Notice

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our knowledge, changes in practice, treatment, and drug therapy may become necessary or appropriate. Readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of the practitioner, relying on his or her own experience and knowledge of the patient, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions. To the fullest extent of the law, neither the Publisher nor the Editors assume any liability for any injury and/or damage to persons or property arising out of or related to any use of the material contained in this book.

Library of Congress Cataloging-in-Publication Data

Pediatric respiratory medicine / [edited by] Lynn M. Taussig, Louis I. Landau.—2nd ed.
p. ; cm.
Includes bibliographical references and index.
ISBN 978-0-323-04048-8
1. Pediatric respiratory diseases. I. Taussig, Lynn M. (Lynn Max), 1942- II. Landau, Louis I.
[DNLM: 1. Respiratory Tract Diseases. 2. Child. 3. Infant. WS 280 P3707 2008]

Contributors

Steven H. Abman, MD
Professor of Pediatrics, University of Colorado School of Medicine, Denver; Director, Pediatric Heart Lung Center, Children's Hospital, Aurora, Colorado
Cor Pulmonale and Pulmonary Complications of Cardiac Disease

Felice C. Adler-Shohet, MD
Assistant Clinical Professor of Pediatrics, University of California, Irvine, School of Medicine, Irvine, California
Fungal Infections

Julian Lewis Allen, MD
Professor of Pediatrics, University of Pennsylvania School of Medicine; Chief and Robert Gerard Morse Chair in Pediatric Pulmonology, Division of Pulmonary Medicine and Cystic Fibrosis Center, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Respiratory Effects of Anesthesia and Sedation; Neuromuscular and Chest Wall Disorders

Mark A. Anselmo, MD
Assistant Professor of Pediatrics, McGill University Faculty of Medicine; Director, Pediatric Respiratory Training Program, Montreal Children's Hospital, Montreal, Quebec, Canada
Overview [Cystic Fibrosis]

M. Innes Asher, MBChB, FRACP
Professor of Pediatrics, University of Auckland Faculty of Medical and Health Sciences; Respiratory Paediatrician, Starship Children's Health, Auckland, New Zealand
Infections of the Upper Respiratory Tract

Marc D. Berg, MD
Associate Professor of Clinical Pediatrics, University of Arizona Health Sciences Center; Medical Director, Pediatric Intensive Care Unit, University Medical Center, Tucson, Arizona
Gas Exchange and Acid-Base Physiology

Robert A. Berg, MD
Associate Dean for Clinical Affairs and Professor of Pediatrics, University of Arizona Health Sciences Center and University Medical Center, Tucson, Arizona
Cardiopulmonary Resuscitation

Ariel Berlinski, MD
Assistant Professor of Pediatrics, University of Arkansas for Medical Sciences College of Medicine; Attending Pediatric Pulmonologist, Arkansas Children's Hospital, Little Rock, Arkansas
Eosinophilic Lung Diseases and Hypersensitivity Pneumonitis

Alan S. Brody, MD
Professor of Radiology and Pediatrics, University of Cincinnati College of Medicine; Division Chief, Thoracic Imaging, and Associate Director, Radiology Research, Imaging Research Center, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Imaging of the Respiratory System

Mark A. Brown, MD
Professor of Clinical Pediatrics, University of Arizona Health Sciences Center, Tucson, Arizona
Clinical Assessment and Diagnostic Approach to Common Problems

Ann M. Buchanan, MD, MPH
Chief Resident, Department of Pediatrics, University of Rochester School of Medicine and Dentistry, Rochester, New York; Pediatric AIDS Corps Physician, Baylor International Pediatric AIDS Initiative, Malawi and Tanzania
Other Infectious Agents

David Burgner, BSc (Hons), MBChB, FRACP, PhD, DTM and H
Senior Lecturer, University of Western Australia School of Paediatrics and Child Health; Paediatric Infectious Diseases Consultant, Princess Margaret Hospital for Children, Perth, Western Australia, Australia
Mycobacterial Infections

Michael R. Bye, MD
Professor of Clinical Pediatrics, Columbia University College of Physicians and Surgeons; Attending Physician, Division of Pediatric Pulmonary Medicine, Department of Pediatrics, Morgan Stanley Children's Hospital of New York–Presbyterian Hospital/Columbia University Medical Center, New York, New York
Human Immunodeficiency Virus Infection

Kai-Håkon Carlsen, MD, PhD
Professor of Paediatrics, University of Oslo Faculty of Medicine; Professor of Sports Medicine, Norwegian School of Sports Sciences; Senior Consultant, Voksentoppen, Department of Pediatrics, Rikshospitalet-Radiumhospitalet Medical Center, Oslo, Norway
Atelectasis

John L. Carroll, MD
Professor of Pediatrics, Physiology, and Biophysics, University of Arkansas for Medical Sciences College of Medicine; Director, Pediatric Pulmonary Medicine, Arkansas Children's Hospital, Little Rock, Arkansas
Eosinophilic Lung Diseases and Hypersensitivity Pneumonitis

Annick Clément, MD, PhD
Department of Pediatric Pulmonology and INSERM UMR-S 719, Hôpital d'Enfants Armand Trusseau, Paris, France
Sarcoidosis

Rachel A. Collins, PhD
Research Assistant, Telethon Institute for Child Health Research, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences, Perth, Western Australia, Australia
Applied Clinical Respiratory Physiology; Lung Function in Cooperative Subjects

John L. Colombo, MD
Professor, University of Nebraska College of Medicine; Chief, Pediatric Pulmonology, University of Nebraska Medical Center and Children's Hospital, Omaha, Nebraska
Aspiration Syndromes

Ronina A. Covar, MD
Assistant Professor, Division of Allergy and Clinical Immunology, Department of Pediatrics, University of Colorado Denver School of Medicine; Assistant Professor, National Jewish Medical and Research Center, Denver, Colorado
Clinical Features, Outcomes, and Prognosis [Asthma]

Susan E. Crawford, MD
Associate Researcher, University of Chicago Pritzker School of Medicine, Chicago; Attending Physician, Department of Pediatrics, Lutheran General Hospital, Park Ridge, Illinois
Bacterial Pneumonia, Lung Abscess, and Empyema

Eric Crotty, MB, BCh
Assistant Professor of Radiology, University of Cincinnati College of Medicine; Director, Pediatric Radiology Fellowship Program, Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Imaging of the Respiratory System

Robert S. Daum, MD
Professor of Pediatrics, University of Chicago Pritzker School of Medicine, Chicago, Illinois
Bacterial Pneumonia, Lung Abscess, and Empyema

Robbert de Iongh, BSc (Hons), MSc, PhD
Senior Lecturer, Department of Anatomy and Cell Biology, University of Melbourne Faculty of Medicine, Dentistry and Health Sciences, Parkville, Victoria, Australia
Respiratory Ciliary Dysfunction

André Denjean, MD, PhD
Professor of Physiology, Faculté de Medecine Université Denis Diderot Paris VII; Head of Clinical Physiology Department, Hôpital Robert Debre, Paris, France
Developmental Anatomy and Physiology of the Respiratory System

Robin R. Deterding, MD
Professor of Pediatrics and Associate Dean, Clinical Curriculum, University of Colorado Denver School of Medicine, Denver; Pediatric Pulmonologist, Children's Hospital, Aurora, Colorado
Interstitial Lung Disease; Pulmonary Alveolar Proteinosis; Thoracic Tumors

Sunalene G. Devadason, PhD
Senior Postdoctoral Research Fellow and Coordinator, Postdoctorate Programme, School of Paediatrics and Child Health, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences, Perth, Western Australia, Australia
Aerosol Therapy and Delivery Systems

Kevin C. Doerschug, MD, MS
Assistant Professor of Medicine, University of Iowa Carver College of Medicine; Medical Director, Medical Intensive Care Unit, University of Iowa Hospitals and Clinics, Iowa City, Iowa
Mechanisms of Acute Lung Injury and Repair

Richard Donnerstein, MD
Professor, Department of Pediatrics and Steele Children's Research Center, University of Arizona Health Sciences Center, Tucson, Arizona
Pulmonary Embolism

Trevor Duke, MD, FRACP, FJFICM
Associate Professor, Department of Paediatrics, University of Melbourne Faculty of Medicine, Dentistry and Health Sciences; Intensive Care Specialist, Royal Children's Hospital, Parkville, Victoria, Australia
Respiratory Failure and Acute Respiratory Distress Syndrome

Sean P. Elliott, MD
Associate Professor of Clinical Pediatrics, University of Arizona College of Medicine, Tucson, Arizona
Viral Infections of the Lower Respiratory Tract

Charles R. Esther, Jr., MD, PhD
Assistant Professor of Pediatric Pulmonology, University of North Carolina School of Medicine; Attending Physician, North Carolina Children's Hospital, Chapel Hill, North Carolina
Genetics and Disease Mechanisms [Cystic Fibrosis]

Mark L. Everard, MB ChB, FRCPCH, DM
Consultant in Respiratory Medicine, Sheffield Children's Hospital, Sheffield, United Kingdom
Aerosol Therapy and Delivery Systems; Respiratory Syncytial Virus–Associated Lower Respiratory Tract Disease

Leland L. Fan, MD
Professor of Pediatrics, Pediatric Pulmonary Section, Baylor College of Medicine; Pediatric Pulmonologist, Texas Children's Hospital, Houston, Texas
Interstitial Lung Disease

Brigitte Fauroux, MD, PhD
Professor of Pediatrics, Université Pierre et Marie Curie; Professor of Pediatrics, Department of Pediatric Pulmonology and INSERM UMR-S 719, Hôpital d'Enfants Armand Trusseau, Paris, France
Sarcoidosis

Eli Gabbay, MBBS, FRACP
Associate Professor of Medicine, Centre for Asthma, Allergy and Respiratory Research, School of Medicine and Pharmacology, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences; Medical Director, Western Australian Advanced Lung Disease Program, Pulmonary Hypertension Service and Lung Transplant Unit, Royal Perth Hospital, Perth, Western Australia, Australia
Pulmonary Arterial Hypertension

Claude Gaultier, MD, PhD
Professor of Physiology, Faculté de Medecine Université Denis Diderot Paris VII and Hôpital Robert Debre, Paris, France
Developmental Anatomy and Physiology of the Respiratory System

Cameron C. Grant, MBChB, PhD, FRACP
Associate Professor, Department of Pediatrics, University of Auckland Faculty of Medical and Health Sciences; General Paediatrician, Starship Children's Health, Auckland, New Zealand
Infections of the Upper Respiratory Tract

Christopher G. Green, MD
Professor and Vice Chairman, Department of Pediatrics, University of Wisconsin School of Medicine and Public Health; Medical Director, American Family Children's Hospital, Madison, Wisconsin
Foreign Body Aspiration

Karen Webster Gripp, MD
Associate Professor of Pediatrics, Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania; Chief, Division of Medical Genetics, Alfred I. duPont Hospital for Children, Wilmington, Delaware
Neuromuscular and Chest Wall Disorders

Juan A. Gutierrez, MD
Director, Pediatric Critical Care, Goryeb Children's Hospital, Morristown, New Jersey
Respiratory Failure and Acute Respiratory Distress Syndrome

Margaret R. Hammerschlag, MD
Professor of Pediatrics and Medicine and Director, Division of Pediatric Infectious Diseases, State University of New York Downstate Medical Center, Brooklyn, New York
Chlamydial Infections

Thomas C. Hay, DO
Clinical Associate Professor, Department of Radiology, University of Colorado Denver School of Medicine, Denver; Pediatric Radiologist, Children's Hospital, Aurora, Colorado
Collagen Vascular Disorders

Mark Helfaer, MD
Professor of Anesthesia, Critical Care, and Pediatrics, University of Pennsylvania School of Medicine; Chief, Division of Critical Care, and Medical Director, Pediatric Intensive Care Unit, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Respiratory Effects of Anesthesia and Sedation

Robert Henning, MB BS, FJFICM
Staff Specialist in Intensive Care, Royal Children's Hospital, Melbourne, Victoria, Australia
Respiratory Failure and Acute Respiratory Distress Syndrome; Lung Trauma: Near-Drowning and Toxin Inhalation

Lauren D. Holinger, MD
Professor of Otolaryngology—Head and Neck Surgery, Northwestern University Feinberg School of Medicine; Head, Division of Otolaryngology, and Paul H. Holinger, MD, Professor of Pediatric Otolaryngology, Children's Memorial Hospital, Chicago, Illinois
Foreign Body Aspiration

Patrick G. Holt, DSc, FRCPath, FAA
Deputy Director and Head, Division of Cell Biology, Telethon Institute for Child Health Research, and Professor, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences, Perth, Western Australia, Australia
Disease Mechanisms and Cell Biology [Asthma]

Gary W. Hunninghake, MD
Sterba Professor of Medicine and Director, Divison of Pulmonary, Critical Care and Occupational Medicine, University of Iowa Carver College of Medicine, Iowa City, Iowa
Mechanisms of Acute Lung Injury and Repair

Laura S. Inselman, MD
Professor of Pediatrics, Jefferson Medical College of Thomas Jefferson University, Philadelphia, Pennsylvania; Active Attending Pulmonologist and Medical Director, Pulmonary Function Laboratory, Alfred I. duPont Hospital for Children, Wilmington, Delaware
Pulmonary Manifestations of Systemic Disorders

Lance C. Jennings, PhD
Senior Clinical Lecturer, University of Otago Christchurch School of Medicine and Health Sciences; Clinical Virologist, Canterbury Health Laboratories, Christchurch, New Zealand
Epidemiology of Respiratory Infections

Alan H. Jobe, MD, PhD
Professor of Pediatrics, University of Cincinnati College of Medicine and Cincinnati Children's Hospital Medical Center, Cincinnati, Ohio
Respiratory Disorders of the Newborn

Marcus Herbert Jones, MD, PhD
Professor of Pediatrics, Pontifícia Universidade Católica do Rio Grande do Sul Faculty of Medicine; Pediatric Pulmonologist, Hospital São Lucas da PUCRS, Porto Alegre, Brazil
Bronchiectasis

J. Brian Kang, MD
Instructor of Pediatrics, University of Utah School of Medicine; Instructor, Division of Pediatric Pulmonary Medicine, University of Utah Health Sciences Center, Salt Lake City, Utah
Host Defense Systems of the Lung

Andrew S. Kemp, MB BS, PhD, FRACP
Professor of Paediatric Allergy and Immunology, University of Sydney Faculty of Medicine; Attending Physician, Department of Allergy, Immunology and Infectious Diseases, Children's Hospital at Westmead, Sydney, New South Wales, Australia
Congenital Immunodeficiency Syndromes

Sailesh Kotecha, MA, FRCPCH, PhD
Professor and Head, Department of Child Health, Cardiff University School of Medicine; Honorary Consultant Neonatologist, University Hospital of Wales, Cardiff, United Kingdom
Chronic Respiratory Complications of Prematurity

Swati Kumar, MD
Assistant Professor of Pediatrics, Medical College of Wisconsin; Attending Physician, Infectious Disease Program, Children's Hospital of Wisconsin, Milwaukee, Wisconsin
Chlamydial Infections

Jean-Martin Laberge, MD, FACS, FRCSC
Professor of Surgery, McGill University Faculty of Medicine; Division Director, Pediatric General Surgery, Montreal Children's Hospital, Montreal, Quebec, Canada
Congenital Malformations of the Lungs and Airways

Louis I. Landau, AO, MD, D Litt (Hon), FRACP
Emeritus Professor and Senior Research Officer, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences; Acting Director, Child Health Research Network, Princess Margaret Hospital for Children, Perth, Western Australia, Australia
Early Childhood Origins and Economic Impact of Respiratory Disease throughout Life; Treatment [Asthma]

Larry C. Lands, MD, PhD
Professor, Department of Pediatrics, McGill University Faculty of Medicine; Director, Pediatric Respiratory Medicine and Cystic Fibrosis Center, Montreal Children's Hospital, Montreal, Quebec, Canada
Overview [Cystic Fibrosis]

Gary L. Larsen, MD
Professor of Pediatrics, University of Colorado School of Medicine; Professor and Head, Division of Pediatric Respiratory Medicine, National Jewish Medical and Research Center, Denver, Colorado
Host Defense Systems of the Lung

Rees L. Lee, MD
Assistant Professor, Department of Pediatrics, Uniformed Services University of the Health Sciences F. Edward Hébert School of Medicine, Bethesda, Maryland; Staff Pediatric Pulmonologist and Director, Cystic Fibrosis Center, Naval Medical Center Portsmouth, Portsmouth, Virginia
Bronchiolitis Obliterans

Margaret W. Leigh, MD
Professor and Vice-Chair, Department of Pediatrics, University of North Carolina School of Medicine; Attending Physician, North Carolina Children's Hospital, Chapel Hill, North Carolina
Genetics and Disease Mechanisms [Cystic Fibrosis]

Peter N. Le Souëf, MBBS, MD, FRACP
Professor of Paediatrics, School of Paediatrics and Child Health, Faculty of Medicine, Dentistry and Health Sciences, University of Western Australia, Perth, Western Australia, Australia
Aerosol Therapy and Delivery Systems; Genes, Environment, and Their Interactions [Asthma]

Jay M. Lieberman, MD
Professor of Clinical Pediatrics, University of California, Irvine, School of Medicine, Irvine; Medical Director, Infectious Diseases, Quest Diagnostics, San Juan Capistrano, California
Fungal Infections

Andrew H. Liu, MD
Associate Professor, Division of Allergy and Clinical Immunology, Department of Pediatrics, University of Colorado Denver School of Medicine; Associate Professor and Training Program Director in Pediatric Allergy and Immunology, National Jewish Medical and Research Center, Denver, Colorado
Clinical Features, Outcomes, and Prognosis [Asthma]

Paulo José Cauduro Marostica, MD, PhD
Professor of Pediatrics, Universidade Federal do Rio Grande do Sul Faculty of Medicine; Pediatric Pulmonologist, Hospital São Lucas da PUCRS, Porto Alegre, Brazil
Bronchiectasis

Fernando D. Martinez, MD
Swift-McNear Professor of Pediatrics and Director, Arizona Respiratory Center, University of Arizona Health Sciences Center, Tucson, Arizona
Environmental Determinants of Childhood Respiratory Health and Disease; The Global Burden of Asthma; Disease Mechanisms and Cell Biology [Asthma]; Treatment [Asthma]

Oscar Henry Mayer, MD
Assistant Professor of Clinical Pediatrics, University of Pennsylvania School of Medicine; Attending Physician, Division of Pulmonology, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Neuromuscular and Chest Wall Disorders

Karen S. McCoy, MD
Associate Professor, The Ohio State University College of Medicine; Chief, Division of Pulmonary Medicine, Columbus Children's Hospital, Columbus, Ohio
Idiopathic Pulmonary Hemosiderosis

Robyn J. Meyer, MD, MS
Associate Professor, University of Arizona Health Sciences Center; Medical Director, Pediatric Intensive Care Unit, University Medical Center, Tucson, Arizona
Gas Exchange and Acid-Base Physiology

Gregory S. Montgomery, MD
Assistant Professor of Clinical Pediatrics, Indiana University School of Medicine; Attending Physician, James Whitcomb Riley Hospital for Children, Indianapolis, Indiana
Thoracic Tumors

Yuben Moodley, MB BS, FRACP, MD, PhD
Senior Research Fellow, Monash Immunology and Stem Cell Laboratories, Monash University Faculty of Medicine, Nursing and Health Sciences; Respiratory Physician, Alfred Hospital, Melbourne, Victoria, Australia
Lung Cell Biology

Lucy Morgan, BMed, PhD, FRACP
Lecturer, University of Sydney Faculty of Medicine; Staff Specialist Thoracic Physician, Concord Repatriation General Hospital, Sydney, New South Wales, Australia
Respiratory Ciliary Dysfunction

Wayne J. Morgan, MD, CM
Professor of Pediatrics and Physiology, Associate Head for Academic Affairs, and Chief, Pediatric Pulmonary, Allergy, and Immunology Section, Department of Pediatrics, University of Arizona Health Sciences Center, Tucson, Arizona
Clinical Assessment and Diagnostic Approach to Common Problems; Respiratory Function Testing in Infants and Preschool-Aged Children; Lung Function in Cooperative Subjects

Alan R. Morton, Dip PE, MSc, EdD, FACSM, FACHPER, FAAESS
Emeritus Professor, School of Movement and Exercise Science, University of Western Australia Faculty of Life and Physical Sciences, Perth, Western Australia, Australia
Exercise Physiology

Richard B. Moss, MD
Professor of Pediatrics, Stanford University School of Medicine, Stanford; Chief, Allergy and Pulmonary, Lucile Packard Children's Hospital, Palo Alto, California
Allergic Bronchopulmonary Aspergillosis

Erika von Mutius, MD, MSc
Professor of Pediatrics, University Children's Hospital, Munich, Germany
Clinical Assessment and Diagnostic Approach to Common Problems

Vinay M. Nadkarni, MD
Medical Director, Center for Simulation, Advanced Education, and Innovation, Department of Anesthesia and Critical Care, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Cardiopulmonary Resusciation

Béatrice Oberwaldner, PT
Head of Respiratory Physiotherapy, Respiratory and Allergic Disease Division, Department of Paediatrics and Adolescent Medicine, Medical University of Graz, Graz, Austria
Chest Physiotherapy

Howard B. Panitch, MD
Professor, Department of Pediatrics, University of Pennsylvania School of Medicine; Attending Pulmonologist and Director of Clinical Programs, Children's Hospital of Philadelphia, Philadelphia, Pennsylvania
Home Ventilation and Respiratory Support

Philip Keith Pattemore, BHB, MBChB, MD (Auckland), FRACP
Associate Professor of Paediatrics, University of Otago Christchurch School of Medicine; Consultant Paediatrician, Christchurch Hospital, Christchurch, New Zealand
Epidemiology of Respiratory Infections

J. Jane Pillow, PhD, FRACP
Senior Lecturer, School of Women's and Infants' Health, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences; Consultant Neonatologist, Women's and Children's Health Service, Perth, Western Australia, Australia
Respiratory Disorders of the Newborn

Paulo Márcio Condessa Pitrez, MD, PhD
Professor, Pediatric Pulmonary Service, Pediatrics Division, Pontifícia Universidade Católica do Rio Grande do Sul Faculty of Medicine; Pediatric Pulmonologist, Hospital São Lucas da PUCRS, Porto Alegre, Brazil
The Global Burden of Asthma

Christian F. Poets, MD
Professor, University of Tübingen Faculty of Medicine; Director and Chair, Department of Neonatology, Tübingen University Hospital, Tübingen, Germany
Apnea of Prematurity, Sudden Infant Death Syndrome, and Apparent Life-Threatening Events

Pramod S. Puligandla, MD, MSc, FRCSC, FACS
Assistant Professor of Surgery and Pediatrics, McGill University Faculty of Medicine; Attending Physician, Pediatric General Surgery and Pediatric Critical Care Medicine, Montreal Children's Hospital, Montreal, Quebec, Canada
Congenital Malformations of the Lungs and Airways

Surender Rajasekaran, MD, MPH
Assistant Member, St. Jude Children's Research Hospital, Memphis, Tennessee
Respiratory Infections in Immunocompromised Hosts

C. George Ray, MD
Clinical Professor of Pathology and Medicine, University of Arizona Health Sciences Center, Tucson, Arizona
Viral Infections of the Lower Respiratory Tract

Gregory J. Redding, MD
Professor of Pediatrics, University of Washington School of Medicine; Pediatric Pulmonologist, Children's Hospital and Regional Medical Center, Seattle, Washington
Interstitial Lung Disease

Philip Robinson, BMed Sc, MB BS, MD, PhD
Associate Professor, Department of Paediatrics, University of Melbourne Faculty of Medicine, Dentistry and Health Sciences; Director, Cystic Fibrosis Unit, Department of Respiratory Medicine, Royal Children's Hospital, Parkville, Victoria, Australia
Other Clinical Manifestations [Cystic Fibrosis]

Margaret Rosenfeld, MD, MPH
Associate Professor, Division of Pulmonary Medicine, Department of Pediatrics, University of Washington School of Medicine; Attending Physician, Children's Hospital and Regional Medical Center, Seattle, Washington
Respiratory Manifestations [Cystic Fibrosis]

Lewis J. Rubin, MD
Professor of Medicine, University of California, San Diego, School of Medicine, La Jolla, California
Pulmonary Arterial Hypertension

Jonathan Rutland, BSc, MB BS, FRACP, FCCP
Conjoint Associate Professor, University of New South Wales Faculty of Medicine; Senior Thoracic Physician, Concord Repatriation General Hospital and Bankstown-Lidcombe Hospital, Sydney, New South Wales, Australia
Respiratory Ciliary Dysfunction

Robert A. Sandhaus, MD, PhD
Professor of Medicine, National Jewish Medical and Research Center, Denver, Colorado
α_1-Antitrypsin Deficiency

Daniel V. Schidlow, MD
Professor and Chair, Department of Pediatrics, and Senior Associate Dean, Pediatric Clinical Campus, Drexel University College of Medicine; Physician-in-Chief and Chief Academic Officer, St. Christopher's Hospital for Children, Philadelphia, Pennsylvania
Therapy-Induced Pulmonary Disease; Abnormalities of the Pleural Space

Ziad M. Shehab, MD
Professor of Clinical Pediatrics and Pathology and Head, Section of Pediatric Infectious Diseases, University of Arizona Health Sciences Center, Tucson, Arizona
Pertussis; Mycoplasma Infections

Shahid Ijaz Sheikh, MD
Associate Professor of Clinical Pediatrics, The Ohio State University College of Medicine; Attending Physician, Divisions of Pulmonary Medicine and Allergy and Immunology, Department of Pediatrics, Children's Hospital, Columbus, Ohio
Idiopathic Pulmonary Hemosiderosis

Delane Shingadia, MBBS, MPh, MRCP, FRCPCH
Honorary Senior Lecturer, Infectious Diseases and Microbiology Unit, University College London Institute of Child Health; Paediatric Infectious Diseases Consultant, Great Ormond Street Hospital, London, United Kingdom
Mycobacterial Infections

Peter D. Sly, MBBS, MD, DSc, FRACP
Head, Division of Clinical Sciences, Telethon Institute for Child Health, Research Director, WHO Collaborating Centre for Research on Children's Environmental Health, and Professor, School of Paediatrics and Child Health, University of Western Australia Faculty of Medicine, Dentistry and Health Sciences; Adjunct Professor, School of Public Health, Curtin University of Technology; Respiratory Physician, Princess Margaret Hospital for Children, Perth, Western Australia, Australia
Applied Clinical Respiratory Physiology; Respiratory Function Testing in Infants and Preschool-Aged Children; Lung Function in Cooperative Subjects; Disease Mechanisms and Cell Biology [Asthma]

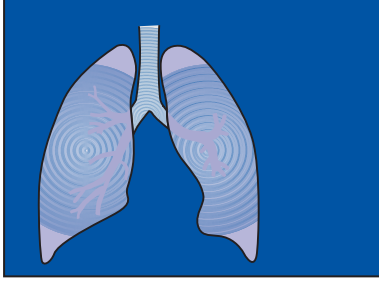
Human Immunodeficiency Virus Infection

To the Landau, Le Souëf, Martinez,

Morgan, Sly, and Taussig families

for their love, encouragement,

patience, and understanding.



Foreword

"The needs of children should not be made to wait."
John F. Kennedy, 1963

It is reported that the Kahun papyrus, written around 1825 B.C., proposed some specific treatments for what was then considered obscure childhood disease. For example, chewing a field mouse was the recommended remedy for teething pain!

Thereafter, it took quite some time to establish pediatric medicine as a specialty. The incentive to concentrate on problems of children developed in the 18th century in Germany and France; in the United States, a German native, Abraham Jacobi (1830-1919), gave the field such impetus that he is hailed as the father of American pediatrics.

Since that time, pediatrics has become a vibrant specialty, thriving on the basis of fundamental and clinical research, which gained extraordinary momentum in the years following World War II. For example, during the 1960s and 1970s, pioneer researchers in the United States uncovered the mechanism of neonatal respiratory distress syndrome; this led to the development of effective therapeutic interventions, resulting in an amazing decrease in deaths from this condition. Another example is the research that led to our understanding of the immune system; this, in turn, enabled development of modern vaccines that have revolutionized the control of childhood infectious diseases. Also noteworthy is the tremendous progress we have witnessed in asthma treatment and control as a result of outstanding research in pediatric medicine.

These examples well illustrate the immense value of biomedical basic and clinical research. However, effective communication is needed to bring the outcomes of this research work to the practice of medicine and the benefit of public health.

Pediatric Respiratory Medicine—the encyclopedia of respiratory health and illness in children—accomplishes just that. This new edition offers the reader an updated review of ongoing pursuits in basic sciences and clinical principles. Moreover, 75 chapters authored by more than 130 well-known experts discuss specific clinical conditions from which children can suffer. The authors represent twelve different countries and many of the major U.S. medical centers.

A treatise of such dimension is a major educational contribution to the field, but its significance depends on whether the readers can, or will, improve their practice of pediatrics. Clearly the editors, Drs. Lynn M. Taussig and Louis I. Landau, and their associate editors had this in mind when they selected contributors highly skilled in translating the science base into information that can readily be applied in the daily practice of pediatric medicine. The result will undoubtedly help the readers in their efforts to meet the needs of children with respiratory illness.

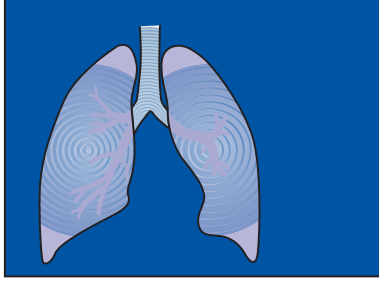
From the Foreword to the First Edition

Welcome to a new textbook, *Pediatric Respiratory Medicine*, authored by authorities from around the world. We might ask what is so special about an international perspective in this age of telecommunication and frequent world congresses. Practices do differ, and insight into approaches based on varied experiences can be thought provoking and enriching.

I cannot think of a better way for the student of pediatric pulmonology to acquire an authoritative overview of the state of the specialty than to refer to this book over and over again.

MARY ELLEN AVERY, MD
Thomas Morgan Rotch
Distinguished Professor of Pediatrics
Harvard Medical School
Boston, Massachusetts



Preface

From its inception, *Pediatric Respiratory Medicine* was to be an international textbook. This second edition broadens that international perspective. The tremendous advances in communication, the expansion of professional societies globally, and the interactions among clinicians and scientists on different continents make it essential that medical textbooks be international in scope, summarizing different geographic and social approaches to advance the understanding of health and disease.

A number of major influences contributed to the evolution of pediatric pulmonology as a distinct pediatric subspecialty. These included the following:

- Growing interest by pediatricians in childhood respiratory problems, especially asthma and pneumonia
- Growth of adult pulmonology, which provided training for pediatricians and spawned an expanded interest in the research, clinical, and educational aspects of pediatric pulmonary disorders
- The establishment of cystic fibrosis centers
- Increasing interest by pathologists in the growth and development of the lung
- Increasing technologic and epidemiologic research in respiratory disease
- Increased interest in childhood tuberculosis in the 1950s and dramatic changes in the worldwide patterns of this disease, particularly with the presence of HIV infection
- Development of neonatology as a discipline and heightened interest in respiratory problems of the newborn and subsequent chronic lung disease
- Growth of academic departments of pediatrics and the desire and need for research and teaching in the pediatric subspecialties
- Establishment of pediatric intensive care units
- Increasing publication of books and journals focusing on various respiratory illnesses of infants and children

As the discipline grew, there was progressive recognition by funding and certifying agencies. This culminated in the establishment of certification examinations in a number of countries, enhanced funding of research programs for pediatric respiratory disorders by governmental agencies, increased focus on pediatric respiratory problems by academic societies, and proliferation of training programs.

The breadth and depth of clinical and research interests encompassed in this discipline have increased markedly over the past five decades. However, major challenges still face our children. The global burden of disease falls disproportionately on children, especially those living in developing countries. Environmental conditions play a major role in disease initiation and severity in children, not just in the traditional infectious diseases but in the so-called "lifestyle" diseases such as asthma, obesity, and type 2 diabetes. These chronic diseases are posing threats to children's health in developing countries as well as those in high-income developed countries. Emerging issues such as the impact of climate change on children's health are going to become important.

Although no book can cover all issues of current and future interest, this book attempts to meet these varied concerns. The chapters have been written to provide more epidemiologic, anatomic, biochemical, pharmacologic, physiologic, cellular, and molecular information for those interested in these areas while also increasing discussion of the clinical aspects of both common and rarer presentations and diseases for the clinicians caring for the millions of children who suffer from respiratory disorders. Thus we trust that the book will be of benefit to students at all levels of training as well as experienced pediatric respiratory and primary care physicians. The major purpose of this textbook is to provide a relatively quick and concise overview of a topic, thereby allowing the reader to have a better foundation as he or she reads current articles that focus on more specific aspects of the subject. This edition is published in a new format for greater ease of use of content and graphics, with recommended selected readings, and access to an extensive collection of references on the accompanying web site, www.pedrespmedtext.com.

Many thanks are in order. First, to our publisher, Elsevier, and especially to Dolores Meloni, Karen Carter, Anne Snyder, and Michael Goldberg, for advice, patience, persistence, guidance, and encouragement. Second, to all of our contributing authors, some the same as for the last edition and some new, for their enormous contribution of time and effort. We also acknowledge the great support of our wives and families. Finally, to the children with respiratory illnesses and their families, who have helped us to better understand and manage these conditions and shown us courage in the face of adversity.

CHAPTER 1

Early Childhood Origins and Economic Impact of Respiratory Disease Throughout Life

Louis I. Landau and Lynn M. Taussig

TEACHING POINTS

- Much respiratory disease throughout life is programmed during pregnancy and/or early life as evidenced by associations with birth weight, lung function, and immunologic studies in the first year of life.
- Manifestations of respiratory disease are usually a result of a combination of gene(s) expression and the timing and dose of exposure to environmental factors such as microbes, allergens, diet, and toxins.
- Bacterial lower respiratory infections remain a major cause of morbidity and mortality globally.
- The global burden of the short- and long-term effects of respiratory illnesses in childhood is at least $1 trillion annually.
- Improved nutrition, immunization, decreased smoking, reduced pollution, new approaches to immune modulation, and the development of new drugs could dramatically reduce this burden.

Epidemiologic studies are increasingly reporting that a tendency to respiratory disease throughout life is programmed during fetal life and the early years after birth. The evidence now justifies further causality, mechanistic and interventional studies to better define the gene-environment interactions responsible for this early programming. Appropriate population-based education and therapeutic interventions may then significantly affect the considerable burden of respiratory disease on the individual, health services, and the community. This chapter will provide an overall worldwide perspective of these issues, with greater detail provided in the individual chapters.

Epidemiologic studies frequently have a temporal or geographic base within which the independent (explanatory) variables are used to explain the dependent (response) variables. Response variables have changed with time from indices such as mortality and hospitalization to morbidity and quality of life.

Considerable differences in disease patterns persist between developing and developed countries. The cycle of poor housing, poor sanitation, malnutrition, and infections continues to underlie the major causes of death and disability in developing countries—aggravated, particularly in Africa and Asia, by the emergence of human immunodeficiency virus. Improved standards of care have led to an increase in the median life expectancy for inherited disorders such as cystic fibrosis and acquired conditions such as chronic neonatal lung disease—both conditions now requiring long-term adult care. The changes in the environment, with improved socioeconomic status, have led to both a reduction in microbes in the home and, in many societies, an increase in exposure to pollutants such as tobacco smoke, pesticides, preservatives, and other chemicals. These independently or together are associated with new morbidity, particularly atopy and other inflammatory disorders.

The characterization of the human genome is leading to the promise of a better understanding of the genetic and molecular basis for most diseases. However, the substantial variation in the phenotypic expression for single gene disorders, the important contributions of multiple genes to common disorders, the recognition of epigenetic influence of modifier genes, and the impact of environmental factors such as diet on gene expression are highlighting the important role of environment-gene interactions in the disease spectra in both developing and developed countries.

Environmental factors may affect the outcomes in genetically predisposed individuals with different affects early or late in pregnancy, perinatally, during infancy, and later childhood. The outcome will depend on the timing and sequence of environmental insults during development from conception to maturity. Exposure to an infection at one stage in development under certain conditions may lead to a reduction in atopy while, at another stage with different conditions, may potentiate the emergence of atopic features. Both low and high birth weight may be associated with increased risk for the development of the metabolic syndrome (obesity, cardiovascular disease, diabetes), and higher birth weight is sometimes reported in association with subsequent atopy and asthma.[1] Excessive weight gain after birth, especially if born small, may be associated with more severe manifestations of the metabolic syndrome[2] and the development of asthma.

Chronic lung disease in adulthood has been associated with lower respiratory illnesses in childhood.[3,4] Do the

symptoms in early life identify the at-risk individual who continues to have problems in adult life or does illness in early life cause lung damage that predisposes to progressive lung disease? There are studies that support each hypothesis. Factors common to both hypotheses include active and passive smoking, family history of atopy and/or respiratory disease, social conditions, and gender.

GENETICS

Numerous candidate genes have been identified that affect atopic status and airway function.[5] Asthma appears to be the result of expression of a number of these genes that are influenced by environmental factors. No single genomic region has been linked in all studies and no individual genetic marker has been found to account for more than 10% of the asthma phenotype. Studies in twins suggest that more than 50% of variance for all cytokines is genetically determined, being particularly high for interleukin (IL)-1 beta and IL-10. Some of the potentially relevant genes identified include those for atopy, such as CD14 (159T) and GM-CSF (117T); for asthma, CC16 (A38G), tumor necrosis factor-alpha (TNF-α) (308G), LTC4 synthase (A444C), and IL-10 (-571C); and for asthma severity, beta 2R (Arg16,Gln27) and IL-4 (-589T).

The gene for cystic fibrosis—the cystic fibrosis transmembrane conductance regulator (CFTR)—was identified in 1989. Since then, more than 1000 mutations of this gene have been identified with varying phenotypic expressions and disease manifestations.[6] Substantial variations of the disease have been noted within the same CFTR genotype—suggesting modification by factors that could be related to diet and the environment or to modifier genes coinherited with the CFTR polymorphism. However, definitive modifier genes for cystic fibrosis remain to be identified.

Primary ciliary dyskinesia is a multisystem disorder characterized by recurrent respiratory tract infections, male subfertility, and, in 50% of cases, with situs inversus (Kartagener syndrome). The disease phenotype is caused by ultrastructural defects of cilia in the mucosa of the respiratory tract, sperm, and other organs. It is a heterogenetic disorder, usually inherited as an autosomal recessive trait. Mutations in some human genes have been shown to cause the disease by alterations in the coding for ciliary proteins such as those in the dynein arms.[7] Tissue-specific expression of mutant genes at different stages of ontogenesis lead to varying clinical presentations.

Severe alpha-1 antitrypsin deficiency is one proven genetic risk factor for chronic obstructive pulmonary disease (COPD) in adult life. Apart from manifesting as liver disease in early life, COPD develops at an age when a patient may have commenced smoking and lung disease rapidly develops. The World Health Organization has recommended that all patients with chronic lung disease and all adolescents and adults with asthma be tested. Homozygous alpha-1 antitrypsin deficiency PiZZ occurs in 1 in 5000 to 1 in 500 whites. Argument has been made for neonatal screening to identify those at risk before they are likely to be exposed to cigarette smoke. This must be balanced against the issues of psychological consequences, impact on insurance, and the effectiveness of antismoking programs.[8]

It is suggested that sudden infant death syndrome (SIDS) is a result of polygenic inheritance which, in combination with environmental risk factors such as mild infection, prone posture, non-breastfeeding, exposure to environmental tobacco smoke, and preterm delivery, predisposes infants to sudden unexpected death. The genetic component of SIDS can be divided into two components[9]: mutations that lead to disorders that cause rapid death and those that predispose infants to death in critical situations. Those that may cause death themselves include mutations in the medium chain acyl-CoA dehydrogenase gene (A985G) causing MCAD deficiency but is seen in less than 1% of SIDS; polymorphisms associated with severe hypoglycemia; and mutations in genes such as KVLQT1 and SCNA5, which encode for cardiac ion channels and are associated with the long QT syndrome.

Those with predisposing polymorphisms for death in critical situations include partial deletions of the "complement component 4" gene and "interleukin 10" gene promoter (ATA/ATA) which impair the immune response to infection. Others affect the serotonin transporter gene which may have an important autonomic regulatory role. In spite of some genetic component, the recurrence risk is not high.

Toward the end of gestation, the fetal lung prepares for the transition to air breathing at birth. Respiratory epithelial cells synthesize lipids and surfactant proteins that are necessary for alveolar stability with air breathing. The components of surfactant are developmentally regulated. SP-B and SP-C are detectable in early gestation. Type 2 cells appear around 20 to 24 weeks when SP-A and DP-D synthesis is noted. Numerous, usually isolated, genetic disorders have been reported in these processes leading to perinatal morbidity and death related to respiratory distress syndromes, as well as alveolar proteinosis and familial lung fibrosing disorders in later life. These abnormalities include genetic variations of surfactant proteins and Foxa2-regulated expression of genes mediating surfactant protein and lipid synthesis.[10,11]

DEVELOPMENTAL ORIGINS OF RESPIRATORY HEALTH AND DISEASE

Prenatal

It has been assumed that the womb is a warm and safe place, but it has been clearly documented that the placental barriers can be breached by infectious agents such as syphilis, cytomegalovirus (CMV), *Toxoplasma* and rubella; allergens; toxins; metabolites such as maternal phenyl ketones; radiation; hyperthermia; tobacco smoke; alcohol; nutritional agents such as folate; and antioxidants with major impact on the developing fetus, including the developing respiratory and immune systems, which affect long-term respiratory health and disease.

The impact will be influenced by the time in gestation when the insult occurs. Periconceptually, metabolites and growth regulators influence placentation and morphogenesis. Maternal age and age of menarche of the mother may influence fetal development and maturation, possibly associated with variance in hormonal levels. Later age of menarche has been reported to be associated with lower rates of atopy but not asthma.[12] Later in gestation, insults will influence placental and fetal growth and maturation of organ systems. Birth

weight has been reported as a surrogate for fetal insult and low birth weight has been reported to be a predictor of subsequent cardiovascular and respiratory health.

