Mechanical complications such as oxygenator or cannula malfunctions are more common in pediatric respiratory ECMO than patient-related complications. However, mechanical complications are associated with a lower mortality than those suffering patient-related complications. The most common

◘ **Table 21.1** ECMO outcomes by etiology and age

	Cases (*n*)	Survived ECMO *n* (%)	Survived to discharge or transfer *n* (%)
Neonatal			
Respiratory	30,062	25,297 (84)	22,040 (73)
Cardiac	7242	4697 (65)	2988 (41)
ECPR	1554	1048 (67)	641 (41)
Pediatric			
Respiratory	8162	5487 (67)	4699 (58)
Cardiac	9479	6482 (68)	4844 (51)
ECPR	3469	1995 (58)	1444 (42)

patient-related complication was intracranial hemorrhage, which is associated with a 79% mortality rate.

Factors associated with hospital mortality for patients receiving ECMO for respiratory failure include age, pulmonary diagnosis, concurrent organ dysfunction, severity of ventilator-associated lung injury prior to ECMO, and mode of ECMO. Increased mortality was associated with age >10 years, pertussis, sepsis, opportunistic infections, renal failure, hepatic injury, immunodeficiency, cardiac arrest prior to ECMO, severe acidosis, high mean airway pressures, duration of mechanical ventilation >14 days prior to ECMO, and the use of VA ECMO.

Increased survival was observed in those patients with a younger age, asthma, viral pneumonia or bronchiolitis, aspiration pneumonia, absence of concurrent organ dysfunction, and the use of VV ECMO.

21.2.3.2 Outcomes for ECMO Used for Cardiac Indications

Over the past several decades, the use of ECMO in both neonates and pediatric patients for cardiac failure continues to increase. Survival to discharge for cardiac ECMO is less than that seen for respiratory ECMO but has remained constant between 40% and 50%. In contrast to neonatal cardiac ECMO, pediatric cardiac ECMO patients usually have a longer average ECMO duration and better survival.

Congenital heart disease is the most common indication for neonatal and pediatric cardiac ECMO. Patients with hypoplastic left heart syndrome have the longest duration of ECMO and the lowest survival rate, while those pediatric patients with right-sided obstructive lesions have shorter ECMO runs and a higher survival. Neonates with cardiomyopathy or myocarditis have a higher rate of survival. Among pediatric cardiac ECMO patients, those with myocarditis have the highest survival rate.

Bleeding at the surgical site is common and occurs approximately in 25% of both neonatal and cardiac patients requiring cardiac ECMO. Intracranial pathology, cerebral infarction, or intracranial hemorrhage is associated with reduced survival in both neonates and children.

During ECMO blood is removed from the venous circulation, oxygenated, and then returned to either the venous or arterial circuit (i.e., veno-venous or veno-arterial ECMO, respectively).

ECMO for patients with cardiorespiratory failure should be deployed recognizing that ECMO supports the cardiorespiratory system, but does not treat the underlying illness.

ECMO is used as a bridge to recovery, a bridge to transplant, a bridge to provide time for a decision to be made, or a bridge to a ventricular assist device (i.e., destination therapy).

21.2.4 Extracorporeal Cardiopulmonary Resuscitation (ECPR)

ECMO cannulation during active chest compressions is termed extracorporeal cardiopulmonary resuscitation (ECPR). ECPR is increasingly being deployed as an adjunct to conventional CPR. Currently there is insufficient evidence to recommend the use of ECPR for pediatric out-of-hospital cardiac arrests. When ECPR is used during in-house pediatric cardiac arrest, the outcome for children with underlying cardiac disease is better than for those with non-cardiac disease. In centers where rapid initiation of ECMO is possible, ECPR may be considered in children with cardiac disease following in-house cardiac arrest. Compared with ECMO for cardiac and/or respiratory failure, the overall survival for ECPR is lower in both neonatal and pediatric patients undergoing ECPR.

Non-cardiac diagnosis, pre-arrest renal insufficiency, and longer duration of CPR prior to ECMO initiation are all associated with an increased odds of death. Adverse events including neurologic, pulmonary, renal, metabolic, cardiovascular, and hemorrhagic occurring during ECMO are also associated with increased odds of death with higher odds occurring when multiple adverse events are documented during ECMO.

Recirculation is a phenomenon in which reinfused oxygenated blood during VV ECMO is withdrawn by the drainage cannula without passing through the systemic circulation, which decreases the efficiency of VV ECMO. If repositioning the cannula does not reduce recirculation, the ECMO flow rate may need to be reduced.

Neonatal respiratory failure is the most common indication for ECMO and has the highest rate of survival.

When ECPR is used during in-house pediatric cardiac arrest, the outcome for children with underlying cardiac disease is better than for those with non-cardiac disease.

21.3 Mechanical Assist Devices

Although the development of pediatric mechanical circulatory support devices has lagged behind that of adults, the gap between them is steadily closing. The type of pediatric mechanical circulatory support selected is determined by the type of organ support needed, anticipated duration of support, patient's body size, and the goal of mechanical circulatory support (recovery, destination, or transplant). Mechanical circulatory support options in children include ECMO, intraaortic balloon pumps (IABP), and ventricular assist devices (VADs). VA ECMO remains the most common form of mechanical support allowing for complete cardiopulmonary support. As previously noted, VV ECMO is indicated for patients with severe respiratory failure. Classically VA ECMO has been utilized for cardiopulmonary support whereas VADs have been used solely for cardiac support. In contrast to VA ECMO, single ventricle VADs require an adequate degree of native cardiac and lung function. Within the past several years, there are case reports describing the use of oxygenators in combination with biventricular VADs to provide adequate oxygenation and ventilation.

21.3.1 Intraaortic Balloon Pumps (IABP)

The use of an IABP in a pediatric patient was first described in 1989. A balloon pump can be inserted peripherally or centrally and consists of a long balloon positioned in the descending aorta. Balloon timing is synchronized with ventricular diastole and systole. The balloon is inflated during ventricular diastole and deflated during ventricular systole (Fig. 21.1). During inflation (ventricular diastole) the balloon enhances coronary perfusion by displacing aortic blood into the coronary circulation as well as facilitating antegrade blood flow, while during deflation (ventricular systole), ventricular afterload is reduced by

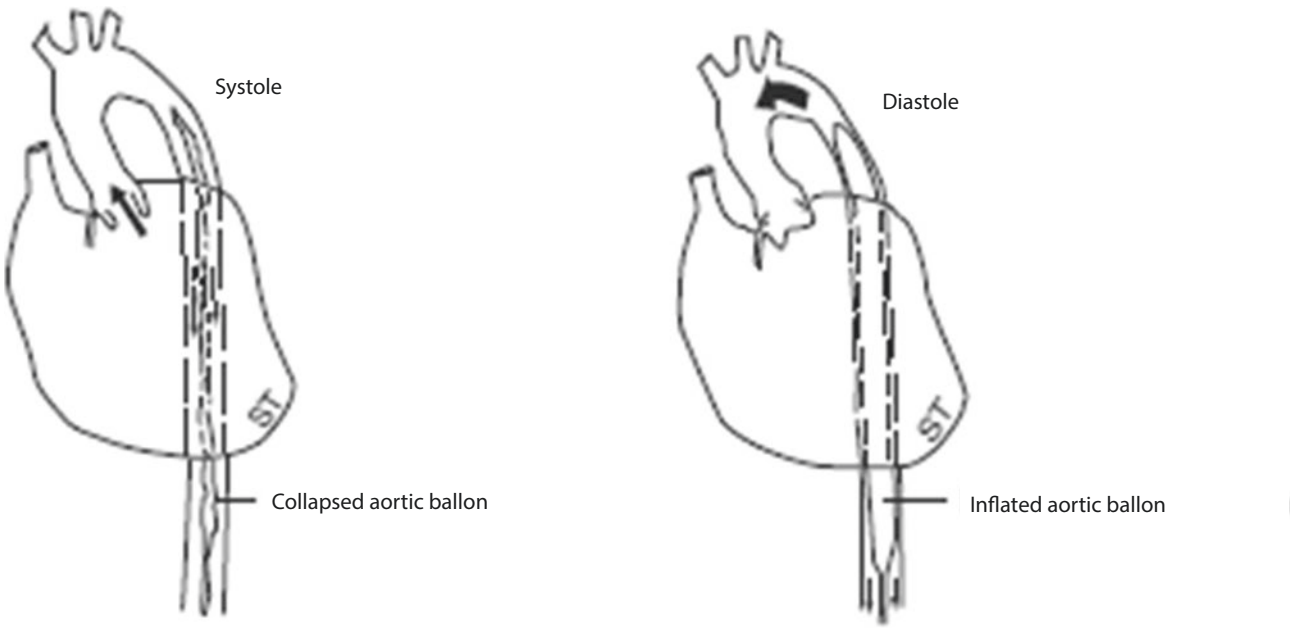

Fig. 21.1 Intraaortic balloon pump position during diastole and systole. Note that inflation during diastole increases diastolic pressure and displaces blood from the aorta into the coronary circulation

creating an "empty" space in the aorta that is filled by ventricular contraction. The reduced afterload enhances ventricular emptying (i.e., increases stroke volume) and reduces ventricular wall stress by reducing end-diastolic pressure and volume.

IABP provides support only to the left ventricle and is indicated for those conditions associated with left heart failure. Unfortunately, balloon size and the increased compliance of the juvenile aorta limit the use of balloon pumps in pediatric patients. The usage of IABPs for temporary circulatory support in children has not been widespread. Balloon pumps may be reasonable for short-term support in larger children and adolescents with isolated left heart failure. Complications following IABP include sepsis, bleeding, and transient limb, mesenteric, renal, and celiac artery ischemia.

21.3.2 Ventricular Assist Devices (VADs)

VADs are designed to assist either the right ventricle (RVAD), the left ventricle (LVAD), or both ventricles (BiVAD). The type of ventricular assistance device applied depends upon the type of underlying heart disease and pulmonary arterial resistance. RVADs pump blood from the right atrium or ventricle to the pulmonary artery whereas LVADs pump blood from the left ventricle to the aorta. BiVADs are composed of two separate devices: one for support of the RV and one for support of the LV. For patients with minimal native cardiac function and no hope for a recovery, a BiVAD or total artificial heart (TAH) can be used to replace all functions of the native heart. Left VADs (Fig. 21.2) are the most commonly used support devices in pediatrics followed by BiVADs. RVADs and total artificial hearts are infrequently used in pediatric patients.

Initially, VADs were classified according to blood flow characteristics, placement of the VAD in relation to the patient, and the duration of intended use. Blood flow can be pulsatile or continuous. Placement could be intracorpo-

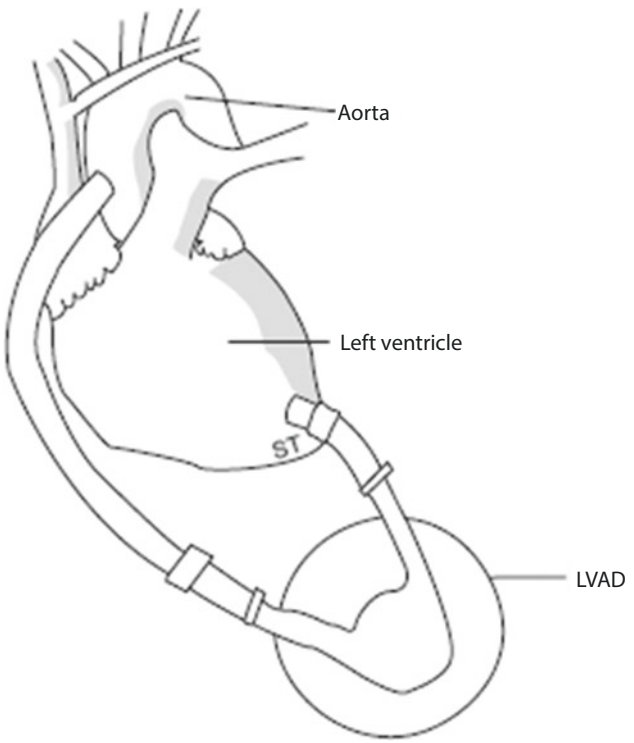

Fig. 21.2 Left ventricular assist device (LVAD)

Table 21.2 Summary of VAD types and devices

VAD type	Device brand
Paracorporeal pulsatile	AbioMed AB 5000, Berlin Heart EXCOR, Thoratec PVAD
Paracorporeal continuous	Thoratec Centrimag & Pedimag, Maquet Rotaflow, Sorin Revolution
Implantable continuous	HeartWare HVAD, HeartMate II LVAD, HeartMate III
Percutaneous	Abiomed Impella 2.5/5.0 & CP, Tandem Heart
Total artificial heart	Syncardia Total Artificial Heart

real, paracorporeal, or percutaneous. Currently, there is a trend toward using devices previously defined as temporary for long-term support. As a result, categorization of device type is now based on design and flow characteristics. Device brands based on design and flow characteristics categories are summarized (Table 21.2)

The first VAD used in a pediatric patient was the Berlin EXCOR pulsatile pump, which is currently the only Food and Drug Administration (FDA)-approved pediatric VAD available in the United States and the only long-term VAD available for newborns and infants; the device is also available for children and adolescents. Device selection differs significantly by the age of the patient and is often a reflection of patient size limitations for implantation. In children weighing less than 20 kg or less than 5 years old, paracorporeal continuous and paracorporeal pulsatile devices are almost exclusively used. Considering all patients less than 19 years of age, intracorporeal continuous flow devices are the most commonly used, followed by paracorporeal pulsatile and paracorporeal continuous flow devices. Percutaneous and total artificial hearts are infrequently used in pediatric patients.

21.3.2.1 Impella (Abiomed Inc.)

The Impella is a temporary percutaneous VAD consisting of an axial flow pump that crosses the aortic valve to unload the left ventricle by delivering nonpulsatile blood flow to the ascending aorta. The Impella has been used for short-term circulatory support in children and adolescents with refractory or ongoing cardiogenic shock, following an acute myocardial infarction, or following open heart surgery. In contrast to VA ECMO, the Impella provides both hemodynamic support and cardiac unloading. The benefits of left ventricular volume unloading include reduction in LV wall stress, improvement in coronary blood flow, and reduced myocardial oxygen consumption. As noted previously, VA ECMO may increase left ventricular afterload and inadequately decompress the left ventricle, especially in patients without a left atrial vent or septostomy and severely depressed systolic function. Reported complications include device malfunction, limb ischemia, vascular injury, hemolysis, bleeding, and infection.

21.3.2.2 TandemHeart (CardiacAssist, Pittsburgh, Pennsylvania, United States of America)

The TandemHeart VAD is an external centrifugal pump traditionally used in adults with heart failure. In adults, the TandemHeart device may be placed percutaneously with an inflow cannula placed transeptally into the left atrium and an outflow cannula placed into the femoral artery. In children, the TandemHeart has been surgically placed via central cannulation similar to ECMO. However, most temporary VADs do not support oxygenation and

require a high minimum flow rate. In pediatrics, several reported circuit modifications to the TandemHeart have been performed to provide lower flow including recirculation shunts, flow occlusion clamps, and, in some cases, an oxygenator. Within the last decade these modifications have allowed for the successful use of the TandemHeart in neonates, infants, and children.

21.3.3 Indications for Use of a VAD

Cardiomyopathy is the most commonly indicated diagnosis, followed by congenital heart disease and myocarditis. VADs can be used as a bridge to heart transplant, to recovery of heart function, or as permanent support for the failed heart (i.e., destination therapy). The primary indication for VAD use in pediatric patients is a bridge to transplant. VAD implantation as a bridge to recovery or destination therapy continues to be infrequent in children.

Contraindications for VAD therapy include significant preexisting neurologic injury, very low birth weight <2 kg, and life-limiting congenital or major chromosomal anomalies. Multisystem organ failure may also be considered a contraindication if organ function is not predicted to be reversible following hemodynamic improvement via the VAD.

21.3.4 Complications Associated with the Use of a VAD

The most frequent complications associated with pediatric VAD use are infection, neurologic dysfunction, and bleeding. Common neurologic complications include stroke, subarachnoid hemorrhage, and seizures. Independent of device type, infection, bleeding, and stroke tend to occur within the first 90 days of support. Reported differences in adverse event rates noted amongst different devices may be due to major differences in the patient population rather than the device type.

21.3.5 Outcomes of Patients Who Require VAD

The Pediatric Interagency Registry for Mechanical Circulatory Support (Pedimacs) is a National Heart, Lung, and Blood Institute-supported North American registry. Pedimacs was developed in 2012 to serve as a comprehensive registry for temporary and durable VADs in children and adolescents <19 years of age. The third annual Pedimacs report summarizes the most current data between September 2012 and December 2017. During this time span, 30 institutions implanted 508 devices in 423 patients. Dilated cardiomyopathy was the most commonly indicated diagnosis, followed by congenital heart disease, and myocarditis. The majority of children with congenital heart disease have single ventricle anatomy.