Many have now suggested subsequent ill health may be associated with either low or high birth weights, this being evident for cardiovascular disease, diabetes, and asthma associated with high IgE/atopy. The low birth weight babies may be those whose cerebral development has been protected to the detriment of other systems, impacting on immunologic maturation and the high birth weight babies may represent those with fetal adaptation to a compromised placenta that allowed transplacental movement of allergens or mediators. Excessive catch-up growth during infancy for low birth weight babies has been reported as a more important factor for the development of obesity, cardiovascular disease, and asthma than the low birth weight itself. Xu and colleagues[13] reported that at age 31 years, those born small, with rapid postnatal weight gain and body mass index (BMI) above the 95th percentile had the highest risk for asthma (OR 3.27:1.32 to 8.11).

In fetal life, there is a skew to a Th2 immune response to prevent maternal rejection of the foreign placenta and fetus. Those primed to develop asthma and/or atopy have evidence of immaturity of both their Th1 and Th2 immune systems at birth with a propensity to Th2 as reflected by cytokine levels (high IL-4/IFN gamma ratios) and cord blood mononuclear cell proliferation studies.[14] Low IFN gamma levels are associated with increased infections in early life and with increased atopy in later life.

Cord blood IgE and cytokines suggest that in-utero priming of the fetoplacental unit by allergens or mediators crossing the placenta or absorbed from swallowed amniotic fluid via the fetal gut may result in allergic sensitization but is unlikely to be significant when it is the sole factor.[15] Lung function measured soon after birth suggests that airway structure and function have also been affected by factors leading to these immunologic changes as well as by other stimuli such as exposure to maternal cigarette smoking before birth, thus predisposing to the development of respiratory symptoms in later life.[16]

Many authors have reported lower prevalences of atopy with increasing birth order.[17] Turner and coworkers[18] have found that the lower prevalence in those not first born is transient and is lost by 11 years of age. The effect of birth order on immunologic development may be related to different hormonal levels, reduced transplacental allergens or IgE, variation in nutritional status during subsequent pregnancies, or to the different microbial exposures after birth likely to occur with contact with other young children in the household.

Maternal smoking is associated with elevated cord blood IL-4, lower IFN gamma, altered responses of IL-5, IL-9, and IL-13 production to stimulation of cord blood cells and abnormal lung function soon after birth.[19] Nicotine causes growth dysfunction of the airways with increased airway branching and increased airway wall thickness and reduced alveolar elastin in animal models. Humans demonstrate an association of prenatal smoking with transient wheezing during infancy, increased sudden infant death syndrome, and continuing reduced lung function but the associations with asthma, atopy, and persistent wheezing are less consistent.[20-22]

High vitamin E levels in the maternal diet are associated with changes in cord blood macrophage proliferation, but this is not related to blood levels of vitamin E, suggesting that the dietary intake may be a marker of some other factor that influences immunologic development and atopic priming.[23] Lower levels of vitamin E in the maternal diet have been reported to be associated with increased atopy, wheeze, and elevated exhaled nitric oxide measured at 5 years.[24] A potential reduction in subsequent infant allergy has been seen with maternal supplementation with polyunsaturated fatty acids.[25]

Congenital abnormalities such as lung hypoplasia, diaphragmatic hernia, lobar emphysema, cystic adenomatoid malformation and sequestration may occur as a result of genetic predisposition or in utero insult. The impact on neighboring normal lung tissue may be caused by mechanical factors or nonmechanical influences such as vasoactive mediators or endothelin dysregulation.[26] Some early studies suggest that lung underdevelopment may be attenuated by dietary interventions such as vitamin A.[27]

Steroids given to a mother with the risk of impending premature delivery have contributed to major improvements in outcomes by accelerating maturation of airway surfactant production and function with subsequent reduction in severity of hyaline membrane disease. Steroids upregulate the SP-B and SP-C production at the transcription level.[28] The effect may be an explanation for a gender difference in response to steroids.

Some longitudinal cohort studies have reported that stressful delivery may be associated with respiratory illness and reduced levels of lung function later in life. Long duration of delivery has been reported to be associated with increased atopy.[29] This could be a result of stress hormones such as cortisol driving the immune response toward a Th2 profile.

Postnatal

Postnatally, commensal gut flora appear to be a strong stimulus for maturation of the immune status, particularly the Th1 response. There are more than 400 species of bacteria in the human gastrointestinal tract and these compete for adhesion receptors, stimulate antimicrobials and gut-associated lymphoid tissue. Kalliomaki and Isolauri[30] reported that probiotics (lactobacillus) given to the mother and infant was associated with a 23% prevalence rate of eczema compared with a 46% rate in controls. Probiotics have been demonstrated to promote IL-2, IFN gamma, TGF beta production and inhibit IL-4, IL-5 and IL-13 production, as well as improve gut barriers and reduce gut permeability.

Some house dust mite studies have reported that attempts to reduce exposure pre- and postnatally may reduce subsequent asthma and atopy, but these results are inconsistent and many other studies have shown that reduced exposure may, in fact, lead to increased sensitization in later childhood. Perzanowski and colleagues[31] have found that exposure to cat fur in early infancy may induce tolerance with higher levels of protective IgG4. Those living on farms with grass exposure and those in Africa sleeping on grass mattresses show relative protection from grass sensitization.[32]

Attendance at day care, larger families, and living on farms with increased exposure to animals in the houses have been

associated with protection from atopy and it is argued that this may be due to stimulation of a Th1 response by microbes, lipopolysaccharides, or endotoxins.[33,34] The lipopolysaccharides could affect innate immunity via TLR2, TLR4 and CD14, and there may be genetic predispositions in different polymorphisms of these receptors. This imbalance of Th1/Th2 activity oversimplifies the complexity of T cell function and the hypotheses do not explain the contemporaneous rise in Th1-based conditions such as diabetes. The explanation is more likely to be complex because the Th1/Th2 paradigm is not so explicit with Th1 cells able to increase some Th2 mediators and the influence of factors including exposure dose and timing.

The development of atopic disease and asthma should be considered in a number of discrete phases: induction, progression, and exacerbations of acute episodes. During the induction phase, the underlying inflammatory response and airway hyper-reactivity are induced by environmental agents affecting a genetically predisposed host. Once induced, environmental agents will then trigger exacerbations and/or progression of inflammation and airway reactivity—usually resulting in clinical symptoms. The impact of the same environmental agent can be different in these phases. Microbes and high levels of allergens may be protective during induction but responsible, in smaller doses, for heightened responses resulting in progression/exacerbations in those already induced. The sequence of exposure to either microbes or allergens may affect the response to the other.

Breastfeeding has a variable effect on atopy. Most studies show no significant decrease in atopy. Wright and coworkers[35] and others have reported reduced lower respiratory illnesses with breastfeeding but subsequent increased atopy if the mother is atopic.

Indirect measures of airway development by lung function testing soon after birth relate variably to the presence or absence of asthma, the severity of asthma, or the presence of transient wheezing. Reduced lung function, suggesting reduced airway size, may be a result of changes in the mucosa (epithelium, mucus glands, submucosal tissue), muscle, lung elastic properties, or airway compliance in addition to airway growth. The mucosa is a source of cytokines, growth factors, nitric oxide, epithelial-derived peptides, and adhesion molecules, which may contribute to these changes.

The rapid thoracic compression technique has allowed measurements of maximum flow at functional residual capacity (FRC) in early infancy, and low levels have been associated with maternal smoking during pregnancy, wheezing illnesses, continuing low lung function (tracking) and bronchial hyper-responsiveness in later life. Most studies show associations of reduced infant lung function with transient wheezing of infancy[36,37] and some,[36] but not all, with persistent wheezing. Many studies also find that reduced lung function in infancy and early childhood is associated with lower lung function and asthma in adolescence.[36] Persistent bronchial hyper-responsiveness in early life is also associated with abnormal lung function and asthma in later life,[38] but measurements of airway responsiveness may reflect different processes, with increased responsiveness in infancy being associated with airway structure and in later childhood and adult life with current asthma.

Chronic neonatal lung disease/bronchopulmonary dysplasia is found increasingly with the improved survival of extremely low birth weight babies. It appears to be a result of the impact of high pressure ventilation and high inspired oxygen on immature lungs. Genetic predisposition, maternal smoking, use of steroids prenatally, and a family history of asthma have all been reported to influence the development and severity of the lung disease. The family history of asthma appears to relate to severity rather than prevalence.[39]

Intrauterine chorioamniotic infection may do harm (lead to acute and chronic neonatal lung disease) or be advantageous (promote alveolar maturation).[40,41] Its role in the evolution of chronic neonatal lung disease and subsequent lung growth is uncertain. Many cord blood cytokines and mediators such as IL-6, IL-8, soluble TNF-1, E-selectin, and matrix metalloproteinases[42,43] have been reported to be associated with the development of chronic neonatal lung disease.

Following chronic neonatal lung disease, recurrent wheezing illness is common in early childhood, but tends to become less problematic with age, although impairment of lung function—varying from very subtle to severe—persists into later childhood and adult life.[44]

Early Childhood

Lower respiratory illnesses in early childhood have been shown to be associated with chronic lung disease in adulthood,[3,4] either the symptoms in early life identifying at-risk individuals who continue to have problems in adult life or the illnesses in childhood causing lung damage. Lung damage can occur with organisms such as adenovirus and mycoplasma, and with irritants such as aspirated gastric contents and toxic inhalations, but the longitudinal cohort studies are suggesting that the predisposed infant who gets a serious lower respiratory tract illness with respiratory syncytial virus (RSV), rhinovirus, or meta-pneumovirus is already at risk for continuing respiratory disease.[45]

More than 30% of infants in the first 3 years of life will wheeze due to a number of underlying causes and more than one half of these will be transient wheezers.[37] Transient wheezing is seen with reduced airway function, respiratory viral infections, neonatal lung disease of prematurity, heart failure, foreign body aspiration, and maternal smoking. Persistent wheezing may be due to asthma, cystic fibrosis, or congenital abnormalities of the airways. Those who become persistent wheezers due to asthma are usually atopic, have frequent wheezing episodes, and are often admitted to hospital in the first year of life with more severe lower respiratory tract illness such as with RSV infection.[46] Those who commence wheezing after 2 to 3 years of age are more likely to have asthma or, if of sudden onset, may have an inhaled foreign body.

Viral infections, particularly those caused by RSV, metapneumovirus, and rhinovirus, occur frequently in infants and often cause wheezing. Those exposed to tobacco smoke, especially in utero, are more likely to develop severe symptoms requiring hospitalization.[47] Some studies would suggest that the virus interacts with the immune system in those genetically predisposed to initiate asthma. Sigurs and associates[48] and Welliver and Ogra[49] reported a high rate of asthma and atopy following RSV bronchiolitis. This was not con-

firmed in other studies. Most studies have followed those hospitalized with bronchiolitis, but those following community based cohorts have generally not shown that RSV infection per se predisposes to subsequent asthma.[50] It is likely that those with a genetic predisposition to atopy and asthma are more likely to have coexistent evidence of atopy and to respond differently to the RSV or other viruses, resulting in more severe symptoms requiring admission to hospital. It is the severity of response that is more likely the predictor, not the virus. Neutrophilia and elevated IL-8 and IL-9 are found in RSV bronchiolitis. Different phenotypes for these cytokines may predispose to more severe bronchiolitis and to asthma.

Helminthic infections are highly prevalent in many parts of the developing world, stimulate strong Th2 responses associated with high levels of polyclonal (non-antigen specific) IgE and eosinophilia, but are associated with lower prevalence of skin reaction to common allergens such as house dust mites.[51] It is suggested that the Th2 response to worms is protective for the host and is a mechanism to dampen potentially damaging inflammatory responses against the parasite. The downregulating mechanism responsible for the incongruity between the immune response to the helminths and other environmental allergens could be due to the non-antigen-specific nature of the IgE, dampening effects on dendritic antigen-presenting cells, on toll-like receptor innate immunity or to stimulation of regulatory T cells producing anti-inflammatory cytokines, such as IL-10 and TGF beta.[52,53] Anthelmintic treatment of chronically infected children is noted to result in increased atopic skin reactivity.[54]

It has been proposed that early identification of those with asthma and early use of inhaled corticosteroids may have a positive effect on the inflammatory process and prevent airway remodeling and disease progression. Studies so far have not shown any major benefit of early steroids, unless justified by symptoms, with no long-term impact on lung function or prevalence of persistent or more severe asthma.[55] They do lead to some reduction in somatic growth, although minimal, and mainly in the first year of use. There is a potential effect on immune maturation and alveolar septation with chronic high-dose usage in early life[56]; most septation occurs between birth and 2 years but continues until 7 years and to a lesser degree up to 20 years. This deleterious effect may be partially rescued by retinoic acid.[57]

A number of prospective cohort studies in childhood show a significant association between excess weight gain and asthma prevalence, especially in girls. The mechanistic relationship between an increase in BMI and asthma has yet to be defined, but there are a number of possibilities. The increased weight usually antedates the asthma and there is a dose-response effect. Overweight children breathe at a lower functional residual capacity with associated reduced load on the airway smooth muscle and airway narrowing which will result in increased airway responsiveness. These children also breathe at a faster rate with smaller tidal volumes, further reducing airway smooth muscle stretch. Increased BMI is also associated with a systemic inflammatory response with increased levels of potentially proinflammatory hormones such as leptin, adiponectin, and plasminogen activator inhibitor from adipose tissue and increased cytokines such as TNF-α and IL-6. The continuing increase in the frequency of overweight children, especially in developed countries, is a major public health issue not only for the impact on asthma but also on cardiovascular disease, diabetes, cancer, and psychological health.[58]

The prevalence of tuberculosis (TB) is still a major global health problem. In spite of dramatic advances through the 20th century when the prevalence of childhood TB fell from 100/100,000 to 60/100,000 in the 1950s and then to 5/100,000 following the introduction of national tuberculosis programs, it is predicted that there are currently more than 1 million new childhood cases of tuberculosis each year (10% of all cases). Prevalence is currently highest in Asia and the Indian subcontinent, and when seen in developed countries, it is often in the immigrant population.[59] Mortality was initially an accurate guide to disease because there was a constant relation between infection, disease, and death. Once this relationship was broken by highly effective treatment, it was necessary to use other indices, such as the tuberculin test, to determine the prevalence of infection. In the 19th century, the mortality was highest in young adults infected in childhood, but following the introduction of chemotherapy, it is now highest in the very young and in the elderly. In 1950, more than 40% of 14-year-old children in the United Kingdom were tuberculin positive, and this rate has fallen to nearly 1%.[60] Infection with human immunodeficiency virus is putting a new group of younger people at risk for tuberculosis.

The control of tuberculosis resulted from a combination of public health initiatives to identify cases and contacts by effective screening processes, effective chemotherapy administered according to standardized regimens, directly observed therapy, and chemoprophylaxis for those with infection reflected by positive Mantoux tests without evidence of active disease (clinical or radiologic), which prevents disease that would otherwise evolve in 1% to 2%. The bacille Calmette-Guérin vaccination is widely used even though considerable controversy about its effectiveness (0% to 80%) persists. The potential benefit certainly declines as infection rates decline, so that in developed countries it is used only in high-risk groups.[61]

On a global scale, respiratory infections remain a major cause of morbidity and mortality in developing countries. The annual incidence of new cases of pneumonia has been estimated at about 150 million., of which 11 to 20 million require hospitalization.[62] Approximately 20% (around 2 million) of all childhood deaths in developing countries can be attributed to acute respiratory infections. Many are related to conditions preventable by immunization such as pertussis, measles, diphtheria, pneumococcus, *Hemophilus influenzae*, and tuberculosis. The relative rate of bacterial versus viral lower respiratory tract illness in developing countries is difficult to determine because of the lack of sensitivity and specificity for most tests available. The rate of lower respiratory illness with bacterial infections probably lies between 15% and 60% or more. Studies of lung aspirates in lower respiratory illnesses in developing countries have suggested that more than 60% are associated with bacterial infection, with 25% being viral alone.[63] The therapeutic approach to acute respiratory illnesses in developing countries cannot be extrapolated from that in developed countries. Implementation of WHO guidelines for treating suspected bacterial

pneumonia is associated with dramatic falls in morbidity and mortality.

Non–cystic fibrosis bronchiectasis in childhood is still one of the most common causes of childhood morbidity and chronic adult lung disease in developing countries.[64] In New Zealand, the incidence of bronchiectasis, especially in Pacific Islanders, is double that of cystic fibrosis.[65] Bronchiectasis is particularly common posthospitalization in Australian indigenous children.[66] This is likely because of malnutrition, preterm delivery, and recurrent episodes of pneumonia. Breastfeeding has a protective effect. Bronchoscopic lavage analyses in infants with cystic fibrosis who are asymptomatic suggest that airway inflammation may start very soon after birth before clinical evidence of infection.[67] Better understanding of these findings will affect long-term outcomes for all causes of chronic suppurative lung disease.

Children and infants are among the most susceptible to ambient air pollution. Links have been reported between air pollution and preterm birth, low birth weight, infant mortality, respiratory symptoms, asthma emergency department visits and hospitalizations.[68] Pollutants clearly exacerbate asthma, but a specific influence on the induction of asthma has not been shown. Eighty percent of alveoli are formed postnatally and lung growth continues through adolescence. Children spending more time outdoors in communities with higher levels of urban pollution show deficits in the growth of lung function into adult life.[68]

Children are more vulnerable to air pollution levels because they have a higher relative minute ventilation, spend more time outdoors, and are more physically active. Pollutants that have an effect on the respiratory tract in children include ozone, sulfur dioxide, particulate matter, and nitrogen dioxide. Air pollution is also associated with increased health care utilization and school absences.

Ozone, formed from the action of sunlight on motor vehicle exhaust and industrial emissions, is associated with respiratory symptoms and asthma exacerbations in children and decreased lung function that continues into adult life. Children in Mexico City given antioxidants were less affected by pollutants than those who were not treated.[69] This effect needs to be further explored. Particulate matter (PM2.5) is emitted from engines, industrial sources, and wood burning. In children, particulate pollution affects lung growth and lung function and is associated with increased bronchial symptoms. Nitrogen dioxide is produced by high temperature combustion from engines and power plants. Nitrogen oxides cause respiratory symptoms and asthma exacerbations and have been shown to enhance the allergic response. Strong associations with hospital admissions for asthma have been reported.[70]

Indoor pollution is increased with gas burners, particularly unflued combustion heaters, dampness, and molds. The effect is most marked in children, both with and without asthma, who demonstrate increased risk estimates for wheezing and breathlessness.[71]

Altitude is known to have acute and long-term effects on the lungs, but this has been less well documented in children. Comparing one population group living at both low and high (4000 m) altitudes, it was found that those born at high altitude were smaller and weighed less, although economic factors could not be excluded as contributing factors.[72] Differences in altitude did not affect thoracic dimensions relative to stature. Lung volumes were higher, possibly reflecting the effect of hypoxia on alveolar growth. The Sa_{O_2} in children living at 4000 m is lower, at an approximate mean of 87%. Younger children were shown to have a lower Sa_{O_2}, falling further during sleep, suggesting physiologic adaptation to high altitude over time.[73]

Children demonstrate acute physiologic responses to exposure above 3000 m with increased respiratory rate, decreased end tidal CO_2, and reduced oxygen saturation—this reduction again being greater in infants. An inflammatory illness, such as a viral respiratory tract infection, may contribute to the development of high altitude pulmonary edema in children.

Allergen avoidance at high altitude has been reported to lead to reduced clinical symptoms, improved lung function, and reduced responses to specific and nonspecific bronchial challenges in asthmatic children. However, others have found that children with atopy and asthma living in a high altitude mite-free environment still have major morbidity with sensitization to other allergens.[74]

Children with chronic lung disease such as bronchopulmonary dysplasia and cystic fibrosis may develop significant hypoxia at high altitudes during flight or on vacation. The level cannot be easily predicted from baseline lung function, and a laboratory hypoxic challenge may be wise so that appropriate advice can be given.[75]

ECONOMIC BURDEN OF RESPIRATORY DISEASE

Respiratory illness throughout life is a global burden on individuals, families, health care services, and societies. The impact includes direct health service costs, family functioning and social costs, years of life lost, loss of productivity from days off work or school absenteeism. There are at least 200 million children with asthma worldwide. Taking an estimated cost of $100 to $10,000[76-78] per year for mild to severe disease respectively, this would result in an average total burden of around $200 billion per year. The economic impact for adults continuing from childhood with asthma, with fewer numbers but more severe disease, would be at least $50 billion per year.

Smoking rates in various countries range from more than 60% to less than 1%. Most start to smoke during childhood or adolescence. Taking an average of 10% heavy smokers (400 million) and assuming a burden of $1000 per smoker per year, would suggest a total cost of $400 billion per year in health care related costs. However, this is much less than predicted from assessment of adult disease costs in Germany, with a population of 82 million and 33% male and 20% female smokers, where the annual costs are estimated to be 16.6 billion EURO,[79] which could extrapolate to a global burden of $1 trillion for all adult diseases resulting from smoking. In Korea, with 66% male and 3.3% female smokers, the total annual cost of smoking-related illnesses in adults was between $6.79 and $9.86 million per 100,000 population,[80] extrapolating to a global burden of $200 to $400 billion. The annual avoidable direct health care costs associated with exposure to tobacco smoke in children from birth to 12 years in Hong Kong, with 990,972 children to 12 years

of age, ranged from $0.34 to $3.34 million,[81] which would extrapolate to between $676 million and $6 billion annually and *only* for direct costs. Therefore a total global burden of the effects of smoking throughout life of $402 billion annually seems consistent with these data.

Worldwide, there would be at least 3000 children newly diagnosed with cystic fibrosis each year, with costs varying from $1000 to $1 million per year. Taking an average cost of $10,000 per year, the total burden for all cystic fibrosis patients would be around $1 billion per year.

One hundred and fifty million children with pneumonia and 15 million with tuberculosis, living mostly in developing countries, generate a potential cost of at least $1000 per child per year.[82-84] This would result in a minimum burden of $165 billion annually.

Excessive weight in childhood is reaching levels of 30% in developed countries, with at least 5 million children in these countries having health problems that could be estimated to cost at least $1000 annually, resulting in a burden of $5 billion. Overweight-associated annual hospital costs for 6- to 17-year-old youth in the United States in 1997 to 1999 were $127 million.[85] This would extrapolate globally to $2.5 billion for overweight-related hospital costs alone. Asthma and sleep apnea were among the more common primary diagnoses when obesity was listed as a secondary diagnosis.

Pollution has been considered to affect 1% of children, with direct health costs relating to respiratory symptoms and medical consultation as well as lifelong quality of life affected owing to school absenteeism and chronic illness, to be at least $1000 per year and a burden of $20 billion annually.

These estimates are hypothetical and conservative, but they provide a perspective showing that many preventable causes of respiratory illness in children are currently resulting in a burden of at least $1 trillion per year globally—greater than the gross domestic product of many countries. Attention to prevention of these illnesses in early childhood is not at the forefront of policy, which is more often directed to those diseases affecting the elderly and the affluent.

Interventions that could significantly reduce this economic burden include improvement in health and nutrition for women of reproductive age and of young children, minimization of smoking, immune modulation by appropriate adjustments to the responses to the microbial and allergen exposures during pregnancy and early childhood, development of new drugs which will positively affect immunologic maturation, early prevention of progressive lung disease in those identified at risk, better regulation of pollution, improved immunization and other public health measures for prevention of infectious diseases. If these measures had a similar impact as the education on sleeping position, breastfeeding, and smoking have had on the prevention of sudden infant death syndrome, there would be, at reasonably modest cost, a reduction in the economic burden resulting from respiratory disease starting in early childhood of at least $300 to $500 billion per year.

CHAPTER 2

Environmental Determinants of Childhood Respiratory Health and Disease

Fernando D. Martinez

TEACHING POINTS

- Environmental exposures in early life can drastically change developmental trajectories of the lung and airways in ways that predispose children to the development of respiratory diseases later in life.
- In cystic fibrosis, asthma, and other conditions in which genetic factors have an important role, environmental factors may change the expression of the phenotype in ways that are often specific for each exposure and for different critical periods during growth and development.
- Exposure to viral infections in early life may be associated with early expression of airway obstructive disease in predisposed individuals. Microbial burden during the growing years, on the other hand, can modulate the developmental patterns of the immune system and can protect against the development of allergies and asthma in susceptible individuals.

Although the phenotypic manifestation of the genetic material is the essence of biology, factors that are external to the genotype control its expression at all times. In its broadest sense, the "environment" is the lifetime accumulation of external effects on cellular configuration and gene expression. This definition provides a broader view of the environment than that usually attributed to this concept. In fact, the biological "environment" has been increasingly made synonymous with our physical surroundings: water, land, and atmosphere. This restrictive concept fails to consider the significance of the interaction between all body functions and flora and fauna (including viruses and bacteria) and the important role of the uterine milieu in determining the patterns (normal or abnormal) of fetal development.

ONTOGENIC SELECTION OF DEVELOPMENTAL PATTERNS

There is now strong evidence suggesting that the pathways followed by the lung and the immune system during the developmental phase are not mechanically determined by the genetic background of the individual alone. It has become increasingly apparent that both systems usually have the potential for alternative developmental pathways. There is little doubt that genetic factors limit these developmental choices, but for the great majority of individuals (i.e., those lying away from the extremes of the gaussian distribution of compounded polygenic influences[1]), the history of encounters with external influences determines to a large extent the final outcome. This property of phenotypic selection mediated by external influences is probably common to all organs, but should be expected to be particularly important for the immune and respiratory systems, which have among the widest and most active relations with the environment of all body systems.

It is reasonable to surmise that these choices between different developmental pathways can occur only early during ontogeny, when organs and their cell components are still in a more primitive, malleable form. It is also likely that, once a developmental pattern is selected, the potential for a shift back to other alternatives may be very limited. In a certain sense, "natural selection" of ontogenic pathways may behave much like natural selection of species as hypothesized to occur during evolution. If this were true, however, a mechanism would need to exist by which specific cell system selections occurring during the developmental phase would favor the individual's adaptation later in life. Although this could be an efficient mechanism of anticipated or "preemptive" adaptation, there is very little empirical evidence that such a mechanism exists. One of the best examples of developmental responses to external stimuli during fetal life is the induced early maturation of surfactant synthesis by corticosteroid administration to the mother.[2] This "environmental" induction of a vital metabolic function seems to be suspiciously useful: increased corticosteroid production occurs naturally in association with intrauterine stress, and stressful events in the perinatal period are often associated with premature birth and sure death in the absence of a surface-tension-reducing mechanism for lung and airways. It is possible to speculate that, during evolution, a variety of preemptive adaptive responses to specific external influences may have been selected that resulted in subsequent enhanced survival of those individuals who had the potential of developing those responses.

It can be deduced from the foregoing discussion that critical periods could be defined during which external stimuli can influence the development of the lung and the immune system in ways that would not be possible in other life periods. These stimuli may even give rise to irreversible changes in organ structure and function. An extraordinary example of this pattern of lung response to external stimuli was accidentally discovered by Dr. Thurlbeck and his coworkers.[3] These authors were interested in the effects of beta-amino-propionitrile on lung structure and function in suckling rats. They thus designed an experiment in which the active substance dissolved in saline was injected intraperitoneally to the experimental group and saline was injected by the same route to control animals. When subsequently studying the elasticity and microscopic anatomy of the lungs in these two groups, the investigators noted that the control group had abnormally larger alveoli and significantly fewer alveoli per unit volume than untreated animals. Saline-treated animals also had higher static lung compliance than expected. When saline-treated animals and untouched animals were sacrificed early during adult life (at 8 weeks of age), Thurlbeck and coworkers observed that the changes in lung structure in saline-injected animals had persisted up to that age. Other researchers[4] have shown that similar changes to those observed by Thurlbeck and colleagues in their "control" animals can be elicited in the lungs of animals receiving low doses of corticosteroids, but these doses need to be administered during a very precise developmental window: from postnatal day 4 to postnatal day 13. The same doses of corticosteroids, administered at any other time, produce no significant long-term changes in lung structure or function.

Studies by Barker and coworkers[5] have suggested that very long-term consequences of environmental influences on the lung may also occur in humans. They studied the relation between birth weight and subsequent level of lung function. They observed that birth weight was directly correlated with lung function up to 70 years later. More recently, Stern and coworkers[6] reported that maximal flows at functional residual capacity (VmaxFRC) measured shortly after birth are strongly and positively correlated with indices of airway function measured in the same subjects at age 22. There is little doubt that these two neonatal parameters (birthweight and airway function) are determined both by genetic and by environmental factors, including among the latter maternal nutrition, maternal age, and maternal exposure to noxious stimuli such as tobacco smoke. By altering developmental patterns of the respiratory system, these external stimuli may have consequences that can still be detected decades after their initial effects.

DEVELOPMENTAL TRAJECTORIES AND LUNG DISEASE

In this context, many chronic respiratory diseases can be considered deviations in the normal developmental design of the lung and immune systems that render the subject unable to adequately cope with the environment in which he or she is raised and lives. It is obvious that we are not dealing here with the environmental factors that determine acute diseases or even exacerbations of chronic lung ailments in children. These factors are so disparate and specific to each illness that it would be impossible to deal with them in a single, introductory chapter. What we are dealing herewith is the mechanism by which external influences determine the *inception* of long-term illnesses or create the conditions for the incidence of recurrent acute illnesses.

The paradigm of ontogenic "natural selection" that we are proposing also applies to "monogenic diseases" such as cystic fibrosis (CF). It is well known to all those involved in the care of CF patients that large phenotypic differences may exist between CF siblings who, by definition, have the same CF genotype. It is now clear that the CF phenotype is determined only partially (albeit substantially) by the CF genotype, and that other genes and an important environmental component determine the expression of the disease, particularly in the lungs.[7] Unfortunately, few studies of the natural history of CF have addressed this issue. Of interest is the fact that the long-term course of CF in children with meconium ileus (MI), a form of intestinal obstruction that occurs during the neonatal period in 15% to 20% of CF patients, seems to be different from that of children without MI. Specifically, MI children showed significantly worse lung function tests and shorter median times to the development of obstructive lung disease than children without MI.[8] Two potential explanations for these findings are that complications associated with surgical treatment of MI may affect lung development[9] or that MI may be associated with a developmental pattern that is globally different than that of children without MI. A recent study[10] showed that concordance for MI is very high (82%) among monozygotic twins and much lower (22%) in dizygotic twins with CF, suggesting that non-CF modifier genes play a major role in the development of MI in CF. However, a linkage study failed to identify a single modifier gene as responsible for these findings. It is thus possible that many genes may interact with the CF gene to cause MI, or that an environmental factor, interacting with one or more non-CF genes, may induce the expression of MI. In any of these scenarios, the developmental pathway would be affected in such a way that the long-term clinical outcome of the child would also worsen.

INCEPTION OF ASTHMA AND THE ENVIRONMENT

The case can be made even more convincingly for asthma. Results of twin studies have shown that up to one half of the susceptibility to asthma is inherited. Although this suggests a strong genetic component, it also indicates that the expression of the disease is modulated by the environment. Because the incidence of asthma is highest during childhood and up to three fourths of all cases develop during this age period,[11] it is reasonable to assume that the developmental paradigm we have described applies to asthma. Recent evidence strongly suggests that this may indeed be the case (see also Chapter 58).

Emerging data suggest that the developmental pattern followed by the immune system in early life may be strongly influenced by external stimuli. Initially, T-helper cells, which play a pivotal role in determining the nature of the immune response to external stimuli, are characterized by a primitive, multipotential program of cytokine production. When stimulated, these so-called Th-0 cells secrete cytokines that will

later be produced exclusively by one or the other *but not both* of the two main mature T-helper cell phenotypes, so called Th1 and Th2 subtypes. These two T-helper cell types are well characterized in the mouse, but appear to exist more as extreme developmental poles than as two unique T-helper cell types in humans. Th1-like cells produce mainly interferon-gamma and IL-2, whereas Th2-like cells produce (among other cytokines) IL-4, IL-5, and IL-13. Th1-like cells promote cell-mediated and IgG-mediated responses, and they also block the development of Th2-like responses to antigen. Conversely, Th2-like cells promote IgE-mediated responses to antigen and they may block Th1-like responses as well.

Role of Exposure to Microbial Products in Early Life

Studies of children raised on animal farms,[12] taken to day care as infants[13] or exposed to dogs in early life[14] have provided new insights into the potential role of environmental factors, interacting with genetic variants, in changing developmental trajectories in children. These three exposures were shown to be associated with decreased likelihood of developing atopic asthma and associated traits, such as allergic rhinitis and aeroallergen sensitization, and all were found to be associated with increased concentrations of endotoxin, a marker of microbial exposure, in house dust. These findings supported the hypothesis that the development of immune responses in early life is influenced by the microbial burden to which the child is exposed, and that the final result of these exposures is a decreased risk of Th2-like responses and atopic asthma. Studies in which both indices of microbial exposures and variants in genes encoding for components of the receptor system for these same exposures revealed that the considerable variance in responsiveness to these exposures in the population was determined, at least in part, by hereditary factors. For example, polymorphisms in the gene for toll-like receptor 2 (TLR-2) modulate the degree of protection against asthma and atopy conferred by a farm environment.[15] The most widely studied gene, however, has been that for CD14, a central player in the receptor system for endotoxin and other microbial products. A functional polymorphism at position -159 with respect to the transcription start site of the gene showed strong evidence of antagonistic interaction with microbial exposure in house dust in four separate studies.[16-19] This means that the same allele that protects against asthma and allergies at high levels of endotoxin exposure is a risk factor for asthma and allergies at low levels of exposure.

These results provide insights into the multidimensional influences on developmental trajectories that determine the inception of asthma. What emerges is a system that is sensitive to environmental influences, with great inter-individual variability in responsiveness to these influences.

Role of Exposure to Allergens in Early Life

The characteristics of the response to the first encounters with antigen in early life (and even during fetal life) may have a profound effect on the nature of subsequent responses to antigen. It has been suggested, for example, that exposure to allergens, when occurring at a particular period during infancy, could drive the immune system toward a persistent Th2-like response to these same allergens. Data by Holt and colleagues[20] showed that, in mice, development of immune tolerance is a normal phenomenon by which animals exposed to certain antigens initially develop IgE responses to those antigens, but later show no IgE responses when re-exposed to these same antigens. Interestingly, Holt and colleagues[21] observed that tolerance did not develop when animals were exposed to antigens during a very precise age interval during the newborn period; these animals in fact showed persistent production of specific IgE against these antigens when re-exposed during adult life. Because asthma is known to be strongly associated with high concentrations of circulating IgE against certain specific allergens during childhood, it was postulated that exposure to these allergens during critical periods in early life could block the development of immune tolerance to these allergens. This could thus predispose to persistent production of IgE against asthma-related allergens and to asthma.

This conclusion appeared to be reinforced by the finding of a relation between sensitization to certain seasonal allergens and being born during the season of highest allergen exposure.[22] In addition, an inverse relation was reported between bedroom exposure to house dust mites during the first 2 years of life and age at first episode of asthma in asthmatic subjects who were allergic to mites.[23] Finally, it was observed that asthmatic children who were strongly sensitized against house dust mites became symptom-free when transferred for somewhat prolonged periods of time to a mite-free environment in the Italian Alps.[24] It was thus proposed that a causal relation existed between early life exposure to house dust mite antigen and the development of asthma and that prevention of exposure could be a strategy for the primary prevention of the disease.[25] Moreover, it was recently suggested that a strategy of early activation of immune tolerance by administration of high doses of antigen could prevent sensitization to allergens,[26] with the implicit conclusion that it could also prevent the development of asthma. This proposed strategy implied the administration of antigen via the oral route, based on the assumption that this route is a much stronger inducer of tolerance, as demonstrated by the high incidence of tolerance to ingested allergenic foods such as egg or milk products.

This line of thought has had considerable influence on the design of strategies for the prevention and treatment of asthma in the last 10 years. Unfortunately, new evidence suggests that the factors determining the development of asthma are more complex than a simple cause and effect relation between certain exposures and asthma inception. Data from the inland desert districts of Australia[27] and from Arizona[28] and New Mexico,[29] two arid regions of the United States, have shown that childhood asthma is not less frequent in these areas than in the coastal regions of both countries. What is particularly intriguing about these findings is that house dust mites are found either in very low amounts or are simply absent from indoor environments in these arid regions. Asthmatic children were thus very unlikely to be sensitized to house dust mites in these regions, and sensitization to other allergens such as molds was more prevalent. Of particular interest are studies performed in the arctic regions of

Sweden, where none of the aeroallergens against which children with asthma are most often sensitized in lower latitudes were detected.[30] In these areas, the prevalence of childhood asthma is as high as that observed in Stockholm, but children with asthma are either sensitized against furred pets or not at all, in spite of having higher total serum IgE levels than their nonasthmatic peers.

Of great importance are two clinical trials, in which children at high risk for the development of asthma were randomized to either drastic (and ultimately quite successful) interventions to decrease exposure to house dust mites in areas with high infestation rates in homes or to a sham intervention.[31,32] These studies showed either similar prevalence of asthma in the early school years in the active arm as compared with the sham arm or paradoxical increased sensitization to house dust mites in the active arm. These data thus suggest that allergic sensitization to specific allergens has a complex, nonlinear association with the degree of exposure to those allergens in the environment.[33] Subjects predisposed to asthma seem to have the potential for becoming sensitized to many allergens, and especially to those present in their specific locales in early life.[34] It is likely that predisposition to asthma (and not primarily exposure to aeroallergens) may be the main risk factor for allergic sensitization in chronic asthma. This may explain the tendency of asthmatics to become sensitized to multiple aeroallergens,[35] including food allergens to which they rapidly become tolerant after infancy.[36] Conversely, sensitization among nonasthmatics (for example, among subjects with allergic rhinitis) may be much more strongly related to exposure, and symptoms may be more strongly related to exposure to these aeroallergens than that which is usually evident in asthma.

Role of Infection in Early Life

The role of infections in the inception of asthma has been one of the most intensely studied and debated issues in pediatric pulmonary medicine. Several reports starting in the early 1970s and into the 1980s suggested that bronchiolitis in infancy was associated with increased likelihood of subsequent bronchial hyper-responsiveness,[37-39] increased prevalence of wheezing,[40] and lower levels of lung function.[41] One possible explanation for these findings was that viral infections caused changes in the lungs and in the immune system that predisposed to the outcomes described earlier. This hypothesis was attractive because it offered the possibility of a prevention strategy for asthma aimed at avoiding or immunizing against viral respiratory infections in early life. It soon became clear, however, that most children become infected at least once during the first 2 years of life with the most common respiratory viruses such as respiratory syncytial virus (RSV).[42] It also became clear that certain predisposed subjects had a peculiar reaction to *infections* with RSV, and that this gave rise to specific *illnesses* such as bronchiolitis or wheezing respiratory illnesses.[43] This predisposition may also extend to responses to rhinovirus, because children infected with this virus, and who developed wheezing episodes in the first year of life, were more likely to still be wheezing at age 3.[44] The connection between these *illnesses* and the subsequent development of asthma would be not one of cause and effect, but would be attributable to a pattern of response to environmental stimuli that determine both the *illnesses* and the subsequent development of asthma. The nature of this connection is the matter of considerable debate, but it is most likely heterogeneous, involving different mechanisms in different individuals.[45]

Role of Other Environmental Factors

Unfortunately, very little is clearly established regarding the role of other environmental factors on the inception of asthma. Some studies have suggested that younger maternal age predisposes to the development of asthma in their children.[46] Maternal age is directly related to birth weight,[47] and it has been postulated that younger mothers may compete for nutrients with their children during pregnancy.[48] There is also some evidence of a direct relation between infant lung size and maternal age.[49] Difference in hormonal levels associated with the parity and with the age of the mother may influence the development of the fetal lung and immune system.

Diet in early life has been extensively investigated, but the evidence suggesting a protective role of prolonged breastfeeding on the development of asthma is not convincing. Breastfeeding may decrease the likelihood of developing wheezing in non-atopic preschool children,[50,51] but it has also been reported to increase the likelihood of developing asthma in the breastfed child when the nursing mother has asthma herself.[52] One study suggested protection by breastfeeding and food allergen avoidance on the development of asthma into the teen years,[53] but other studies have been unable to confirm this finding.[54] Observational studies had suggested that, when eaten regularly, certain foods such as fish may decrease bronchial responsiveness and the likelihood of developing asthma.[55] However, a clinical trial in which omega-3 fatty acids, to which this preventive effect was attributed, were added to the diet of high-risk children from birth showed no protective effect for asthma or allergies up to age 5 years as compared with placebo.[31]

The role of indoor and outdoor contamination has been extensively studied. The only indoor factor that has been clearly linked to the development of asthma is environmental tobacco smoke,[56] but the issue is still controversial.[57] Other indoor contaminants such as nitric oxides have not been shown to be associated with an increased incidence of asthma. Paradoxically, an inverse relation has been reported between the use of coal or wood for heating and the prevalence of bronchial hyperresponsiveness and allergies.[58] Recently, studies of children living close to major highways suggested that lung function growth during childhood may be negatively affected by exposure to traffic-related contaminants.[59] In addition, children living in areas with high outdoor exposure to ozone reported increased asthma-like symptoms if they exercised outdoors as compared with children living in the same areas who did not exercise outdoors.[60]

CONCLUSIONS

Many external factors regulate the expression of genotype as a specific phenotype. The paradigm that these external factors contribute to the selection of developmental pathways for the respiratory and immune system in utero and during early

life, in a complex interaction with genetic variants that regulate responses to these factors, offers a framework for the understanding of the complex role of the environment on the development of most childhood respiratory illnesses and especially of asthma.

CHAPTER 3

Developmental Anatomy and Physiology of the Respiratory System

Claude Gaultier and André Denjean

TEACHING POINTS

- Immaturity of the upper airways can lead to obstructive apneas during sleep in infants.
- Immaturity of the respiratory muscles, combined with high chest wall compliance, can cause ventilation asynchrony and promote respiratory fatigue.
- Branching and septation are essential to the development of the conducting airways and alveoli, respectively.
- Alveolization is incomplete at birth and continues during the first 2 postnatal years.
- Numerous factors contribute to the control of lung morphogenesis. They include epithelium-mesenchyme interactions, growth factors, cell-cell interactions, extracellular matrix, and intercellular adhesion molecules.
- Vasculogenesis, angiogenesis, and intussusception are the mechanisms of pulmonary vascular development, which is closely associated with airway growth.
- Cell proliferation and apoptosis occur in combination throughout lung development and maturation.
- Lung mechanics, lung volume, and gas exchange in infants are closely dependent on complete and harmonious processes of fetal and neonatal lung development.
- Maturation of respiratory control is dependent on development and plasticity of the brain stem respiratory network, which are controlled and influenced by many neurotrophic factors and neurotransmitters.

In the first year of life, major maturational changes occur in the respiratory system and its control mechanisms, and respiratory disorders are particularly common and severe. Lung immaturity contributes substantially to the morbidity and mortality associated with prematurity. Chest-wall immaturity limits the ability of infants to adapt to increased breathing loads related to respiratory disorders, especially during sleep. Respiratory control immaturity is involved in the pathophysiology of apnea of prematurity, apparently life-threatening events, and sudden infant death syndrome (SIDS). Importantly, respiratory system development occurs as one component of a broader maturation process that modifies respiratory effectors, respiratory control, behavioral states, and metabolic demands.

Research into respiratory system development has moved from developmental anatomy and physiology to developmental molecular biology. Environmental insults during early respiratory-system maturation may alter developmental programming, leading to respiratory system abnormalities that may persist in infancy and even into adulthood. Recent studies in newborn mice with targeted gene deletions have shown links between the expression of specific genes and the development of individual respiratory system components. Improved knowledge of the underpinnings of developmental processes will help to prevent antenatal and postnatal exposure to insults and to devise effective treatment strategies.

UPPER AIRWAYS

Developmental Anatomy

The configuration of the upper airways changes with growth.[1,2] In the newborn, the epiglottis is large and can cover the soft palate, forming a low epiglottic sphincter and encouraging nasal breathing. A horizontal position of the tongue and an elevated position of the hyoid bone and laryngeal cartilage are other specific features. Over the first 2 years of life, changes in upper airway anatomy lead to the formation of a dynamic velolingual sphincter that permits buccal respiration and speech. The epiglottis, larynx, and hyoid bone move downward. The posterior portion of the tongue becomes vertical during late infancy. The facial skeleton grows vertically during late infancy, and the mandible lengthens from front to back.

Recent studies using magnetic resonance imaging have investigated the growth relationships of the bone and soft tissues surrounding the upper airways in normal children (47% males; age range, 1 to 11 years).[3] The results indicate that (1) the lower facial skeleton grows linearly in the sagittal and axial planes from the 1st to 11th year; and (2) the soft-tissue structures, including the tonsils and adenoids, grow proportionally to the skeletal structures during the same period. Family aggregation of upper airway soft tissue structures was recently shown, suggesting that genetic determinants may predispose to obstructive sleep apnea syndrome.[4]

Developmental Physiology

FUNCTION

Human newborns and infants have difficulty breathing through their mouths when their nasal passages are occluded. Although nasal breathing is considered obligatory in the

newborn and infant, mouth-breathing can occur when the nose is blocked. Oropharyngeal structures have been examined using fluoroscopy during nasal occlusion in healthy infants.[5] Infants can breathe through the mouth by detaching the soft palate from the tongue, thus opening the pharyngeal isthmus. However, the time required to establish mouth breathing varies with age, state of alertness, or both, with younger and sleeping infants responding more slowly than older and awake infants.[6,7]

Few studies have investigated the upper airway dilator muscles during development. No phasic activity of the genioglossus muscle was found during quiet breathing in normal sleeping preterm infants[8] or normal children.[9,10] Interestingly, a delay in the genioglossus muscle response at early inspiration relative to the diaphragm has been reported in preterm infants and may promote upper airway collapse.[8]

An early study documented pharyngeal dynamics at autopsy in infants.[11] The closing pressure was 0.82 cm H_2O on average and was lower than the opening pressure. Neck flexion raises the closing pressure, making the upper airway prone to collapse.[11] Another early study showed that pharyngeal collapsibility decreased gradually during development in infants.[12] Recent work further documented the developmental changes in pharyngeal collapsibility during infancy.[13] The static pressure–area relationship of the passive pharynx was endoscopically quantified under general anesthesia with complete paralysis, allowing an evaluation of pharyngeal properties without any influence of neuromuscular regulation of the upper airway muscles. Pharyngeal wall thickness increases significantly during development, and the resulting increase in passive pharynx stability helps to maintain airway patency. The prone position increases the collapsibility of the passive pharynx in infants.[14] A study of the static mechanical properties of the passive pharynx in anesthetized and paralyzed children showed that the closing pressure (P, close) was more negative than in infants (Fig. 3-1).[13] Thus, airway stability increases during childhood in terms of pharyngeal wall compliance and closing pressure.[15] One half of the children closed their airways primarily at the soft palate edges and one third closed their airways at the tongue base.[13] Closing pressure increased during adulthood to the level seen in infants, whereas compliance was lower in adults than in infants.[13] Lateral positioning increased the upper airway cross-sectional area and total upper airway volume compared with the supine position in sedated, spontaneously breathing children.[16] A study using respiratory-gated magnetic resonance imaging showed that changes in upper airway area were small during tidal breathing in mildly sedated children.[17]

Nasal resistance has been measured in white and black infants during the first year of life, using an adapted posterior rhinomanometric method. The percentage contribution of nasal resistance to airway resistance was significantly higher in the white than in the black infants (mean values, 49% and 31%, respectively).[18] Active anterior rhinomanometry was used to measure nasal airflow and resistance in a large group of white children and adolescents.[19] Nasal inspiratory airflow and nasal inspiratory airflow from the right and left nostrils increased significantly with body height and age. Total nasal inspiratory airflow resistance and inspiratory flow resistance for the right and left nostrils decreased as body height and age increased. No difference was found between boys and girls.

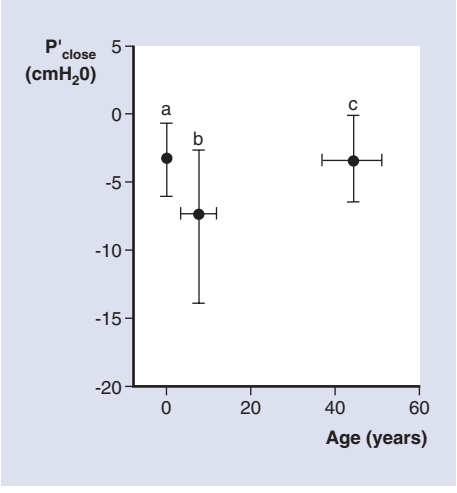

Figure 3-1 Differences in P'close (closing pressure, i.e., the pressure corresponding to zero of the measured cross-sectional area obtained under general anesthesia with complete paralysis) in healthy infants (a), children (b), and adults (c). *Closed circles* represent mean values; bars indicate standard deviation. REFLEXES ORIGINATING IN THE UPPER AIRWAYS

The upper airway is less susceptible to collapse in the pediatric population than in adults. This difference may be related, at least in part, to differences in neuromuscular reflex responses. In adults, upper airway neuromuscular activity increases in response to subatmospheric pressure loading, but this response is blunted during sleep compared to wakefulness.[20] In contrast, reflex responses are strong in children, who are thus able to maintain upper airway patency despite increasing subatmospheric pressure loading during sleep.[21] The ventilatory drive during wakefulness is stronger in children than in adults.[22] Interestingly, the level of the upper airway response to subatmospheric pressure loading is significantly related to the level of ventilatory drive during sleep in children, and both levels decrease with age until adulthood.[21]

In human infants and newborn mammals, reflexes originating from the laryngeal mucosa can induce apnea and bradycardia.[23,24] In anesthetized puppies, the duration of apnea elicited by water instillation into the larynx decreased as age increased.[24] In nonsedated lambs, the inhibitory cardiorespiratory response was more pronounced in preterm than in full-term lambs.[25-26] In premature human infants, reflex apnea has been reported to occur after instillation of water or saline into the larynx during sleep.[27-29] Prolonged apnea in preterm infants may be an abnormal extreme that extends the normal spectrum of airway-protecting responses to upper airway fluids.[29] Studies in newborn animals showed that the degree of apnea and bradycardia elicited by the laryngeal chemoreflex was increased by respiratory syncytial virus infection,[30] a condition associated with central and obstructive apneas during sleep in human infants.[31] The apnea and bradycardia elicited by the laryngeal chemoreflex in human infants increase dramatically in the presence of hypoxemia, because of a cardio-inhibitory effect on peripheral

chemoreceptors during apnea with suppression of input from pulmonary stretch receptors.[32]

During the neonatal period, stimulation of other upper airway receptors can result in apnea. Activation of upper airway mechanoreceptors by negative pressure causes apnea in puppies.[33] In human infants, trigeminal airway stimulation can elicit a response similar to that seen during the diving reflex and can induce apnea and bradycardia. The ventilatory response to trigeminal stimulation became increasingly blunted during rapid eye movement (REM) sleep as infants matured.[34]

CHEST WALL

Developmental Anatomy

RIB CAGE

At birth, the ribs are composed mainly of cartilage and project at right angles from the spine. As a result, the rib cage is more circular than in adults[35-37] (Fig. 3-2) and lacks mechanical efficiency.[38] In adults, elevating the ribs increases the volume of the rib cage, whereas in neonates rib cage movements produce little change in volume.[38] Acquisition of the upright posture is the main factor leading to the change in rib orientation that occurs with age. The pull of gravity moves the ribs caudally, so that the thoracic cavity lengthens and changes in section from circular to ovoid.[36,37] The thoracic index, which is the ratio of the anteroposterior over the lateral diameter, decreases significantly during the first 3 years of life, and gradual ossification of the ribs occurs concomitantly.[37] These changes in shape and structure are important because they help to stiffen the rib cage.

RESPIRATORY MUSCLES

In the newborn, the diaphragm seems ill-suited to the heavy burden of respiratory work. The angle of insertion of the diaphragm is not oblique as in adults but almost horizontal, which results in decreased contraction efficiency. With its open angle of insertion and small area of apposition (Fig. 3-3),[39] the flat diaphragm of the newborn seems designed to suck the chest wall inward rather than to draw air into the chest cavity. Because of its almost horizontal insertion, the contracting diaphragm tends to pull the lower rib cage inward. For the same reason, the downward course of the contracting diaphragm is shorter, the abdominal pressure increase is smaller and, consequently, the rib cage expansion is less marked.

The immature diaphragm is composed chiefly of type IIC undifferentiated fibers, which are gradually replaced by type I and type IIB fibers.[40,41] Type IIC fibers coexpress fetal and adult myosin heavy chains (MHCs), whereas type I and type IIB fibers express only the adult MHC isoform. The fetal MHC isoform predominates between 16 and 24 weeks of gestation, after which transition to the adult isoform occurs, between 24 and 42 weeks.[42,43]

The enzymatic oxidative capacity of the diaphragm changes significantly with postnatal maturation.[44-46] Succinyl dehydrogenase activity is very low at birth, then increases dramatically between the first and sixth postnatal weeks, whereas

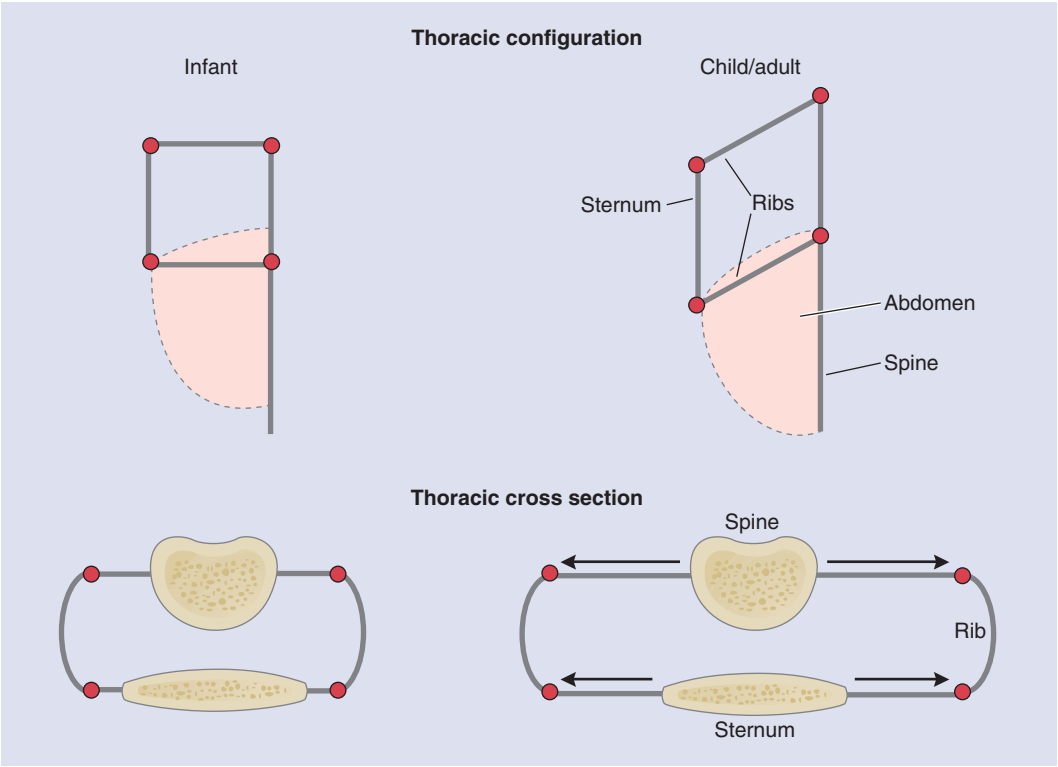

Figure 3-2 Changes in configuration and cross-sectional shape of the thorax from infancy to early childhood. (Redrawn from Openshaw P, Edwards S, Helms P: Changes in rib cage geometry during childhood. Thorax 39:624-627, 1984.)

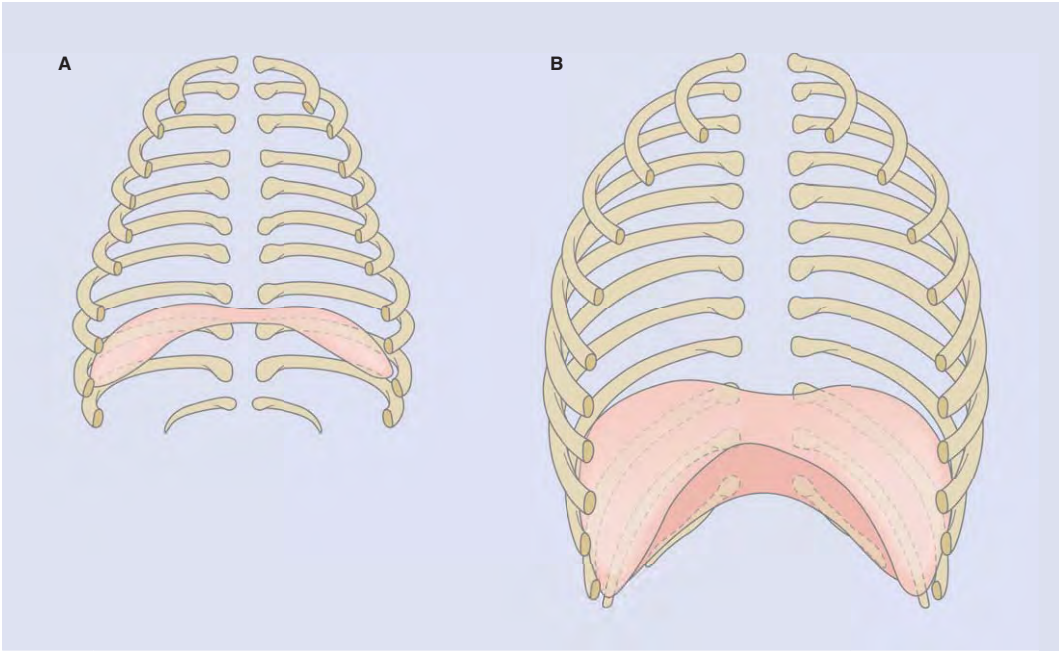

Figure 3-3 Area of costal apposition of the diaphragm in newborn **(A),** and adult **(B).** (Redrawn from Devlieger H, Daniel H, Marchal G, et al: The diaphragm of the newborn infant: Anatomic and ultrasonographic studies. J Dev Physiol 16:321-329, 1991.)

global oxidative capacity is higher at the first than at the eighth postnatal week.[46] The first postnatal month is also characterized by a considerable increase in ryanodine receptor (RyR1) expression in the sarcoplasmic reticulum, which is required for the maturation of the excitation-contraction coupling system.[47-49] Expression of the ryanodine receptor RyR3 occurs gradually during fetal development and reaches its peak after the second postnatal week in rats; RyR3 expression is higher in the diaphragm than in the other skeletal muscles.[49] Neuromuscular transmission undergoes postnatal maturation, with changes in the morphology of the neuromuscular junction and an increase in postsynaptic receptor density.[51,52] Finally, the phrenic motoneurons undergo morphologic changes after birth, increasing their cross-sectional area and their numbers of primary and secondary dendrites.[52]

These modifications in anatomy, morphology, contractile properties, and energetic capacity probably explain why the susceptibility to respiratory muscle fatigue changes with advancing age. Premature neonates cannot handle increases in respiratory demand.[53] However, the mechanisms underlying the susceptibility of premature infants to respiratory failure are probably complex and multifactorial. Thus, recent studies have established that the neonatal diaphragm is less susceptible to fatigue than the adult diaphragm, although the mechanisms underlying this age-related change remain unclear.[46,54-57]

Developmental Physiology

CHEST WALL COMPLIANCE

High chest wall compliance relative to lung compliance (with a 3:1 ratio) is an inherent characteristic of newborn mammals.[58] Few studies have investigated chest-wall mechanics in infants and children.[59-61] High chest wall compliance contributes to the respiratory vulnerability of preterm infants during early postnatal life,[61,62] as incomplete rib cage ossification and underdevelopment of the respiratory muscles predispose the chest wall to distortion. The high chest wall compliance relative to lung compliance results in a limited thoracic volume with a low functional residual capacity (FRC). By 2 years of age chest wall compliance is similar to lung compliance, which is the pattern seen in adults.

THORACOABDOMINAL MOTION

Developmental changes in thoracic properties over time influence the pattern of thoracoabdominal motion during infancy and early childhood. The contribution of the rib cage to tidal breathing increases with postnatal age, from 34% during non-rapid eye movement sleep (non-REM) sleep at 1 month to approximately 60% at 1 year.[63]

Chest wall muscle contractions help to stabilize the compliant infant rib cage, minimizing inward displacement of the ribs during diaphragmatic contractions. However, when the stabilizing effect of the intercostal muscles is inhibited (e.g., REM sleep), paradoxical inward motion of the rib cage occurs during inspiration (Fig. 3-4).[38,64] This is important because REM sleep accounts for more than one half the total sleep time in full-term infants and for an even larger proportion in preterm infants.[65]

Asynchronous chest wall movements during REM sleep are associated with a number of mechanical derangements in healthy newborns, including a decrease in FRC,[66,67] a decrease in transcutaneous partial pressure of oxygen,[68] and an increase in diaphragmatic work of breathing.[69] During REM sleep, a large proportion of the force of the diaphragm is wasted in distorting the rib cage and is, therefore, not available for inducing volume exchange. Furthermore, infants can use their abdominal muscles to optimize diaphragmatic length, but this

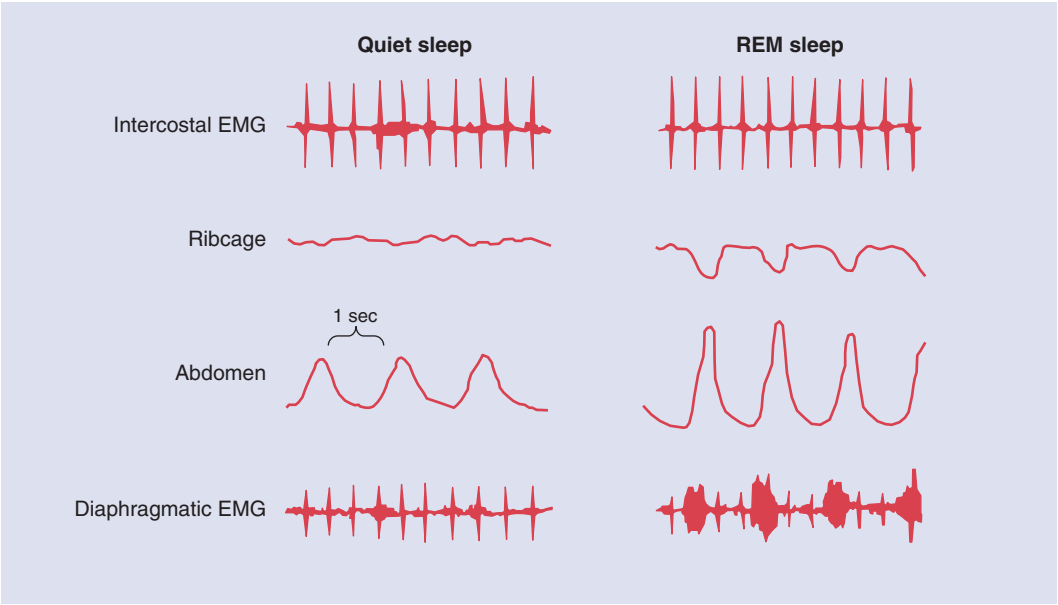

Figure 3-4 Movement of the rib cage and abdomen measured with magnetometers and electromyograms (EMG) using surface electrodes on the intercostal muscles and the diaphragm of a newborn during non-REM *(left)* and during REM *(right)* sleep. During REM sleep, there is marked inward distortion of the rib cage with increased outward movement of the abdomen; the intercostal electromyogram is decreased, and the diaphragmatic electromyogram is increased. (Redrawn from Bryan AC, Gaultier CL: The thorax in children. In Macklem PT, Roussos H [eds]: The Thorax, part B, New York, 1985, Marcel Dekker, pp 871-888.)

abdominal muscle activity is inhibited during REM sleep.[70] The increased diaphragmatic work of breathing in young infants represents a significant expenditure of calories and may contribute to the development of diaphragmatic fatigue and respiratory failure.

With the changes in rib cage geometry and chest wall compliance that occur with age, the time spent with paradoxical rib cage motion during REM sleep decreases, nearing or reaching zero after 3 years of age.[71] Recently, a study involving respiratory inductive plethysmography in 22 infants confirmed that inward rib cage movement during REM sleep decreased with age.[72] Paradoxical movements disappeared completely at 3.3 years of age. In adolescents, no paradoxical movements were observed.[73]

The mechanical properties of the chest wall have clinical implications for respiratory adaptation during sleep in infants who have respiratory disorders associated with increased resistive loads of breathing, such as upper airway obstruction and chronic lung disease. In young infants with such disorders, thoracoabdominal asynchrony occurs even during non-REM sleep.[74-76] As growth proceeds and the thoracic cage becomes less compliant, the increases in resistive load lead to heightened activation of the inspiratory thoracic muscles, which maintains inspiratory rib cage movement. However, the inspiratory intercostal muscles are inhibited during REM sleep, and the need for lower negative pressures during inspiration leads to paradoxical motion of the destabilized rib cage.[77]

PRESSURES GENERATED BY RESPIRATORY MUSCLES AND RESPIRATORY MUSCLE FATIGUE

Maximum pressures exerted by infants are surprisingly high compared to adult values, probably because of the small radius of curvature of the rib cage, diaphragm, and abdomen. According to the Laplace law, a smaller radius results in higher pressures. Esophageal pressures reaching –70 cm H_2O have been reported during the first breath.[78] Inspiratory and expiratory pressures of about 120 cm H_2O have been recorded during crying in normal infants.[79] During late childhood and adolescence, gradual increases in maximum static inspiratory and expiratory pressures occur, with substantial differences between males and females in all age groups.[80,81] Transdiaphragmatic pressure ($\bar{P}di$) measured using magnetic phrenic-nerve stimulation was significantly lower in preterm than term infants and was correlated with gestational age and postconceptional age.[82]

However, despite a relatively high maximum static inspiratory pressure, the inspiratory force reserve of respiratory muscles appears reduced during early infancy compared with adulthood because the inspiratory pressures are higher at rest.[22,83] The high pressure demand at rest in infants is due to the high minute ventilation and high metabolic rate normalized for body weight.[84] Occlusion pressure and inspiratory time measurements have been used to estimate the inspiratory pressure demand in children older than 4 years of age.[22] The ratio of mean inspiratory pressure to maximum static inspiratory pressure at FRC was 0.2 at 7 years of age (i.e., more than twice the value in adults).[83] It has been suggested that the tension-time index of the diaphragm in healthy newborns may be close to the fatigue threshold.[85]

Under all breathing conditions, two important parameters, i.e., pressure and time, determine the tension-time index, which allows the clinician to evaluate the position of the breathing pattern in relation to the critical level of muscle function or to the threshold of muscle fatigue (Fig. 3-5).[86-88] Their small inspiratory force reserve places young

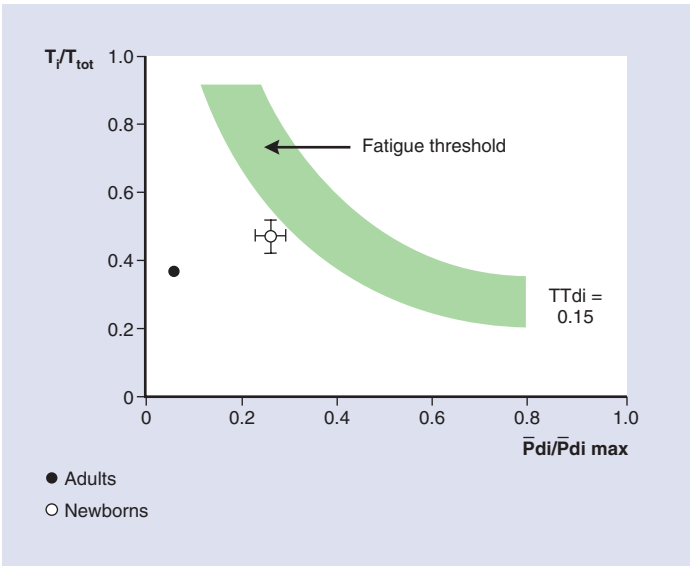

Figure 3-5 Relation between ratio of inspiratory time (T_i) over total duration of the respiratory cycle (T_{tot}) and mean transdiaphragmatic pressure used to breathe at rest over maximal transdiaphragmatic pressure ($\bar{P}$di max). The green area defines the diaphragmatic fatigue threshold and corresponds to the so-called tension-time index of the diaphragm (TTdi = 0.15). Breathing patterns below the fatiguing threshold can be obtained indefinitely. *Filled circle* refers to the average value for normal adults during resting breathing. *Open circle* is the estimated value for normal infants. Bars indicate 1 standard deviation. (Redrawn from Milic-Emili J. In Cosmi EV, Scarpelli EM [eds]: Pulmonary Surfactant System, Rome, 1983, Elsevier Science, pp 135-141.)

children closer to the diaphragmatic fatigue threshold than older children. All conditions characterized by prolonged muscle contraction or increased pressure demand may lead to respiratory muscle fatigue. Young children with croup or epiglottitis are at especially high risk for fatigue because obstructed and prolonged inspiration is combined with a need for high pressures to produce adequate ventilation. Thus, infants can develop ventilatory failure rapidly after small changes in mechanical loads. Infants can use other muscles to unload (rest) the diaphragm. When the respiratory drive is increased because of carbon dioxide breathing or increased upper airway resistance, infants and young children recruit their intercostal muscles, abdominal muscles, or both.[70] However, this muscle recruitment aimed at preventing an increase in diaphragmatic work of breathing and diaphragmatic fatigue is suppressed during REM sleep.

The paucity of fatigue-resistant type I fibers, high proportion of fatigue-susceptible type IIc fibers, and low oxidative capacity of the neonatal diaphragm suggest that the muscle may be relatively prone to fatigue. This hypothesis has been contradicted by in vitro[56] and in situ findings. However, an in vivo study in rabbits found that fatigue occurred more quickly in neonatal than in adult animals.[89] Thus, whether fatigability of the neonatal respiratory muscles is increased compared to adults remains controversial.

LUNGS

Developmental Anatomy

Lung development includes growth of lung structures and maturational cell differentiation processes. Alveolar development occurs both before and after birth and extra-acinar airway development is complete by week 16 of gestation. The development of extra-acinar arteries follows airway development and that of intra-acinar arteries follows alveolar development.[90] Figures 3-6 and 3-7 show the timetable of antenatal and postnatal lung development.[91,92]

Four processes are essential to lung development. They operate throughout the prenatal and early postnatal periods to create this organ essentially dedicated to exchanging gases through the blood-gas barrier. These processes include *branching* of the airways to form conducting and respiratory airways, *septation* to divide the airspaces and participate in *alveolization*, and formation of blood vessels, or *lung vascularization*, which accompanies the development of bronchi. These four essential processes, together with cell differentiation and maturation, contribute to lung formation and development.

ANTENATAL LUNG DEVELOPMENT

The antenatal development of the human lung can be subdivided into an early embryonic period, during which most organs are formed; and a fetal period, which includes several stages.[91-94]

Embryonic Lung Development

The lung appears around day 26 as a ventral bud of the esophagus at the caudal end of the laryngotracheal sulcus. The epithelial components of the lung are thus derived from the endoderm and the enveloping connective tissue from the mesodermal germ layer. The tracheal bud rapidly divides into two branches that develop into the two main bronchi. The future airways continue to grow and branch dichotomously into the surrounding mesenchyme. By the end of the sixth week, the lobar and segmental portions of the airway tree are preformed as tubes of high columnar epithelium. Simultaneously with the early stages of pulmonary organogenesis, vascular connections develop. The pulmonary arteries branch off from the sixth pair of aortic arches and descend to the newly developed lung buds, forming a vascular plexus in the surrounding mesenchyme. The pulmonary veins start to develop around the fifth week as a single evagination in the sinoatrial portion of the heart. Merging of the embryonic period into the fetal period is thought to occur on day 50. At that time, the lung resembles a small tubuloacinar gland, which is why the subsequent stage is called the *pseudoglandular stage*.

Fetal Period

The fetal period includes the pseudoglandular stage to week 16, the canalicular stage to weeks 24 to 26, and the saccular-alveolar stages to term.[90-94]

Pseudoglandular Stage. The extra-acinar bronchi and arteries develop during the pseudoglandular stage by continuous growth and branching. The proximal airways are lined with a high columnar epithelium (Fig. 3-8) and the distal airways with a cuboidal epithelium. The cytoplasm of airway epithelial cells is poorly differentiated and rich in glycogen. Differentiation of the airway wall occurs in a centrifugal direction, so that ciliated, nonciliated, and goblet cells first appear in the proximal airways. The luminal surfaces of the columnar cells have scarce microvilli with or without primary

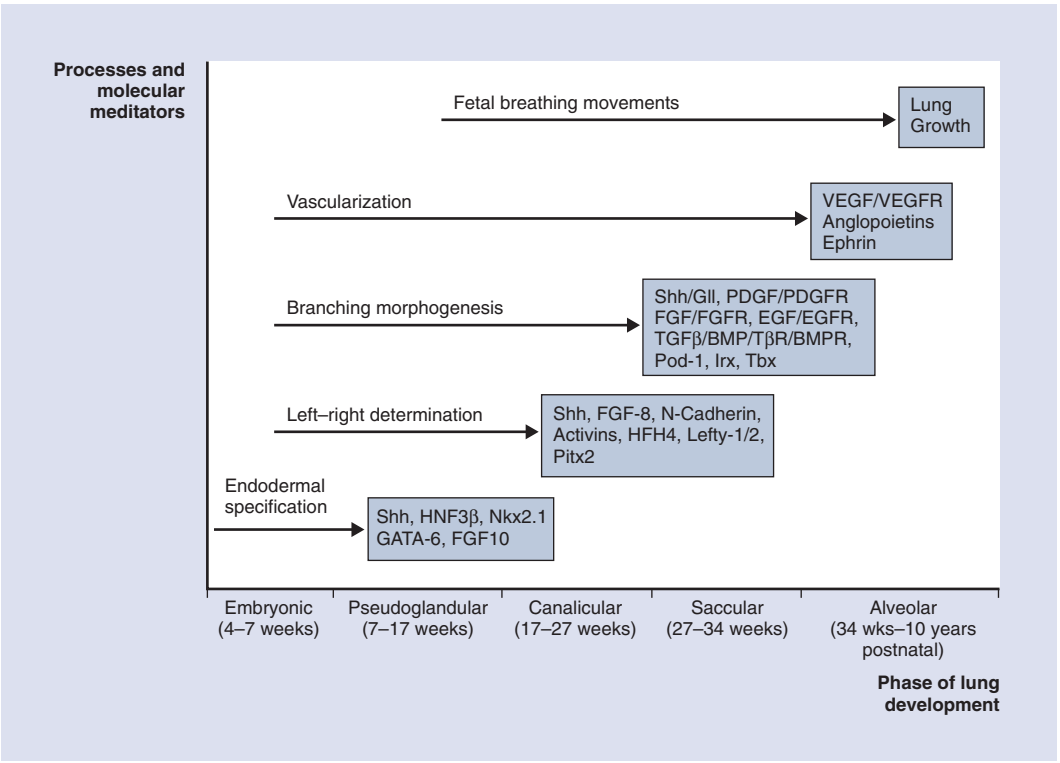

Figure 3-6 Regulatory factors implicated in the different phases of respiratory morphogenesis. Transcription factors: Nkx2.1, forkhead homolog hepatocyte nuclear family proteins (HNF3β, HFH4), GATA family of zinc finger transcription factors (GATA-6), basic helix-loop-helix (bHLH) proteins (öd-1), Gli zinc finger transcription factors (gli), Iroquois complex homeobox family members (Irx), and Tbox family proteins (Tbx). Growth factor signaling pathways: sonic hedgehog (Shh), fibroblast growth factors (FGF), platelet-derived growth factors (PDGF), transforming growth factors (TGFβ)/bone morphogenetic proteins (BMP), epidermal growth factor (EGF) proteins and vascular endothelial growth factor (VEGF) proteins. Receptors for growth factors: PDGFR, FGFR, TGFβR/BMPR, EGFR, VEGFR. (From Copland I, Post M: Lung development and fetal lung growth. Paediatr Respir Rev 5:S259-S264, 2004.)

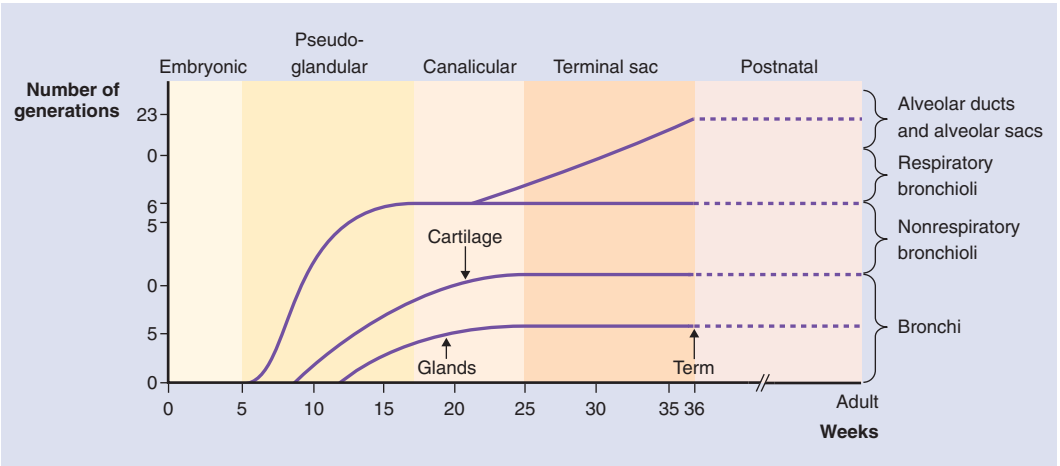

Figure 3-7 Timetable for development of the airway tree, its generations, and typical wall structures. Generation numbers are fitted to the average airway tree of Weibel's dichotomous branching model. (Redrawn from Burri P: Circulatory and nonrespiratory functions. rudimentary cilia.[95] Precursors for neuroendocrine cells appear at this stage.[96] Mucus glands are also present.[97] Mesenchymal cells differentiate into chondrocytes[98] and smooth muscle cells.[99] Capillaries are randomly distributed in the mesenchyme (Fig. 3-9). As a rule, the arteries develop and grow according to the same pattern as the airways. In contrast to the airway system, which averages 23 generations in adults, the arterial system has 28 to 30 generations. By 34 days of gestation, the capillary network around each main bronchus connects both cranially and caudally with the aortic sac and

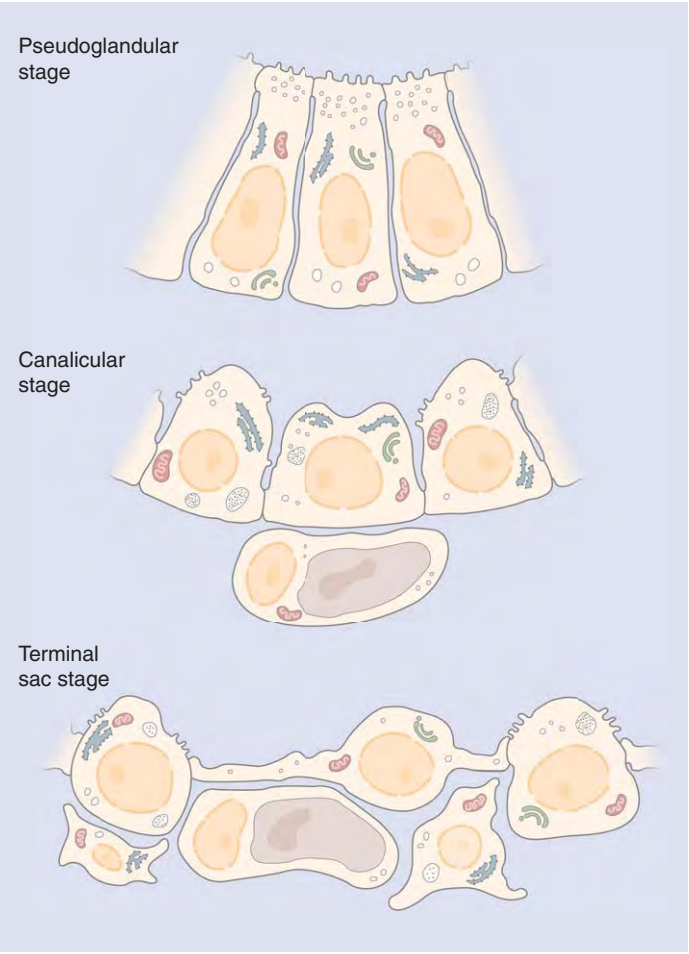

Figure 3-8 Phases of epithelial transformation. *Top,* Pseudoglandular stage: high columnar epithelium and cells rich in glycogen. *Middle,* Canalicular stage: epithelium beginning to differentiate into two cell types, secretory (type 2, containing lamellar body) and lining cells (type 1), and characterized by the low position of the junctional complex with neighboring cells and close contact with capillaries. *Bottom,* Terminal sac stage: differentiation of type 1 and type 2 cells. (From Burri P: Circulatory and nonrespiratory functions. (Redrawn from Burri P: Circulatory and nonrespiratory functions. In Fishman P, Fisher A [eds]: Handbook of Physiology, Section 3: The Respiratory System, vol 1: Bethesda, Md, 1985, Williams & Wilkins, pp 1-46.)

the left atrium, respectively.[100] These capillaries coalesce to form small blood vessels alongside the airways. As each new airway buds into the mesenchyme, a new plexus forms and adds to the circulation, thus extending the arteries and veins. Arteries that follow the divisions of the airways are called *conventional arteries;* the smaller arteries with intermediate branchings that supply alveolar regions adjacent to airways are called *supernumerary arteries*.[101,102] By week 12, both types are present. The branching pattern of the veins matches that of the arteries.[103]

Canalicular Stage. Events during the canalicular stage include acinar anlage formation and epithelial cell differentiation with development of the air-blood barrier. Production of surfactant starts toward the end of the canalicular stage. The transition from the pseudoglandular stage to the canalicular stage is marked by the appearance of rudimentary acini. The acinus is generally defined as the unit of gas-exchanging tissue that is supplied by a terminal bronchus. The acinus margins become recognizable as a result of decreased density of the mesenchyme. At the end of week 17, the newly delineated acinus is composed of the anlage of the terminal bronchiole, two to four rudimentary respiratory bronchioles, and clusters of short tubules and buds. Over the following weeks, the clusters grow by further peripheral branching and by lengthening of each tubular branch. The epithelium differentiates into two cell types: secretory cells (type 2, containing lamellar bodies) and lining cells (type 1) characterized by low junctional complexes with neighboring cells and by close contact with capillaries (see Fig. 3-8). Peripheral growth is accompanied by an increase in capillaries, which begin to develop around the airspaces and subsequently establish close contact with the lining cells to form the future air-blood barrier (see Fig. 3-9).

Saccular-Alveolar Stage. The saccular-alveolar stage starts at weeks 24 to 26 of gestation. At this time, the fetal lung can theoretically function in air. However, because of a low level of surfactant synthesis, very premature babies are at high risk for respiratory distress syndrome. At the beginning of this stage, the airways end in clusters of thin-walled saccules, which produce the last generations of airways (i.e., alveolar ducts and alveolar sacs). Between weeks 28 and 36, there is a striking change in the appearance of the lung characterized by a marked decrease in interstitial tissue with thinning of saccule walls. Secondary crests divide the saccules into smaller units. The margins of the crests contain elastic fibers. The saccule walls retain their earlier double capillary

network. The formation of alveoli marks the beginning of the alveolar phase. According to recent studies, alveolar development starts between weeks 29 and 32.[104,105] The internal surface area of the lung increases rapidly after the onset of alveolar development, from 1 or 2 to 3 or 4 m^2 at full term. The number of alveoli present at birth is still controversial. Early studies[106,107] examining a single lung found numbers ranging from 17×10^6 to 24×10^6. More recently, larger mean numbers of 50×10^6 and 150×10^6 were reported.[104,105] Despite these discrepancies, there is no doubt that the number of alveoli is lower at birth than in adulthood (i.e., 300×10^6 to 600×10^6).[108] During the saccular and alveolar phases, intra-acinar blood vessels increase in width, length, and number.