Actuarial survival of all pediatric VAD patients at 6 months is approximately 74%. Older patients (aged 11–19 years old) have a higher actuarial survival (86%) at 6 months compared with patients less than 1 year of age (50%), who have the highest mortality.

Differences in survival based on device type may reflect differences in age and severity of illness rather than device-specific outcomes. For example, paracorporeal devices that are mostly used in smaller, younger, and more ill patients are associated with a higher earlier mortality compared with intracorporeal devices that are predominantly used in older and less ill patients. Early death is associated with cardiogenic shock, the use of BiVAD, percutaneous devices, paracorporeal continuous devices, smaller volume, younger age, and low weight.

The type of pediatric mechanical circulatory support selected is determined by the type of organ support needed, anticipated duration of support, patient's body size, and the goal of mechanical circulatory support (recovery, destination, or transplant). Mechanical circulatory support options in children include ECMO, intraaortic balloon pumps (IABP), and ventricular assist devices (VADs). ECMO remains the most common form of mechanical support.

During inflation (ventricular diastole) the intraaortic balloon enhances coronary perfusion while during deflation (ventricular systole), ventricular afterload is reduced.

The primary indication for VAD use in pediatric patients is a bridge to transplant and cardiomyopathy is the most commonly indicated diagnosis.

Differences in adverse event rates noted amongst different devices may be due to major differences in the patient population rather than the device type.

Differences in survival based on device type may reflect differences in age and severity of illness.

Survival outcomes stratified by diagnoses are superior in patients with cardiomyopathy compared with those patients with congenital heart disease who tend to have a higher severity of illness.

Neurologic dysfunction and multisystem organ failure are the most common causes of death in patients receiving paracorporeal continuous and paracorporeal pulsatile devices. Neurologic dysfunction is the most common cause of death in patients supported by implantable continuous devices.

21.4 Temporary Pacemakers in the PICU

A temporary cardiac pacemaker is a device that delivers electrical stimulation to the heart resulting in a propagated electrical impulse that results in cardiac contraction. A pacemaker can initiate or maintain a heart rate or overdrive pace a tachyarrhythmia. Temporary leads may be in direct or close contact with the heart in multiple ways: transcutaneous (ventricular pacing only), transvenous, epicardial, or trans-esophageal (atrial pacing only).

In the PICU, temporary cardiac pacing is often performed using epicardial wires placed by the cardiothoracic surgeon usually at the time of surgical palliation or repair of a congenital heart defect. Epicardial temporary pacemakers can pace the atrium if the patient has intact atrioventricular conduction, or the ventricle to provide a minimum ventricular rate in the presence of complete heart block. Dual-chamber pacemakers can pace either or both the atrium and the ventricle, therefore providing atrioventricular (AV) synchrony. Temporary pacemakers are often used to treat symptomatic bradyarrhythmias frequently due to transient postoperative atrioventricular (AV) nodal block. Surgically acquired heart block persisting beyond 14 days is likely to be permanent.

Temporary atrial pacing wires may be used to help the clinician diagnose arrhythmias by obtaining a pure atrial electrogram on a 12-lead electrocardiogram (ECG). An atrial ECG is extremely helpful when P waves are not clearly visible on the surface electrocardiogram. The most useful way to perform an atrial electrogram is to attach the atrial wires to the right-arm and left-arm ECG leads, which will produce a bipolar atrial electrocardiogram in lead I and a unipolar atrial electrocardiogram in the remainder of the limb leads (see Fig. 21.3a, b, Atrial electrocardiogram).

Another useful application of temporary atrial pacing wires is to treat tachyarrhythmias. In junctional ectopic tachycardia the atrial wire may be used to pace faster than the tachycardia (over drive pace) and provide an atrial kick. In reentry supraventricular tachycardia, such as atrial flutter and atrioventricular reciprocating tachycardia, overdrive pacing may terminate the tachycardia. Typically, the pacing rate is set at 10–20 beats faster than the tachycardia rate with pacing intervals at 5–20 s in duration. Multiple attempts with progressively faster rates can be attempted to terminate the tachyarrhythmia.

21.4.1 Normal Cardiac Conduction

The cells in the cardiac myocardium have properties of automaticity. The fastest site of cardiac automaticity will act as the intrinsic cardiac pacemaker. Under normal conditions this site is the sinoatrial (SA) node which is an epicardial structure located near the junction of the superior vena cava (SVC) and the right atrium (RA). The electrical impulse spreads across the RA and

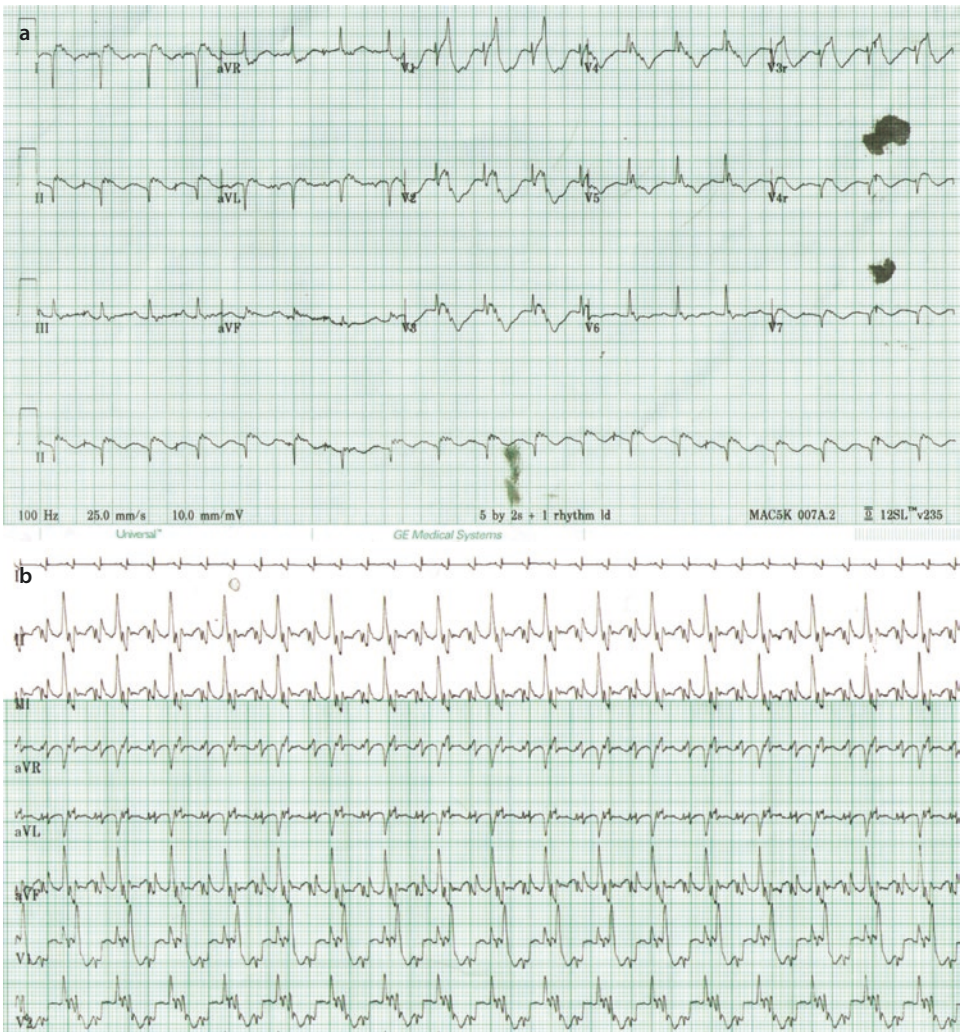

Fig. 21.3 Atrial electrocardiogram. A. Surface electrocardiogram of a patient with Ebstein's anomaly following tricuspid valve replacement who now has an intra-atrial reentry tachycardia with 2:1 AV conduction. The P waves are not clearly seen B. Atrial electrocardiogram of the same patient shows the P waves with 2:1 AV conduction more clearly

through fibers of tissue known as Bachman's bundle to the left atrium. This electrical impulse causes atrial depolarization. The electricity pauses for a fraction of a second at the atrioventricular (AV) node, which acts as a gatekeeper from the atrial to ventricular chambers. Following conduction through the AV node, electricity travels through the His and right and left bundle branches, which causes ventricular depolarization.