POSTNATAL LUNG DEVELOPMENT

Alveolar Development

At full term, the in vitro lung volume at a transpulmonary pressure of 25 cm H_2O is 150 mL.[104] Alveolar multiplication continues after birth. Early studies suggested that postnatal alveolar multiplication might end at 8 years of age.[107] However, more recent studies showed that alveolar multiplication was complete by 2 years of age and possibly even earlier, between 1 and 2 years of age.[91,94,109] During postnatal alveolar multiplication, the capillary network of the septa is remodeled from the initial double pattern to the single pattern seen in adults.[110] This process continues after the end of alveolar multiplication, stopping between 3 and 5 years of age. At 2 years of age, the number of alveoli varies substantially among individuals. After 2 years of age, boys have larger numbers of alveoli than do girls. After the end of alveolar multiplication, the alveoli continue to increase in size until thoracic growth is completed.[109]

Airway Development

Airway size and structure in normal lungs of fetuses and infants have been described.[111] The mean airway lumen diameter from the main bronchi to the respiratory bronchi increases linearly with postconceptional age. Each type of airway shows a similar relative increase in diameter of 200% to 300% from birth to adulthood. The absolute amount of cartilage increases until 8 months of age. The area of the submucosal glands (expressed in relation to the lumen perimeter as millimeters squared per millimeter) increases linearly from birth to 8 months of age. The area of the hilar bronchi continues to increase until adulthood. At birth, submucosal glands are supplied by nerves containing peptides. Bronchial smooth muscle is present at birth, even in the respiratory bronchioles. Bronchial smooth muscle area increases from birth to 8 months of age in all airways from the main bronchi to the respiratory bronchioles. In proximal airways only, this area increases from 8 months of age to adulthood. In premature infants, airway size is appropriate for postconceptional age and the airways contain increased amounts of bronchial smooth-muscle and goblet cells. At birth, the smooth muscle is supplied by nerves containing peptides (neuropeptide-tyrosine, vasointestinal peptide, substance P, neuropeptide Y, somatostatin, and gene-related peptide).[112] Smooth-muscle innervation appears to change with age, as the relative number of peptide-containing nerves within the respiratory unit decreases from infancy to adulthood. No developmental changes in myosin chain isoforms have been demonstrated in human airway smooth muscle.[113]

Arterial Development

Pulmonary vascular resistance falls rapidly at birth as a result of dilation of the small muscular arteries and a reduction in the amount of vascular smooth muscle in the lungs.[114] Postnatal adaptation of the pulmonary circulation is thought to be related to changes in endothelial cell function, including increased capabilities for synthesis and release of the endothelium-derived relaxing factor nitric oxide.[115,116] Ultrastructural studies found evidence of postnatal smooth muscle maturation, with changes in contractile myofilaments and in cytoskeletal protein types.[117] The number of arteries increases rapidly during the first 2 months of life.[118] Subsequently, arteries multiply at the same rate as alveoli, and the alveolar-arterial ratio remains fairly constant. Arterial growth is most marked during the first 2 months of life but remains substantial during the first 4 years.

Studies of the structure of the arteries that accompany the peripheral airways have demonstrated that the respiratory bronchiolar arteries acquire a muscle coat as they increase in size during the first year of life. From birth to 6 months of age, the mean number of arteries surrounded by muscle cells is 58% among arteries accompanying terminal bronchioli versus only 23% among arteries accompanying alveolar ducts. These mean proportions reach 92% and 40%, respectively, between 1 and 4 years of age and increase further to 96% and 71%, respectively, after 5 years.[118]

Remodeling of the arterial wall within the acinus is accompanied with an increase in the nerve supply to the arterial wall during childhood.[119] Many respiratory unit arteries do not have accompanying nerve fibers in infants 1 to 4 months of age. The proportion of innervated vessels increases with age. In all age groups, the vasoconstricting neuropeptide tyrosine is the predominant neuropeptide associated with perivascular nerves. In infants with pulmonary hypertension, respiratory unit arteries are prematurely innervated by sympathetic-like nerve fibers. In both the normal and the pulmonary hypertensive lung, sympathetic innervation seems to develop in parallel with an increase in the amount of smooth muscle in peripheral arteries.[119]

FACTORS CONTROLLING LUNG MORPHOGENESIS

Lung morphogenesis is controlled by numerous factors, including transcription factors, growth factors, extracellular matrix molecules, integrins, and intercellular adhesion molecules. These factors can also interact on gene networks responsible for lung branching morphogenesis, septation, vascularization, and response to mechanical stress. A schematic representation of some of the numerous molecular factors involved in the different stages of lung development is given in Figure 3-10.[92]

Lung Branching Morphogenesis

Epithelium-mesenchymal interactions play a key role in regulating lung growth and branching pattern. Transplantation

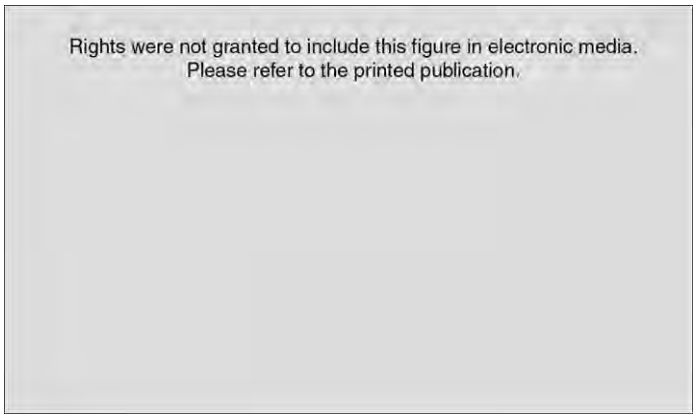

Figure 3-10 Examples of interactions between transcription factors, growth factors, and components of extracellular matrix. (1) Overexpression of Foxa2 decreases VEGF expression; (2) lungs of mice with deleted RAR? have reduced elastin content; (3) Foxa2 modulates expression of TTF-1; (4) exogenously added FGF2 decreases elastin transcription in cultured type II cells; (5) TGFβ hampers activity of TTF-1 and Foxa2 in cytoplasm; (6) blockade of TGFβ signaling pathway favors response to EGF and PDGF activity; (7) integrins modulate transcription factor signaling; (8) proteoglycans form tertiary structures with growth factors, modulating their activity; (9) fibronectin interferes with cell-cell and cell-matrix adhesion properties. (From Roth-Kleiner M, Post M: Similarities and dissimilarities of branching and septation during lung development. Pediatr Pulmonol 40:113-134, 2005.)

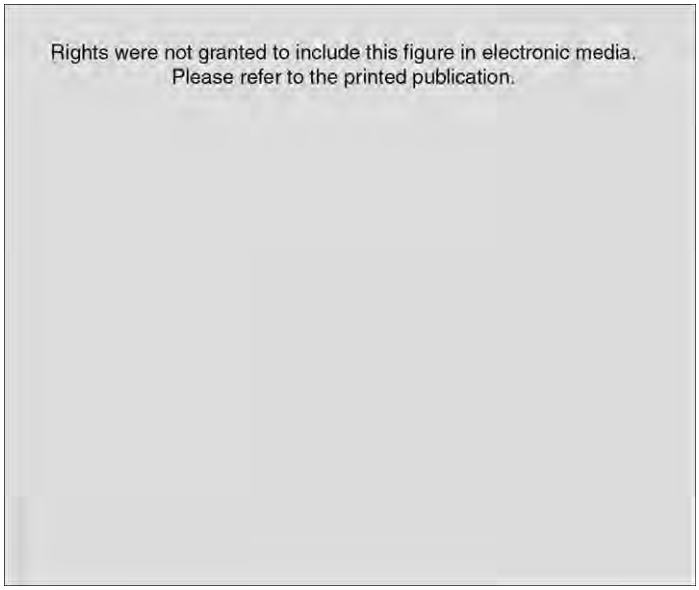

Figure 3-11 Branching morphogenesis in lung. **A,** FGF10 is the driving force for outgrowth of bronchial endbuds. Penetration of surrounding tissue is facilitated by thinned-out basal membrane and increased expression of MMP2. FGF10 stimulates Shh production in epithelium of endbud. **B,** Increasing expression of Shh and BMP4 lateralizes FGF10 activity, which induces outgrowth of new endbuds. At branch point, increased epithelial expression of fibronectin and mesenchymal expression of laminin5 enhance cleft formation. (From Roth-Kleiner M, Post M: Similarities and dissimilarities of branching and septation during lung development. Pediatr Pulmonol 40:113-134, 2005.)

experiments have shown that the mesenchyme is directly responsible for the branching pattern in the lung.[120] The branching process depends on interactions between cell-substrate adhesion molecules and underlying extracellular matrix (ECM) and intercellular adhesion molecules.[121,122] Epidermal growth factor may be an important mediator of this process.[123] The mechanisms responsible for the mesenchymal influences have not been fully elucidated but have been shown to depend on the synthesis of proteoglycans, collagen, laminin, and fibronectin.[124] Cellular attachment to the ECM is mediated by integrin receptors.[124] Branching is decreased in the presence of monoclonal antibodies against integrin receptors.[125] Integrin receptors appear to interact with fibronectin within the clefts that mark the branching points.[126] Transforming growth factor-β_1 co-localizes with fibronectin within these clefts and may regulate fibronectin deposition, thereby indirectly affecting branch formation.[127]

Reduced pulmonary branching was demonstrated in chimeric GATA-6 null mice.[127,128] Thyroid transcription factor-1 (TTF-1) expression occurs in the epithelial cells of dividing lung buds and decreases with advancing gestation.[129] Early branching is impaired in TTF-1 knockout mice.[130] Foxa2 overexpression impairs airway branching, whereas deletion of this factor does not affect lung morphogenesis.[131] Retinoic acid (RA) exerts key effects in regulating heterodimerized transcription factors, retinoic acid receptors (RAR family), and retinoic X receptors (RXR family). RA signaling is active early in lung morphogenesis,[132] and its absence leads to lung agenesis or hypoplasia.[133,134] Fibroblast growth factors (FGF) are expressed in the developing lung. FGF-10 signaling via its receptor (FGFR-2) is crucial to early lung development and branching.[135] In addition to FGF-10, sonic hedgehog (Shh) is essential for early branching and is markedly expressed by the epithelium at the tips of the endbuds.[136] Shh-null mice exhibit reduced lung epithelial branching early in development.[137] Vascular endothelial growth factor (VEGF), which plays a key role in vasculogenesis and angiogenesis, is also expressed in airway epithelial cells and involved in branching morphogenesis.[138,139] Transforming growth factor-beta (TGFβ) is another group of growth factors that is crucial to lung development. Both TGFβ1 and TGFβ2 inhibit airway branching in vitro, whereas inhibition of the TGFβ signaling pathway by downregulation of the receptor TGFβR-II expression stimulates lung branching in vitro.[140,141] This effect of TGFβ is indirect, being mediated by the transcription factors Smad proteins, interactions with matrix proteins and related enzymes, and effects on TTF-1 and Foxa2.[142-144]

The ECM is under the control of the matrix metalloproteases, which are proteolytic enzymes. Inhibition of major ECM molecules (elastin, fibronectin, proteoglycan, laminin, and integrin) leads to branching failure, as does overexpression of matrix metalloproteases.[145-151]

Lung Septation and Growth of the Peripheral Lung

Septation is the formation of secondary septa that divide primary saccules into smaller units, the alveoli. Septation takes place during the alveolar stage of lung development. It is initiated by interactions between smooth muscle cells, elastic fibers, and collagen, which attract the capillary layer of the primary septum (Fig. 3-11A). Thus, the secondary septum contains a double capillary layer (see Fig. 3-11B), which matures into a thin definitive septum containing a single capillary layer (Fig. 3-12). Septation, similar to branch-

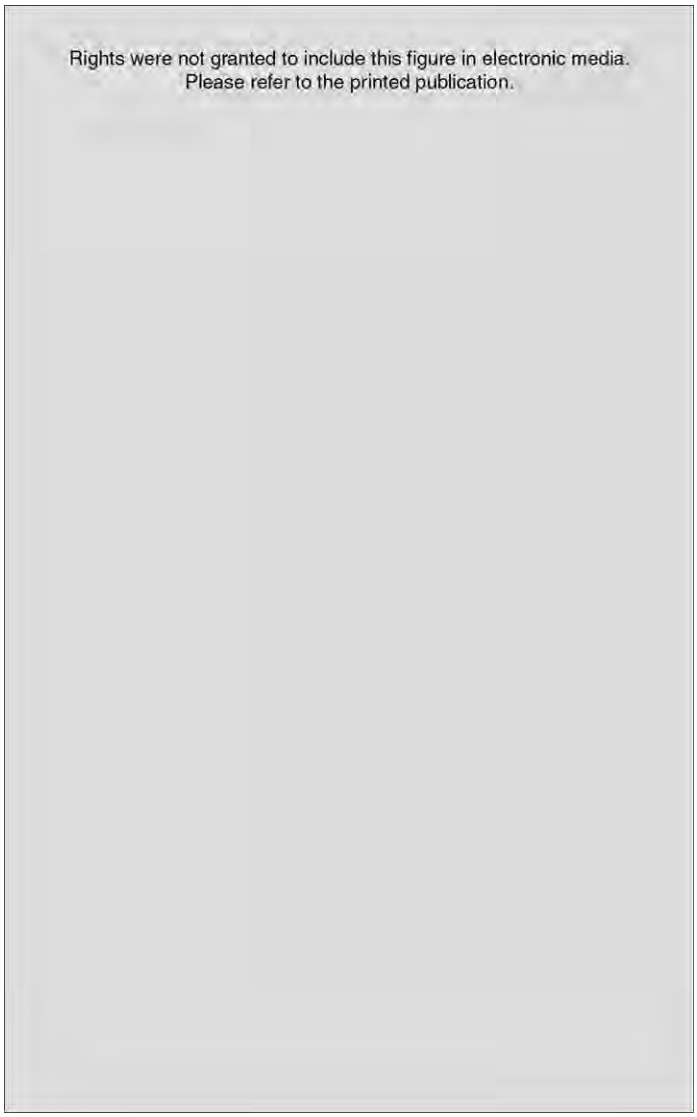

Figure 3-12 Alveolar septal formation and maturation. **A,** Primary septum with double capillary layer. At sites of future secondary septal formation, PDGF-A–positive myofibroblast precursors start to produce ECM proteins elastin and tenascin-C. **B,** Secondary septum is growing into airspace, with elastic fibers as driving force. Further ECM proteins like decorin and chondroitin sulfates are predominantly deposited in septal tips (small rhombs). Expression of matrix metalloproteinases-2/9 *(small dots)* increases after formation of secondary septum. **C,** Mature secondary septum with single layer of capillary and thinned interstitial tissue. (From Roth-Kleiner M, Post M: Similarities and dissimilarities of branching and septation during lung development. Pediatr Pulmonol 40:113-134, 2005.)

ing, is a complex process that is controlled by myriad transcription and growth factors, as well as by numerous interactions involving the mesenchyme and ECM components.[152] Transcription factor GATA-6 overexpression impairs alveolization, probably by altering the differentiation of type I and type II epithelial cells.[153] Similarly, TTF-1 overexpression decreases alveolization and impairs differentiation of type I and type II cells.[154] Retinoic acid (RA) is crucial for the septation process. It is found in alveolar wall fibroblasts, which produce elastin at the sites of outgrowth of secondary septa.[155-156] Alveolization is decreased in RARγ or RAR∝ null mutant mice.[157,158] On the contrary, RARβ signaling inhibits alveolar formation in the early postnatal period. Vitamin A deficiency in premature neonates is considered a risk factor for developing bronchopulmonary dysplasia, which is marked by decreased alveolization.[159] On the other hand, vitamin A supplementation in premature neonates was beneficial in improving lung development and preventing bronchopulmonary dysplasia.[160]

Similar to branching, alveologenesis is influenced by growth factors. FGF signaling via receptors FRFR-3 and FGFR-4 affects alveolization, chiefly via changes in elastin homeostasis.[161] Similarly, PDGF-A and receptor PDGF-R∝ play crucial roles in alveolization via the regulation of tropoelastin.[162] Inhibiting or blocking VEGF signaling reduces both alveolization and pulmonary vascularization.[163,164] Overexpression of TGF∝, whose signaling is mediated through the EGF receptor, impairs secondary septation by affecting metalloproteinase expression and elastin homeostasis.[165,166] Matrix metalloproteinases, particularly MMP-2 and MMP-9, play an important role in septation by contributing to basement membrane thinning and interstitial tissue reduction during this phase of alveolar maturation.[167] Elastin is the key ECM component during septation because it is considered to drive alveogenesis.[155] Its precursor, tropoelastin, is highly expressed by myofibroblasts in the tips of secondary septa,[168] and the tropoelastin production peak coincides with the septation peak in rats.[169] Elastin is essential to alveolar septation and is markedly increased in infants and animals with bronchopulmonary dysplasia.[170]

Lung Vessel Development

Lung vessels develop through at least two concurrent processes: vasculogenesis, or in situ formation of new vessels from angioblasts; and angiogenesis, in which new vessels sprout from existing vessels. Intussusception is another pattern of vessel development, in which an existing capillary divides in two via the formation and growth of transcapillary tissue pillars.[171]

A recent study showed that distinct endothelial cell subpopulations were observed early in the developing lung and possibly arose from distinct genetic lineages.[172] These findings are beginning to suggest explanations for the functional heterogeneity of pulmonary vascular cells in both health and disease.[170,173,174] VEGF is involved in angiogenesis and vasculogenesis and has been found in epithelial cells.[175,176] VEGF receptors are expressed in the endothelium from 38 days of gestation in humans. Recent studies demonstrated reciprocal control between blood vessels and airways: thus, VEGF overexpression disrupted the assembly of the vascular network and stopped the airway branching process.[177] Another tyrosine kinase receptor, Tie-2, is expressed on endothelial cells, binds to angiopoietin, and is involved in vessel assembly and vascular network stabilization.[178,179]

Endothelial nitric oxide synthase is expressed by the lung vessel endothelium throughout development. Nitric oxide stimulates endothelial proliferation, migration, and tube formation and inhibits apoptosis.[180] The control of smooth muscle cell differentiation in vessel walls is regulated in part by angiopoietin and the Tie-2 receptor[181] and in part by TGFβ.[182] Another important regulator of vasculogenesis and angiogenesis during lung development is oxygen

tension.[183] Hypoxia affects many of the genes that regulate molecular vascular development (e.g., VEGF, Flk-1, Tie-2, PDGFb, bFGF, iNOS, and endothelins).[184,185]

Role of Apoptosis in Lung Development

Apoptosis occurs throughout lung development (Table 3-1).[186,187] Apoptosis shifts from the mesenchymal tissue layer during early development to both the epithelial and mesenchymal tissue layers during the canalicular stage of development.[188-189] Increased apoptosis of alveolar epithelial type II cells occurs concomitantly with decreased cell prolifera-tion in late gestation.[190] Throughout lung development, apoptosis occurs in the peripheral mesenchyme, at the site of epithelial branching morphogenesis and interstitial tissue remodeling.[191] Apoptosis is mediated by proapoptotic factors (e.g., TGFβ)[192] and antiapoptotic factors (e.g., IGF-1 and nitric oxide).[193,194] During gestation, fetal breathing movements and fluid secretion are essential to induce cell proliferation, which must be regulated by apoptosis.[195] After birth, apoptosis plays a major role in alveolar development and maturation.[196,197] Normal lung development is associated with apoptosis, which counteracts proliferation. In premature neonates, mechanical ventilation (which induces mechanical stress) may impair the balance between proliferation and apoptosis.

Developmental Physiology

The mechanical properties of the passive respiratory system (i.e., the chest wall and lung plus the extra- and intrathoracic airways) and the action of respiratory muscles determine the resting volume of the lung, the breathing pattern, and ventilation. Intrathoracic and extrathoracic receptors, bronchomotor tone, vagal reflexes, and modifications in respiratory muscle activity can dramatically alter baseline breathing activity.[198] In the newborn, a high ratio between chest and lung compliance (C_W/C_L ratio) decreases resting volume (VR) and transpulmonary pressure, facilitating alveolar collapse and promoting a decline in C_L. During active breathing, vagal receptors sense changes in lung volume and can elicit reflexes that dynamically modify respiratory mechanics by altering the breathing pattern, bronchomotor tone, and respiratory muscle tone.[198,199] Mechanisms that serve to avoid lung collapse in the newborn include an increased rate of vagally mediated augmented breaths and a dynamic increase of the functional residual capacity (FRC) via prolongation of the expiratory time constant of the respiratory system (t_{RS}). The t_{RS} increase results from postinspiratory activity of the inspiratory muscles, which stiffens the chest wall, or from an increase in laryngeal resistance. With increasing age, there is a transition from active to passive maintenance of FRC via stiffening of the chest wall, which becomes more able to resist the inward recoil of the lung.[199]

FUNCTIONAL RESIDUAL CAPACITY

During breathing in the resting state, the volume of gas in the lungs at FRC represents the lung oxygen stores. The FRC is determined by the static passive balance of forces between the lung and the chest wall. In infants, the outward recoil of the chest wall is very small and the inward recoil of the lung is slightly less than in adults.[58] Consequently, the static passive balance of forces dictates a very low ratio of FRC over total lung capacity (TLC) in infants, which would be inadequate for gas exchange. Measured FRC and estimated TLC values in infants[200] indicate that the dynamic FRC/TLC ratio is about 40%, a value similar to that in supine adults. Thus, the dynamic end-expiratory volume is very likely to be substantially greater than the passively determined FRC in newborns and infants with little outward recoil of the chest wall.[201]

Infants, in contrast to adults, terminate expiration at substantial flow rates (Fig. 3-13).[202] This suggests active interruption of relaxed expiration. To slow expiration and to maintain FRC, the newborn can use two active mechanisms, namely, postinspiratory activity of the diaphragm[203,204] and laryngeal narrowing during expiration,[205] the extreme form of which is the grunting observed in newborns with respiratory distress syndrome. Laryngeal braking of expiration has

Table 3-1
Summarized Role of Apoptosis During Lung Development

Stage	Major Events	Role of Apoptosis
Embryonic	Lung anlage appears, branching morphogenesis starts, with extensive proliferation of epithelial and mesenchymal cells	Apoptosis in mesenchyme around branch points and regions of new lung bud formation
	Few pulmonary vascular connections	No epithelial apoptosis
Pseudoglandular	Bronchial airway tree establishment by dichotomous branching	Apoptosis of interstitial tissue contributes to mesenchymal involution
	Airways are lined with thick epithelium while epithelial cells differentiate	No epithelial cell apoptosis
Canalicular	Respiratory bronchioli appear, decrease of interstitial tissue, airway widening	Apoptosis of interstitial tissue contributes to mesenchymal involution and thinning of the alveolar septa
	Differentiation of type II into type I cells	Increase in apoptosis of epithelial cells as cell proliferation decreases
	Rapid increase of vascular network	
Saccular	Terminal airways widen to form saccules	Increase in epithelial cell apoptosis
	Thinning of interstitium between airspaces	
	Vascular network expands	
Alveolar	Extensive alveolar septation	Transient increase in apoptosis at birth
Microvascular	Double capillary layer in alveolar septa is reduced to a single layer	Final increase in apoptosis to remove excess cells

Data from Del Riccio V, van Tuyl M, Post M: Apoptosis in lung development and neonatal lung injury. Pediatr Res 55:183-189, 2004.

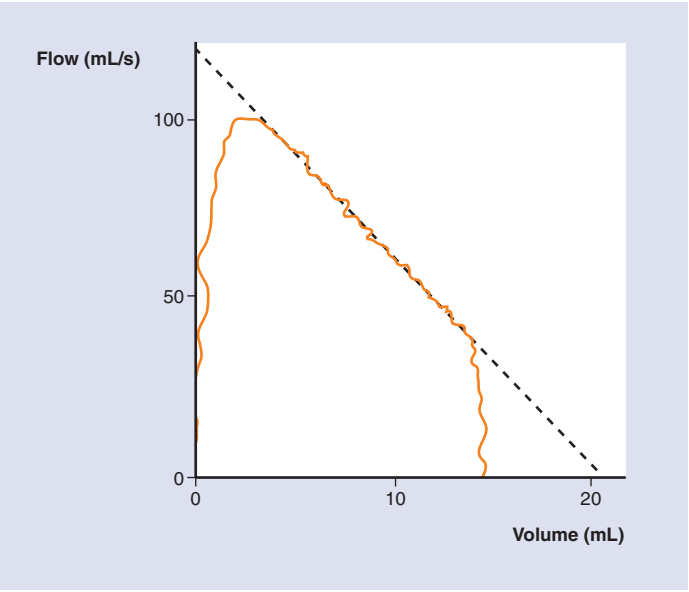

Figure 3-13 Passive flow-volume curve in an infant, showing abrupt inspiration substantially above passive FRC. (From Le Souëf PN, England SJ, Bryan AC: Passive respiratory mechanics in newborns and children. Am Rev Respir Dis 129:552-556, 1984.)

an effect similar to that of autopositive end-expiratory pressure, which increases FRC. FRC would be expected to fall during REM sleep. It has been firmly established that expiratory airflow braking mechanisms are disabled during REM sleep in preterm infants. Postinspiratory diaphragmatic activity is reduced during REM sleep, and animal studies have demonstrated that expiratory laryngeal adduction is substantially diminished during REM sleep.[205] Furthermore, flow studies in human preterm newborns show clear evidence of expiratory braking during non-REM sleep but suggest passive airflow without expiratory braking during REM sleep.[206] The transition from dynamically maintained to passively determined end-expiratory lung volume is believed to occur between 6 and 12 months of age.[207]

MECHANICAL PROPERTIES OF THE LUNG

Elastic Properties

Changes in pressure-volume relationships have been related to changes in the amount, distribution, and structure of elastin and collagen in the growing rat lung.[208] In humans, little is known about the development of the elastic properties of the lung. One study showed that the true elastin content of the lung increased up to a plateau during the first 6 months of life.[209] The pressure-volume relationship has been measured in excised lungs of infants and a few children[210-212] and in vivo in older children using esophageal balloons to measure transpulmonary pressure. In excised preparations, lung pressures of up to 30 cm H_2O were found; in vivo, the TLC is taken to represent full inflation. In excised lungs, when lung volume is expressed as a fraction of the lung volume at 30 cm H_2O, there is a marked change in the overall shape of the pressure-volume curve within the age range examined.[213] The younger lung holds a greater fraction of this volume at low pressure than the older lung. The in vivo quasistatic pressure-volume curves during deflation show that lung recoil increases with age in children older than 6 years.[214]

Studies in animals and in humans have shown that antenatal and postnatal environmental factors modify the elastic properties of the lungs. Protein malnutrition impairs elastin deposition in the lungs and is associated with an upward and leftward shift in the pressure-volume curves.[215] Total respiratory system compliance is higher in neonates born to mothers who live at high altitudes than in those born to mothers who live at sea level.[216]

Compliance, Resistance, and Time Constant of the Total Respiratory System

Compliance of the respiratory system increases during the first year of life, by an estimated 152%.[217] The rate of increase in lung compliance exceeds that of chest wall compliance and accounts in large part for the increase in compliance of the respiratory system during the first year of life. During the same period, the total resistance of the respiratory system decreases by 42%. The considerably smaller decrease in resistance compared to compliance is in line with anatomic findings showing that substantial alveolar formation occurs during the first year of life, whereas the full contingent of conducting airways is present at birth. In human infants, the expiratory time constant of the total respiratory system increases during the first year of life, up to a plateau.[218-220] This change may reflect the increase in compliance caused by rapid alveolar growth. After 1 year of age, the relative stability of this constant suggests that changes in compliance and resistance are balanced after infancy.

Flow-Resistive Properties

During postnatal life, airway growth leads not only to increases in the radius and length of the airways, but also to changes in the mechanical properties of the airway walls. Airway compliance is greater in infants and young children than in adults. In excised preparations, the newborn trachea is twice as compliant as the adult trachea.[222] Radiographic studies in normal infants have shown variations of 20% to 50% in the anteroposterior diameter of the intrathoracic trachea during exertion.[223] This may be related to the smaller amount of cartilage.[111]

Airway, pulmonary, and respiratory resistances have been measured in newborns, infants, and children 5 years of age and older.[215] Airway resistance falls 10-fold on average from full term to adolescence. The inverse of airway resistance, airway conductance, corrected for differences in upper airway resistance and divided by the lung volume at the time of measurement (specific airway conductance) decreases during the first years of life, then remains constant after 5 years of age.[224,225] This profile of change in specific airway conductance strongly suggests that the airways may be well formed and relatively large in newborns but that lung volume may increase disproportionately with airway size during early postnatal life.

The total resistance of the respiratory system is generated by the airways, lung tissue, and chest wall. Little is known about changes in the lung and chest wall components of total resistance. A recent study investigated growth-related changes in the viscoelastic properties of the total respiratory system

by measuring pressure variations after airway occlusion in paralyzed patients aged 3 weeks to 15 years.[226] This measure decreased during the first 2 years of life and increased after age 5, suggesting greater influence of the lung tissue during early postnatal life and greater influence of chest wall viscoelastic properties at older ages. More recently, airway and respiratory tissue mechanics were assessed in normal infants aged 7 weeks to 2 years.[227] Both the forced oscillation technique and the raised volume rapid thoracic compression technique were used to investigate the tissue and airway components of respiratory resistance. Both of these components exhibited a decreasing quadratic relation with increasing length. The maximum volume expired at 0.5 second (FEV0.5) showed an increasing cubic relation with length.

The distribution of resistance along the central and peripheral airways has been studied in excised lungs from infants, children, and adults.[228] These data suggest that the peripheral airways may be disproportionately narrow in children younger than 5 years of age. Disproportionately low peripheral airway conductance values in infants compared to older children should be accompanied by low maximum expiratory flows at low lung volumes. However, relatively high flows at low lung volumes were found in healthy anesthetized infants and children.[229] Furthermore, the maximum expiratory flow at FRC measured from partial expiratory flow-volume curves was higher in neonates and similar in infants to those reported in children and adults.[230,231] Thus, physiologic data do not support the hypothesis suggested by pathologic findings that peripheral airways are disproportionately smaller in infants than in adults.

Abnormal growth of conducting airways (e.g., in lung hypoplasia) is associated with low airway resistance values during infancy.[232] Conceivably, dysregulation during the processes involved in morphogenesis (see Fetal Period in the Developmental Anatomy section) may be responsible for the substantial interindividual variability in postnatal indexes of pulmonary flow-resistive properties.

Postmortem evaluations of airway size in preterm infants show that airway size is normally related to postconceptional age.[111] However, data obtained during childhood suggest that premature birth is associated with impaired airway growth.[233]

The maturation of respiratory mechanics differs between boys and girls. Mixed gender effects were reported in a longitudinal study of 541 infants.[234] Females had significantly lower initial resistance of the respiratory system values (Rrs) than males, but the Rrs decline with increasing length was slower in females. In contrast, although females had lower initial compliance of the respiratory system (Crs) values and a slower Crs decline than males, these differences were not statistically significant. Normal values of respiratory resistance obtained by the interrupter technique (Rint) in preschool children, were reported recently (Fig. 3-14).[235]

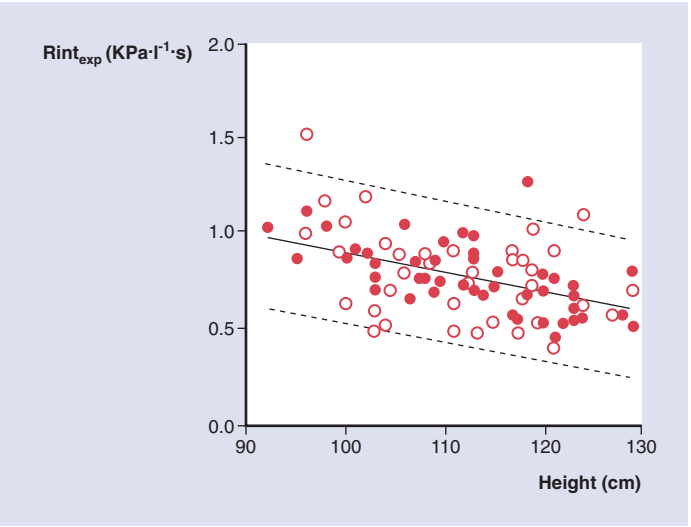

Figure 3-14 Relation between respiratory resistance obtained by the interrupter technique (Rint exp) and length in preschool normal children. (From Beydon N, Amsallem F, Bellet M, et al: Pre/postbronchodilator resistance values in healthy young children. Am J Respir Crit Care Med 165:1388-1394, 2002.)

Gas Exchange

In the newborn, the partial pressure of oxygen in arterial blood (PaO_2) is approximately 70 mm Hg.[236] The PaO_2 in arterialized blood samples rises rapidly until 2 years of age, then slowly until 8 years of age.[237,238] Thereafter, PaO_2 values remain stable and similar to those seen in adults.[239]

The lung volume at which some of the intrapulmonary airways are closed (closing volume, an index of susceptibility to hypoxemia) decreases with age.[240,241] In infants and young children, the closing capacity (closing volume plus residual volume) is sometimes greater than the FRC, and some areas of the lung may be closed throughout part or all of the tidal volume, resulting in impaired gas exchange.

Mechanisms that improve pulmonary gas exchange during growth have been investigated more extensively in piglets than in humans. A study that used the multiple inert gas technique in awake growing piglets showed that low PaO_2 values resulted from both ventilation-perfusion mismatch and limited oxygen diffusion.[242] Oxygen diffusion impairment in piglets was related to an imbalance between oxygen diffusion and oxygen perfusion.[243] This suggests that the capillary transit time in newborns may be too short to achieve the alveolar-capillary diffusion equilibrium and, therefore, that newborns may have little pulmonary vascular reserve for gas exchange. In newborns, the ratio of pulmonary diffusing capacity to FRC is close to that in 11- to 13-year-old boys during submaximal exercise.[244]

The fairly low PaO_2 values in infants and young children are close to the steep part of the oxygen-hemoglobin dissociation curve. Any further decrease in PaO_2 can induce severe oxygen desaturation, for instance during sleep apneas (see Respiratory Control section). Using new techniques for noninvasive measurements of oxygen saturation, data have been obtained in healthy full-term infants and children during sleep.[245-247]

RESPIRATORY CONTROL

Developmental Aspects

Breathing in mammals relies on a neuronal respiratory network located within the brain stem,[248-249] which receives influences from suprapontine structures involved in sleep-wake, thermoregulation, and arousal processing.[250] Evolving concepts

regarding respiratory control development have stemmed from new knowledge—most notably in the areas of plasticity and genetics.[251] Environmental insults may alter the developmental programming of the neuronal respiratory network, leading to abnormalities that may persist in infancy and perhaps adulthood. Recent studies in newborn mice with targeted gene deletions showed links between the expression of specific genes and the development of individual components of respiratory control.[252] Mechanisms underlying respiratory control immaturity in newborns remain incompletely understood. Immaturity affects all facets of respiratory control including breathing rhythmicity and its modulation by suprapontine influences and by afferents from central and peripheral chemoreceptors and other sources. Because of this immaturity, infants, particularly those born prematurely, are vulnerable to homeostasis disruption by apneas. Respiratory control immaturity may contribute to the mechanisms that lead to SIDS,[253] especially in preterm infants.[254]

The brain stem neural network includes three groups of neurons[248]: (1) the dorsal respiratory group containing the tractus solitarius, the first central relay of the arterial chemoreflex; (2) the ventral respiratory group with the pre-Bötzinger complex (preBötzC), which contains part of the rhythm-generating neurons; and (3) the pontine respiratory group. During early embryonic development, shortly after neural tube closure, the hindbrain is temporarily partitioned into rhombomeres along an anterior-posterior axis. This process takes place during the second half of the first month of pregnancy in humans. At the end of the segmentation period, a primordial regular rhythm can be recorded in isolated hindbrain preparations from mice.[255] Loss of genes responsible for hindbrain segmentation during early embryonic development, such as *Krox20,* leads to severe breathing instability at birth that usually results in death.[255-256] *Krox20* deletion leads to rostral medulla hypoplasia and loss of neurons of the reticular formation closed to the noradrenergic groups of neurons A5 (Fig. 3-15).[256,257]

Later during development, each of the neuronal populations exhibiting specialized functions in the brain stem respiratory network exhibits specific developmental programming and gene expression profiles, which appear to be controlled by a set of transcription factors that are specific of particular types of neurons participating in the generation and modulation of respiratory rhythm at birth (see Fig. 3-15).[257] It has been shown that the transcription factor *MafB* is a marker for a subpopulation of preBötzC neurons in null mutant *MafB* newborn mice that die from central apneas at birth.[258] Development of the noradrenergic nuclei is governed by a cascade of transcription factors that includes *Phox2b, Phox2a,* and *Mash-1* in the locus coeruleus (A6). *Phox2b* is also expressed

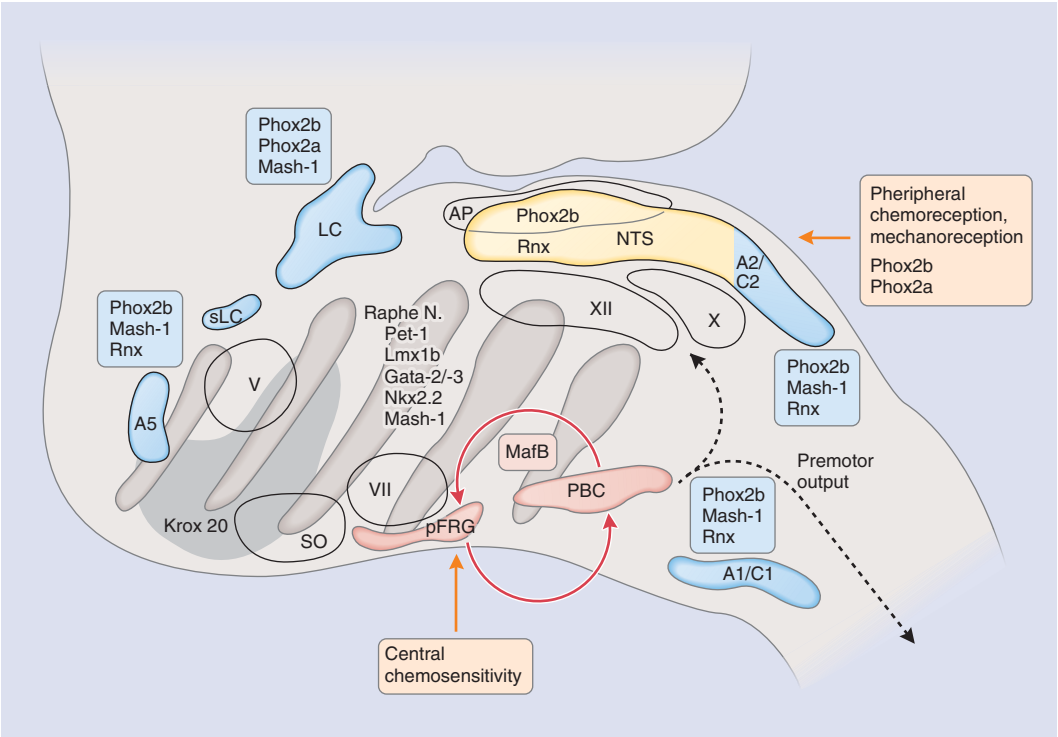

Figure 3-15 Transcription factor requirement in the development of respiratory hindbrain neurons. Transcription factors required for correct development of each group of neurons are indicated next to the affected groups. *Krox20* deletion leads to rostral medulla hypoplasia and the loss of neurons of the reticular formation close to the A5. (From Blanchi B, Sieweke MH: Mutations of brainstem transcription factors and central respiratory disorders. Trends Mol Med 11:23-30, 2005.)

in the NTS. Differentiation of the serotoninergic neurons of the brain stem is controlled by transcription factors such as *Mash-1*. Studies of the respiratory phenotype of mutant newborn mice have helped to understand how disruption of genes such as *Phoxa*, *Phox2b*, or *Mash-1* can alter one or more components of respiratory control.[259-261] Furthermore, transcription factor mutations were identified recently in human developmental central respiratory disorders. *PHOX2B* is the disease-causing gene of congenital central alveolar hypoventilation.[262] Mutations or polymorphisms of genes involved in the development of modulatory neurons have been described in victims of SIDS.[263] The development and plasticity of the brain stem respiratory network also depends on neurotrophic factors, such as brain-derived neurotrophic factor (BDNF).[264-265]

Neurotransmitters that mediate synaptic communication exhibit dramatic changes during fetal and postnatal life.[266] Perinatal surges occur for some of them, including the excitatory amino acid glutamate.[266] Postnatal developmental changes in brain stem neurotransmitters were described recently in rats.[267] A dramatic shift occurs on postnatal day 12, with drops in glutamate and its *N*-methyl-D-aspartate (NMDA) receptors and sharp rises in receptors for the inhibitory neurotransmitter GABA. The transient predominance of inhibitory over excitatory neurotransmission during this period may increase the risk of respiratory-control failure in response to stress. Such neurochemical changes may contribute to the underlying mechanisms of SIDS during a critical period of vulnerability. Furthermore, prenatal and postnatal stress may alter the programming of neurotransmitter expression, thereby leading to further respiratory control vulnerability.

Pattern of Breathing, Apneas, and Gasping

Fetal breathing has been chiefly investigated in sheep. During early fetal life, the sheep fetus shows regular continuous breathing.[268] With differentiation of the electrocortigram at about 120 days of gestation (term being 147 days), the fetus exhibits an irregular breathing pattern with apneas. Breathing movements occur during a behavioral state akin to REM sleep in the newborn[269] and are governed by the behavioral respiratory control system rather than by the metabolic respiratory control system.[270] During high-voltage electrocortical activity, fetal breathing movements are inhibited and near-total apnea occurs.[271] Prenatal maturation of respiratory control allows generation of rhythm-driving ventilation that can adjust to homeostatic demands after birth.[272] At birth, respiratory control switches from discontinuous to continuous. Figure 3-16 shows changes in the relative importance of various respiratory drive mechanisms at birth, in newborns, and in infants.[273]

Over the last decades, many studies have shown that periodic breathing and apnea are common respiratory patterns that resemble fetal breathing in premature infants. These respiratory patterns are inversely related to gestational age, with the youngest infants having the most significant apneic events. With advancing postconceptional age, apneas decrease in frequency.[274-276] However, apneas of prematurity can persist beyond full term in very preterm infants.[277] Central, mixed, or obstructive apneas occur in preterm

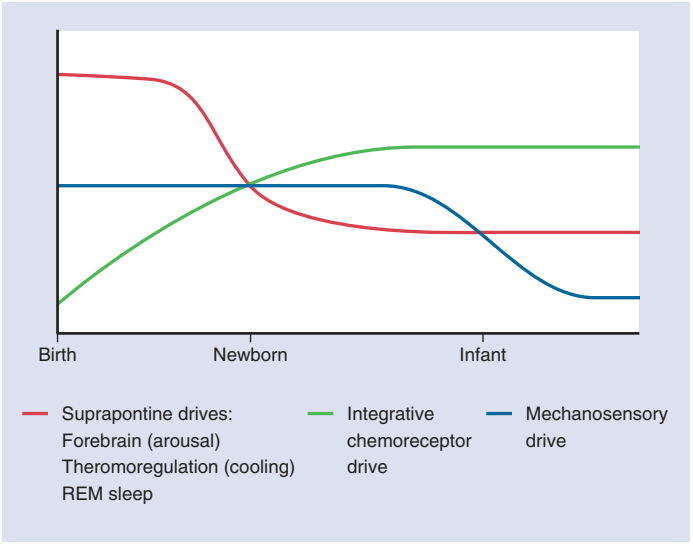

Figure 3-16 Relative importance of different respiratory drive mechanisms after birth. (From Lagercrantz H, et al. In Crystal RG, West J [eds]: The Lung: Scientific Foundations. New York, Raven, 1991, pp 1711-1722.)

infants. Studies in preterm lambs have shown that upper airway closure is an important feature not only of mixed or obstructive apneas, but also of central apneas, and involves both passive pharyngeal collapse and active glottal closure.[278] A beneficial consequence of glottal closure during central apneas is maintenance of a high lung volume, which increases alveolar O_2 stores and limits arterial O_2 desaturation. Bedside experience shows that the severity of hypoxemia after apnea is not closely related to apnea duration: thus, even brief apneas can cause profound hypoxemia in some infants. Periodic breathing has often been considered benign in premature infants. However, data are now available showing that periodic breathing frequently precedes apneas[279] and may be associated with upper airway obstruction[280] and with significant desaturation in some preterm infants. Repeated hypoxemia due to severe apneas can induce major neurologic disabilities including neurocognitive impairments.[281]

Reflexes originating in the laryngeal chemoreceptors, including laryngeal chemoreflexes (see upper airway section) and non-nutritive swallowing, contribute to the occurrence of apnea, bradycardia, and hypoxemia in early life. Immaturity of the preterm newborn impairs the coordination between swallowing and breathing. This may lead to apnea, especially in preterm infants. Non-nutritive swallowing has been reported with central, obstructive, or mixed apneas in human newborn.[282] In preterm lambs, apneas associated with non-nutritive swallowing occur chiefly during non-REM sleep.[283]

In full term infants, apneas are chiefly central and of short duration. The frequency of apneas decreases with postnatal age. Mixed and obstructive apneas are rare in term infants. Table 3-2 shows indices of mixed and/or obstructive apneas during the first 6 months of life in term infants.[284-287] One study conducted in more than 1000 infants between 2 and 28 weeks of postnatal age showed that obstructive and mixed apneas were significantly more common between 2 and 7 postnatal weeks than in any other age group and that obstruc-

Table 3-2
Indices of Mixed and/or Obstructive Apneas in Healthy Infants During the First 6 Months of Life

Reference	Type of Apneas	Duration of Apnea	Mean Index (age in parentheses)		
285	M and OA	≤10 sec	1.04 (6 wk)	0.40 (12 wk)	0.20 (24 wk)
		>10 sec	0.07 (6 wk)	0.02 (12 wk)	0,00 (24 wk)

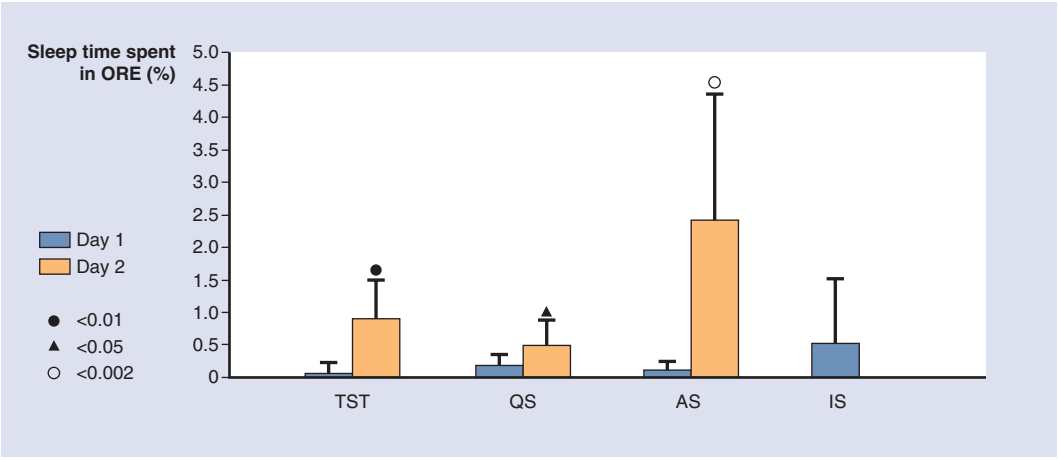

Figure 3-17 Sleep spent in an obstructive respiratory event (ORE) during total sleep time (TST), quiet (non-REM) sleep (QS), active (REM) sleep (AS), and indeterminate sleep (IS). The values are expressed as percentages. Day 1 is the baseline; day 2 figures were taken after a sleep deprivation recovery nap. *Bars* indicate the standard deviation. Percentage of time spent in an obstructive respiratory event significantly increased after sleep deprivation during total sleep time (full circle, $P < 0.01$), quiet sleep *(triangle, $P < 0.05$)*, and active sleep *(open circle, $P < 0.002$)*. (Redrawn from Canet E, Gaultier CL, D'Allest AM, Dehan M: Effect of sleep deprivation on respiratory events during sleep in healthy infants. J Appl Physiol 66:1158-1163, 1989.)

tive apneas were significantly more frequent in boys than in girls.[287]

The frequency of apneas during early life is influenced by sleep state. Apneas are more common in REM sleep than in non-REM sleep in both preterm and term infants.[276] The greater instability of REM sleep compared to non-REM sleep during early life may result from overall immaturity of brain stem respiratory network, as well as from phasic inhibitory mechanisms inherent to REM sleep. Frequent apneas during REM sleep may reflect exaggeration of normal phasic inhibitory-excitatory central mechanisms that occur during this sleep state. Irregular phasic respiratory patterns of REM sleep occur in synchrony with other brain stem phasic activities, such as rapid eye movements.[288]

A number of factors can suddenly increase the number and duration of apneas, thereby compromising infant's homeostasis. Medications such as phenothiazine increase the number of apneas, especially of the obstructive type.[289] The prone position is associated with a higher frequency of central and obstructive apneas.[290] An increase in body temperature exacerbates breathing instability, inducing higher rates of periodic breathing episodes and central apneas in REM sleep but not in non-REM sleep.[291,292] Brief sleep deprivation increases the number of short obstructive respiratory events (apneas and hypopnea) in REM sleep (Fig. 3-17).[293] In infants whose homeostasis is disturbed, the risk of increased respiratory instability appears greater in REM than in non-REM sleep.[289,291,293]

Prenatal insults such as maternal smoking lead to increased postnatal breathing instability. Increases in both the frequency and duration of obstructive apneas have been reported in babies born to mothers who smoked during pregnancy.[294] Infants who subsequently died of SIDS experienced higher rates of obstructive and mixed apneas than did healthy infants[295] and frequent obstructive apneas may predispose infants to SIDS.[253] A study of apnea monitor recordings from infants who died at home indicated that complete airway obstruction occurred immediately before death.[253]

Recovery from apnea depends on arousal from sleep (see arousal section). Failure to terminate apnea results in auto-resuscitation, the last-resort mechanism used by mammals to ensure survival during exposure to severe hypoxia. Studies in newborn rats and mice identified factors that influence hypoxic gasping patterns, such as postnatal age,[296] core temperature,[297] prenatal nicotine exposure,[298] and intermittent hypoxia.[299] Failed auto-resuscitation from hypoxic apnea by gasping has been documented in SIDS victims.[300,301] In children, apneas are rare and predominantly central. Recent studies provided normative values for apneas in healthy children.[246,247]

Reflexes Originating from the Lung and Chest Wall

Reflexes originating from the tracheobronchial tree and within the lung parenchyma have significant effects in newborns, who differ in this respect from adults. Vagal innervation is of crucial importance in maintaining postnatal breathing and alveolar ventilation.[302,303] The Hering-Breuer inflation reflex is an important mechanism for regulating the rate and depth of respiration in newborn mammals. In human infants, the activity of this reflex can be expressed as the relative change in expiratory time after end-expiratory occlusion compared to the resting expiratory time during spontaneous breathing. This parameter has been measured during non-REM sleep in infants younger than 1 year of age. The results showed that the reflex persisted beyond the neonatal period and exhibited no variation in activity during the first 2 months of age.[304] Later, activity of the reflex correlated negatively with age.[304] The postnatal period characterized by high reflex activity is longer in preterm infants, suggesting delayed maturation.[305] The reflex is stronger during REM sleep than during non-REM sleep in newborn infants.[306] The Hering-Breuer deflation reflex occurs in newborn infants, including those born prematurely.[307] It may play an important role in protecting FRC in the newborn infant. Irritation of the tracheobronchial tree induces apneas in human preterm infants.[308] Activation of bronchopulmonary C-fiber afferents induces bronchoconstriction in newborn dogs.[309] Activation of C-fiber afferents may play a role in inflammatory lung diseases in infants.

Various reflexes that arise in the rib cage influence the intercostal and phrenic motoneurons. These reflexes are of potential importance in newborns, whose rib cage is compliant and therefore prone to distortion during REM sleep. Rib cage distortion is associated with breathing pattern changes, including decreases in inspiratory time and tidal breathing, prolongation of expiratory time, irregular breathing, and even apnea.[310,311]

Chemoreception

PERIPHERAL CHEMORECEPTORS

Peripheral chemoreceptors are activated by changes in the partial pressure of oxygen and trigger respiratory drive changes aimed at maintaining normal partial pressure levels. Studies in fetal lambs have demonstrated that peripheral chemoreceptors are functionally active and can be stimulated by further decreasing the already low fetal PaO_2.[312] The initiation of breathing at birth immediately results in a very substantial PaO_2 increase. After birth, developmental changes affect carotid body histology with increases in the numbers of type I-cells and nerve fibers,[313] changes in biological properties of O_2-sensitive K^+ and O_2-sensitive Ca^{2+} channels in the type I-cell membranes[314] and in levels of neurotransmitters and/or their receptors.[315] All these changes may play a role in the maturation of peripheral chemoreceptor responses to hypoxia. Furthermore, growth factors such as BDNF and GDNF (glial cell line-derived neurotrophic factor) are synthesized in the developing carotid body and mediate trophic support for chemoafferent survival.[264]

The mechanisms underlying postnatal carotid body resetting of O_2 sensitivity remain unelucidated. Resetting of peripheral chemoreceptors is essentially complete about 24 to 48 hours after birth in healthy human full-term infants tested during non-REM sleep using either the hyperoxic test[316] or alternations in inspired oxygen.[317] Studies of peripheral chemoreceptor function must take into account environmental temperature and behavioral states. The ventilatory response to hyperoxia is greater in REM than in non-REM sleep, in both warm and cool environments.[318] Importantly, the ventilatory response to the hyperoxic test varies widely in infants,[319] perhaps at least partly as a result of genetic factors affecting chemoreceptor function.[320] Delayed resetting of peripheral chemoreceptors has been reported in newborn mammals subjected to hypoxia during the perinatal period.[321,322] Perinatal hypoxia increases the amount of dopamine, the most abundant inhibitory neurotransmitter, in the carotid body.[322] A similar delay has been reported in infants with chronic hypoxia resulting from bronchopulmonary dysplasia.[323-324] Because peripheral chemoreceptors play a key role in initiating the ventilatory, cardiovascular, and arousal responses to hypoxia and asphyxia, this delay may be among the factors that place infants with bronchopulmonary dysplasia at greater risk for SIDS.[323] The relation between apnea occurrence and peripheral chemoreceptor function requires further investigations. Impaired function, as well as exacerbated function, of peripheral chemoreceptors has been reported in preterm infants with frequent apneas.[325,326]

In newborns, steady-state hypoxia produces a biphasic response with a transient increase in ventilation (hyperpneic phase) followed by a decrease to or below the baseline level (hypoxic ventilatory decline) (Fig. 3-18).[327] The hypoxic ventilatory decline has been ascribed to various mechanisms such as immaturity of the peripheral chemoreceptors, decreased oxygen consumption,[328] and central inhibitory transmission.[329-331] The biological significance of the hypoxic ventilatory decline is debated. The hypoxic ventilatory decline may be an adaptive respiratory response of the developing mammal that conserves oxygen while decreasing the meta-

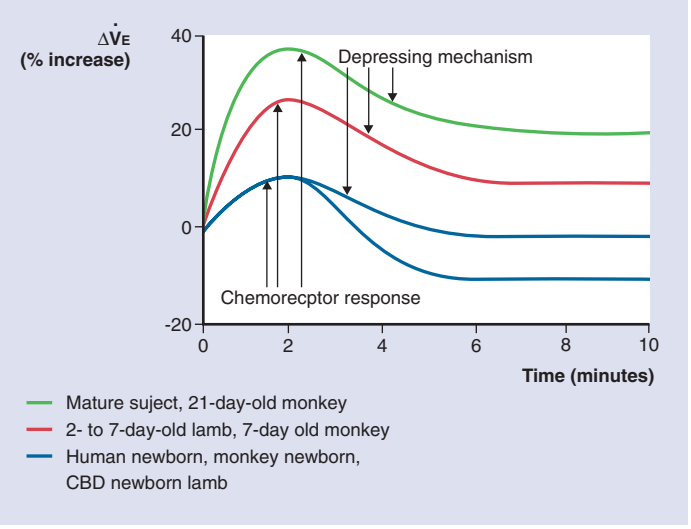

Figure 3-18 Ventilatory response to steady-state hypoxia in the newborn. The newborn has a biphasic response to hypoxia. $\Delta\dot{V}_E$, change in expiratory gas flow. bolic rate, a combination that protects the brain from hypoxic damage.[328] Alternatively, the hypoxic ventilatory decline may be a potentially harmful consequence of immaturity of the O_2-sensing pathways. Prenatal insults, such as hypoxia[332] or exposure to nicotine,[333,334] and postnatal insults, such as hypoxia or hyperoxia,[335-337] compromise the defense mechanisms against hypoxia during early life. Perinatal O_2 plays a role in the development of the hypoxic ventilatory response. Perinatal hypoxia elicits plasticity in developing O_2 sensitivity that has consequences in adulthood.[335] Intermittent hypoxia during the early period of life induces an excitatory form of plasticity with increased hypoxic ventilatory response in neonatal rats.[336,337] Neonatal separation from the mother has been shown to affect early programming of the hypoxic ventilatory response.[338] Finally, the ventilatory response to hyperoxia was increased in preterm infants treated with caffeine for apneas.[339]

CENTRAL CHEMORECEPTORS

Central chemoreception is believed to occur at widely distributed sites.[340] However, there is little agreement on when and how each of the sites is involved in respiratory control.[341] Hypercapnia is a major stimulus for increasing ventilation in neonates, as shown by many studies of the ventilatory response to hypercapnia in newborn mammals.[342] Hypercapnia seems to elicit no metabolic response, in contrast to hypoxia.[343] The ventilatory response to hypercapnia is influenced by gestational and postnatal age. In preterm infants, hypercapnia induces a sustained increase in tidal volume; however, respiratory rate drops as a result of an increase in expiratory time that may originate in central inhibitory mechanisms.[344] Postnatal changes in hypercapnic ventilatory responses appear to vary across species. Early studies in humans found that ventilatory responses increased with postnatal age.[345] However, a decline of the ventilatory response to hypercapnia at the end of the first week followed by an increase was found in rats, suggesting a critical postnatal biphasic ventilatory response period with low CO_2 sensitivity.[346,347] This critical period may be associated with increased vulnerability, which may contribute to the mechanisms underlying SIDS.[348] Studies in children showed stronger hypercapnic ventilatory responses compared to adults.[349]

The roles for central and peripheral chemoreceptors in ventilatory responses to hypercapnia during development have not been fully separated.[350] Ventilatory responses to hypercapnia are weaker during REM sleep than during non-REM sleep (Fig. 3-19),[351] in both preterm and full term infants.[70,351-353] Mechanisms that contribute to the decreased responses during REM sleep may include a smaller contribution of the rib cage to ventilation,[352] a weaker central output to the diaphragm,[353] and inhibition of abdominal muscle recruitment.[70]

The influence of genetic factors on the considerable interindividual variability of hypercapnic ventilatory responses in human infants is an important issue for future research. A weak hypercapnic ventilatory response may predispose to apnea in infants.[354] Attenuation of the hypercapnic ventilatory response has been reported in disorders such as myelomeningocele or Prader-Willi syndrome.[354] Congenital central hypoventilation syndrome, the autosomal genetic disorder related to a heterozygous *PHOX2B* gene mutation,[262] is characterized by absent or markedly reduced hypercapnic ventilatory responses.[354]

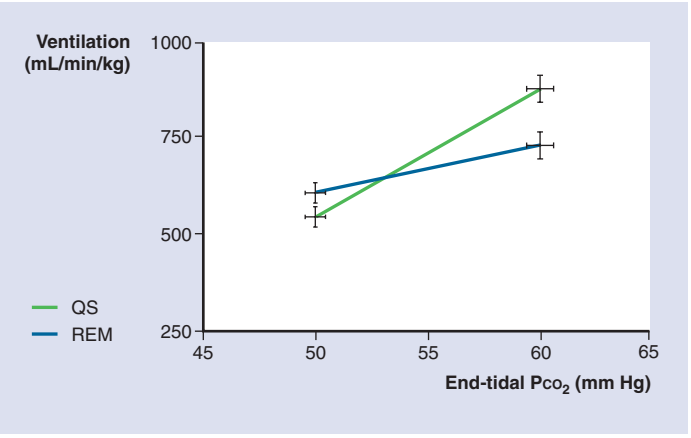

Figure 3-19 Partial end-expiratory pressure of carbon dioxide versus minute ventilation for REM sleep and quiet (non-REM) sleep (QS). Data are means ± 95% confidence intervals for position. Data are from 46 tests in five full-term babies. (Redrawn from Cohen G, Xu C, Henderson-Smart D: Ventilatory response of the sleeping newborn to CO_2, during normoxic rebreathing. J Appl Physiol 71:168-174, 1991.)

Perinatal hypercapnia in the first 2 weeks of life causes a transient decrease in hypercapnic ventilatory responses in both male and female rats.[355] Thus, perinatal hypercapnia elicits only transient plasticity, contrasting with the long-lasting plasticity induced by perinatal hypoxia.[335]

Thermoregulation

Hypothalamic mechanisms that increase ventilation are active before birth.[356] Cooling of the skin provides a potent drive to breathing in the neonatal period (see Fig. 3-16). Ambient temperature is closely linked to metabolic rate, especially in early postnatal life, when the basal metabolic rate is high and provides an abundant tonic sensory input that influences the breathing pattern. Metabolic rate is the lowest when environmental temperatures are within the neutral range.[357,358] In a hypoxic environment, the body temperature of the newborn decreases, which contributes to decreased oxygen consumption and to improved hemoglobin oxygen saturation.[330]

In adults, thermoregulatory mechanisms are impaired during REM sleep. In contrast, in newborns, REM sleep seems associated with maintenance of homeothermia in both cool and warm environments.[357] Greater activity of the metabolic response during REM than non-REM sleep favors instability of breathing. Thus, a small increase in body temperature is associated with a significant increase in the time spent with periodic breathing during REM sleep, but not non-REM sleep, in preterm infants[291] and with an increase in the number of central apneas in infants.[292] In preterm infants, thermal challenges within the physiologic range increase peripheral chemoreceptor gain during REM sleep but not during non-REM sleep.[319] High body temperature was associated with decreases in the threshold and latency for reflex contraction of the laryngeal adductor in newborn dogs,[359] suggesting that hyperthermia may permit reflex laryngeal closure in newborns. Finally, the vagally mediated reflex response to lung inflation is stronger during hypoxic hyperthermia than during normoxia.[360] Interactions between

developmental changes in thermoregulation, respiratory control, and metabolic demands may play a role in the risk of SIDS.[361]

Arousal Responses

Arousal from sleep is the most important protective response to danger-signaling stimuli during sleep. Decreased arousability may be a risk factor for SIDS.[362] Spontaneous arousals, arousal patterns after apneas, and arousal responses to various stimuli (such as hypercapnia, hypoxia, and auditory stimuli) have been studied in infants. Many studies included infants within the peak age range of SIDS occurrence (i.e., 2 to 4 months). Criteria for scoring arousals varied across studies. The infant arousal response typically starts by subcortical arousal with an augmented breath followed by a startle then by cortical arousal.[363-365] Different types of arousal have been considered: awakening (behavioral arousal), electroencephalographic (EEG) arousal (cortical arousal) longer than 1 or 3 seconds,[366] movement arousal,[367] and subcortical arousal.[363-365] Finally, subcortical activation was scored when there was no EEG modification longer than 3 seconds despite at least two of the following: gross body movement, heart rate change, or breathing pattern change.[368]

Spontaneous arousal activity occurred more frequently during REM sleep than non-REM sleep in infants.[365] Spontaneous subcortical arousals were more frequent than cortical arousals in infants.[365] Spontaneous cortical arousals were less common in the prone sleeping position compared to the supine position during REM compared to non-REM sleep in infants.[366] The mean number of spontaneous cortical arousals (EEG arousals longer than 3 seconds) was 9 per hour of sleep in children.[246,247]

The occurrence of arousals at the end of apneas was studied in infants and children. Behavioral arousal occurred in fewer than 10% of apneas in preterm infants.[370] Arousal was more common in long versus short, mixed versus central, and severe versus mild apneas.[370] EEG arousal longer than 1 second was uncommon at the end of obstructive apneas in infants and children with obstructive sleep apnea (OSA),[371] whereas movement arousal occurred at the end of most respiratory events in children with OSA.[369]

Hypercapnia is a potent stimulus causing arousal from sleep. Behavioral arousal has been studied in infants and young children during non-REM sleep.[372-374] All tested infants and children exhibited behavioral arousals when the end-tidal partial pressure of carbon dioxide ($PETCO_2$) was around 50 mm Hg. In children with OSA, arousal occurred at higher $PETCO_2$ values than in control children.[375]

Hypoxia is less effective than hypercapnia in causing arousal from sleep. Few infants exhibited behavioral arousal in response to hypoxic stimuli during non-REM sleep.[372,373,376,377] Studies in lambs showed that arousal in response to severe hypoxia was delayed during REM sleep compared to non-REM sleep.[378] However, in a recent study human infants invariably showed arousal in response to mild hypoxia during REM sleep but often failed to arouse in non-REM sleep.[379]

Other stimuli can lead to arousal from sleep in infants. In near-term infants, the esophageal acid infusion test increased the rate and duration of EEG arousals during REM sleep.[380] The auditory arousal threshold decreased with maturation between 44 and 52 weeks of post-conceptional age and remained unchanged thereafter.[381]

Several factors impair arousal from sleep. Arousal to auditory stimuli was less frequent in the prone than in the supine sleeping position,[382] after short-term sleep deprivation,[383] in warm thermal conditions,[384] when bedclothes covered the face of the infant,[385] and in infants born to mothers who smoked during pregnancy.[386] In contrast, swaddling was associated with increased arousal responsiveness to auditory stimulation during sleep.[387] Incomplete arousal was suggested in SIDS victims, who had fewer cortical arousal responses than control infants.[368]

Arousal response habituation occurs with repeated exposure to stimuli such as intermittent hypoxia in newborn mice[388] or intermittent hypercapnic hypoxia in piglets.[389] Repetitive tactile stimulation induced habituation of the arousal response in human infants.[390] The cortical response is eliminated first, then the startle response, and finally the augmented breath. Elimination of each of these responses occurred more rapidly in REM than in non-REM sleep. Rapid habituation to innocuous stimuli is probably beneficial in avoiding sleep disruption. However, in situations requiring protective arousal, habituation may have deleterious effects. Furthermore, REM sleep, during which habituation develops more rapidly, is the predominant sleep state in young infants.

CHAPTER 4

Lung Cell Biology

John W. Upham, Stephen M. Stick, and Yuben Moodley

TEACHING POINTS

- The various cells within the lung serve to facilitate gas exchange, maintain the anatomic structure of the airways and alveoli, provide protection against infection, and maintain immunologic tolerance against innocuous foreign proteins.
- While cell types are often classified as having predominantly structural or immunologic functions, this distinction is artificial. Many structural cells play a key role in lung inflammation, whereas the various migratory immune cells affect the phenotype and function of structural cells.
- Recent decades have seen a rapid increase in knowledge of cell lung biology in both health and disease, providing an important foundation for the development of new approaches to the treatment of lung disease.

The lung consists of a variety of cell types that function together to supply the body with oxygen and eliminate the carbon dioxide produced by cellular metabolism. These cells include both structural elements that maintain the anatomic structure of the airways and alveoli, and a variety of migratory cells (generally of hemopoietic origin) that provide protection against infection and the maintenance of immunologic tolerance. This chapter describes the biology of the key cells within the lung, and while for convenience the discussion is divided into *structural* cells and *immunologic* cells, such a distinction is artificial. For example, although epithelial cells do exert an important barrier function within the lung, they also secrete a variety of biological molecules that regulate immune processes. Similarly, although the immunologic functions of T cells are well recognized, they may also influence the behavior of structural cells such as airway smooth muscle cells.

EPITHELIAL CELLS

Epithelial tissue is found throughout the body and performs a variety of functions, many of which are organ specific. In the lung, the epithelium forms a protective lining in the airways and alveoli. The lung epithelium is not, however, a simple passive barrier because it plays an active role in lung homeostasis and immunity—both innate and adaptive. The epithelium also produces the airway surface liquid layer that contributes to the mechanical properties of the lung and is an essential component of the lung's defense against infective, irritant, and toxic exposures.

Epithelial Structure

The airway epithelium is composed of at least 12 different cell types, which vary in abundance throughout the lung. In the proximal airways (the trachea and main bronchi), the epithelial cell layer is thicker, and composed of tall, ciliated cells, basal cells, and secretory cells known as *goblet cells*. As the airways branch out and become smaller, the epithelial layer becomes thinner, until at the level of the bronchioles, it is composed of a single layer of short cuboidal cells (Fig. 4-1).

Junctional complexes bind epithelial cells, permit intercellular communication, and form a barrier that regulates the passage of water and solutes from the lumen across the epithelium. The junctional complexes consist of tight junctions, adherens junctions, and desmosomes (Fig. 4-2). In addition to these junctions, the gap junction forms an intercellular channel that allows the exchange of ions and small molecules between adjacent cells. Epithelial cells are not only attached to each other, but are also anchored by hemidesmosomes to the basement membrane—a thin sheet of collagen, laminin, and fibronectin.

Epithelial tissues can be classified on the basis of their structure. In the proximal airways, the epithelium is pseudostratified. Although there appears to be a layer of ciliated columnar cells overlying basal cells, each cell is, in fact, anchored to the basement membrane.

The diversity of cell types, each with distinct physiologic functions, that makes up the epithelium serves to optimize mucociliary clearance, regulation of fluid homeostasis, and the synthesis and secretion of a large number of host defense proteins. The various cell types are influenced by infection and other inflammatory stimuli and can themselves influence host defense function and epithelial repair. In the healthy lung, the normal spatial arrangement and activation state of epithelial cells are tightly regulated, and epithelial cells interact with professional phagocytes and lymphoid cells of the acquired immune system. Furthermore, an extensive system of tracheal-bronchial glands is lined by distinct epithelial cell types that produce mucus, fluid, and other host defense proteins critical for mucociliary clearance. Type II epithelial cells found predominantly in the alveoli are important for surfactant secretion, an essential factor for maintenance of normal mechanical function of the lung. A deficiency of

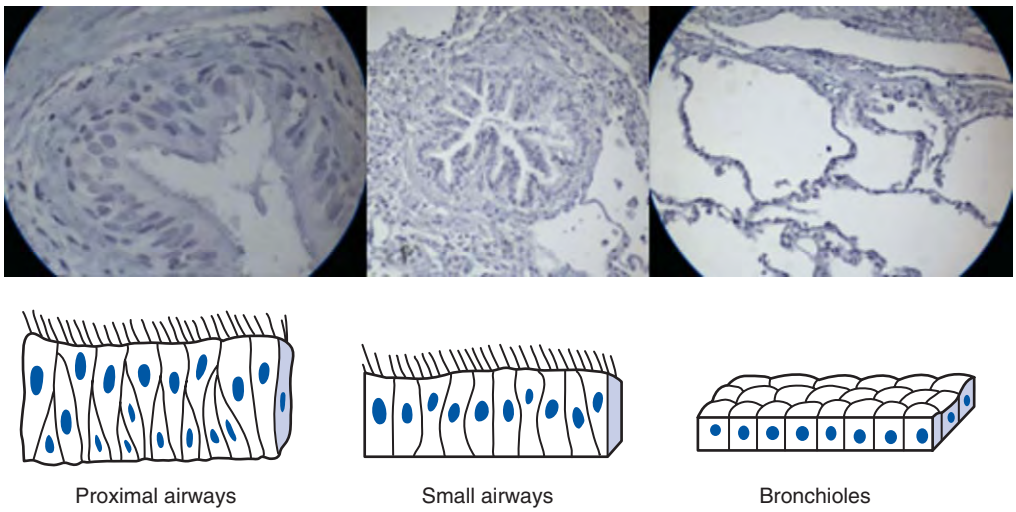

Figure 4-1 Structure of the epithelium throughout the airways. The proximal airways are lined with pseudostratified columnar epithelium. As the airways decrease in diameter the height of the epithelium also decreases, until, in the alveoli and bronchioles, it is composed of short nonciliated cuboidal cells.

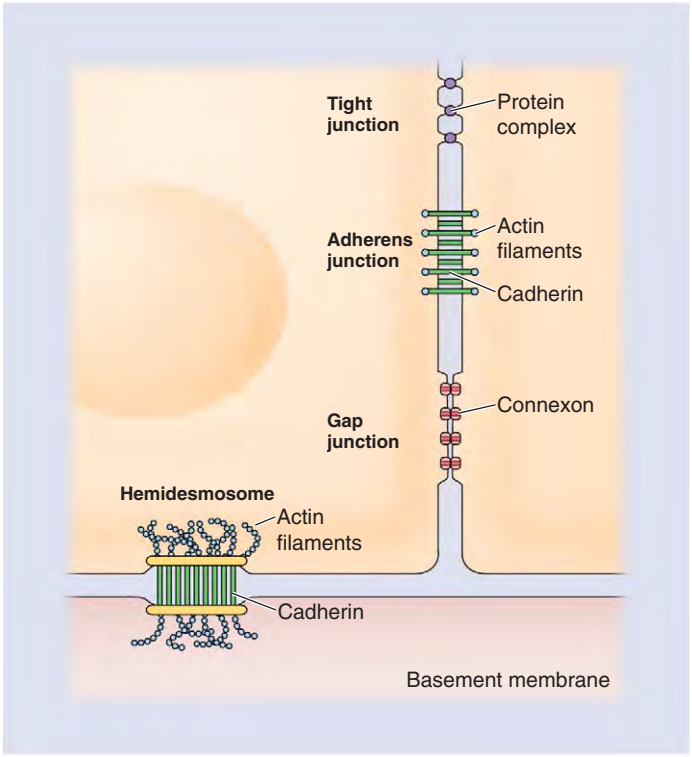

Figure 4-2 Epithelial cells are connected by junctional complexes. Junctional complexes consist of tight junctions, adherens junctions, and desmosomes. Gap junctions allow the exchange of ions and small molecules. Epithelial cells are anchored by hemidesmosomes to the basement membrane.

normal surfactant such as is found in preterm infants and genetically determined deficiency syndromes can result in respiratory distress.

Epithelial function

BARRIER FUNCTION

The epithelium in the lungs is constantly exposed to particulates, viruses, bacteria, pollen, allergens, oxidants, and other potentially toxic substances. The epithelium acts as a barrier, protecting the highly sensitive underlying smooth muscle and sensory nerves from stimulation and damage by these agents. There are two mechanisms hypothesized to explain the effective barrier function of the respiratory epithelium. In the *mechanical model,* epithelial cells control the volume of the airway surface liquid (ASL) that overlies the epithelium that is critical for effective mucociliary clearance. Epithelial cilia propel this mucus layer upward (the mucociliary escalator) toward the throat, where it is expectorated or swallowed. The *chemical shield model* predicts that the epithelium absorbs salt but not water from the ASL to form a low salt environment that facilitates the antimicrobial activities of defensins. The mucus layer also contains antioxidants in sufficient quantities to protect the lung from inhaled oxidants, growth factors, cytokines, and chemokines that are required for airway homeostasis and repair. In addition to the defense provided by the combined action of the cilia and production of ASL, epithelial tight junctions that play a major role in maintaining epithelial integrity are able to restrict the movement of molecules across the epithelium. Desmosomes and gap junctions also contribute to the structural integrity of the epithelium (see Fig. 4-2). Epithelial cells are capable of internalizing particles to clear them from the lung.[1]

BEYOND BARRIER FUNCTION

Although traditionally thought of as a simple barrier, the epithelium plays a central role in maintaining airway homeostasis and responds to inadvertently inhaled agents such as pollutants, allergens, and microorganisms, as well as intentionally inhaled agents such as aerosol therapy.

The airway epithelium plays an important role in airway homeostasis. For example, epithelial cells can directly influence underlying smooth muscle tone by releasing an array of bronchoconstrictors such as endothelin[2] and leukotrienes,[3] and bronchodilators such as prostaglandin E_2 (PGE_2),[4] and nitric oxide (NO).[5] The epithelium also produces enzymes such as neutral endopeptidase,[6] that are responsible for the breakdown of potent bronchoconstrictors such as tachykinins, bradykinin, endothelin, and angiotensin I and II from inflammatory cells.

Airway epithelial cells can be activated by inhaled allergens and particulates to produce proinflammatory mediators. This process can be either direct, where the inhaled sub-

stance interacts directly with the epithelium, or indirect, via activation of other constituent airway cells (e.g., macrophages). House dust mite allergens such as Der p 1 and Der p 9 induce epithelial cells to release granulocyte-macrophage colony-stimulating factor (GM-CSF), interleukin (IL)-6, and IL-8,[7] via the activation of protease activated receptors on epithelial cells.[8] Diesel exhaust particles,[1] bacterial endotoxins,[9] and pollutants such as NO_2,[10] also activate epithelial cells and cause increased release of proinflammatory mediators. Alternatively, epithelial cells can be indirectly activated when macrophages or granulocytes release cytokines such as tumor necrosis factor (TNF)-α, IL-1β, and IL-6 in response to stimulation by allergens and viruses.[11]

The epithelium recruits inflammatory cells to the airway by releasing inflammatory cytokines and chemokines. For example, lipopolysaccharide induces release of LTB_4, a potent neutrophil chemoattractant.[3] Indirect activation of epithelial cells by TNF or IL-1 causes them to release RANTES, a cytokine with potent chemotactic activity for monocytes[12] and eosinophils.[13] Epithelial cells also release IL-8, which can attract $CD4^+$ lymphocytes.[14]

Epithelial cells can also enhance the inflammatory response by preventing inflammatory cell apoptosis, thereby delaying the clearance of inflammatory cells from the lung. Intercellular adhesion molecule (ICAM)-1, expressed on epithelial cells, is a ligand for integrins expressed on the surface of neutrophils, and leads to their retention in the airway.[15] Granulocyte colony-stimulating factor (G-CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), released from epithelial cells, promote neutrophil survival.[16]

In addition to nonspecific responses to environmental exposures, the epithelium also expresses specific receptors that recognize viral and bacterial components. The responses triggered by these receptors are crucial elements of the innate immune system. The best characterized are the Toll-like receptor (TLR) family. TLRs sense infection through recognition of PAMPs (pathogen-associated molecular patterns), leading to dendritic cell maturation and antigen presentation, and the activation of pathogen-specific T cells.[17] Although TLR expression is classically associated with bone marrow-derived immune cells, human airway epithelial cells can also express functional TLR2, TLR3, and TLR4,[18-20] and possibly a range of other TLRs. In doing so, epithelial cells are able to convert the recognition of pathogen-associated molecules into signals for antimicrobial peptide expression, barrier fortification, proliferation of epithelial cells and modulation of the host immune response.[21] Bacterial lipopeptides induce epithelial cells to produce the antimicrobial peptide beta defensin-2 in a TLR2-dependent manner,[20] whereas respiratory viral infections can induce airway epithelial cell expression of TLR3, thereby sensitizing the airway epithelium to subsequent microbial pathogens.[18]

FIBROBLASTS

Fibroblasts are important structural cells and are especially prominent within the interstitium of the normal lung. A prominent endoplasmic reticulum and Golgi apparatus characterize their ultrastructure. The cytoplasm contains numerous vesicles, mitochondria, vacuoles, and intermediate filaments. In vivo, they display a few microfilaments and intermediate filaments, and in culture they establish gap junctions. In addition, cultured fibroblasts are more flattened, polarized, and possess numerous stress fibers and a smooth nuclear outline.[22] In a resting state, the cytoplasm is reduced and spindle-shaped with long cytoplasmic extensions. When activated, however, such as in healing wounds, fibroblasts display a rounded nucleus with a prominent nucleolus. The cytoplasm is extensive with a prominent granular appearance of the rough endoplasmic reticulum indicative of active protein synthesis.[22]

Until recently, the fibroblast was thought to be a homogeneous cell with limited roles and functions related to tissue structure. However, it is now well established that the fibroblast is central to wound healing.[23] During resting physiologic conditions, fibroblasts provide scaffolding for the extracellular matrix (ECM) proteins. In addition, they are responsible for the synthesis and turnover of ECM proteins such as type 1 collagen and proteoglycans.[24] However, more recent studies have demonstrated an expanding role for fibroblasts in tissue homeostasis. To this end, fibroblasts have a role in angiogenesis,[25] physiologic aging,[26] remodeling of tissue,[27] cell differentiation, and the release of mediators that may be instrumental in fertility and parturition.[28]

In addition to the aforementioned functions, fibroblasts also serve as sentinel cells, expressing a number of surface molecules that are more traditionally associated with immune cells. As such, they express CD40, originally described on B lymphocytes and dendritic cells,[29] which induces the expression of the intercellular adhesion molecule (ICAM-1), vascular cell adhesion molecule (VCAM-1), the cytokines interleukin-6 (IL-6), IL-8, IL-1, and prostaglandins.[29] Under resting conditions, only low-level surface expression of CD40 occurs, but this increases dramatically during inflammation, constituting a significant pathway by which fibroblasts mobilize inflammatory cascades during tissue injury and wound repair.[29]

There is increasing evidence from both cell cultures and tissue biopsy specimens demonstrating that the fibroblast phenotype is heterogeneous. Fibroblasts for example, expressing the thymocyte antigen 1 (Thy 1(+) fibroblasts) show profibrogenic characteristics by expressing higher levels of collagen.[30] In contrast, Thy 1-negative fibroblasts have a greater proliferative responsive to cytokines such as IL-6, TGF-β, and PDGF.[30,31] As such, different types of fibroblasts may play distinct roles during inflammation and repair. Differences between fibroblasts may also occur as a result of their site of origin in the body[32] or in terms of the receptors that they express, such as major histocompatibility (MHC) class II antigens, complement C1q, IL-1 receptor, and integrins.[30,33]

However, during wound healing and under the influence of mediators released from neighboring cells, fibroblasts assume a more dynamic role and become important effector cells.[24] They acquire a migratory phenotype and enter the wound where they deposit ECM[34] and induce wound contraction.[35] Fibroblasts are implicated in the active immune response of the tissue and release numerous cytokines, growth factors, chemokines, and other inflammatory mediators.[36] The growth factors involved in fibroblast activation include TGF-β, connective tissue factor (CTGF), insulin-like growth

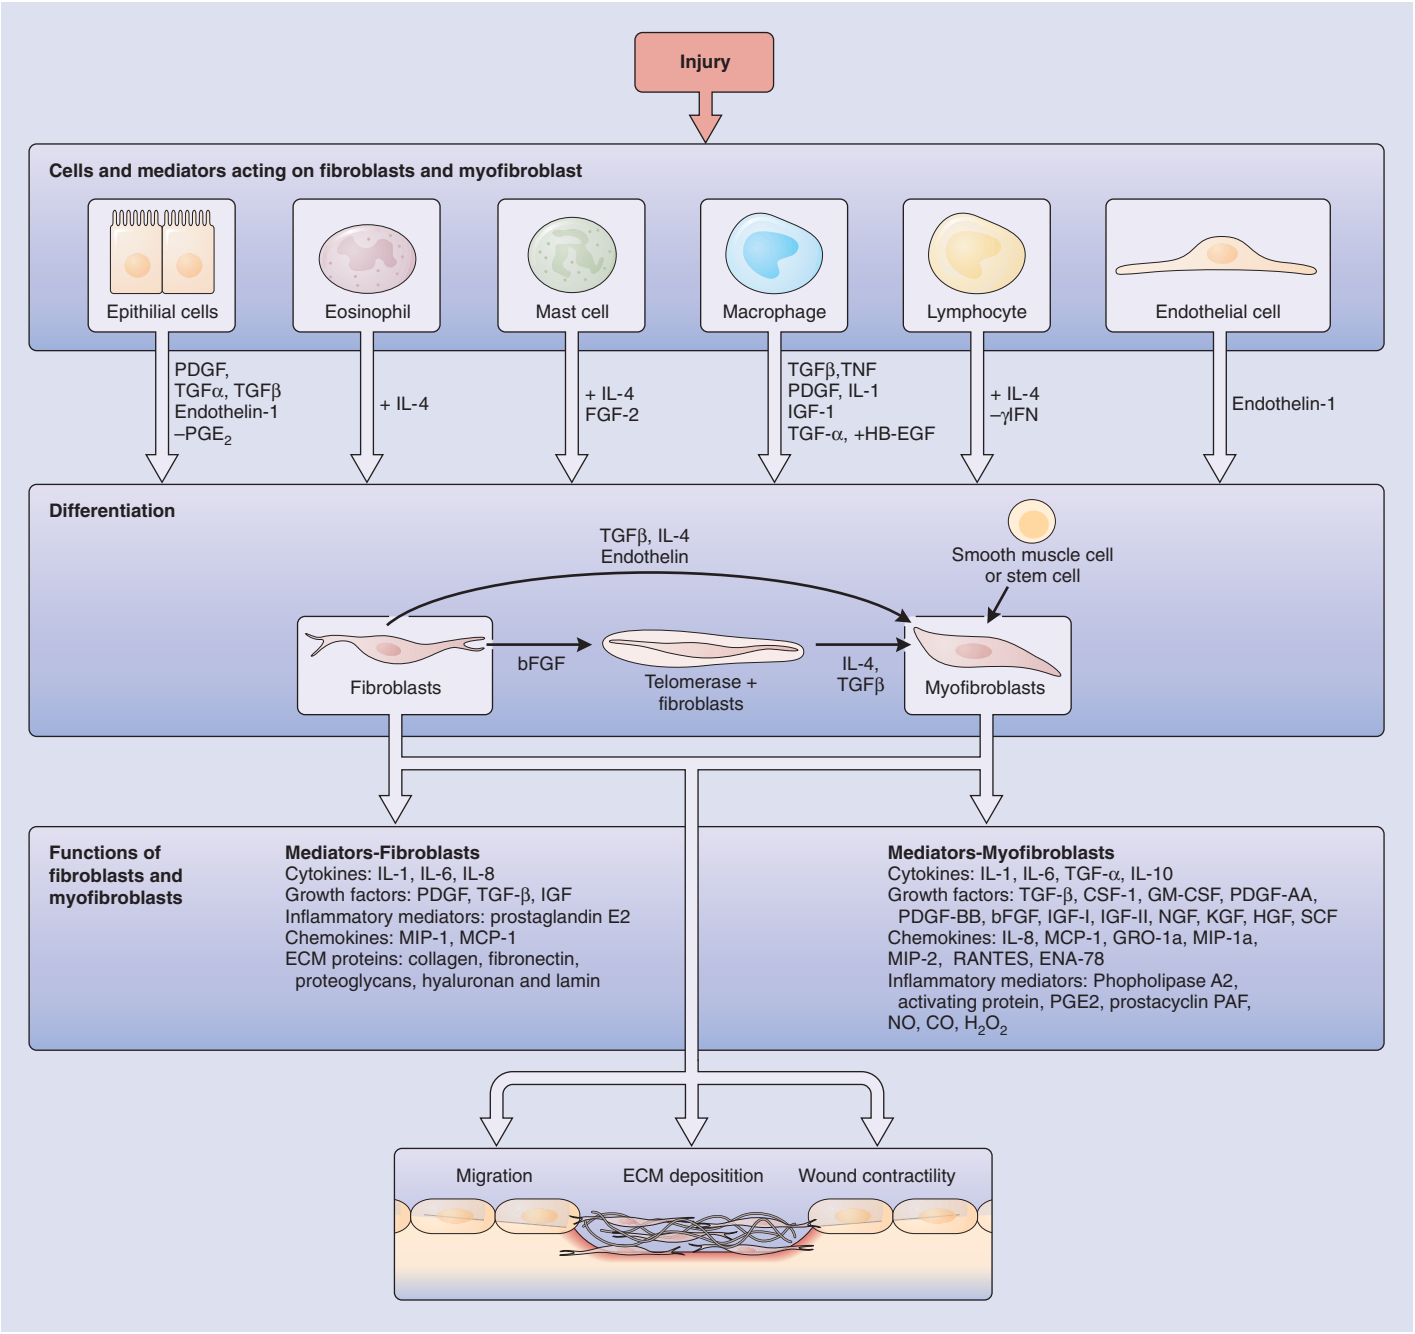

Figure 4-3 The role of fibroblasts and myofibroblasts in fibrosis. An initial injury results in the release of proinflammatory and profibrotic mediators from cells within the lung. These mediators result in the differentiation of fibroblasts to myofibroblasts. In addition, they influence fibroblast and myofibroblast migration, ECM deposition, and wound contractility. In turn, fibroblasts and myofibroblasts release mediators that perpetuate inflammation and fibrosis.

factor (IGF), platelet-derived growth factor (PDGF) and fibroblast growth factor (FGF). Cytokines such as IFNγ, IL-10, and IL-12 can inhibit fibroblast proliferation, whereas IL-1, IL-13, TNF-α, and endothelin-1 are fibroblast mitogens. Of note, IL-6 can act both as an inhibitor or promoter of fibroblast proliferation.[37] Figure 4-3 outlines the role of fibroblasts in pulmonary fibrosis.