21.4.2 Special Considerations for Pediatric Patients

Sinus node dysfunction is rare in the pediatric population but may occur in newborns or infants with the left atrial isomerism variation of heterotaxy since the SA node is missing. Symptomatic bradycardia is more likely due to disease/injury of the AV node. Causes of AV node disease/injury include those that are surgically acquired, drug-induced dysfunction, rheumatic heart disease, Lyme disease, myocarditis, cardiomyopathy, or acute rejection in heart transplant. Patients born with ventricular inversion (L-transposition of the great vessels) have a high risk of AV block throughout their life. The finding of complete heart block is often the presenting finding prior to the diagnosis of isolated

ventricular inversion. There is a risk for operative AV block in any patient undergoing cardiac repair of a defect located near the normal conduction system including aortic, mitral, or tricuspid valve surgeries; ventricular septal defect repair, atrioventricular septal defect repair; or repair of congenitally corrected transposition of the great arteries. In a patient undergoing repair of a cardiac defect with concurrent L-transposition of the great vessels, the risk of postoperative AV block is significantly higher. If surgically acquired heart block persists for more than 14 days, it is likely to be permanent. Temporary epicardial pacing can be used to bridge this interval between intermittent postoperative heart block and recovery of spontaneous conduction; otherwise permanent postoperative heart block requires permanent pacemaker implantation.

Junctional ectopic tachycardia (JET) is sometimes seen as a transient arrhythmia in the immediate postoperative period. It is thought to arise from abnormal automaticity near or within the AV node secondary to stimulation or inflammation associated with surgery in this region. Mildly elevated junctional rates are often well tolerated; however, loss of AV synchrony may be detrimental to some patients in the immediate postoperative period. Atrial overdrive pacing at a slightly faster rate (5–10 beats over the actual JET-rate) may reestablish AV synchrony and improve ventricular filling with the atrial contraction ("atrial kick"). This is usually performed using the temporary atrial pacing wires placed during surgery but may also be accomplished by trans-esophageal pacing of the atria. The pacing rate needs to be continuously adjusted during the treatment of JET to provide the minimal necessary pacing rate.

Children have relatively small blood vessel diameters; therefore, in infants and small children, an epicardial pacing system is preferred over a transvenous endocardial system. Placement of transvenous pacemaker leads in smaller patients may lead to venous congestion or occlusion and preclude future transvenous lead placement. Transvenous pacing leads should not be placed in patients with intracardiac shunts secondary to the risk of paradoxical emboli to the systemic circulation.

Recent literature suggested a benefit to simultaneous pacing of both ventricles compared to conventional right ventricular pacing. This may be performed when the surgeon places a right ventricular and left ventricular epicardial lead at the time of surgery and both wires are connected to the same pacemaker pulse generator. The literature has suggested that this may be especially beneficial in improving cardiac performance if there is a need for temporary pacing after repair of congenital heart disease. Biventricular pacing may also improve pacing-induced ventricular dysfunction associated with right ventricular pacing. Biventricular pacing requires evaluation and adjustment of the threshold energy required on each ventricular lead separately. The final pacemaker ventricular output should be based on the ventricular lead with the highest threshold. In general, the ventricular output should be set 2–3 times greater than the threshold.

21.4.3 Which Temporary Pacemaker Should Be Used?

Choice of the temporary pacemaker settings depends on the clinical situation and the underlying conduction defect. Patients with symptomatic bradycardia (secondary to heart block, sick sinus syndrome, or drugs) may benefit from single-chamber pacing to provide a steady baseline heart rate. With symptomatic sinus bradycardia or sick sinus syndrome and intact AV conduction, single-chamber atrial pacing is preferred. Patients with transient heart block usually have a normal atrial rate and a slow ventricular escape rate. In this situation, hemodynamics are optimized if a dual-chamber pacemaker is used to sense ("track") the intrinsic atrial electrical activity, and sequentially pace the ven-

tricle accordingly. Dual-chamber pacing mimics normal cardiac electrical activity and augments cardiac output by improving ventricular filling with the atrial contraction ("atrial kick") preceding ventricular systole. This is especially important in patients with single ventricle physiology.

21.4.4 Types of Temporary Pacemakers

There are single-chamber and dual-chamber temporary pacemakers. The most commonly used ones are: Medtronic models 5348 (single-chamber) and 5388 (dual-chamber) and St. Jude Medical models 3077 (single-chamber) and 3085 (dual-chamber).

21.4.5 Use of Controls

Caution: Always learn the specific model in your unit before using it on your patient.

21.4.5.1 Single-Chamber Pacemaker

The basic controls on a single-chamber pacemaker include rate (pulse per minute, ppm), output (milliamps, mA), and sensitivity (millivolts, mV). Most temporary models are also able to deliver rapid atrial pacing (RAP) for overdrive atrial pacing to attempt to terminate JET or reentry supraventricular tachycardia (atrial flutter, intra-atrial reentry tachycardia, atrioventricular reciprocating tachycardia, and atrioventricular nodal reentry tachycardia). A rapid atrial pacing rate of up to 800 pulses per minute (ppm) is possible but rates beyond 400/min are rarely used. Modes are designated by a three-letter code corresponding to chamber paced, chamber sensed, and response to sensing (Table 21.3). Mode choices for single chamber temporary pacemakers include: VVI, VOO, AAI, and AOO.

21.4.5.2 Dual-Chamber Pacemaker

The controls for dual-chamber pacemakers follows the basic principles of a single-chamber pacemaker. There are three main controls: rate (ppm), atrial output (mA), and ventricular output (mA). In the secondary menu, in the lower half in the Medtronic model (Fig. 21.4), and adjacent to the major dials on the Abbott/St. Jude Medical model, atrial and ventricular sensitivity and AV interval can be adjusted. The rate and AV delay can be set to maximize cardiac output for a patient's age and clinical status. In general, the AV delay is set between 100–140 ms in most children. Post-ventricular atrial refractory period (PVARP) can also be adjusted. RAP is also available with most dual-

Table 21.3 Standard nomenclature for pacemaker modes

I Chamber paced	II Chamber sensed	III Response to sensing
0 = none	0 = none	0 = none
A = atrium	A = atrium	T = triggered
V = ventricle	V = ventricle	I = inhibited
D = dual (A + V)	D = dual (A + V)	D = dual (T + I)

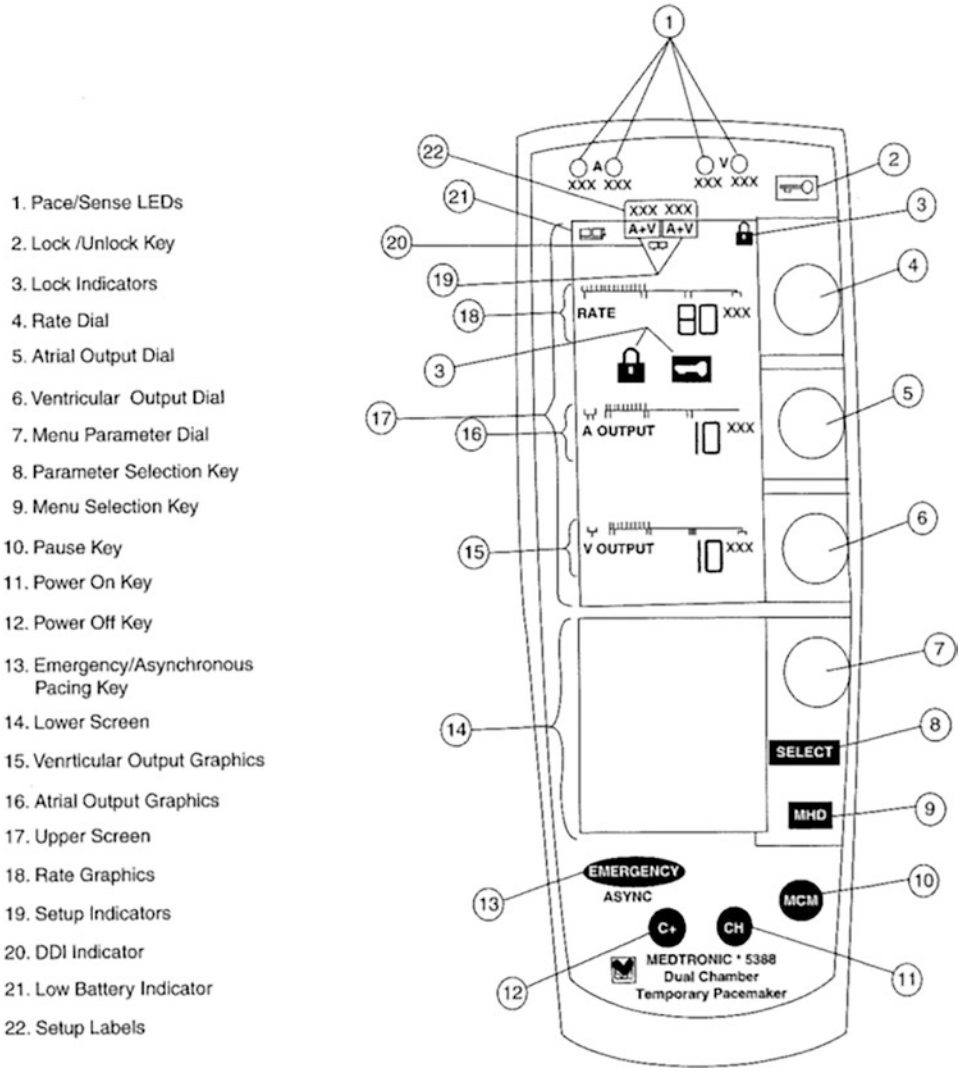

Fig. 21.4 Medtronic 5388 dual chamber temporary pacemaker – pulse generator

chamber temporary pacemaker models. Mode choices for dual chamber temporary pacemakers noted above include: DDD, DDI, DVI, DOO, VVI, VOO, AAI, AOO.

21.4.6 Nomenclature and Parameters to Aid Pacemaker Setting

The different modes of pacing are standardized and described using the North American Society for Pacing and Electrophysiology, and British Pacing and Electrophysiology Group (NASPE/BPEG) devised standard pacemaker codes, the NBG coding system (Table 21.3)

21.4.7 Thresholds

21.4.7.1 Pacing or Capture Threshold

The pacemaker threshold is the minimum amount of energy measured in milliamperes (mA) needed to result in cardiac contraction of the chamber being tested (resulting in an atrial P wave, or ventricular QRS complex). The thresh-

old may vary from beat to beat, and the set output of the pacemaker should be 2–3 times the threshold to provide an adequate safety margin to deliver consistent capture of the heart. Pacing thresholds usually increase significantly over the first 7–10 days and should be checked at least daily in temporary pacemakers.

How to Check the Pacing Threshold?

Pacing threshold is checked by dialing down the output of the chamber being tested. The chamber being tested needs to be set to a rate above the intrinsic rate and actively pacing (otherwise the pacemaker would be inhibited). Testing one lead at a time turn the output to maximum. A pacing spike will be followed by a P wave if the atrium is being paced and capture is present or an R wave if the ventricle is being paced and capture is present. While slowly dialing down the output, note the point at which the pacemaker fails to capture the chamber being tested. Increase the output until capture is achieved. This is the pacing threshold.

Why Should the Pacing Threshold Be Checked?

The pacing threshold is the minimum level of energy measured in mA that produces capture. Over time the pacing threshold is likely to increase secondary to inflammation around the surface of the myocardium where the wire is attached. As noted above, the pacemaker should be set 2–3 times the pacing threshold to allow an adequate margin of safety. It is important to monitor the rate the threshold is increasing as this may be a predictor of impending lead failure. In pacemaker-dependent patients (i.e., patients with inadequate intrinsic rhythm who experience hemodynamic compromise after cessation of pacing), it may be reasonable to check thresholds on a more frequent basis.

21.4.7.2 Sensing Threshold

Sensing threshold is the sensitivity level, measured in millivolts (mV), at which the pacemaker recognizes (senses) an intrinsic cardiac electrical impulse. It is helpful to think of pacemaker sensitivity as the height of a wall that one tries to see over. The higher the number, the higher the wall and the less one sees over its top; therefore, the less the pacemaker senses. The lower the number (the lower the height of the wall), the more one sees over the wall and the more sensitive the pacemaker.

Why Is It Important to Know the Sensitivity Threshold?

If the pacemaker is too sensitive, oversensing can occur. Pacemaker oversensing is when the pacemaker sees electrical activity that it inappropriately recognizes as native cardiac activity and subsequently inappropriately inhibits pacing function. The inappropriate electrical activity may be secondary to muscle tremors, respiratory movement, far-field cardiac electrical activity (sensing intrinsic paced activity from a chamber other than where the pacemaker lead is placed), or environmental electrical interference. If the pacemaker sensitivity is not sensitive enough, undersensing will occur. During undersensing the pacemaker continues to pace at a set rate even when intrinsic cardiac electrical activity is present at a rate faster than the pacemaker is set (i.e., the pacemaker will not inhibit pacing appropriately). This is potentially dangerous during ventricular pacing. If the pacemaker fails to sense the R wave appropriately, and paces on a T wave, it could result in ventricular tachycardia or ventricular fibrillation via an R on T phenomenon. However, in certain emergency situations, such as a patient with symptomatic bradycardia, it may be necessary to accept this risk of ventricular undersensing. An example

is a pacemaker-dependent patient with extra-cardiac electrical interference that produces larger electrical amplitude than the intrinsic cardiac electrical activity. In these situations, the pacemaker could be made totally insensitive (high sensitivity number) and therefore would pace asynchronously.

How to Check Sensitivity Threshold?

The pacemaker rate should be at or below the intrinsic heart rate. Start by turning the sensitivity knob to higher numbers, making the pacemaker less sensitive. Note the point when the pacemaker begins to inappropriately pace. At this point the pacemaker should pace regardless of the intrinsic rhythm. Then begin turning the sensitivity level toward the lowest number (most sensitive setting). Note the point at which the pacemaker senses and is appropriately inhibited. This is the sensitivity threshold.

How to Set Sensitivity Level?

Once the sensitivity threshold is found, the sensitivity level should be set to half or one-third of the threshold.

21.4.8 Intrinsic Rhythm

The underlying intrinsic rhythm can most easily be checked by slowly dialing down the pacemaker rate in VVI mode. The pacemaker should not be stopped abruptly if the patient is in a persistently paced rhythm; doing so may cause a significant period of asystole and discomfort to the patient or loss of consciousness. By dialing the pacemaker rate down slowly, the intrinsic rhythm will slowly resume. When checking the intrinsic rhythm, it is recommended to have the patient lying down. In children, one should not dial down below 50 ppm, and in adolescent or adults, below 40 ppm. Patients may become symptomatic during these checks and experience dizziness, yawning, or nausea prior to loss of consciousness. The temporary atrial and ventricular leads can be connected to a 12-lead ECG machine to record intrinsic atrial or ventricular electrograms.

21.4.8.1 Battery

When a temporary pacemaker is in use, a spare battery should be taped to the pacemaker, making it readily available. The battery should be changed every 24 hours.

21.4.8.2 Documentation

The following is a guideline of the parameters which should be documented each time the pacemaker is checked (at least once a day):

- Pacing threshold
- Sensitivity threshold
- Intrinsic cardiac rhythm
- Pacemaker setting

21.4.9 Contraindications and Precautions

All the new temporary pacemakers are designed to only deliver high rate therapy in AOO mode since rapid ventricular pacing may cause ventricular tachycardia or ventricular fibrillation. High atrial pacing rates may cause unintended

conduction to the ventricles. Thus, defibrillation equipment should be available when delivering high-rate therapy to the atrium. The patient's bed and electrical equipment must be properly grounded because the temporary leads provide a low-resistance circuit through which electrical current can pass through to the heart, causing significant arrhythmias.

21.4.10 Sites and Techniques of Placement

21.4.10.1 Temporary Epicardial (Post-Cardiac Surgery)

Depending on institutional practice, these systems are placed either prophylactically (in operations with high risk of creating heart block) or when AV block develops intraoperatively. Temporary leads are made of stainless steel Teflon-coated wire and are available in unipolar and bipolar forms. The wires are sutured onto the epicardium and brought out through the chest wall. Atrial wires are usually brought out to the right of the sternum, ventricular wires to the left, and are usually clearly labeled. Since they are loosely sutured to the epicardium, these leads should be fixed to the skin to avoid accidental displacement. Patients should be monitored on telemetry while the temporary leads are being used. The exit sites of the wires should be cleaned and dressed daily to avoid infection. In general, pacing thresholds will begin to increase after day 4 from implant, which is thought to be secondary to inflammation at the lead implantation site.