An important, but largely unexplained role for fibroblasts in wound healing is their apparent ability to differentiate into myofibroblasts. Myofibroblasts resemble a smooth muscle cell in many respects and are central to wound repair. The transdifferentiation of adventitial fibroblasts to myofibroblasts is induced by TGF-β, IL-4, and endothelin-1.[38] Recently a fibroblast representing a telomerase-expressing phenotype has also been shown to differentiate into a myofibroblast.[39]

MYOFIBROBLASTS

The myofibroblast is characteristically found during wound healing and morphologically displays an indented nucleus, a feature associated with cellular contraction, a large endoplasmic reticulum, and numerous mitochondria.[40] Notably, the myofibroblast is best defined by its cytoskeletal protein

content which may comprise either vimentin (V-type), vimentin and desmin (VD-type), vimentin and α-smooth muscle actin (VA-type), or vimentin, desmin and α-smooth muscle actin (VAD-type).[40-42] The contractile protein most abundant in myofibroblasts is α-smooth muscle actin (α-SMA), although desmin and smooth muscle myosin may also be present. The myofibroblasts found in the lung septa are usually desmin positive.[41,42] Specialized structures of myofibroblasts such as microfilament bundles or stress fibers that are usually found below the cell membrane and parallel to the main axis of the cell usually force wound contraction, whereas a well-developed rough endoplasmic reticulum signifies a prominent synthetic function.[43] There are qualitative differences in the synthesis of collagen I, III, and IV between the various types of myofibroblasts. Myofibroblasts arising from various phases of wound healing, such as those obtained from granulation tissue, display structural differences such as an abundance of cytoplasmic microfilaments, dense bodies, and basal lamina-like material.[43]

Myofibroblasts play a role in normal physiological processes such as organogenesis, tissue morphogenesis, mesenchymal-epithelial interactions, and cell differentiation.[32] In addition, the unique characteristics of the myofibroblast, namely the expression of contractile proteins, makes this cell well adapted for its role in wound repair. However, the source of myofibroblasts involved in wound repair is unknown. Possible precursors include progenitor stem cells, the neural crest, or as a result of the transdifferentiation from peribronchial tissue, perivascular fibroblasts, and epithelial cells.[41,44] Myofibroblasts are a key source of collagen production and ECM proteins. An additional property is their capacity for wound contractility as a result of the rearrangement of the abundant intracellular microfilaments.[45] Myofibroblasts are also inflammatory cells and generate a variety of cytokines, chemokines, inflammatory mediators, and growth factors that may perpetuate the inflammatory response and fibrosis.[41] Activated myofibroblasts also express cell adhesion molecules that recruit inflammatory cells to the sites of injury.

Fibroblasts and Myofibroblasts During Wound Repair

Following an injury, fibroblasts and myofibroblasts infiltrate the wound where they perform a variety of roles. Several lines of evidence have demonstrated that these cells undergo apoptosis (programmed cell death) and this is a crucial phase for normal wound repair.[46-48] Apoptosis is highly regulated by pro-and anti-apoptotic molecules. The cell membrane is characteristically intact during apoptotic cell death as compared with cell necrosis. The intact cell membrane prevents the extrusion of proinflammatory cell contents into surrounding tissue, thereby promoting wound repair. Much of our knowledge of apoptosis of fibroblasts and myofibroblasts has been gleaned from cutaneous models of wound healing. Following wound healing of the skin, fibroblast and myofibroblast apoptosis begins on day 12, peaks at day 20, and is resolved by day 60 of wound repair. The postulated mechanism of apoptosis in fibroblasts is via the IL-1β-dependent production of nitric oxide (NO) that reduces the expression of the anti-apoptotic molecule Bcl-2.[49,50] In contrast, TGF-β inhibits fibroblast and myofibroblast apoptosis by not only inhibiting the expression of NO but also by inducing the anti-apoptotic Bcl-2 molecule without affecting the expression of the pro-apoptotic Bax protein.[49] The fall in TGF-β levels during wound repair is a further mechanism implicated in fibroblast apoptosis. Apoptotic fibroblasts are then phagocytosed by macrophages.[51]

SMOOTH MUSCLE CELLS

The smooth muscle cell is flat with a large nucleus, no nucleolus, and occupies the walls of both airways and blood vessels. This brief review will limit discussion to airway smooth muscle. Smooth muscle in the airway surrounds the lamina propria and the concentration of smooth muscle differs between the proximal, cartilaginous, and distal noncartilaginous airways. Matsuba and Thurlbeck demonstrated that the percentage of the airway occupied by smooth muscle in children is 2.8 in proximal and 10 in distal airways.[52] The orientation of airway smooth muscle is transverse in the trachea and helical or geodesic around the central and peripheral airways, with this arrangement functioning to control airflow to the alveoli.

There is heterogeneity in smooth muscle cells in the airway with at least three different types of smooth muscle cells identified in the airway. These include a contractile, synthetic, and "hypercontractile" subtype.[53] The nonproliferative contractile phenotype is characterized by a high concentration of contractile proteins and reduced synthetic intracellular organelles.[54] In contrast, the synthetic smooth muscle, which may differentiate into a contractile phenotype, possesses numerous synthetic organelles and a low density of contractile proteins. The hypercontractile cell shortens at high velocity in cell culture because of elevated concentrations of smooth muscle light chain kinase.[55] The role of these subtypes in vivo needs to be further investigated.

The smooth muscle consists of thick (predominantly myosin), thin (predominantly actin) and intermediate (predominantly desmin) filaments. Actin is arranged in hexagonal bundles that run along the long axis of the cell and are surrounded by myosin filaments. The intermediate filament forms connections with the cell membrane and is thought to maintain the myofilament system and structure of the smooth muscle cell.[56] The thin and intermediate filaments breach the inner membrane of the cell and form electron-dense areas called *dense plaques*. These plaques are coupled to each other in adjacent cells and mediate the transmission of tension between the contractile machinery and the ECM. The myosin fibers have a globular end—the myosin head—at the amino terminus that contains the functional motor domains comprising the actin-binding regions and the nucleotide adenosine triphosphate (ATP).[57] Neural stimulation results in an increase in intracellular calcium, leading to the enzymatic hydrolysis of ATP and conformational change in the myosin head. Myosin generates a force by repeatedly attaching to the actin, undergoing a conformational change and detaching.[58] This "lever arm hypothesis" suggests that the force is generated in repeated mechanical cycles. Contraction of smooth muscle is regulated by external factors such as the ECM. The smooth muscle cells are sensitive to external mechanical

Table 4-1
Inflammatory Mediators Released by Smooth Muscle

Adhesion molecules	Growth factors	Chemokines	Cytokines	Other mediators
ICAM	PDGF	MCP-1,2,3	IL-8	PGE_2

stimuli by the binding of their transmembrane integrin receptors to ECM ligands. Mechanical forces result in the activation of the integrin receptors and their related transducer proteins vinculin, talin, and paxillin. The transducer proteins result in the phosphorylation of focal adhesion kinase (FAK) that in turn allows an increase in intracellular calcium and activation of the contractile proteins.[59]

In addition to the role of contraction, smooth muscle also plays a central part in immune regulation in the airway, as summarized in Table 4-1. The smooth muscle cell expresses the adhesion molecules ICAM and VCAM following stimulation by TNF-α, IL-1, interferon (IFN), and lipopolysaccharide.[60] These adhesion molecules augment the interaction of smooth muscle cells with inflammatory cells, thereby further perpetuating the release of inflammatory cytokines and chemokines as well as the proliferation of smooth muscle cells. The cytokines secreted by smooth muscle following stimulation by IL-1, TNF-α, and IFN include macrophage chemotactic factor (MCP)-1, 2, and 3, RANTES, eotaxin, GM-CSF, IL-8, IL-6, IL-11, IL-5, IL-2, and IL-12.[61-63] Growth factors secreted include PDGF-BB, stem cell factors, and lipid mediators such as PGE_2, s-PLA2, and NOS.[64] As such, smooth muscle plays an intrinsic role in the augmentation of the inflammatory cascade.

The signaling pathways that drive smooth muscle growth are divided into the polypeptide growth factors that activate receptor tyrosine kinase and receptors linked to the guanosine triphosphate-binding proteins (G proteins).[65] These mitogens associated with tyrosine kinase include PDGF, EGF, FGF-2, and IGF.[66] The G proteins binding molecules are thrombin, serotonin, endothelin and leukotriene D4. A third group of mitogens constitute the proinflammatory cytokines such as IL-1 and TNF.[67] These cytokines act via the receptors acting through Src kinase, mitogen-activated protein kinase, Janus kinase, and signal transducer and activation of transcription (STAT) pathways.[68] The PI-3 kinase plays a prominent role in both smooth muscle hyperplasia and migration to sites of injury.[69] Beta 2 agonists and glucocorticoids attenuate the proliferative response of smooth muscle cells.[70] These antiproliferative effects are limited by IL-1β and collagen I, however.[71] The factors regulating smooth muscle proliferation are outlined in Table 4-2.

There are several secondary messenger systems that mediate smooth muscle constriction or relaxation. The seven domain transmembrane G-coupled receptor plays a vital role in smooth muscle cells. This receptor comprises stimulatory (Gs) and inhibitory (Gi) subunits.[72] The major agents causing constriction are histamine (H1 receptor), acetylcholine (M3), leukotriene (D4) and bradykinin (B3).[73,74] Ligation of these receptors stimulates the Gi protein of the G-coupled receptor and the activation of phospholipase C, resulting in an increase in intracellular calcium and muscle constriction. Beta 2 agonists cause smooth muscle relaxation by receptor activation of the Gs subunit of the G coupled receptor. This subunit results in the activation of adenyl cyclase and protein kinase leading to membrane hyperpolarization, inhibition of myosin light chain activation, and increased reuptake of calcium.[75]

Several studies have demonstrated that there is both hyperplasia and hypertrophy of smooth muscle cells in the asthmatic airway. The mechanisms are as yet undefined but molecules implicated in this process include cytokines, endothelin, leukotriene D4 and a variety of growth factors.[76] Smooth muscle cells in the lung are heterogeneous. Ebina and colleagues demonstrated that there are two patterns of thickening in lungs of patients with fatal asthma.[77] In the type I group, there was thickening in the large airways in contrast to the diffuse thickening throughout the lung in the type II subgroup. The significance and pathogenesis of these changes need further verification. The role of fibroblasts, myofibroblasts, and smooth muscle cells in pathologic states will be further highlighted in subsequent chapters.

IMMUNE RESPONSES TO INHALED ANTIGENS

The mucosal surfaces lining the airways and alveoli are exposed to an array of inhaled environmental antigens and particulate matter, and the lung has remarkably little inflammation under normal circumstances, given the volume of air inspired each day and the large surface area of the respiratory epithelium. A key task for the immune system is, therefore, to discriminate between innocuous antigens and potential pathogens, minimizing the risk of tissue damage and at the same time defending against the risk of serious infection. Under normal circumstances, and in the absence of tissue damage, inhaled soluble proteins do not induce strong immune reactions, but instead lead to a state of immunologic hyporesponsiveness known as *inhalation tolerance*. In contrast, immune mechanisms within the lung become highly activated when exposed to replicating pathogenic microbes that are able to activate the innate immune system via TLRs and other pattern-recognition receptors.

The lungs have specific defense mechanisms to protect them from microbial pathogens. The nose and upper airway filter and condition inspired air, and the cough reflex and mucociliary blanket remove many inhaled particulates. The innate immune system relies on a relatively restricted range

of receptors that are able to respond in a rapid but stereotyped way to pathogens. Collectins (surfactant proteins), defensins, lactoferrins, mannose-binding lectin, complement, and lysozyme are secreted into the airway and alveolar lumen to provide nonspecific protection against infection, whereas alveolar macrophages and neutrophils express pattern recognition receptors and are the principal innate immune cells in the normal lung. In contrast, the adaptive immune system relies on dendritic cells, T cells, and B cells to generate an enormously diverse and exquisitely specific response to foreign antigens. Although the response to initial antigen exposure is relatively slow, the adaptive immune system generates long-lasting immune memory and provides a measure of protection against subsequent antigen exposure. Further description of the mechanisms of host defense against infection are provided in Section VII, Chapters 31 through 43. Mast cells and eosinophils are discussed elsewhere in relation to asthma.

Inhaled antigens are generally deposited on the epithelium by impaction or sedimentation. The mucociliary layer and tight junctions between epithelial cells limit access of antigen to immunocompetent cells. Those antigens that are able to penetrate the epithelial barrier are taken up by antigen-presenting cells (APCs). If the host has not previously been exposed to a particular antigen, activation of naïve T cells takes place in regional lymph nodes following presentation by migrating dendritic cells. In contrast, recall or memory responses to previously encountered antigens can occur within the airway submucosa or lung interstitium. The mechanisms by which inhalation tolerance develops and is maintained involve APCs (alveolar macrophages and lung dendritic cells) and T cell deletion, T cell anergy, and suppression by specific regulatory T cells.

DENDRITIC CELLS

Dendritic cells (DCs) are highly migratory cells that were first described over 30 years ago as a novel population of cells in mouse lymphoid organs, and were subsequently shown to be highly potent accessory cells.[78,79] Their major role within mucosal tissues is to sample environmental antigens, and then to migrate to regional lymph nodes where they present processed antigenic peptide to T cells. As such they are fundamental to the generation of appropriate immune responses to inhaled foreign antigens.

DCs are a heterogeneous class of antigen-presenting cells, and several DC subpopulations have been identified in humans and mice.[80,81] These include both myeloid, or *conventional* DCs, and the plasmacytoid DCs that have a unique ability to produce large amounts of type I interferons, and are thus critical for host defense against virus infection. Various DC populations with differing functions have been described in the mouse lung[82] although complete characterization of human lung DC subsets is very much in its infancy.

In the airway, DCs form a tightly-meshed network above and below the basement membrane of the respiratory epithelium,[83] such that they are ideally situated to monitor the external environment, sample inhaled antigens, and function as *sentinels* of the immune system. Studies in experimental animals have suggested that postnatal maturation of DCs in the respiratory tract is delayed relative to other tissues,[84] and the limited available data suggest that a similar situation exists in humans.[85] The paucity of functioning lung DCs in early life may play a role in the increased susceptibility of neonates to allergic and infectious respiratory diseases.

DCs in the gut epithelium are able to extend their processes through tight junctions in order to sample antigens from the gut lumen,[86] and lung DCs are likely to utilize a similar approach to take up inhaled antigens. While mucosal DCs in healthy tissues are adept at antigen uptake, they have a poor capacity to present antigen to T cells. Pathogens, tissue damage, and inflammation induce DCs to undergo a process of *maturation* or activation, leading to enhanced costimulatory molecule expression and an increased capacity to activate antigen-specific T cells. In contrast, when DCs take up innocuous antigens in the absence of inflammatory stimuli, DC activation does not occur. This leads to immune tolerance via a variety of mechanisms, including the induction of regulatory T cell populations.

Following antigen uptake, lung DCs rapidly transport antigen to the T cell zones of regional lymph nodes,[87] although a significant proportion of antigen-loaded DCs can also remain within the lung where they are able to activate T cells locally long after antigen exposure.[88-90] Although migration of DC to regional lymph nodes has traditionally been thought to be inextricably linked to DC activation, this now appears to be an oversimplification because some DCs clearly migrate to regional lymph nodes under steady-state conditions without undergoing maturation and are thus able to induce tolerance.

Not only are DCs major players in the initiation and amplification of immune responses, they also regulate the qualitative nature of these events, significantly influencing Th1/Th2 polarization,[91-93] through their expression of costimulatory molecules (e.g., CD80, CD86, CD40, OX40 ligand, and inducible costimulatory ligand) and via their secretion of soluble mediators such as IL-6, IL-10, IL-12, and prostaglandin E_2. A variety of microbial stimuli have the ability to program DCs to induce Th2 responses, including components of fungi, nematodes and cholera toxin.[94-96] Inhaled lipopolysaccharide (LPS), signaling through TLR4, can promote either a Th1 or a Th2 response in the airways depending on the dose of LPS, suggesting that the strength of microbial signaling may play a role in Th1/Th2 polarization.[97]

DCs are particularly responsive to signals received from the tissue microenvironment. Exposure of DCs to epithelial cell-derived thymic stromal lymphopoietin or PGE_2 and mast cell-derived histamine polarize the maturation of myeloid DCs into Th2 promoting DCs.[98-100] In contrast, other cytokines such as transforming growth factor β (TGF-β) and vascular endothelial growth factor promote *tolerogenic* DCs.[101,102] TLRs on DCs react not only to microbial components but also to endogenous ligands such as fibronectin, heparan sulfate, and heat shock proteins that are released in response to tissue injury,[103-105] and this is likely to be a mechanism by which DCs monitor tissue well-being.

For most healthy individuals, lung DCs induce tolerance to inhaled innocuous antigens, whereas in those who develop allergic asthma, tolerance induction is thought to be defective such that otherwise harmless allergens induce airway inflam-

mation. In contrast, lung DCs become activated and highly immunogenic when exposed to pathogenic microbes.

ALVEOLAR MACROPHAGES

Macrophages are specialized for the phagocytosis of particulate matter and the recognition of microbial pathogens, and are the most common immune cell in normal bronchoalveolar lavage fluid. Under normal conditions, they closely adhere to alveolar epithelial cells, and are generally kept in a quiescent state, producing minimal amounts of proinflammatory cytokines in order to minimize the risk of damage to the delicate gas-exchanging structures of the lung. In steady state, lung macrophages release inhibitory molecules such as TGF-β, IL-10, PGE_2, IL-1 receptor antagonist, and nitric oxide through which they inhibit the function of nearby DCs and T cells—thereby suppressing the induction of adaptive immunity.[106,107] Although normal alveolar macrophages have a high capacity for phagocytosis and antigen uptake and express major histocompatibility molecules, they are poor at presenting antigen to T cells, and do not generally migrate to regional lymph nodes where immune responses are initiated. Accordingly, macrophages may not play a major role in antigen presentation in the normal lung, although they may transfer antigen fragments to DCs that then migrate to lymph nodes and activate T cells.

Macrophage function changes abruptly in response to microbial pathogens. Engagement of TLRs and other pattern-recognition receptors leads to macrophage activation with the release of cytokines such as IL-1, IL-6, and TNF and activation of phagocytosis and cytotoxicity. Inflammatory monocyte precursors are recruited by chemokines from the circulation to the lung. These newly recruited monocytes are permissive for DC activation and T cell priming such that the usual macrophage "brake" on the adaptive immune system is temporarily released, and a window of opportunity opens up to allow immune responses to be initiated. Once the microbial load has been contained, the newly recruited monocytes will revert to the typical suppressive phenotype of resident alveolar macrophages.

Whereas phagocytosis of microbes leads to proinflammatory cytokine release, when macrophages ingest apoptotic cells, they do so in a way that does not induce inflammation,[108] but rather they release inhibitory molecules such as TGF-β and PGE_2.[109] The ability of macrophages to clear apoptotic cells is thought to be crucial to the resolution of inflammation and development of fibrosis, and there is some evidence that this function is defective in human disease.[110,111]

T CELLS

Most T cells within the lung express a T cell receptor (TCR) made up of α and β chains that recognize short peptides complexed to major histocompatibility (MHC) antigens. CD8 cells recognize antigenic peptide in the context of class I MHC and initiate cytotoxicity, typically directed against virally infected host cells. In contrast, CD4 cells respond to antigenic peptide in the context of class II MHC and provide help for B cells and antibody production. A second lineage of cells display a TCR made up of γ and δ chains. These γδ T cells are preferentially localized to the epithelium and recognize a more limited range of antigens than αβ T cells.

Within the circulation both naïve and memory (antigen-experienced) T cells are found in similar numbers. Naïve T cells traffic from the peripheral blood to lymph nodes and spleen, have a higher threshold for antigen activation, and can only respond to antigen-bearing dendritic cells. In contrast, memory T cells have a lower threshold for antigen activation, and can respond to a variety of APCs, in addition to dendritic cells. Memory T cells can traffic to a wider range of anatomical locations compared with their naïve counterparts because of a differing pattern of adhesion molecule and chemokine receptor expression, allowing them to accumulate in both lymphoid tissues and epithelial organs such as the lung. Most of the T cells in the normal lung display the phenotype of effector memory cells, with few detectable naïve or central memory cells.[112]

Functionally distinct subsets of T cells have been defined, based on differing patterns of cytokines that they produce (Table 4-3). This was initially defined in relation to CD4 T cells, where polarized T helper 1 (Th1) cells express the transcription factor T-bet and produce the cytokines interferon-γ and lymphotoxin, whereas T helper 2 (Th2) cells express the transcription factor GATA-3 and secrete the cytokines IL-4, IL-5, IL-9, and IL-13. CD8 cells (Tc1 and Tc2 subsets), natural killer (NK) cells, and eosinophils can also produce similar cytokine profiles. The definition of these T cell subsets has been extremely useful in understanding the pathogenesis of inflammatory lung diseases such as allergic asthma, sarcoidosis, tuberculosis, and a variety of other respiratory infections.

However, the Th1/Th2 paradigm is less useful in understanding immune responses to noninfectious antigens in the healthy lung. The recent recognition of a third class of T cells, the various regulatory T cells (Tregs), has shed light on the processes that mediate immune tolerance in the lung. Tregs were initially identified as a population of CD25+ CD4 cells that were able to inhibit both type 1 and type 2 immune responses. Some Tregs develop in the thymus, while others develop in the periphery. Further research has shown that the transcription factor Foxp3 is critical to the development of functional Tregs.[113,114] TGF-β is a critical factor regulating the development of Tregs, whereas TLR engagement of dendritic cells can inhibit Treg function.[115] Tregs can regulate allergic airway inflammation in animal models,[116] although this can be inhibited via IL-6 signaling.[117] CD4+ CD25+ Foxp3+ cells mediate their regulatory effects via contact-

Table 4-3
Characteristic Features of Th1, Th2, and T Regulatory Subsets

	Th1	Th2	T regulatory
Differentiation induced by:	IL-12	IL-4	TGF-β
Transcription factors	T-bet, STAT-4	GATA-3, STAT-6	Foxp3
Secreted cytokines	IFN-γ	IL-4, IL-5, IL-9, IL-13	IL-10, TGF-β
Role	Cell-mediated immunity	Humoral immunity	Immunoregulation

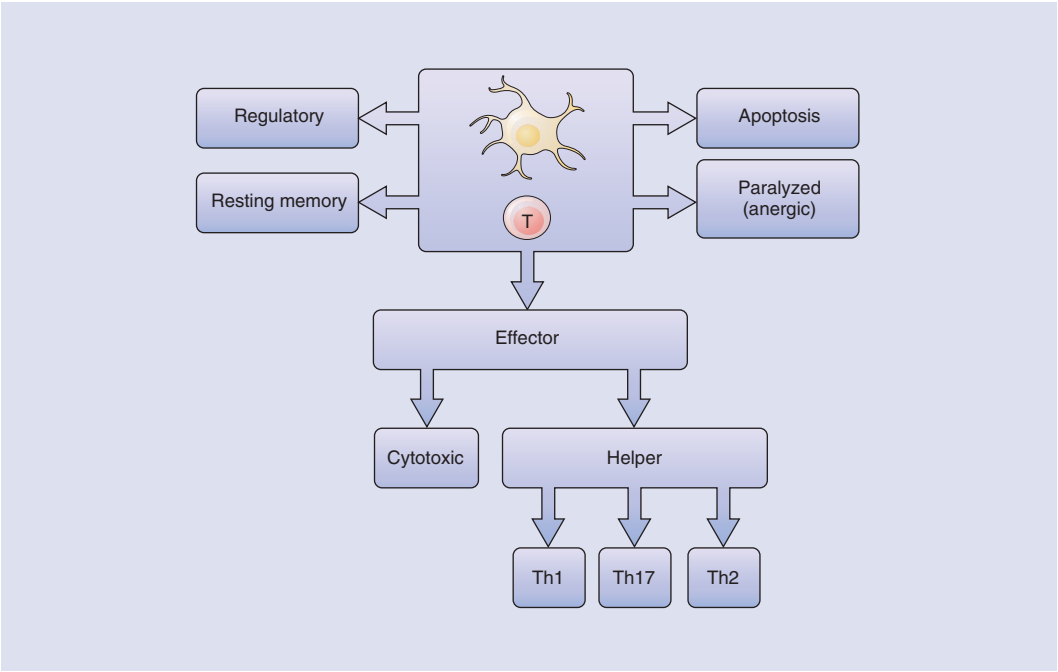

Figure 4-4 T cell responses can take many directions. Following an encounter with an antigen-presenting cell, naïve T cells can respond in a variety of ways, including apoptosis (programmed cell death), the induction of effector T cells, regulatory T cells, and a form of immunologic paralysis known as anergy. After initial T cell expansion, a small number of cells will survive as long-lasting memory cells, ready to respond rapidly in the event of later exposure to the same antigen.

dependent mechanisms, whereas there are other populations of suppressive T cells that mediate their effects directly through secreted IL-10 and TGF-β.

A distinct subset of helper T cells has recently been defined by their capacity to make the IL-17 family of cytokines. This cytokine provides defense against extracellular bacteria but may contribute to tissue inflammation in autoimmune disease,[118] and appears to be involved in neutrophil recruitment to the lung.[119] Thus, when T cells first encounter antigenic fragments presented by dendritic cells, their survival and differentiation can proceed in several different directions, as shown in Figure 4-4.

NATURAL KILLER CELLS AND NATURAL KILLER T CELLS

NK cells and NK T cells are characterized by natural cytotoxicity, the ability to rapidly lyse targets, especially virally infected cells. Although NK cells are devoid of TCR, NK T cells express a restricted repertoire of T cell receptors and are able to recognize a limited range of glycolipid antigens presented in the context of the MHC-like protein CD1d. Aside from their well-known role in host defense against infections, NK cells and NK T cells possess important immunoregulatory roles, releasing cytokines that are important in the early phase of Th1/Th2 polarization. Large numbers of NK T cells can be found in the lungs of people with asthma, and may play a role in disease pathogenesis.[120]

B CELLS

Relatively few isolated B cells are present in the airway mucosa and alveolar walls, and are instead congregated in regional lymph nodes, or in loosely organized lymphoid aggregates. These lymphoid aggregates are thought to be capable of T- and B-cell responses to inhaled antigens, and appear to be most prominent in young children, or in the context of lung inflammation.[121-123]

CHAPTER 5

Host Defense Systems of the Lung

J. Brian Kang and Gary L. Larsen

TEACHING POINTS

- Host defense of the lung is mediated by several complex but complementary processes, which include mechanical, nonimmunologic, and immunologic responses.
- The different components of the host defense mechanism undergo developmental changes. Young children are more susceptible to pulmonary infections because of these normal maturational processes.
- The mechanisms that protect the lung can also have the potential to produce harmful effects (e.g., inflammation).

From the first breath at the time of birth, the lungs must be protected from numerous insults from the environment. This defense takes many forms and has evolved to include mechanical as well as biochemical processes that work in an integrated fashion to safeguard the respiratory tract. This chapter reviews the host defense systems found in humans that protect this organ from injury. Because of this book's focus on pediatric respiratory medicine, information on the developmental aspects of the various components of lung defense is presented.

GENERAL CONCEPTS OF LUNG DEFENSE

Protection of the respiratory tract is provided by several complex but complementary processes.[1,2] The host defense systems normally prevent entry into or rapidly remove foreign material from the lungs. These systems include filtration of potential environmental pathogens from inspired air, cough to clear material from air passages, and mucociliary clearance to eliminate substances not cleared by the first two mechanisms. Both nonimmunologic and immunologic responses of the lung to potentially injurious agents commonly lead to inflammation.

FILTRATION AND DEPOSITION OF ENVIRONMENTAL PATHOGENS

The upper airway and the branching airways within the lung constitute the first line of defense against airborne particles. As ambient air containing suspended solid and liquid particles is drawn toward the gas-exchanging areas of the lung during inspiration, three major mechanisms of deposition come into play: inertial impaction, gravitational settlement, and diffusion.[3] In general, many larger particles (>10 μm) are trapped in the nose and upper airways (above the cricoid ring) as a result of inertial impaction. This mechanism of deposition is based on the principle that the inertia of a particle causes it to maintain its original direction for a distance depending on the density of the particle and the square of its diameter. Thus, when the stream of air changes direction or velocity, such as happens in the nasopharynx and at the divisions of larger airways within the lung, the larger and more dense particles are likely to hit the walls in these areas and be trapped. This is the primary means of deposition for the majority of larger particles within the respiratory tract. Indeed, because of this mechanism, the lung is spared the task of dealing with many large particles because they are filtered from inspired air before they penetrate the lung. Smaller particles are deposited primarily by gravitational settlement in the deeper recesses of the lung, with the speed of this process again related to the density of a particle and the square of its diameter. Diffusion takes place because airborne particles are displaced by the random bombardment of gas molecules, leading to collision with the airway walls. Compared to the first two processes, diffusion is responsible for a smaller percentage of total lung deposition.

Factors Influencing Particle Deposition

Regional deposition within the upper and lower respiratory tract as a function of particle size has been estimated by several investigators.[4] Figure 5-1 summarizes the results for uncharged, unit-density spheres orally inhaled at the mean breathing pattern of an adult male at 5-second respiratory cycle period and 300 cm^3/second flow rate. The total deposition of particles was partitioned into four regions of the respiratory tract: extrathoracic, upper bronchial, lower bronchial, and alveolar regions. The alterations that might be expected in a smaller subject are discussed later.

Several factors other than particle size also influence deposition. Primary among them are flow rates during inspiration. The greater the flow rate (as seen with exertion), the greater the impaction of particles. Conversely, the probability of a particle being deposited in an airway as a consequence of gravity or diffusion increases as airflow at the mouth decreases or breath-holding occurs. Other factors that may be important include changes in the size of a particle such as occurs with either evaporation or hygroscopic growth. Electrostatic changes may also have significant effects. A change from nose to mouth breathing also alters patterns of

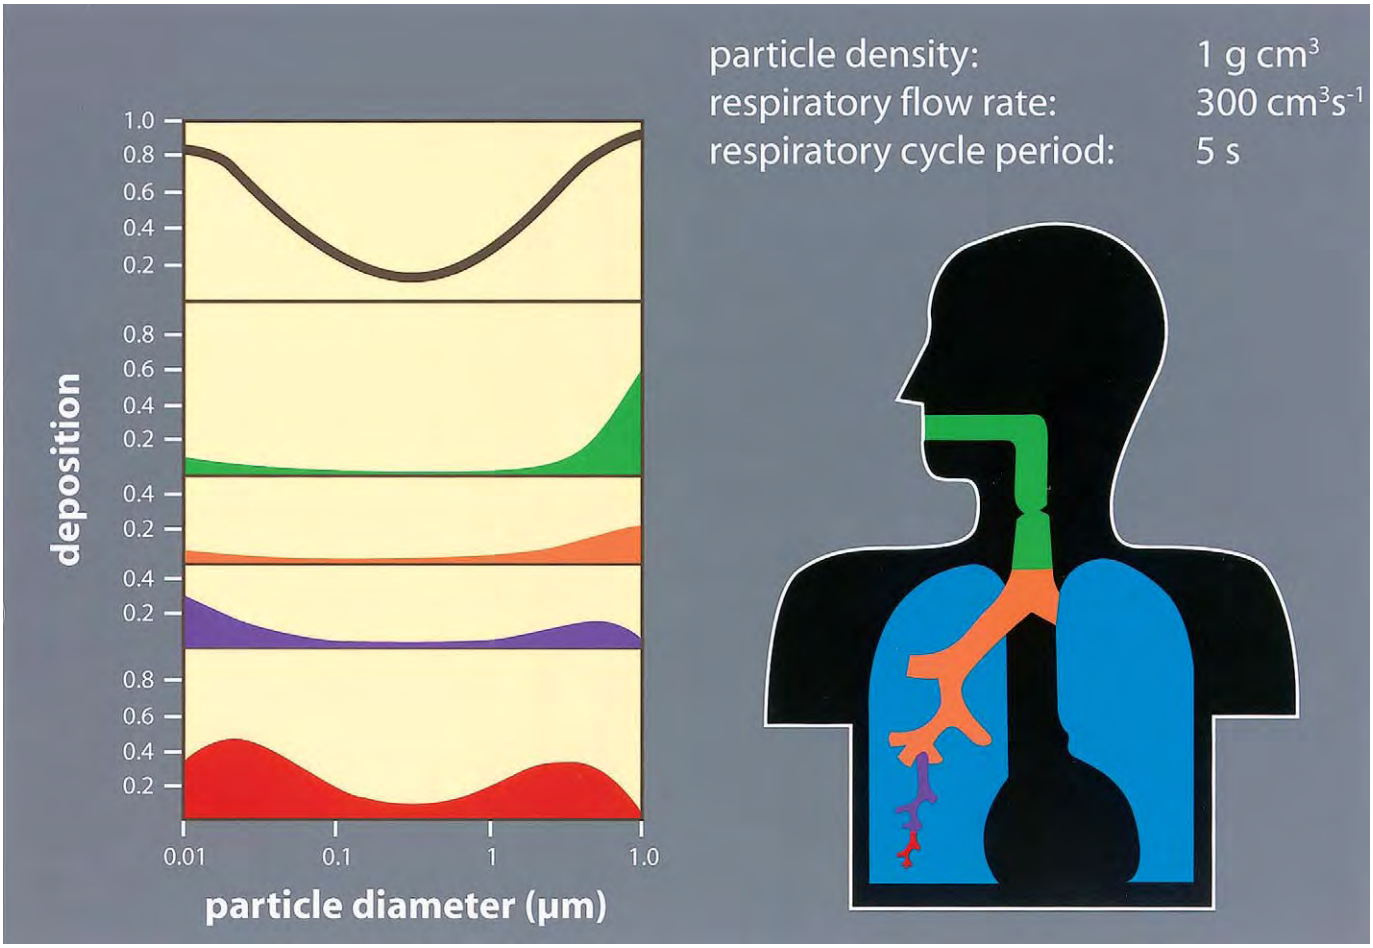

Figure 5-1 Total and regional deposition of orally inhaled unit-density spheres in the human respiratory tract as predicted by the International Commission on Radiological Protection deposition model. See text for discussion. (From Heyder J: Deposition of inhaled respiratory particles in the human respiratory tract and consequences for regional targeting in respiratory drug delivery. Proc Am Thorac Soc 1:315-320, 2004.)

deposition. These and other factors, including the influence of diseases of the airways on particle deposition, have been reviewed.[3]

A child's airway may be subjected to many types of insults (Fig. 5-2).[5] In this figure, the aerodynamic diameter of the particles is plotted against the deposition fractions taken from the calculations of Yu and colleagues.[6] The sizes and sites of deposition are of pathogenic importance in terms of the pulmonary symptoms produced by these insults. For example, the size of pollens leads to their deposition in the larger central airways before they reach the "pulmonary" compartment. As discussed in Chapter 57, allergic asthma in children is felt to be associated with inflammation within the central airways, with less pathology found within the gas-exchanging areas of the lung.

Changes in Particle Deposition with Growth

Studies of particle deposition have been performed primarily on adults; thus relatively little is known about particle deposition in infants and children. However, studies to date suggest that some important differences exist. For example, it has been estimated that the young child receives a potentially larger nasal dose of an aerosol than an adult because of aerosol deposition.[7] In addition, calculations based on casts of airways from infants to adults indicated that smaller (younger) subjects usually have greater tracheobronchial deposition efficiencies than larger (older) individuals.[8] For example, it has been estimated that the tracheobronchial dose per kilogram of body mass for particles with diameters of 5 μm may be six times higher in the resting newborn than in the resting adult if equivalent deposition efficiencies are operative above the larynx.[8] Additional predictions of tracheobronchial deposition have been made for infants, children, and adolescents.[9] Thus, for most particle diameters between 0.01 and 10.0 μm and for most states of physical activity, smaller individuals probably exhibit greater tracheobronchial deposition efficiencies than larger individuals. Considering the greater ventilation capacity per kilogram of body mass for smaller subjects, this suggests that the initial deposited tracheobronchial dose for young children may be well above that for the adult.

COUGH AS A MECHANISM TO PROTECT THE AIRWAYS

Several neurally mediated reflexes help protect the airways. These reflexes, which may occur separately or together, include sneezing, coughing, and bronchoconstriction. This discussion focuses on cough because of its important role in

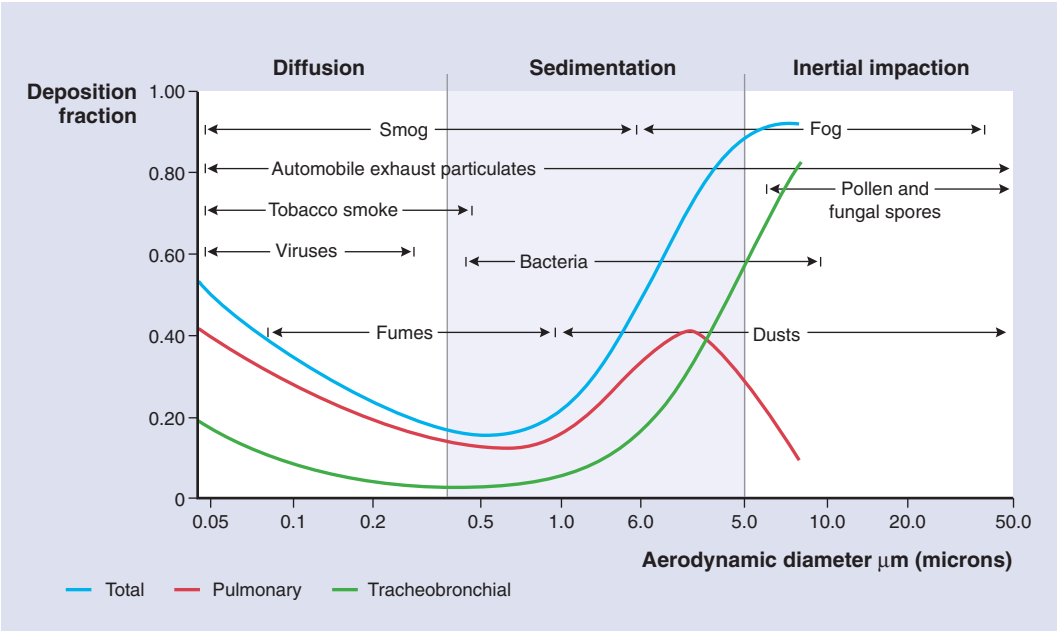

Figure 5-2 The size-deposition relation is shown for several stable particles of varying aerodynamic diameter for the tracheobronchial and pulmonary compartments of the lung. The total curve represents the sum from the two compartments. The deposition fractions are from the calculations of Yu and colleagues[6] and are for mouth breathing at less than 0.25 L/sec. The particle diameters over which diffusion, sedimentation, and inertial impaction are most important are displayed as are the approximate sizes of some common environmental insults. (From Dolovich MB, Newhouse MT: Aerosols: Generation, methods of administration, and therapeutic applications in asthma. In Middleton E, Reed CE, Ellis EF, et al. [eds]: Allergy: Principles and Practice, 4th ed. St Louis, Mosby, 1993, pp 712-739.)

limiting exposure to and deposition of potentially pathogenic material within the airways.

Cough must be considered an integral part of the mechanisms of airway defense against inhaled particles (e.g., dust) as well as noxious substances (e.g., cigarette smoke, ammonia fumes). Thus, the cough that occurs in otherwise normal individuals within a smoke-filled environment should be considered a protective reflex that helps limit the insult to the lower respiratory tract. In addition, cough should be considered an adjunct to the normal mechanisms of mucociliary clearance (see later section), becoming especially important when usual methods of mucus clearance are impaired or overwhelmed. This section emphasizes cough as a protective defense in otherwise normal individuals. The differential diagnosis of cough is dealt with in Chapter 10, whereas specific disease states in which cough is a prominent feature are discussed in the chapters on those disorders.

Although much is known about the stimuli and disease processes that elicit cough, knowledge concerning cough receptors in humans is incomplete and based on findings from animal models.[10] However, several general comments can be made. First, it is clear that cough-sensitive nerves extend from the larynx to the division of the segmental bronchi. Based primarily on studies performed in animals, it appears that several nerve fibers are involved in the production of cough. Adaptations of the cough reflex seen in humans in response to different types of airway stimulation suggest that there are different receptor populations with separate afferent neuronal pathways within the airways.[11] Sensory fibers and their specific stimuli have been delineated in the cough reflex of several animal models. Most authorities agree that more than one fiber type makes up the afferent neural fibers leading to cough and these fibers can differ from those that reflexively narrow the airways.[12]

Vagal afferent receptors that may be involved in cough and the regulation of airway tone have been reviewed.[10] Within the airways, the larynx and points of proximal airway branching appear to be especially important as sites where receptors initiate the cough reflex. Within the larynx, "irritant" receptors with myelinated afferents mediate cough and bronchoconstriction; less is known about laryngeal nonmyelinated afferents and their receptors. Thus, when cough and bronchoconstriction have been evoked from the larynx, myelinated afferents are usually implicated, but participation of laryngeal C-fiber receptors cannot be excluded. It is helpful to divide the afferent nerve endings of the lower airways (tracheobronchial tree) into four types: slowly adapting pulmonary stretch receptors (SARs); rapidly adapting stretch or irritant receptors (RARs); pulmonary C-fiber receptors or J receptors; and bronchial C-fiber receptors.[10] Although all four types have been implicated in regulating bronchomotor tone and in mediating cough, the myelinated irritant receptors (RARs) have received the most attention as initiators of cough reflexes. Various stimuli to C-fiber receptors and RARs are outlined in Table 5-1. Although the receptors respond to many of the same stimuli, the sensitivities vary greatly. C-fibers are activated by many of the same chemical and irritant stimuli that excite RARs; however when compared with RARs they are less sensitive to mechanical stimuli.[13] There is lack of clear evidence that C-fiber receptors are primary sensory input to the cough reflex. It appears that in response to stimuli, C-fiber receptors may release neuropep-

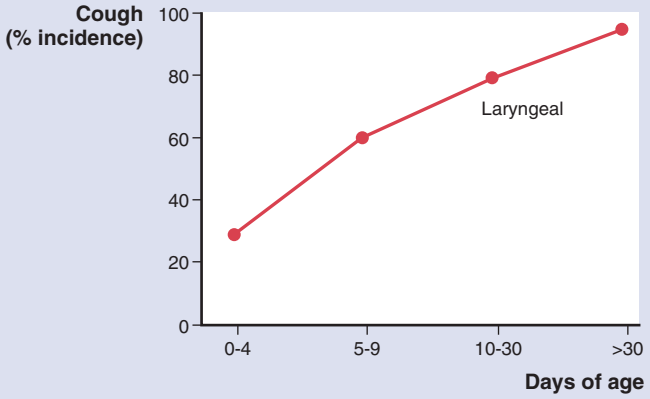

Figure 5-3 The percent incidence of cough in full-term infants as a function of age. Stimulation of the pharynx and vocal cords was obtained by direct laryngoscopy followed by the squirting of saline onto the vocal cords. Any cough resulting from either the introduction of the scope or exposure to saline was considered a positive result. The cough reflex was present in only 27% of 63 infants within the first 4 days of life but occurred in 90% (19 of 21 infants) when the postnatal age was 2 to 11 months (greater than 30 days in the illustration). (Data from Miller HC, Proud GO, Behrle FC: Variations in the gag, cough, and swallow reflexes and tone of the vocal cords as determined by direct laryngoscopy in newborn infants. Yale J Biol Med 24:284-291, 1952; and from Karlsson J-A, Sant'Ambrogia G, Widdicombe J: Afferent neural pathways in cough and reflex bronchoconstriction. J Appl Physiol 65:1007-1023, 1988.)

tides, such as substance P, which in turn stimulates RARs to cause cough and neurogenic inflammation.[12]

Most of what is currently known about the central nervous system relay for cough reflexes is in animal models.[14,15] The afferent system described earlier is transmitted to the first synaptic target in the nucleus tractus solitarius (NTS). The neurons in the NTS interact with a complex network of synapses within the brain stem network to elicit an efferent response via medullary motoneurons. The neuronal interactions within the brain stem network still need to be clarified.

The physiologic consequences of the efferent pathway are better understood and characterized in terms of the four phases of cough. First, inspiration may occur, leading to more efficient use of the expiratory muscles. This is followed by compression, which occurs when the rib cage and abdominal muscles contract while the glottis is closed. Compression leads to increased intrathoracic pressures, which help achieve the high airflows that occur when the glottis opens during expression, the third phase of cough. The final phase, relaxation, is characterized by expiratory muscle relaxation, leading to a fall in intrathoracic pressures. In addition to the clearance of particles by high velocity in the larger airways, there is progressive upward dynamic compression of the smaller airways, thus squeezing materials upward during a series of coughs throughout expiration.

Developmental Aspects of Cough

The development of cough has been reviewed.[16] Based on the observation that less than one half of both term and premature infants cough when stimulated by direct laryngoscopy and spraying of the vocal cords with saline (Fig. 5-3),[17] there has been speculation that the peripheral receptors and central neural mechanisms mediating cough reflexes are ineffective early in life. This, combined with a musculoskeletal system that is undergoing development (e.g., compliant rib cage and airways, mechanically disadvantaged diaphragm), has led to the concern that cough is not only less common but also less effective in the neonatal period.[16] Studies in newborn animals have led to speculation that sparse RAR activity as well as lower activity of SARs in newborns contributes to the weaker response to tussigenic stimuli in the early stages of development.[18] In terms of changes with age, a cough reflex was present in 90% of infants older than 1 month (see Fig. 5-3),[17] suggesting that this potential impairment in lung defense is not long lasting in these otherwise normal subjects. This same investigation found that less than one half of premature infants had cough reflexes at comparable postnatal ages.

MUCUS SECRETION AND CLEARANCE

A critical mechanism for removing particles from the entire system of conducting airways (nasopharynx and tracheobronchial tree) is mucociliary clearance. The contributions of the nose to lung defense have been reviewed[19] and are not addressed except to emphasize that many larger particles are removed from inspired air in the nasopharynx before they enter the lungs. Particles that escape this first line of defense encounter a film of mucus that covers most of the surface of the tracheobronchial epithelium. Deposition on this film leads to eventual removal from the airways as the mucus is propelled to the oropharynx, where it, along with unwanted particles, is swallowed or expectorated.

Secretory cells and their products are important for maintaining a healthy environment within the lower respiratory tract.[20] Respiratory secretions consist of a double layer on the surface of the airway epithelium. The inner layer of periciliary fluid (sol phase) is the environment in which cilia beat and is probably supplied by transepithelial ion and water transport. The outer mucus layer (gel phase) is viscous in nature. Because it is nonabsorbent to water, it may prevent dehydration of the sol phase. Respiratory mucus in the tracheobronchial tree is produced by both submucosal glands and goblet cells. The former are confined to cartilaginous airways, whereas the latter extend farther into the periphery of the conducting airways. Although goblet cells are present in the epithelia of all ciliated regions of human airways, they become progressively fewer in number in the more distal bronchioles. The submucosal glands are primarily under parasympathetic neural control, and goblet cells secrete products when directly irritated. The thickness of the mucus layer is fairly constant, at least throughout the larger airways (5 to 10 μm). It appears possible that mucus is normally secreted in response to stimulation of the airway surface and that the small plaques generated in this fashion become the vehicles for removing trapped particles, including bacteria.[21] Mucus may appear to be a continuous sheet within the trachea because the impact of particles is greater in this larger airway and because mucus generated in all lower airways converges for clearance within the trachea. The importance of mucus in the defense of the lung was suggested by the observation that particle transport failed in the absence of mucus but was restored by the placement of autologous or heterologous mucus on the ciliated epithelium.[22]

Tracheobronchial mucus consists of a mixture of secretions from the surface epithelium and submucosal glands as well as tissue fluid transudate.[23] It is composed primarily of water (95%), glycoproteins (2% to 3%), proteoglycans (0.1% to 0.5%), and lipids (0.3% to 0.5%). The major glycoproteins are mucins which are found in two forms: the secreted gel-forming mucins which give the mucus its characteristic elasticity and the membrane-bound mucins present on the epithelial surface, which may act as cell surface receptors.[20] By forming oligomers, the mucin proteins form a gel that possesses fairly low viscosity and elasticity, allowing it to be easily cleared by the cilia. Although currently there are 19 identified mucin genes (MUC), the principal secreted mucins for the airway mucus gel are MUC5AC and MUC5B. MUC5AC mucins are produced predominantly by goblet cells in the surface epithelium, whereas the MUC5B mucins are secreted from the submucosal glands. The gel-forming mucins can be changed in amount, type, and size in certain inflammatory airways disease (e.g., asthma, cystic fibrosis) thereby impairing mucociliary clearance.[24]

Ciliated cells within the tracheobronchial tree of humans have approximately 200 cilia per cell.[25] Cilia are complex structures, with their axonemes enclosed in extensions of the epithelial cell membrane (Fig. 5-4).[26] Congenital ciliary defects that cause respiratory disease and infertility, as well as acquired abnormalities found in cilia, are dealt with in Chapter 67.

Cilia beat in one plane with a fast, effective stroke (power stroke) followed by a recovery stroke that is two to three times slower. The normal beat frequency in several species, including humans, ranges between 12 and 22 Hz.[27] Throughout most of the beat cycle, cilia move through the periciliary fluid beneath the layer of mucus, with their tips penetrating the mucus only during the effective stroke. Cilia work not alone but as members of a metachronous wave. Although there is evidence in mammalian respiratory epithelia for nervous and hormonal control of mucus secretions, there is no convincing evidence of direct nervous or hormonal control of ciliary beat frequency. Rather, it may be that an increase in the mucus load stimulates ciliary activity.[21]

Mucociliary Clearance as a Function of Age

Cells needed for the production and clearance of mucus are present within the developing airway from a very early period of prenatal development.[28] Ciliated cells are differentiated in the proximal airways by week 13 of gestation, with differentiation proceeding centrifugally during fetal development. Ciliary activity that is coordinated begins during the saccular phase. Submucosal or bronchial glands are present in the trachea by week 10 of gestation, whereas goblet cells appear by week 13. The rate at which mucociliary clearance occurs at various postnatal ages has not been well characterized because of the difficulty of performing such studies in infants and small children. However, it is known that mucociliary clearance does decrease in older subjects. By analyzing the decrease in the bronchial radioactivity of an aerosol of resin particles labeled with technetium 99m, researchers noted that clearance was significantly lower in subjects older than 54 years of age compared with subjects 21 to 37 years of age. In addition, a significant negative correlation was obtained between the ages of the healthy subjects and their rate of mucociliary clearance.[29]

PULMONARY INFLAMMATION

Nonspecific and antigen-specific (immune) mechanisms of lung defense commonly lead to an inflammatory response that is responsible for protecting this organ. Inflammation also has the potential to injure the lung,[30] but discussion of the deleterious aspects of inflammation is reserved for Chapters 6, 57, and 61.

Definition and General Features of Inflammation

Inflammation is broadly defined as a nonspecific protective reaction of vascularized tissues to injury.[31] The classic clinical features of this phenomenon are related to an increase in blood flow in vessels (calor and rubor), an increase in vascular permeability and cellular infiltration (tumor), and the release of materials at the site of inflammation that leads to pain (dolor). In general, this process is self-limited and leads to the return of the tissue or organ to a normal state both structurally and functionally.

The hemodynamic changes associated with inflammation are often the first to be manifested. Vasodilation, increased blood flow, and enhanced permeability are the fundamental elements of inflammation. These alterations apparently allow the body maximal opportunity to recruit inflammatory cells and bring plasma proteins to the site of injury. This has practical importance in terms of both effectively mounting an

appropriate response and limiting the process when it is no longer needed. For example, the plasma proteins may lead to resolution of the process by bringing plasma proteinase inhibitors to sites of inflammation (see later section).

The histologic picture seen in an acute inflammatory reaction within the lung is shown in Figure 5-5. The response was produced by the instillation of C5a des Arg into the peripheral airways of normal rabbits.[32] This proinflammatory (phlogistic) fragment is generated from the fifth component of complement (C5) during complement activation through either the classic or alternative pathway and induces neutrophil chemotaxis (directed migration of neutrophils), oxygen radical generation, and neutrophil granule exocytosis.[33] The same type of inflammatory response may be seen in other vascularized tissues of the body after exposure to C5a des Arg or in the lung after exposure to other stimuli, such as immune complexes and bacteria. Thus, this example is meant to display the typical histologic picture of inflammation within one region of the lung (alveoli). The sequence of permeability, neutrophil accumulation, and later mononuclear phagocyte infiltration occurs before resolution of the process. Over several days, the alveoli clear, and the alveolar walls assume their normal thickness and cellularity. A similar histologic evolution in terms of progression and resolution of the process is seen in both the large and small airways.[34]

One of the fundamental features of inflammation is the redundant nature of the process. Interactions of the kinin, clotting, fibrinolytic, and complement pathways are, in part, responsible for this redundancy in that they each permit generation of inflammatory mediators while also allowing for amplification of the response by recruiting mediators from the other systems. In addition, a mediator or mediators with similar actions may be produced by many different cells within the lung. Therefore, the inflammatory response is complex, with the possibility for generating multiple phlogistic mediators by several types of cells. This built-in redundancy amplifies the response in a normal individual and preserves the response if one system is deficient.

Ontogeny of the Inflammatory Response

Knowledge about the ontogeny of inflammatory responses within the lung is limited. Most studies of ontogeny have been performed in animals, leaving researchers to speculate

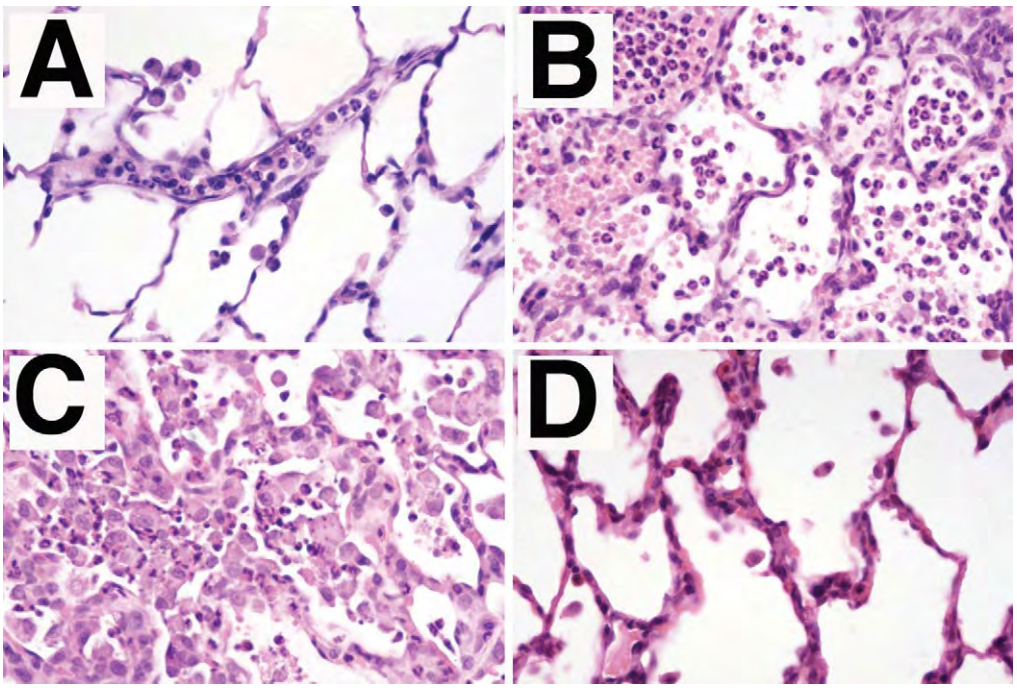

Figure 5-5 Inflammatory response produced by instillation of C5a des Arg into the airways of rabbits. **A,** In the normal lung, resident alveolar macrophages are present in some alveoli, but neutrophils are not seen. **B,** After 6 hours of administration of this C5 fragment, granulocytes (primarily neutrophils) and a protein-rich fluid are apparent in the alveoli. **C,** By 24 to 48 hours the neutrophils are replaced by mononuclear cells. **D,** Over several days, the alveoli clear, and there is almost complete return of the alveolar wall to its normal thickness and cellularity. (Courtesy Gary L. Larsen and Cori Fratelli: National Jewish Center for Immunology and Respiratory Medicine, Denver.)

about the relevance of the findings in humans. However, a few observations should be cited to stress that the inflammatory response has age-dependent features.

Macrophages have not been identified within the lung during the pseudoglandular and canalicular phases of fetal development.[35] In the rabbit, the influx of pulmonary macrophages into the alveoli precedes birth by several hours and occurs when phosphatidylcholine is released into the extracellular space by type II cells.[36] Animal studies have also shown that neonatal pulmonary macrophages have reduced opsonic receptor function, defects in ingestion or killing of bacteria, diminished free radical production, and impaired chemotaxis.[37] In terms of other inflammatory cells, some studies suggest that cellular functions (i.e., intracellular killing of organisms, oxidative metabolism, migration) of circulating human neutrophils are also immature in the neonate.[38] In addition, newborn and perinatal animals are hyporesponsive to several vasoactive mediators as well as mediators that produce directed migration (chemotaxis) of inflammatory cells.[39] This immaturity or defect in the pulmonary inflammatory response may help explain the observation that bacterial infections of the respiratory tract are frequently encountered and can be quite severe in the young infant (see Chapter 34).[37]

Chemical Mediators of Inflammation

An *inflammatory mediator* may be defined as a chemical messenger that acts on blood vessels and cells to contribute to an inflammatory response.[31]

VASODILATION

Of the features associated with the inflammatory process, vasodilation has been the least studied. Despite this limitation, this feature is generally considered to be critically important for the full expression of an acute inflammatory reaction. In this respect, local blood flow is an important determinant of the amount of exudate produced. A number of mediators, including histamine and various eicosanoids (products of arachidonic acid metabolism), are involved in the regulation of local blood flow. For example, prostaglandins (PGs) may exert their effects in part by modulating blood flow. In addition, it is now apparent that PGs can have marked proinflammatory effects as potentiators of the effects of other mediators. PGE_2 and PGI_2 injections induce vasodilation, presumably by acting on cells of the blood vessel wall.[31] In addition, vasodilator PGs have been detected in inflammatory exudates. At physiologic concentrations PGE_2 and PGI_2 have been shown to synergize with other mediators, such as histamine and bradykinin, to cause increased vascular permeability and edema.[40] Although prostaglandins have little or no effect on leukocyte migration in vivo,[40] a potentiating effect of vasodilator PGs has been noted with chemotactic factors,[41] suggesting that local vasodilation enhances the migration of neutrophils into tissue.

Other products of the cyclooxygenase pathway of arachidonic acid metabolism, such as thromboxane A_2, have vasoconstricting properties.[31] Thus, the eicosanoids generated during an inflammatory process may have contrasting actions. In addition, a vasodilating PG may have effects that may be either proinflammatory or antiinflammatory. For example, PGs may inhibit leukocyte and mast cell secretion,[31,40] thus limiting the inflammatory response. Therefore, the concentration and mix of mediators generated at a site within the lung may define the overall effect on the tissue.[42]

ALTERED PERMEABILITY

In many types of tissue injury, increased permeability occurs in at least two phases: an early, transient increase occurring almost immediately after an insult to the tissue and a late or second phase beginning after a variable latent period but persisting for hours or days. Evidence indicates that the early,

transient permeability seen with certain types of challenges is due to the release of histamine. Mediation of the delayed phase of exudation is more complex and has been attributed to various factors, including kinins, PGs, neutrophils, and lipoxygenase products of arachidonic acid metabolism.[31]

Histamine is the mediator most often associated with an early increase in permeability after various insults to the lung. Although histamine is widely distributed, the histamine contained in mast cells within the lungs provides the primary source for acute pulmonary inflammatory reactions. Mast cells are commonly located around blood vessels and may be stimulated to release their products by several stimuli, including various drugs, allergen immunoglobulin E (IgE) interactions, and complement fragments (C3a and C5a) produced through activation of either the alternative or the classic pathway. The concept that histamine increases vascular permeability by causing contraction of the endothelial cells of the postcapillary venule, thus creating inter-endothelial junctions for the passage of fluid and proteins, has been reviewed.[43]

Bradykinin can also increase vascular permeability. The generation of this mediator is complex and involves several steps and pathways.[44] First, Hageman factor (factor XII of the clotting system) is activated by contact with a negatively charged surface or by contact with a variety of biological materials. This enzyme then activates (and is activated by) plasma kallikrein. The kinin is cleaved from kininogen by this kallikrein or kallikrein from tissues, as well as possibly by other proteases such as plasmin. Once generated, kinins are rapidly broken down in plasma and tissues by kininases and within the circulation undergo almost complete inactivation during one passage through the pulmonary circulation.[45]

Platelet-activating factor, or acetylglyceryl ether phosphorylcholine, is another mediator that can cause increases in vascular permeability as well as other proinflammatory events.[46] When inhaled into the human lung, platelet activating factor is thought to generate secondarily eicosanoids,[47] making it possible that these secondary products are responsible for some of the acute effects of this mediator. Because of its ability to aggregate rabbit platelets, this lipid was initially referred to as *platelet-activating factor*. However, it has subsequently been shown to also be a potent chemotactic factor for polymorphonuclear leukocytes. In addition, the molecule causes these cells to degranulate and stimulates an increase in oxidative metabolism. Appropriately stimulated neutrophils, eosinophils, monocytes, alveolar macrophages, and endothelial cells synthesize and release this biologically active lipid.

Several other molecules generated within the lung can increase permeability.[31] These include fibrinopeptides, fibrin degradation products, various lymphokines, and anaphylatoxins (C3a, C5a).

CELLULAR INFILTRATION

As displayed in Figure 5-5, one of the most noticeable histologic features of an inflammatory response is accumulation of cells within the pulmonary tissue. Early in the reaction, the infiltrate is predominantly composed of neutrophils, whereas at a later time the picture is dominated by mononuclear phagocytes. The molecular mechanisms by which leukocytes migrate out of blood vessels are now being defined.[48] Central to the whole process is the concept that chemotactic factors are generated at an extravascular site and pass through the vessel wall to initiate the first step in the emigration of the cells from the vasculature: the adhesion of leukocytes to the endothelium. A number of inducible cell adhesion molecules, including vascular cell adhesion molecule-1 and intercellular adhesion molecule-1, have been identified as being critical to this process.[48]

Research in the area of inflammation has emphasized the identification of molecules that produce directed motion of inflammatory cells along a concentration gradient (chemotaxis). Some of the most potent neutrophil chemotaxins are C5 fragments.[32] These fragments are low-molecular-weight factors produced through the cleavage of C5 by a variety of endopeptidases. C5 convertases derived from the classic or alternative complement pathways cleave the 74-amino acid terminal fragment termed *C5a*. Other proteases, including plasmin, trypsin, kallikrein, and bacterial proteases, may cleave the C5 molecule at the same or a different site, generating fragments with similar biological activities.

Within the lung, the chemotactic factors produced by alveolar macrophages after various challenges probably act with the complement system to mount a full inflammatory response. Alveolar macrophages have been recognized for some time to synthesize and secrete low-molecular-weight protein chemoattractants as well as low-molecular-weight lipids with chemoattractant activity.[49,50] One characterized mediator that is a potent chemoattractant for neutrophils in vitro and that is expressed after immune stimulation of many cell types, including macrophages, is interleukin-8 (IL-8).[51] The observation that this cytokine may also be expressed in human bronchial epithelial cells[52] again underscores the potential for redundancy of the inflammatory process.

Other specific chemoattractants for inflammatory cells include lymphokines such as IL-1 produced by monocytes and macrophages,[53] factors produced by mast cells, and lipid mediators. One potent lipid chemotactic for neutrophils is the arachidonic acid metabolite, 5,12-dihydroxyeicosatetraenoic acid, or leukotriene B_4 (LTB_4). Arachidonic acid is converted to LTB_4 and related compounds in human neutrophils, monocytes, eosinophils, and macrophages. In some leukocytes, such as the human alveolar macrophage, LTB_4 may be the major product formed from arachidonic acid.[49,54] LTB_4 stimulates neutrophil chemotaxis, enhances neutrophil-endothelial interactions, and stimulates neutrophil activation, leading to degranulation and the release of mediators, enzymes, and superoxides.[54]

In much of the systemic microvasculature, the predominant site of neutrophil margination and emigration is the postcapillary venule.[55] In the lung however, much of the neutrophil sequestration and emigration occurs throughout the pulmonary capillaries.[56,57] Studies suggest that inflammatory mediators reduce the deformability of neutrophils in the narrow capillaries, thereby lengthening the capillary transit times, and/or stop neutrophils, increasing the concentration of neutrophils at inflammatory sites.[57]

OXYGEN RADICALS

The neutrophil is armed to use both the reduced form of nicotinamide-adenine dinucleotide phosphate (NADPH) oxidase system and the granule constituents in a cooperative

manner to fight invading organisms. In terms of the former, the plasma membrane of the neutrophil is the location of the enzyme NADPH oxidase that underlies this cell's ability to generate a family of reactive oxidizing chemicals, including superoxide anion, hydrogen peroxide, and the hydroxyl radical.[58] The bulk of superoxide generated by the cell dismutates to hydrogen peroxide, which is rapidly catabolized. Myeloperoxidase, an enzyme that is localized to the azurophilic granules of neutrophils and that is released in substantial amounts into the extracellular fluid when this cell is triggered, catalyzes peroxidative reactions.[59] In combination with hydrogen peroxide, myeloperoxidase can oxidize halides to their corresponding hypohalous acids. In most instances, this reaction involves chloride with the formation of hypochlorous acid (HOCl). Studies have now revealed that under a variety of conditions, human neutrophils can be triggered to generate HOCl as a major product of oxidative metabolism.[58] HOCl is a powerful oxidant that rapidly attacks biologically relevant molecules, creating a derivative group of oxidants known as *chloramines*. Although chloramines are less powerful oxidants than HOCl, they are able to chlorinate or oxidize a wide range of target molecules.[58,60] As long as hydrogen peroxide is supplied, myeloperoxidase uses plasma chloride to generate HOCl until the pool of oxidizable targets is consumed. Only then does HOCl generation come to a halt as the oxidant attacks and oxidatively autoinactivates myeloperoxidase itself.[60] Using in vitro systems, Klebanoff[59] and Test and Weiss[60] have shown that neutrophils can use the large quantities of reactive chlorinated oxidants to mediate extracellular cytotoxicity. However, it has been more difficult to implicate these oxidants in vivo. This is probably because most in vitro systems use simple, plasma-free buffers to maximize the interactions of HOCl and the target population of cells, whereas in more physiologic surroundings, HOCl attacks both cellular targets and plasma constituents. Thus, the oxidant's extracellular cytolytic potential is dissipated.

Another mechanism through which products of the respiratory burst might participate in lung defense is through the production of mediators of inflammation that potentiate an inflammatory response. A link may exist between the occurrence of aggressive oxygen species and the stimulation of eicosanoid biosynthesis.[61] Reactive oxygen species have also been shown to be signal transduction molecules to activate the chemotactic cytokine IL-8 and the cell surface adhesion protein, intercellular adhesion molecule-1, which orchestrate the transendothelial migration of neutrophils to sites of inflammation.[62]

NEUTROPHIL GRANULES

Neutrophils contain many storage granules, which in turn contain microbicidal substances and digestive enzymes.[49] There are four major groups of secretory compartments within neutrophils: primary (azurophilic) granules, secondary (specific) granules, tertiary (gelatinase) granules, and secretory vesicles.[63,64] The granules are distinguished by their protein content and the physiology of their secretory processes. Primary granules are related to lysosomes and contain myeloperoxidase (MPO); a variety of proteolytic enzymes, including elastase, cathepsins, and proteinase-3; and several microbicidal substances, including lysozyme, defensins, and bactericidal permeability increasing protein. Secondary granules contain most of the cell's lysozyme as well as lactoferrin, which may facilitate the formation of the hydroxyl radical,[65] making it a potentially important contributor to the microbicidal activity of neutrophils. Other specific granule contents include procollagenase, plasminogen activator, cytochrome *b*, histaminase, vitamin B_{12} binding protein, and receptors for fMet-Leu-Phe, iC3b, and laminin.[63] Tertiary granules contain gelatinase, a matrix metalloproteinase, and integrins. Secretory vesicles appear to replenish membrane enzymes (alkaline phosphatase and ATPase) on release to the cell surface after cell activation. Activation of neutrophils results in discharge of primary granules into developing phagosomes and the secretion of specific granule contents into these phagosomes as well as into the extracellular milieu. Thus, secondary granules are thought to have more of an external secretory function in cases in which their contents modify the external environment. This modification of the environment may be important for neutrophil infiltration into tissues as well as for tissue remodeling that is part of the reparative process after an insult.

A critical part of the role of the neutrophil in defense of the lung is the cell's adherence to and ingestion of particles and microorganisms by the process of phagocytosis and the subsequent killing of potentially pathogenic organisms.[63] The membrane surface components that mediate the phagocytosis of inert particles (e.g., carbon) are not well characterized. However, receptor-mediated phagocytosis can occur when microorganisms are opsonized by C3b, iC3b, or antibody. When neutrophils come in contact with such particles, there is an accumulation of actin filaments at the site of particle attachment. As the advancing pseudopod comes into contact with the particle, further receptor-opsonin interaction occurs. When the particle to be ingested is completely surrounded, the opposing pseudopods fuse to form a sealed phagosome within the cytoplasmic compartment. The contents of the phagosome fuse with primary granules to form the phagolysosome. Within the phagolysosome, defensins are major antimicrobial agents with activity against a variety of bacteria, fungi, and certain viruses.[66] The actions of these and other highly cationic proteins involve the donation of protons to form bonds with negatively charged substances at the microbial surface. Disruption of cell membrane permeability and transport mechanisms may lead to death of the cell. Other antimicrobial agents work through other mechanisms. For example, lysozyme is bactericidal because of its enzymatic cleavage of the β-1-4 bond between *N*-acetylglucosamine and *N*-acetylmuramic acid residues in bacterial cell walls. In addition to facilitating hydroxyl radical formation, lactoferrin may retard bacterial growth by binding iron so that it is not readily available to the microorganism. Elastase, a neutral protease found within primary granules, degrades proteins of gram-negative rods.[67] These and other microbicidal mechanisms of defense used by neutrophils have been reviewed.[63]

The contents of neutrophil granules also have the potential to injure the lungs and other organs.[58] Although neutrophil granules contain a large family of enzymes, their greatest potential for acting as mediators of tissue destruction probably resides in three particular enzymes: elastase and collagenase found in primary granules and gelatinase found in secondary granules. Normally, tissues are protected against

injury because they are bathed in powerful plasma antiproteinases. For example, the host's primary defense against unchecked elastase-mediated damage is α_1-proteinase inhibitor, a 52-kD glycoprotein that irreversibly inhibits neutrophil elastase by forming an enzyme-inhibitor complex. Additional protection is provided by the fact that metalloproteinases (collagenase, gelatinase) are synthesized in a latent, inactive form.

NONIMMUNOLOGIC RESPONSES OF THE LUNG

Stimuli Leading to Inflammation

Stimuli that produce inflammation may do so through immunologic and nonimmunologic mechanisms, part of the innate host response. For example, the inhalation of endotoxin or noxious gases may lead to inflammation through the direct effects of the agents without participation of antigen-specific cell or humoral mechanisms directed at the stimulus. Gram-negative bacteria to which the host has been previously exposed may produce inflammation through a combination of processes. Thus endotoxin within the cell wall may serve as a stimulus for the migration of polymorphonuclear leukocytes into the site of infection.[53] When bacteria-specific antibodies are also present, an antigen-antibody complex may also initiate an inflammatory reaction. Because both processes are critical in lung defense and may provide effective deterrents only when combined, their separate components should be understood. For this reason, various aspects of nonimmune and antigen-specific defenses are considered separately. As will become apparent, some cells (e.g., macrophages, mast cells) and extracellular factors (e.g., complement) have important roles in both types of defense.

Cells of Importance in Nonimmune Responses

Some resident cells within the respiratory tract can initiate and perpetuate inflammatory reactions by virtue of their location and cellular functions. These include pulmonary macrophages, airway epithelial cells, mast cells, and polymorphonuclear leukocytes.

PULMONARY MACROPHAGES

Macrophages are pulmonary representatives of the mononuclear phagocytic system and are present in alveoli and respiratory bronchioles (alveolar macrophages) as well as more central airways. For simplicity, the term *pulmonary macrophage* as used in this section refers to the entire population of mononuclear phagocytes within the lung, independent of the maturity of the cell, and thus includes recently recruited blood monocytes as well as macrophages that have resided within the lung for several weeks. The interstitial compartment as well as the walls of conducting airways also contain macrophages.[49] These mobile cells represent a critical line of defense against injurious agents that escape clearance by the mechanisms of impaction, cough clearance, and mucociliary clearance. Many of these cells reside within the periphery of the lung, where these protective mechanisms are no longer effective because of the small size and structure of the airways.

Pulmonary macrophages have an important role in maintaining normal lung function through their ability to scavenge particulates, kill microorganisms, recruit and activate other inflammatory cells, and function as accessory cells in normal immune responses. A critical activity of pulmonary defense is the phagocytosis and killing of microbial organisms performed by macrophages. Pulmonary macrophages engulf particulates, including microorganisms and macromolecular debris, nonspecifically as well as via a variety of receptors that include Toll-like receptors (TLRs), complement receptors that recognize C1q and C3b fragments, Fc receptors, and surfactant protein A (SP-A) receptors that recognize SP-A opsonized bacteria.[68] TLRs derive their name from the *Drosophila* protein Toll, with which they share sequence similarity. This family of receptors is recognized as important in host defense and function through recognition of primitive repetitive microbial patterns and subsequently produces a number of responses, including antimicrobial peptide production, cytokine release, and apoptosis.[69] Besides pulmonary macrophages, TLRs are also found on airway epithelial cells, neutrophils, lymphocytes, mast cells, and endothelium.[70]

The highly ruffled plasma membrane and numerous surface folds (lamellae) of a macrophage indicate the active motile and phagocytic potential of this cell. When a particulate is phagocytized in the airway, the macrophage is usually activated to release a variety of mediators both into the phagolysosome that surrounds the ingested particle and also into the local environment of the cell. Within the cell, the respiratory oxidative burst along with lysosomal proteolytic enzymes, phagolysosomal acidification, and microbicidal cationic proteins are used to kill ingested microorganisms.[68,71] In contrast to the mechanisms of killing described for neutrophils, mature macrophages have little myeloperoxidase, so production of the hypohalide radical is not a factor in macrophage defense unless there is a source of myeloperoxidase in the environment (neutrophils). Although macrophages are thought to be capable of protecting the lung against *Staphylococcus aureus*, they may require help from neutrophils to kill *Klebsiella pneumoniae* and *Pseudomonas aeruginosa*.[71] Thus, it is important that macrophages be able to initiate at least a localized inflammatory response with attraction of neutrophils so that certain microorganisms can be effectively eliminated from the respiratory tract.

The secretory products of pulmonary macrophages are diverse (Box 5-1) and include oxidants, bioactive lipids, cytokines, polypeptide growth factors, and proteases as well as antiproteases.[68] These products are important not only for host defense but also for the resolution of inflammation and repair of the lung (see later section). The secretory products also allow the pulmonary macrophages to initiate and perpetuate an inflammatory response by recruiting and activating other inflammatory cells, primarily neutrophils (Fig. 5-6) but also lymphocytes and monocytes. Specific chemotactic factors include LTB_4[54] and IL-8.[51] Chemotaxins produced directly or indirectly by neutrophils (see later section) may further amplify and propagate an inflammatory reaction.

The ultimate source of the majority of pulmonary macrophages appears to be the bone marrow.[72,73] Monocytes released from the bone marrow enter the lung, where they mature into tissue macrophages. The alveolar macrophage population is also replenished by local proliferation,[74] but it

BOX 5-1 Major Secretory Products of Pulmonary Macrophages

Products that Contribute to Pulmonary Defense

Toxic oxygen species
- Superoxide anion (O_2^-)
- Hydrogen peroxide (H_2O_2)
- Hydroxyl radical (OH)
- Hypochlorous acid (HOCl)

Proteases
- Elastase
- Collagenase
- Cathepsins

Complement components
- C1, C2, C3, C4, C5
- Factor B, factor B, properdin

Bioactive lipids
- Cyclooxygenase metabolites (PGE_2)
- Lipoxygenase metabolites (LTB_4, LTC_4, LTD_4)
- Platelet-activating factor (PAF)

Cytokines/Chemokines
- IL-1, IL-6, IL-8, IL-10, IL-12
- Transforming growth factor beta (TGF-ß)
- Tumor necrosis factor (TNF)

Products that Resolve Inflammation and Repair the Lung

Antioxidant
- Glutathione

Antiproteases
- α_1-Proteinase inhibitor
- α_2-Macroglobulin
- Tissue inhibitor of metalloproteinases

Polypeptide growth factors
- Fibronectin
- Platelet-derived growth factor (PDGF)
- Transforming growth factor-α (TGF-α)

appears that this mechanism is not nearly as important as movement of blood monocytes from the pulmonary capillaries into the lung. In contrast to neutrophils, pulmonary macrophages normally live for longer periods in this environment (weeks to months). The factors that stimulate the influx of monocytes into the respiratory tract during the normal migration of the cell from the bone marrow as well as during inflammatory processes are not as well characterized as those that attract polymorphonuclear leukocytes from the circulation. However, these factors may include complement fragments, fragments of the extracellular connective tissue matrix, and proinflammatory chemokines that are secreted by both resident alveolar macrophages and by airway and alveolar epithelial cells.[68]

AIRWAY EPITHELIAL CELLS

The airway epithelium has a barrier function that in itself is important in defending the lung from environmental pathogens. However, the metabolic activities of cells that line the airways may also be important in responding to potentially injurious agents. In this respect, human airway epithelial cells share with alveolar macrophages the ability to generate the products of arachidonic acid that may initiate or amplify an acute inflammatory reaction.[75] For example, one product of the 15-lipoxygenase pathway, 8,15-dihydroxyeicosatetraenoic acid, is nearly as potent as LTB_4 in its ability to produce chemotaxis of human polymorphonuclear leukocytes. As noted earlier, the potent neutrophil chemoattractant IL-8 may also be expressed in human bronchial epithelial cells.[52] These metabolic properties of airway epithelial cells, coupled with the strategic location of the cells within the respiratory tract, suggest that inhaled materials may stimulate the production of mediators capable of reacting to the challenge by mobilizing neutrophils to the airway. Studies using bronchial epithelial cells from species other than humans also suggest that these cells can produce chemotactic factors for other cells important in host defense and inflammatory responses, including monocytes[76] and lymphocytes.[77]

Airway epithelial cells also play an active role in host defense. Antimicrobial peptides (AMP) are expressed in the respiratory tract and act as endogenous antibiotics.[78,79] AMPs represent a diverse group of peptides with the principal families identified in the respiratory tract being the defensins and the cathelicidins. In vitro studies of animal models and cultured human airway epithelial cells demonstrate that defensins are induced by proinflammatory stimuli, such as cytokines secreted by activated macrophages, and bacterial lipopeptide.[78] Although AMPs are reported to have broad-spectrum activity against gram-positive and gram-negative bacteria, as well as against fungi and enveloped viruses, studies have primarily focused on their antibacterial activity. AMPs are bacteriostatic in nature and appear to mediate their function through disrupting the integrity of the bacterial cell membranes. AMPs also act as chemoattractants for inflammatory cells, including neutrophils, lymphocytes, and macrophages and, therefore, contribute to the inflammatory response.