21.4.10.2 Temporary Transvenous

In the pediatric population, transvenous temporary pacing leads are used primarily for adolescents due to the size of the adolescent's vessels and other anatomical considerations. As mentioned, transvenous leads may cause venous congestion or occlusion in small children. In children with single ventricle physiology, who have had a Fontan-type operation, the ventricle would not be accessible via the systemic venous system. In these patients, a transvenous atrial lead is only appropriate if there is no intracardiac right to left shunt and if AV conduction is intact. Temporary transvenous leads are appropriate in older children who develop symptomatic bradycardia with normal cardiac anatomy. There are several types of temporary pacing catheters available. Both unipolar and bipolar leads are available, but more commonly, bipolar leads are used because of improved sensing threshold. There are two major types of catheters, one is more rigid and firm and requires fluoroscopic guidance for catheter placement, and the other type has a balloon tip and can be floated into position. Details about the variety of catheters in each group are beyond the scope of this chapter. These catheters are positioned in the right atrial appendage for atrial pacing or the right ventricular free wall, for ventricular pacing. Depending upon the patient's clinical status and the operator's experience, leads can be placed via different veins. More commonly, the internal jugular or the subclavian approached is used; however, brachial or femoral veins can also be used. After lead placement, a chest radiograph is obtained to document lead position and the catheter is fixed to the skin using non-absorbable suture. Although thresholds tend to rise less rapidly, sensing and pacing thresholds should still be checked daily and the output and sensitivity levels set accordingly. Risks associated with transvenous temporary pacing leads include lead dislodgment and cardiac perforation.

21.4.10.3 Temporary Transesophageal Pacing

This is especially useful in children and can be used to obtain electrograms as well as for pacing. A 4-Fr, 5-Fr, or 10-Fr transesophageal lead can be inserted and advanced until the largest, most distinct atrial electrogram is recorded. It can be used to diagnose the mechanism of atrial arrhythmias, especially if P waves are not obvious on the surface ECG. It can be used to analyze the electrical relationship between the atrium and ventricle. The catheter can be used for overdrive atrial pacing to terminate supraventricular tachycardia. A disadvantage of transesophageal pacing is that large output (usually above 10 mA) and long pulse width (usually 10 ms) are necessary to capture the atrium and may cause patient discomfort. Temporary transesophageal pacing is only capable of atrial pacing; ventricular capture is not possible. The risk associated with transesophageal pacing includes esophageal damage when used for longer periods of pacing with high energy outputs. Transesophageal pacing is generally used for short intervals to terminate supraventricular tachycardia. Atrial pacing during sinus bradycardia with normal AV nodal conduction longer than 24 hours is not routinely recommended.

21.4.10.4 Temporary External Transcutaneous Pacing

Paul Zoll introduced an external cardiac pacemaker system via "pads" more than 50 years ago, often called "Zoll pads." The Zoll Company continues to develop noninvasive temporary pacemakers that may be safe, effective, and well tolerated by patients. This type of pacing may be lifesaving in patients who progress from bradycardia to cardiac arrest as it is designed for easy and rapid application. It may be uncomfortable for patients who are alert and conscious but can be used while a temporary transvenous system is being placed. It is generally not recommended for periods over 24 h.

In an emergency without the availability of an epicardial or a transvenous pacemaker, pacing pads should be applied on the front and back of the chest, and attached to an external pacing device. When turned on, the heart can be paced. Bradycardia that is unresponsive to ventilation, oxygenation, and medication is an indication for emergency transcutaneous pacing; however, pacing is not useful for pulseless electrical activity or asystole.

Emergency transcutaneous pacing is performed using the following steps:

1. Attach pacemaker pads according to manufacturer recommendations. For children less than 15 kg, pediatric pads are recommended, whereas larger children can utilize adult-sized pads. The negative electrode pad is placed over the cardiac apex (typically at the point of maximal impulse), and the positive electrode is placed either in the anterior right subclavicular area or posteriorly between the spine and left scapula.
2. Set the desired rate – usually 100 bpm.
3. In the unconscious patient, begin with a high current output (200 mA) to rapidly achieve capture and then decrease the output to the level needed to maintain capture. Set output 10 mA above the threshold output.
4. In the conscious patient consider sedation and analgesia. Start with a low output and gradually increase the output in 10 mA increments until capture is demonstrated. Set the output 10 mA above the threshold output.
5. It is often impossible to tell from the surface ECG whether the heart is being captured secondary to the large amount of energy-creating artifact that masks the intrinsic electrical signal. Thus, it is important to assess the patient's hemodynamics and palpate a pulse to confirm appropriate pacing capture.

21.4.11 Troubleshooting Pacemaker Malfunction

Failure to pace and failure to capture produce the same outcome – i.e., unable to cause an atrial or ventricular contraction, therefore emergently, actions taken are the same.

Failure to Pace Also known as output failure, which means that the pacemaker fails to deliver an electrical impulse. There will be no pacing spike evident on the ECG. Causes include lead fracture or dislodgement, loose connections, battery failure, generator failure, or oversensing (see below).

Oversensing The pacer perceives noncardiac electrical activity as a true myocardial electrical event and therefore inhibits the pacemaker. These noncardiac stimuli may occur from distant muscle contraction or electromagnetic interference. Although less dangerous than undersensing, oversensing in the DDD mode can lead to an inappropriate inhibition of pacer electrical activity. To reduce oversensing, the pacer must be made less sensitive to artifact electrical activity. This is accomplished by increasing the sensitivity threshold (mV), allowing the pacer to discriminate true myocardial electrical events from the low millivolt artifact.

Failure to Capture Also known as loss of capture, the pacemaker delivers a discharge but the pacing spike is not followed by an appropriate electrical cardiac event (P wave for atrium, QRS for ventricle). Causes include increased pacing threshold, loose connections, prolongation in myocardial refractoriness (long QT), and poor epicardial lead contact (positioning patient on left side may increase contact). The most important cause of loss of capture is a progressive increase in pacing threshold. Over time, the pacing threshold increases which is why the output is initially set at 2–3 times the threshold. This progressive increase is due to inflammation and fibrosis around the surface of the myocardium where the wire is attached. Other factors that increase the threshold are acid-base changes, electrolyte imbalances, antiarrhythmic drugs, myocardial ischemia and hypothyroidism. An increase in the energy output may be required to treat loss of capture pending identification and treatment of causative factors. If loss of capture is noted, output should be immediately increased to maximum output to reestablish consistent pacing, then the pacing threshold should be rechecked. With temporary pacemakers it is imperative to check the pacing threshold regularly (at least daily) to avoid loss of capture.

Failure to Sense (Undersensing) The pacemaker fails to identify the heart's inherent electrical activity and delivers an electrical stimulus inappropriately. With ventricular pacing this is a potentially dangerous situation as an inappropriate electrical impulse may be delivered to the myocardium during an electrically vulnerable period leading to a ventricular arrhythmia (R on T phenomenon). In this situation, the pacemaker is not sensitive enough to detect inherent cardiac electrical activity and therefore needs to be made more sensitive. Increasing the pacemaker sensitivity for inherent cardiac activity is accomplished by decreasing the sensitivity threshold (mV). This allows the pacemaker to "see" cardiac events occurring at a lower millivolt level.

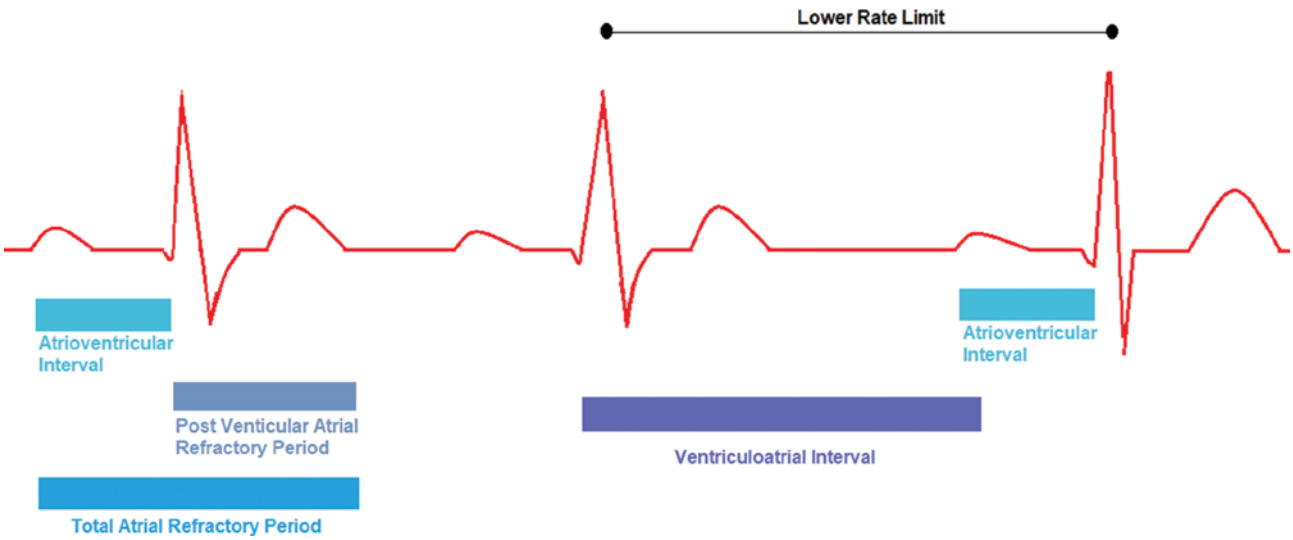

Fig. 21.5 The total atrial refractory period (TARP) is the sum of the atrioventricular interval and the postventricular atrial refractory period (PVARP). The pacer timing cycle in DDD mode takes into account the lower rate limit (LR), an atrioventricular interval, a ventriculoatrial interval, and the post-ventricular atrial refractory period. If intrinsic atrial and ventricular electrical activity is sensed before the LR limit times out, both atrial and ventricular pacer output are inhibited and no pacing occurs. If no atrial activity is sensed before the ventriculoatrial interval is completed, atrial pacing becomes uninhibited and a pacer spike is delivered. If no ventricular activity is sensed before the atrioventricular interval is completed, ventricular pacing becomes uninhibited and a pacer spike is delivered

Temporary pacemakers are often used to treat transient postoperative heart block but may also be used for diagnosing arrhythmias via an atrial electrocardiogram. Surgically acquired heart block persisting beyond 14 days is likely to be permanent

All temporary pacemakers have three major dials: rate (ppm), output (mA), and sensitivity (mV). Dual-chamber models have separate atrial and ventricular output and sensitivity control. Most temporary pacemakers can deliver rapid atrial pacing for overdrive termination of atrial tachyarrhythmias.

Pacing threshold (mA) is the minimum amount of pacemaker output required to capture the heart (a pacemaker spike followed by P or R wave). Output is set at 2–3X the pacing threshold.

Sensing threshold (mv) – minimum amount of intrinsic electric activity that is recognized ("seen") by the pacemaker. Sensitivy is set to one-half to one-third sensitivity threshold.

Alternatively, the pacer may not sense due to lead dislodgement or poor epicardial contact. Placing the patient on their left side may increase the lead and epicardium contact area.

Pacemaker-Mediated Tachycardia (PMT) Depending on intrinsic retrograde AV node conduction, ventricular pacing may result in retrograde ventriculoatrial (V → A) conduction and a subsequent retrograde P wave. With dual chamber sensing and pacing, the pacemaker's atrial lead senses this retrograde P wave and "sees" it as the intrinsic sinus beat, which triggers subsequent ventricular pacing. If this paced ventricular complex again results in a retrograde P wave, a reentrant loop is set up and pacemaker-mediated tachycardia develops. The pacemaker forms the antegrade (A → V) limb of the circuit and the AV node is the retrograde limb (V → A). This potential arrhythmia is best prevented by choosing a post-ventricular atrial refractory period (PVARP) long enough to prevent the sensing of the retrograde P waves. Treatment of PMT typically involves altering the pacemaker programming to make the atrial lead insensitive to the retrograde P wave, or electromagnetic interference. PMT is most easily fixed by prolonging the PVARP. Note that this may affect the upper tracking rate of the pacemaker as this is defined by the total atrial refractory period (TARP), i.e., TARP = AV interval + PVARP (Fig. 21.5). For example, if the AV delay is 170 ms and the PVARP is set to 430 ms, the TARP then is 600 ms, which corresponds to an upper rate of 100/min (rate = 60,000/cycle length in ms). Thus, the pacemaker would not track atrial rates above 100 bpm leading to a 2:1 block for this and higher rates. Other options include programming the pacemaker as DDI, if possible, so as not to track the P waves. If AV conduction is intact, an AAI mode would eliminate PMT by avoiding ventricular pacing.

A suspected pacer malfunction requires rapid support of the child and careful interrogation of the rhythm and pacemaker. Figure 21.6 provides an algorithm to help identify and treat pacemaker malfunctions.

Suspected Pacer Malfunction

↓

Check patient, support ABCs
Call for help

↓

Check ECG for pacer spikes and cardiac electrical complexes

No pacer spike and no subsequent complexes	**Pacer spikes but no subsequent complexes**	**Inappropriately placed pacer spikes (asynchronous pacing)**
↓	↓	↓

Failure to pace	**Failure to capture**	**Failure to sense**
Causes • Battery or generator failure • Lead dislodgment • Wire fracture • Disconnected wire or cable • **Oversensing** Inappropriate inhibition due too versensing of noncardiac electrical activity Pacer should have fired! 	Causes • Battery or generator failure • Faulty connections • Prolonged QT • Electrolyte abnormalities • **Increased Pacer Threshold** Increases resistance at site of epicardial contact 	Causes • Battery or generator failure • Faulty connections • New BBB • Dysrhythmia • **Undersensing** Inadequate sensitivity causing pacer to miss true cardiac conduction and subsequently delivering inappropriate impulses  Note asynchronous pacing spikes should have fired!
Actions • Assure ABCs • Check power • Check connections • Position patient on left side If **oversensing** suspected (inappropriate inhibition of pacer output), make pacer less sensitive by increasing the mV that the pacer will respond to thus eliminating noncardiac artifact.	Actions • Assure ABCs • Check power • Check connections • Position patient on left side If an increase in the pacer threshold is suspected, increase the delivery of the electrical impulse by turning up the output in mA (20 mA emergently).	Actions • Assure ABCs • Check power • Check connections • Position patient on left side If **undersensing** suspected (pacer missing true cardiac conduction), make pacer more sensitive by decreasing the mV that the pacer will respond to thus allowing pacer to see true cardiac conduction.

Fig. 21.6 Algorithm for suspected pacer malfunction. (Courtesy of Frank A. Maffei)

Undersensing results in overpacing and oversensing results in underpacing.

Pacemaker interrogation, documentation, and battery change should be performed at least once every 24 hours.

Rapid atrial pacing may cause inadvertent rapid ventricular pacing, which can lead to ventricular tachycardia or fibrillation; therefore, a defibrillator machine should be available on standby.

The most important cause of loss of capture is a progressive increase in pacing threshold due to local inflammation and fibrous sheath formation over the electrode tip. Other factors that increase the threshold are acid–base changes, electrolyte imbalances, antiarrhythmic drugs, myocardial ischemia, and hypothyroidism.

Undersensing is characterized by the pacemaker failing to identify the heart's inherent electrical activity and results in the inappropriate delivery of an electrical stimulus. This is a potentially dangerous situation as an inappropriate electrical impulse may be delivered to the ventricular myocardium during an electrically vulnerable period, leading to ventricular arrhythmia (R on T phenomenon)

Review Questions

1. Which of the following is true about epinephrine when used during cardiac arrest?
   (a) At a dose of 0.1 mg/kg epinephrine has mostly beta-adrenergic effects which augment inotropy and chronotropy.
   (b) Epinephrine acts on V1 vascular receptors, leading to vascular smooth muscle vasoconstriction.
   (c) At a dose of 10 mcg/kg epinephrine has mostly alpha-adrenergic effects which supports coronary perfusion.
   (d) Epinephrine acts on beta-2 receptors, leading to vasodilation and decreased cardiac afterload.
   (e) Epinephrine causes cerebral vasodilation, optimizing cerebral perfusion during cardiac arrest.

Correct Answer: C: At a dose of 10 mcg/kg epinephrine has mostly alpha-adrenergic effects which supports coronary perfusion.
Rationale:
The heart is perfused through the coronaries only during diastole; thus, coronary perfusion is dependent on adequate diastolic blood pressure. The predominant hemodynamic effect of epinephrine at standard code dose (0.01 mg/kg or 10 mcg/kg) is manifest through its action at alpha-adrenergic receptors, leading to vasoconstriction and elevation of aortic diastolic blood pressure. Epinephrine also augments inotropy and chronotropy via beta-adrenergic effects; however, these hemodynamic effects are observed at lower doses (usually 1 mcg/kg or less) and are not the primary mechanism by which epinephrine helps during cardiac arrest. Indeed, the beta-adrenergic effects may cause adverse effects when epinephrine is used in cardiac arrest since they increase myocardial oxygen demand. Vasopressin acts on V1 vascular receptors, also causing vasoconstriction that increases coronary perfusion pressure; while low-dose vasopressin causes vasodilation of the cerebral circulation. However, there is insufficient evidence to make a recommendation for or against the routine use of vasopressin during pediatric cardiac arrest.

2. Which of the following is a marker of quality CPR?
   (a) Providing chest compressions at a rate of 80–100 per minute.
   (b) Giving ventilations via an advanced airway at a rate of 20 per minute.
   (c) Ensuring compressions at a depth of one-fourth the chest diameter.
   (d) Lifting the palm to allow full recoil between chest compressions.
   (e) Performing regular pulse and rhythm checks every minute.

Correct Answer: D: Lifting the palm to allow full recoil between chest compressions
Rationale:
The five components of high-quality CPR are (1) ensuring chest compressions at an adequate rate of 100–120 per minute, (2) depth of at least one-third the anterior-posterior diameter of the chest, (3) allowing full recoil between compressions, (4) minimizing interruptions in chest compressions, and (5) avoiding excessive ventilation. Ensuring regular switches (approximately every 2 min) in chest compressors is recommended to decrease fatigue-associated leaning during CPR; however, performing pulse and rhythm checks every minute would lead to frequent interruptions in chest compressions that could be deleterious.

3. A previously healthy 1-year-old girl presented 2 weeks ago with tachypnea, tachycardia, and hepatomegaly. On initial chest radiograph she had cardiomegaly with evidence of pulmonary edema. An echocardiogram demonstrated a structurally normal heart with left atrial and left ventricular

(LV) dilation, and moderately depressed LV systolic function. After admission to the intensive care unit, her clinical status rapidly declined, leading to intubation and initiation of vasoactive support. As her hemodynamics continued to worsen over the next 2 days, the decision was made to initiate veno-arterial extracorporeal membrane oxygenation (ECMO) support. After several days of full ECMO support, her lung disease improved, renal function normalized, and her neurologic examination remained reassuring. However, she failed several attempts to wean ECMO support over the following week with persistent LV dilation and severe myocardial dysfunction. An endomyocardial biopsy was obtained and revealed myocyte hypertrophy and degeneration, with areas of fibrosis and no evidence of lymphocytic myocarditis. The cardiology team is now considering listing her for cardiac transplantation.

Of the following, the BEST choice for ongoing mechanical circulatory support in this patient is:

(a) Initiate intra-aortic balloon pump support.
(b) Remain on current extracorporeal membrane oxygenation support.
(c) Transition to a continuous axial flow ventricular assist device.
(d) Transition to a continuous centrifugal ventricular assist device.
(e) Transition to a pulsatile ventricular assist device.

Correct Answer: E: Transition to a pulsatile ventricular assist device since this is the only FDA approved VAD device for children and some data suggests that pulsatile flow better preserves the microvasculature.

4. A 13 kg 3-year-old patient with severe pediatric acute respiratory distress syndrome on VV ECMO develops desaturation and elevated venous drainage saturation. The patient's ECMO flow is 1.6 LPM (approximately 3.2 L/min/m^2). You suspect the patient has developed recirculation.

   Of the following, the BEST choice for correcting recirculation in this patient is:

   (a) Change the oxygenator.
   (b) Increase the ECMO flow to improve systemic oxygenation.
   (c) Reposition the cannula so that the oxygenated venous return to the patient is directed towards the tricuspid valve.
   (d) Decrease the ECMO flow rate.
   (e) Consider transition to VA ECMO.

Correct Answer: D: Decrease the ECMO flow rate

5. A 4-year-old patient with heterotaxy and L-looped ventricles (L-TGA) is post-op following a sub-aortic muscle resection to relieve left ventricular outflow tract obstruction. After surgery the patient was in complete heart block and paced using temporary atrial and ventricular pacing wires placed at the end of surgery. On post-op day 15 the patient continues in complete heart block with ongoing atrially sensed and ventricular pacing. Over the last 3 days the ventricular lead capture threshold steadily increased and is now noted to be 6 mA. The output was adjusted to 18 mA.

   What is the next best step?

   (a) Decrease the sensitivity.
   (b) Speak to the cardiothoracic surgeon regarding epicardial dual-chamber permanent pacemaker implantation.
   (c) Adjust the AV delay and PVARP to allow for the pacemaker to be set at a higher heart rate.
   (d) Check the pacemaker function every 12 h instead of every 24 h.
   (e) Decrease the output to a 2x safety margin.

Correct Answer: B: Speak to the cardiothoracic surgeon regarding epicardial dual-chamber permanent pacemaker implantation

6. A 6-month-old patient is post-op day 2 following repair of a complete AV canal, the patient has been atrially sensed and ventricularly paced for transient postoperative complete heart block. There is intermittent return of AV nodal conduction on the most recent pacemaker interrogation. During morning rounds the patient is noted to be tachycardic with an atrially sensed ventricularly paced rhythm. Pacemaker-mediated tachycardia is suspected and confirmed by switching the pacing mode to VVI. The underlying rhythm continues to show complete heart block.
   In this situation what is the best way to prevent further episodes of pacemaker mediated tachycardia?
   (a) Increase the post-ventricular atrial refractory period (PVARP).
   (b) Increase the sensitivity on the ventricular lead.
   (c) Decrease the output on the atrial lead.
   (d) Switch the pacing mode to AAI.
   (e) Increase the rate setting of the pacemaker.

Correct Answer: A: Increase the post ventricular atrial refractory period (PVARP).

Central and Peripheral Nervous Systems: Development, Structure, and Function

Daniel J. Rogers, Kiran M. Sargar, and Frank A. Maffei

Contents

S. E. Lucking et al. (eds.), *Pediatric Critical Care*, https://doi.org/10.1007/978-3-030-53363-2_22

Learning Objectives

- Review the embryologic development of the central and peripheral nervous system.
- Understand the structure–function relationships within the central nervous system.
- Review the development of the blood supply to the central nervous system.
- Recognize the elements comprising the blood brain barrier.
- Review the development of the blood brain barrier.
- Identify the major arteries and their branches supplying blood flow to the brain and spinal cord.
- Understand the principle of cerebral autoregulation and the elements by which it is modulated.
- Identify the components of the cerebral ventricular system.
- Review the composition, synthesis, and flow of cerebrospinal fluid within the ventricular system.
- Identify the three primary meningeal layers and their function.
- Understand the key elements of the peripheral nervous system and their function.

22.1 Introduction

Participating in the care of critically ill children requires an astute knowledge of the central and peripheral nervous systems. In responding to injury and dysfunction of the nervous system, it is necessary to understand the development, structure, and function of the nervous systems. This chapter will describe the development, structure, and function of the central and peripheral nervous systems within the context of caring for the critically ill child.

22.2 Development of the Nervous System

The nervous system is derived from three primary sources, all of which originate from the early ectoderm of embryogenesis. A subset of ectodermal cells differentiates into the neural ectoderm, which gives rise to the *(1) neural plate, (2) neural crest cells, and (3) ectodermal placodes* (Fig. 22.1). The *neural plate* will ultimately give rise to the central nervous system (CNS), somatic motor neurons, and preganglionic autonomic neurons. *Neural crest cells* differentiate and migrate prior to the fusion of the neural tube to give rise to glial cells and neurons of the peripheral nervous system (PNS), somatic and auto-

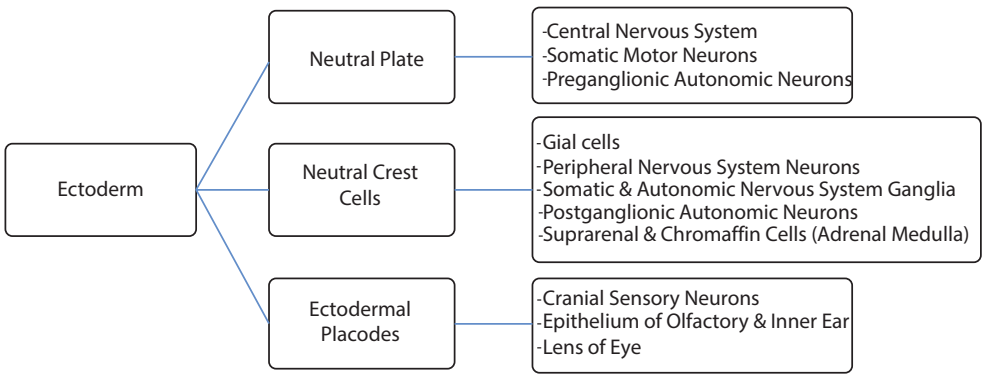

Fig. 22.1 Embryologic development of the nervous system

nomic nervous system ganglia, postganglionic autonomic neurons, and suprarenal and chromaffin cells found within the adrenal medulla. The *ectodermal placodes* are thickenings of the neural ectoderm in the region of the embryonic head from which the cranial sensory neurons, the epithelium of the olfactory and inner ear, and the lens of the eye develop.