Alveolar type II epithelial cells produce and secrete surfactant proteins A (SP-A) and D (SP-D) which are members of the collectin (collagen-lectin) family of proteins. SP-A and SP-D have been shown to play a critical role in the host defense of the lung against diverse bacterial, viral, and fungal pathogens.[80] These proteins bind to the surfaces of microorganisms and act as opsonins, thereby enhancing the clearance of these organisms by alveolar macrophages. In addition, SP-A and SP-D interact with various cell surface ligands on inflammatory cells, and activate or inactivate cellular function involving phagocytosis and production of cytokines and reactive oxygen species.[81]

MAST CELLS

Mast cells are frequently found at the interface of the internal and external environment, including the respiratory mucosal surfaces. Pulmonary mast cells are most abundant in the membranous portion of the trachea, beneath the pleura, and in the connective tissue surrounding the small airways and vessels.[82] In humans, mast cells are subdivided by neutral

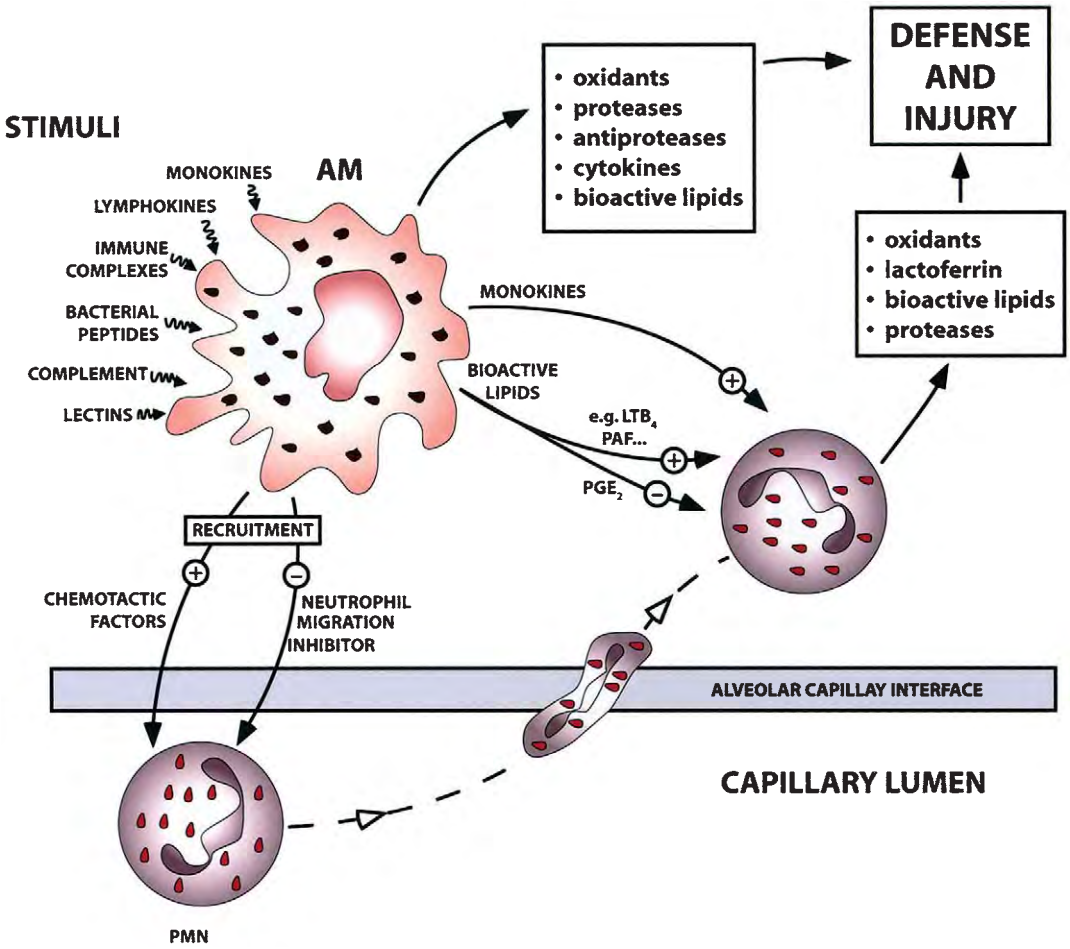

Figure 5-6 Interaction between alveolar macrophages (AM) and polymorphonuclear neutrophils (PMN) in the lung. On stimulation by various stimuli, AM release either chemotactic factors or inhibitory factors for PMN. Chemotactic factors will attract PMN from the capillary lumen to the alveolar space and once in the lumen, the PMN can be activated by various factors released from the AM. Macrophages can also inhibit PMN activity through the release of mediators such as PGE_2, which is important in the resolution of inflammation (see later section). Secretory products released by both AM and PMN are likely to influence defense and injury processes. (From Sibille Y, Reynolds HY: Macrophages and polymorphonuclear neutrophils in lung defense and injury. Am Rev Respir Dis 141:471-501, 1990.)

protease composition.[83] Mast cells with tryptase and not chymase are thought to predominate in the lung (90%), whereas mast cells with both tryptase and chymase make up the other 10% of mast cells identified by the dispersion of mast cells from human lungs. Mast cells are a repository of several mediators with significant inflammatory potential that might limit the entry of unwanted particles into the lung. Two classes of biologically active molecules have long been recognized to be produced by these cells: preformed mediators in secretory granules and membrane-derived lipid mediators, including LTB_4. Mast cells also produce and release other neutrophil chemoattractants including IL-8 and tumor necrosis factor (TNF)-α.[84]

Although mast cells have been most extensively studied in their traditional role as an early effector cell of allergic disease, mast cells have also been demonstrated to play a critical role in defense against bacterial infections, and potentially against viral and fungal pathogens.[85] The role of mast cells is not limited just to recruitment of effector cells via release of chemoattractants. Mast cells also possess a wide variety of membrane receptors that are thought to recognize various microorganims and their constituents, which facilitate its ability to engulf and kill bacteria—including *Escherichia coli* and *K. pneumoniae*.[84] Mast cells also possess a variety of membrane receptors for serum opsonins such as FγR, FcεR, and CR3—which could potentially facilitate mast cell activation by bacteria that are coated with IgG, IgE, and complement molecules, respectively. Mast cells are also known to produce antimicrobial peptides, including cathelicidins and defensins—another important aspect of their function in innate host defense.

POLYMORPHONUCLEAR LEUKOCYTES

Polymorphonuclear leukocytes (neutrophils, eosinophils, basophils) are normally present within the conducting airways and alveolar spaces in very small numbers and are thought to be virtually absent from the interstitial spaces of lung parenchyma.[86] However, a large number of neutrophils, estimated to be up to three times the circulating pool of this cell,[86] are marginated in the pulmonary vascular bed. This pool of cells, as well as the circulating cells, may be attracted to migrate into the lung.

As previously noted, several mechanisms may account for the recruitment of neutrophils into the respiratory tract. First, inhaled substances may directly attract neutrophils.[87] For example, chemotactic factors are present within certain microbial cell walls (formylmethionyl peptides). In addition, complement activation may result in the generation of potent neutrophil chemoattractants.[88,89] Resident alveolar macrophages may also release factors that attract neutrophils.[50] For certain inhaled stimuli, all three mechanisms may be operative and contribute to the pathologic picture.[87]

Neutrophils themselves have the potential to amplify an acute inflammatory reaction in various ways. For example, proteinases such as elastase and cathepsin G that are released from neutrophils during phagocytosis may cleave C5 to yield chemotactically active fragments. This may be especially important in patients with hereditary deficiencies of α-proteinase inhibitor.[90]

Once attracted into the pulmonary tissues, the actions of polymorphonuclear leukocytes include phagocytosis and the removal of particulates from the respiratory tract. The most effective phagocytosis is produced when there is opsonization of particulates with soluble material in the lung. Although the major opsonins are from the IgG class of specific antibodies (especially IgG1 and IgG3), other factors, including the complement fragment C3b, can function in this capacity. Within neutrophils, microbial killing is effected by a variety of systems, including oxygen-dependent and oxygen-independent mechanisms (cationic proteins, proteases, lysozyme).

Extracellular Factors Important in the Defense of the Lung

Although many factors with proinflammatory or antiinflammatory activity are found within the lung,[86,91] one group of proteins stand out in terms of their importance in host defense and participation in an inflammatory response: complement components.

COMPLEMENT

Activation of the complement pathway will lead to one of a series of results: direct lysis of targets, generation of peptides cleaved from complement that aid in the inflammatory process, and opsonization of targets that facilitates phagocytosis. Components of the complement pathways have been found within the lungs of nonhuman primates and humans as defined by examination of bronchoalveolar lavage fluid.[86,91,92] The third component of complement (C3) and the terminal components (C5 to C9) mediate most of the biologically important actions of this series of proteins. Three pathways of complement activation have been defined: (1) classic pathway, (2) alternative pathway, and (3) lectin pathway.[93]

The classic complement pathway is typically activated by antigen-antibody complexes with the involvement of IgM or the IgG1, IgG2, and IgG3 subclasses. Conversely, the alternative complement pathway, in which the early components of the classic pathway are bypassed, can be activated by a wide variety of substances, including complex polysaccharides, lipopolysaccharide, and some immune complexes.[94] The lectin pathway is initiated by the interaction of serum mannose-binding protein (MBP) with microorganisms that bear the appropriate carbohydrates (e.g., mannose, GlcNAc, fucose, and glucose) on their surfaces.[95] On activation, MBP will bind to MBP-associated serine protease (MASP) and activate complement proteins.

The three pathways and the complement components are displayed in Figure 5-7, where it can be seen that activation of the three pathways yields many of the same biologically active products. These products include powerful chemotactic factors derived from C5 that were detailed previously. Activation of the three pathways also leads to the formation of opsonins that facilitate the recognition and killing of microorganisms by phagocytic cells (iC3b). Bactericidal activity is also generated by the activation of the terminal components C5 to C9 and assembly of the membrane attack complex. The site of action of these terminal components appears to be the outer lipid membrane of gram-negative organisms.[96,97] An interesting facet of the complement system is that there exists redundancy in many areas of activity. Although complement deficiencies have been reported, deficiencies of complement protein early in the pathways are typically associated with milder clinical phenotype.[93]

From the standpoint of ontogeny, synthesis of certain components of complement (including C3 and C5) begin in the human fetal liver during the first trimester of gestation.[98] During fetal life, the liver and other tissues continue to produce complement components. Transplacental passage of complement proteins does not occur, and the levels of immunochemically and hemolytically detectable components in normal newborn sera range between 60% and 90% of those found in adult sera. Values found in preterm infants are even lower. The concentrations of these components increase in the first few years of life until they reach normal adult levels. Overall, the activity of alternative pathway components in newborn sera is less than that of the classic pathway proteins.[99]

OTHER FACTORS

Although the complement system is a cornerstone of the noncellular host defense systems, other factors found within the pulmonary environment also contribute to the protection of the lung. The iron-binding protein transferrin is found predominantly in the alveolar spaces,[100] whereas lactoferrin predominates along the airways.[101] Because iron is an essential ingredient for the survival of microorganisms, the ability of these iron-transport proteins to complex free iron in mucosal secretions and alveolar lining fluid may lead to the suppression of bacterial growth. In addition, human lactoferrin has a direct microbicidal effect on several bacteria, including *Streptococcus pneumoniae* and *E. coli*.[102] Two other components of normal bronchoalveolar lavage fluid can be thought of as nonimmune opsonins in that they have the ability to coat certain bacteria and enhance phagocytic uptake of the organism by alveolar macrophages. In this respect, fibronectin has been found to facilitate the uptake of bacteria by macrophages in vitro.[103] Other extracellular bactericidal factors of importance in pulmonary host defense (e.g., lysozymes, degradative enzymes) have been reviewed.[104]

As discussed earlier, various factors within the lung can function as opsonins. For each opsonin, an opsonin-specific membrane receptor on phagocytes is responsible for binding

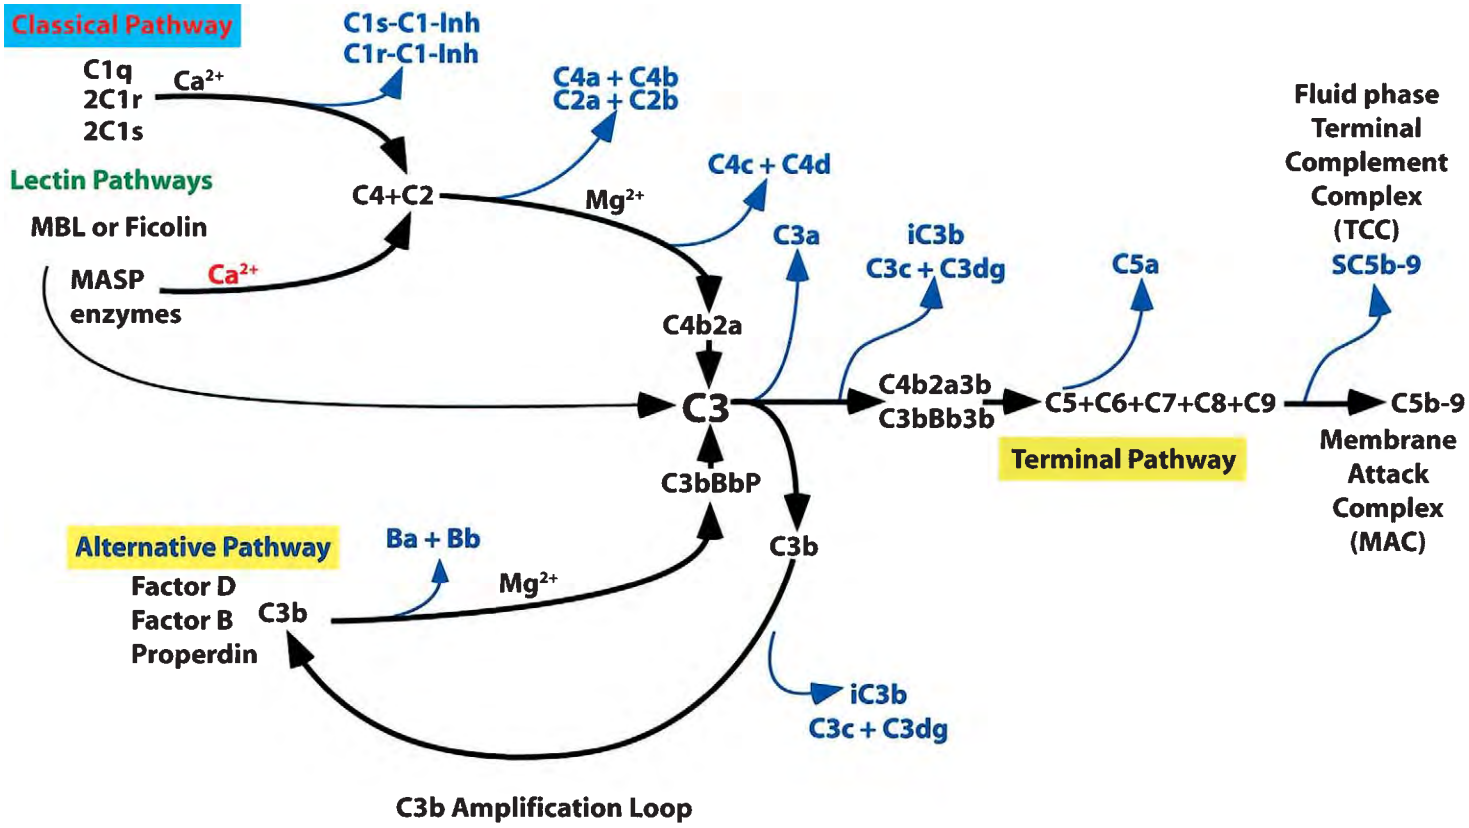

Figure 5-7 Diagram of the classical, lectin, and alternative activation pathways of the human complement system, showing the control steps and where some of the biologically active split products are produced. Products that are important in host defense include chemotactic factors (C5 fragments, including C5a), opsonins (iC3b), and factors with bactericidal activity (membrane attack complex, C5b-9). This system is an important component of the host defense response through its interactions with antibody and through mechanisms that are independent of antibody. (Modified with permission from Giclas P: Introduction. In Rose NR, Hamilton RG, Detrick B, [eds]: Manual of Clinical Laboratory Immunology, 6th ed. Washington, DC, ASM, 2002, pp 109-110.)

particles coated with the opsonin. For example, iC3b is one of the most important non-Ig factors with opsonic activity, with this function mediated via two types of phagocytic receptors: CR1 and CR3. It is beyond the scope of this review to present this information in more detail. Opsonization by various factors and the membrane receptors that help mediate this host defense have been reviewed.[105]

IMMUNOLOGIC RESPONSES OF THE LUNG

Most material with antigenic potential is effectively limited from producing an immunologic response by the mechanisms of defense previously outlined. Thus, for an immunologic response to occur, material must breach defense barriers and reach the responsive lymphoid tissue. When this occurs, a complex series of events transpires that subsequently provides antigen specificity to host defenses within the lung. This specificity is conferred by an elaborate system of receptors on T and B cells and through antibodies. In the context of antigen specificity, a basic function of the immune system is to differentiate "self" from "nonself" at a molecular level, thereby providing additional layers of defense against foreign materials.

It is clear from several lines of investigation that the lung can function as an immune organ. Furthermore, it appears that pulmonary immune reactions are fundamentally similar to those that occur systemically.[106] Although the many studies in which these conclusions were drawn were performed in animal models and not humans, these conclusions appear appropriate, based on current knowledge from many sources. The role of the lung as an immunologic organ has probably evolved in response to the routine exposure of the respiratory tract to microbes and foreign particles that takes place with ventilation.

Overview of Normal Immunologic Responses

Generation of immune responses can be thought of in terms of three functional limbs[107]:

1. The afferent limb includes the processing and presentation of antigen to lymphatic tissue.
2. A central limb involves the interactions of immunocompetent cells that lead to the generation of effector lymphocytes.
3. The efferent limb includes the processes associated with terminal differentiation of effector lymphocytes.

The immune system ultimately exerts its effects through circulating effector cells and molecules that act at locations within the respiratory tract that may be remote from the site of the initial interaction with antigen. In this respect, the immune system consists of two major effector systems: antibody- and cell-mediated immunity. In addition to specificity of antibodies and effector lymphocytes for foreign antigens,

immune responses are generally characterized by clonal expansion of antigen-reactive lymphocytes as well as memory, which leads to accelerated secondary immune responses to antigens.[106] Thus specific antibody and effector T cells may not appear for days after a nonimmune host encounters a foreign antigen that makes its way to lymphatic tissue, but specific antibody as well as sensitized T cells are more readily available in a sensitized host when the invading antigen again finds its way to the respiratory tract.

As noted, the initial phase of an immune response involves the processing, transport, and presentation of antigen to lymphocytes. This is accomplished when antigen deposited within the airways is taken up by an antigen-presenting cell, in which the antigen is processed by partial degradation. To be effective in antigen presentation, the cells must also display relevant antigenic determinants on cell surface membranes, express macromolecular gene products of the major histocompatibility complex (MHC), and secrete cytokines, including IL-1. The cells that can function in this capacity are discussed in a subsequent section.

Lymphocytes are the antigen-reactive cells of the immune system. They are distinguished primarily by certain characteristic cell surface markers called *clusters of differentiation* (CD) and by their receptors for antigen. The nomenclature of the CD markers as well as their expression as a function of T cell maturation has been reviewed in detail.[108] T cells recognize antigens by a membrane structure called the *CD3/T cell antigen receptor complex*, whereas B cells recognize antigens using surface Ig molecules. On T cells, the T cell receptor (TCR) is a disulfide-linked heterodimer composed of either α and β or γ and δ chains. Most mature T cells (more than 90% in both the blood and lungs) have an αβ TCR.[108] The function of T cells expressing the γδ TCR is not clearly understood but could include the downregulation of immune responses in bacterial infections.[109]

In a classic immune response to an exogenous antigen, the antigen-presenting cells interact with helper/inducer T cells (CD4+ cells) on which the TCR recognizes both antigen and class II MHC determinants on the cell presenting the antigen. Interaction of the two cell types, together with secretion of IL-1, leads to activation of the CD4+ cell characterized by elaboration of IL-2 and expression of IL-2 surface membrane receptors. The activated CD4+ cells undergo clonal expansion with differentiation into helper/inducer cells that can activate B cells as well as cytotoxic T cells (CD8+ cells). In addition, activated CD4+ cells can differentiate into effectors of delayed-type hypersensitivity in that this discrete subset of cells elaborate lymphokines such as interferon-γ (IFN-γ), which induce the accumulation and activation of macrophages in the region of the insult.

Pulmonary Cells Important in Immunologic Responses

ANTIGEN-PRESENTING CELLS

Accessory or antigen-presenting cells must be able to engulf and process an antigen by partial degradation. As noted previously, they also display relevant antigenic determinants on cell surface membranes, express both class I and class II macromolecular gene products of the MHC (surface membrane HLA-DR antigens), and secrete cytokines (IL-1 and others). Within the lung, dendritic cells and pulmonary macrophages appear to be the most important in terms of their antigen-presenting capabilities.[110] Dendritic cells have been recognized to be the chief orchestrators of immune responses.[111,112] Even in the absence of active infection, dendritic cells or their precursors are constantly recruited from the blood to the lung. This steady state influx is altered by the presence of inhaled antigens. Various stimuli can induce migration of dendritic cells and include microbial products and inflammatory chemokines, TNF, and IL-1.[113] In rats, inhalation of pathogenic material, such as bacterial or viral particles, induced a very rapid influx of dendritic cells into the airways, and this recruitment was as fast or sometimes ahead of the prototypic neutrophil influx.[111] This observation implies that dendritic cells are an integral aspect of early phases of the innate host response. After antigen capture, dendritic cells will migrate and transport the antigen to the pulmonary lymph nodes. One interesting aspect of this process is that it is rapid and can occur in the absence of any inflammatory stimuli.[111] In the lymph nodes, dendritic cells will interact with T cells to elicit a specific immune response.

LYMPHOCYTES

As with mononuclear phagocytes, lymphocytes are present at or near the airways extending from the nasopharynx to the alveolar spaces. Different levels of lymphatic tissue organization are identifiable in the lung and include lymph nodes (paratracheal and adjacent to major bronchi), lymphoid nodules and aggregates (throughout the submucosa of conducting airways), interstitial lymphoid tissue, and bronchoalveolar cells. The term *bronchus-associated lymphoid tissue* (BALT) has been applied to the organized tissue that is directly subjacent to the bronchial mucosa of the proximal conducting airways.[114] The nodules of lymphoid tissue that make up BALT are separated from the lumen of the airways by lymphoepithelium, a single layer of flattened epithelial cells that lack cilia and are infiltrated with lymphocytes. This structure is thought to facilitate antigen uptake. Although the contribution of BALT to local immune responses is not well defined, it may function as a repository of IgA precursor cells for the synthesis of secretory IgA.

The cellular population found within the more distal airspaces of the lung has become better defined with the use of fiberoptic bronchoscopy, with lavage as a method of sampling the cells and proteins within airways. In this respect, lymphocytes comprise approximately 7% to 10% of the cells obtained by bronchoalveolar lavage from normal humans.[86,91] Of the lymphocytes, the majority are T cells, with the overall number of T and B cells lavaged from airways closely approximating that found in peripheral blood. In addition, it appears that the relative ratio of helper to suppressor T cells in the compartment assessed by lavage is also similar to that in peripheral blood.

The major effector functions of activated T cells include regulation of the various limbs of the immune response, mediation of delayed-type hypersensitivity, and production of cell-mediated cytotoxicity. These biological functions are primarily distributed between CD4+ and CD8+ cells. CD4+ T cells can be divided into two main subsets with distinct cytokine secretion phenotypes, and different functions (Fig. 5-8). T helper 1 (T_H1) cells secrete IL-2, IFN-γ, and TNF-β

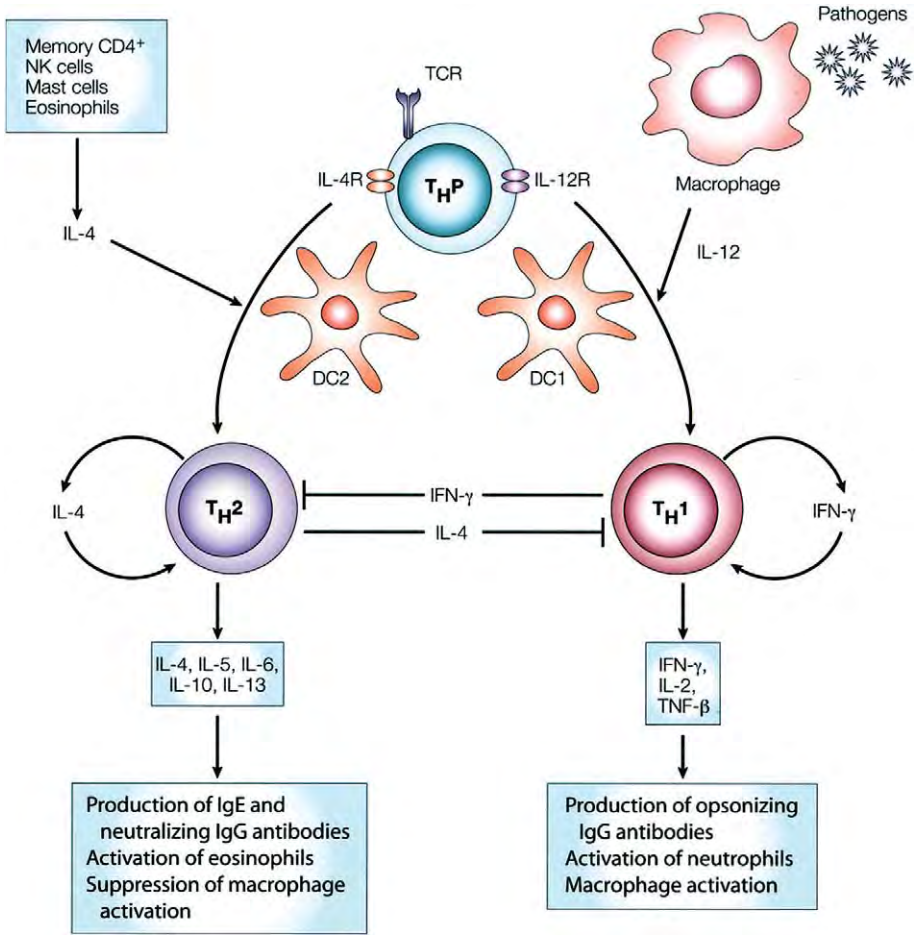

Figure 5-8 Schematic representation of induction and regulation of T_H1 and T_H2 cells. The same T_H-precursor (T_HP) cell can differentiate into T_H1 or T_H2 cells depending primarily on the cytokine microenvironment provided exogenously or from dendritic cells (DC1 or DC2). IL-12 drives T_H1 cells, whereas IL-4 promotes T_H2 cells. IFN-γ and IL-4, produced by T_H1 and T_H2, respectively, can also act as autocrine growth factors as well as inhibitory factors for the opposite subset. T_H1 produces IFN-γ, IL-2, and TNF-ß which mediate production of opsonizing IgG antibodies, activation of neutrophils, and macrophage activation. T_H2 produces IL-4, IL-5, IL-6, IL-10, and IL-13, which mediate production of IgE and neutralizing IgG antibodies, activation of eosinophils, and suppression of macrophage activation. IL-4R, IL-4 receptor; IL-12R, IL-12 receptor. (Modified with permission from Liew FY: T_H1 and T_H2 cells: A historical perspective. Nat Rev Immunol 2:55-60, 2002; Macmillan Magazines Ltd. www.nature.com/reviews.)

which are associated with cell-mediated immunity. The principal role of T_H1 cells is in promoting phagocyte mediated defense against infections. T helper 2 (T_H2) cells secrete IL-4, IL-5, IL-6, IL-10, and IL-13, which can modulate humoral immunity and play a major role in the development of IgE-mediated and mast cell/eosinophil-mediated immune responses.[109] T_H1 cells enhance the microbicidal activity of macrophages, induce IgG antibodies that mediate opsonization and phagocytosis, and support CD8+ antiviral effector T cells.[116] T_H1 cells are central to the development of the delayed-type hypersensitivity reaction. Antigen activation of T_H2 cells leads to the stimulation of IgE class switching in B cells, resulting in the production of antigen-specific IgE, which then mediates the activation of mast cells and eosinophils. The exogenous cytokine microenvironment and dendritic cell interactions strongly determine the nature of the resulting T cell response. IL-12 production drives the development of T_H1 immunity, whereas IL-4 production promotes T_H2 immunity and downregulates production of IL-12. It is thought that IL-12 production is initially triggered through activation of the innate immune response. Macrophages and dendritic cells are the main producers of IL-12; the role of dendritic cell in T_H1/T_H2 polarization has been reviewed.[113,116,117] The cellular sources of the initial burst of IL-4 are still not clearly understood, but could include natural killer (NK) T cells, mast cells, eosinophils, and mature CD4+ T cells.[115] The best understood function of CD8+ T cells is that of cytotoxicity. These cells may also function as suppressors or downregulators of immune response via nonspecific inhibitory cytokines.

Delayed-type hypersensitivity is important in the lung's defense against viruses, fungi, mycobacteria, and other intracellular parasites.[118] As noted previously, this type of response is mediated by T_H1 cells that elaborate lymphokines, inducing the accumulation and activation of additional lymphocytes as well as mononuclear and polymorphonuclear phagocytes. Activation of macrophages in such a fashion is felt to be an important factor in the containment and elimination of intracellular parasites such as *Mycobacterium tuberculosis*. Although the initial stimulus to T_H1 cell activation is antigen specific, the augmented microbicidal activity of macrophages is not restricted to the immunizing organism. In this manner, the T_H1 cells that mediate delayed-type hypersensitivity bring out the important but nonspecific effector cell functions of macrophages.[71] The cellular cytotoxicity mediated by CD8+ cells is important in host defense in that it destroys virally infected host cells. Virally infected host cells display viral antigens on their surface. The CD8+ antigen-reactive cell recognizes the viral antigen as foreign and differentiates into virus-specific cytotoxic T cells.

B cells are the effectors of the humoral arm of the immune response. B cells are present in the lung with the majority existing in BALT or the draining lymph nodes of the lung. B cell development can be divided into two phases: lymphopoiesis, where a multipotent stem cell in the fetal liver and bone marrow undergoes several maturational changes resulting in

mature B cells, and immunopoiesis, which culminates in the generation of a memory B cell or plasma cell.[119] Plasma cells constitutively produce Ig whereas memory B cells produce Ig only in response to reexposure to particular antigens. Mature B cells express both surface IgM and IgG. Crosslinking of these surface Igs with antigen results in B cell activation.

In addition to B and T cells, a third type of lymphocyte is present within the lung: the NK cell.[120] These lymphocytes can bind to and kill both virus-infected and tumor cells by production of cytokines and chemokines (including IFN-γ, TNF-α, IL-8), and by cell-mediated lysis of target cells. NK cells are large, granular lymphocytes that do not express on their surface the CD3 antigen or any of the known TCR chains (α, β, γ, δ) but do express certain characteristic differentiation antigens (CD56 and CD16) and mediate cytotoxic reactions even in the absence of class I or class II MHC expression on the target cells.[121] In children, the most important role of this group of cells may be defense against viral infections, especially members of the herpesvirus family. NK cells kill virus-infected host cells but not normal, uninfected cells. NK cells do not require prior exposure to antigen to respond and thus may provide an initial antiviral defense before antibodies and antigen-specific cytotoxic lymphocytes develop. Although these characteristics of NK cells suggest that they should not be included in a discussion of immunologically specific responses, it is important to note that NK cells also mediate antibody-dependent cellular cytotoxicity through a cell surface receptor located on this effector cell that binds the Fc region of Ig. Thus, antibody dependent cellular cytotoxicity provides a mechanism for NK cells to use the antigen specificity of antibodies to direct their killing activity. The cytotoxic effects of NK cells may also be increased by cytokines, including IL-12, as well as both INF-α and IFN-γ. Because interferons are induced during viral infections, they may play a role in the antiviral immunity mediated by NK cells. Dendritic cells can also influence the proliferation and activation of NK cells through production of IL-12 and through cell-surface interaction. In return, NK cells can provide signals that result in either dendritic cell maturation or apoptosis.[121]

Igs Within the Respiratory Tract

All major Igs (IgG, IgA, IgM, IgE) have been identified in bronchial secretions. Their presence is thought to reflect both local synthesis as well as transudation from serum. Because of relatively low molecular weight of Igs, transudation and exudation into airway secretions may be more important for most subclasses of IgG than for the other classes of Ig (see later section). Conversely, most of the IgA, IgM, and IgE in airway secretions is probably synthesized locally. The two major Igs within the respiratory tract in terms of lung defense are IgA and IgG. In contrast to the relative amounts of Igs found within the bloodstream, the concentration of IgG relative to IgA is low in upper airway secretions but increases in the lower airways so that IgG exceeds IgA in bronchoalveolar lavage fluid.[91]

IgG

An analysis of IgG subclasses was reported on bronchoalveolar lavage fluid analysis in normal adults.[122] In this study, concentrations of IgG1 and IgG2 in lung lavage were similar to those in serum. Local IgG3 concentrations were variable in relation to values in serum, but data pertaining to IgG4 suggested preferential accumulation of this IgG subclass within the lower respiratory tract.

Well-recognized biological activities of IgG are important in the pulmonary immune response of the respiratory tract. The formation of immune complexes either in a fluid phase or on the surface of a cell (including a bacterium and a fungus) leads to the generation of several biologically active products through the activation of complement. In addition, the IgG class of antibody (particularly IgG1 and IgG3) acts as opsonins, facilitating the recognition and killing of microorganisms by phagocytic cells. The frequency with which individuals suffering from agammaglobulinemia or hypogammaglobulinemic states develop significant pulmonary infections illustrates the important role played by this class of proteins in pulmonary defense.

IgA

Secretory IgA is the predominant Ig isotype in the respiratory tract above the larynx. As previously discussed, current evidence suggests that most of the IgA found within the upper and lower respiratory tracts is synthesized locally. IgA has two subclasses, IgA1 and IgA2. Although both subclasses are found in the respiratory tract, it is thought that IgA2 subclass is more important in mucosal immunity. Certain bacterial pathogens produce proteases for IgA1, whereas IgA2 is not susceptible.[119]

The biological activities of IgA relative to pulmonary defense have been reviewed[87] and include activation of the alternative complement pathway with the resultant generation of biologically active products as outlined in the discussion of the complement system. More important, IgA also inhibits viral binding to respiratory epithelial cells and neutralizes toxins. Regulation of antigen entry into the lymphoid tissue of the respiratory tract may also help prevent immune responses to antigens. This antibody isotype may also play a role in antibody-dependent cytotoxicity.

Ontogeny of Immunologic Responses

For the body to mount a fully developed immunologic response, several cells (e.g., macrophages, neutrophils) and mediator systems (e.g., complement pathway, products of macrophages) may be needed. The ontogeny of many of these cells and systems as they relate to lung defense have been summarized in preceding sections. It is beyond the scope of this text to review in detail the ontogeny of lymphocytes starting with fetal development. Therefore, emphasis is placed primarily on the ontogenic events associated with the perinatal period and extending into childhood. Comprehensive reviews that deal with the ontogeny of immunity[123] and the developmental immunology of the lung[98] are available.

All cells of the immune system are derived from pluripotential hematopoietic stem cells, which are first found within the blood islands of the yolk sac.[123] During embryogenesis, these stem cells will migrate to other sites of hematopoiesis: liver, spleen, and bone marrow. Stem cells responsible for generation of T cell and B cell lineage will migrate to the respective sites of development.

The fetal liver by 6 to 8 weeks' gestation contains prothymocytes, which are lymphoid cells that appear to undergo differentiation into T-lineage cells.[124] These prothymocytes colonize the fetal thymus at approximately 8 to 9 weeks' gestation. Shortly after colonization, thymocytes that express proteins characteristic of T-lineage cells are found. In humans, thymocytes from 9-week-old fetuses can express the γδ TCR.[125] By week 10 of fetal development, the αβ TCRs are found, followed by a progressive decrease in the number of thymocytes with γδ TCRs. T cells acquire maturational surface markers by about 16 weeks of gestation. An observed trait of neonatal T cells is their impaired function compared with adult T cells. Diminished functions include T cell-mediated cytotoxicity and T cell help for B cell differentiation. Neonatal T cells also exhibit poor cytokine production in comparison to adults, especially in relation to TH1 cytokines.[126] This particular trait of the neonatal T cell is thought to contribute to impaired responses of other neonatal cell populations that rely on these cytokines for their function. In postnatal life, lymphocytes develop in the primary lymphoid organs, namely the thymus and bone marrow. The development of diversity is felt to occur primarily in these organs, whereas clonal expansion can occur anywhere in the peripheral lymphoid tissue.[108]

The fetal liver is an important site for B cell differentiation during early development. B cells can be detected in human fetal liver at approximately 9 weeks' gestation. Although these cells express IgM on their surface, they lack other Ig classes. By 10 to 12 weeks' gestation, B cells expressing other classes of Ig are detected. B cells become detectable in the peripheral circulation at approximately 12 weeks' gestation and become abundant in the bone marrow at 16 weeks' gestation. Neonatal B cells have increased surface levels of IgM compared to adults and this difference persists for several years.

No information is available on levels of Igs within the respiratory tract of humans as a function of development. However, Ig levels within the blood have been defined as a function of age in healthy individuals.[127] At birth, normal neonates have approximately 10% of the normal adult level of serum IgM, near-adult levels of IgG (the majority from the mother), and little or no IgA. Adult levels of IgM are achieved by 1 to 2 years of age, whereas adult concentrations of IgG are achieved by 4 to 6 years of age. Adult levels of serum IgA are not usually attained until near the time of puberty. Given that IgG is the one antibody isotype found within the lung that relies heavily on transudation from the bloodstream (see previous section), the amounts found within the lung might be expected to reflect these ontogenic differences found within the blood.

The ability to mount an antibody response in the perinatal period differs both quantitatively and qualitatively from the response in an older child or adult. The IgM response is predominant and tends to be persistent, whereas IgG and IgA antibody formation is relatively deficient. Functional studies comparing in vitro responses of neonatal B and T cells with those of adult cells implicated both T and B cells in the impaired capacity to produce IgG and IgA.[123] It appears that in addition to providing poor helper function, neonatal T cells are active suppressors.

It is generally accepted that maturational deficiencies of the immunologic system exist in the young infant and child. This may contribute to the increased susceptibility of this population to infections, including pulmonary infections, and to mechanisms related to the development of tolerance to infection and/or predisposition to atopy.

RESOLUTION OF INFLAMMATION

Although a great deal of information is available on both antigen-specific and nonspecific mechanisms that initiate and perpetuate inflammation in defending the lung, much less is known about resolution of this response.[128] What is clear is if injury to the lung is to be prevented, all of the processes involved in the production of inflammation must be reversed. There must be removal of the stimuli responsible for inciting inflammation; dissipation or destruction of proinflammatory mediators; cessation of granulocyte emigration from blood vessels; restoration of normal vascular permeability and removal of extravasated fluids; limitation of granulocyte secretion of proinflammatory and cytotoxic agents; removal of bacterial and cellular debris and granulocytes and macrophages; and, finally, repair of any injury to the constitutive epithelial and endothelial monolayers.[129]

The host has several mechanisms in place to contain an inflammatory reaction once it has been initiated. Systems known to exist for these purposes include chemotactic factor inactivator and circulating inhibitors of the neutrophil proteinases. Chemotactic factor inactivator, a major serum regulator of C5 fragment-induced neutrophil chemotaxis and neutrophil lysosomal enzyme release, may also markedly reduce the chemotactic activity caused by macrophages stimulated with phagocytic and nonphagocytic stimuli.[130] This mechanism may be important in limiting the neutrophilic component of an inflammatory response once it has been triggered. The major circulating inhibitors of neutrophil proteinases include α_1-proteinase inhibitor as well as α_2-macroglobulin, the tissue inhibitor of metalloproteinases, plasminogen activator inhibitor-1, α_1-antichymotrypsin, C1 esterase inhibitor, and the more recently discovered secretory leukocyte protease inhibitor (SLPI) and elafin.[58,131] In the lung, SLPI is produced by Clara and goblet cells of the surface epithelium, and the serous cells of the submucosal glands. SLPI is also possibly produced by neutrophils, mast cells, and macrophages. Besides its function as a potent inhibitor of neutrophil-derived elastase and cathepsin G, SLPI has been shown to inhibit the proinflammatory activity of bacterial products such as lipopolysaccharide, and regulates the activity of inflammatory cells. This has been suggested by observations that SLPI inhibits nuclear factor-κB (NF-κB), which is a transcription factor involved in the expression of proinflammatory genes.[131]

During resolution of inflammation, the accumulated neutrophils need to be safely removed; apoptosis plays an important role in eliminating such neutrophils from inflamed tissues. The mechanism by which apoptosis occurs has been reviewed.[132,133] The removal of apoptotic neutrophils is essential to prevent the release of cytotoxic intracellular contents during lysis. Although macrophages are well known for acting as scavengers in removing debris, these cells also contribute to the resolution of inflammation by recognizing and ingesting these apoptotic neutrophils. An important observation is that uptake of apoptotic neutrophils suppresses the

release of proinflammatory agents (e.g., TNF-α, IL-8, granulocyte macrophage colony-stimulating factor) from macrophages.[134] These macrophages further suppress the inflammatory response by releasing antiinflammatory mediators, transforming growth factor-β (TGF-β), and PGE_2. TGF-β has also been implicated in fibrosis, tissue repair, and regeneration, suggesting that removal of apoptotic cells in inflammation may also promote the resolution process. The mechanisms by which macrophages recognize and ingest apoptotic neutrophils are an area of active study. A number of receptors have been identified in vitro. These include the vitronectin receptor (αv β3 integrin) which is thought to cooperate with CD36 in binding to thrombospondin on the surface of the apoptotic cell, a phophatidylserine-specific receptor, and scavenger receptors.[134] Alveolar macrophages may also help maintain normal lung architecture through their ability to contribute to both matrix synthesis and degradation by releasing growth factors (e.g., TGF-β, insulin-like growth factor-I) and matrix-degrading metalloproteinases, as well as their inhibitors.[68]

The initial cellular processes involved in tissue repair include matrix accumulation, cell migration, and proliferation of fibroblasts; in the later phases of repair there may be transient proliferation of epithelial and endothelial cells, cellular differentiation, matrix degradation, decreased fibroblast proliferation, and finally apoptosis.[135] Apoptosis is an integral step in tissue repair because this is a likely mechanism for the elimination of granulation tissue. It may also rid the repairing alveolar epithelium of excess hyperplastic type II alveolar epithelial cells.[136] Proliferation of type II cells is thought to occur in the early phases of the repair process. With the elimination of excess type II cells, it will allow the spread and differentiation of the thinner type I cells, which is essential for optimal gas exchange. Although epithelial monolayers display a remarkable capacity to regenerate in the face of insult, if the injury is too extensive, particularly if the basement membrane structural integrity is lost, it is thought that the lesion will heal by an excessive fibrotic response.[137]

Many factors determine whether a pulmonary inflammatory response resolves after protecting the lung or persists and damages the host. A critical determinant is the nature of the insult. The physical characteristics of the agent also help determine how the inflammatory response is initiated (e.g., direct stimulation to lung parenchyma or immune or inflammatory cells, antigen presentation to immunocompetent cells, direct activation of complement). Other factors of importance include the concentration of the foreign agent as well as the length and frequency of exposure to it. In addition to inciting the inflammatory response via one of these pathways, the provoking agent certainly has an effect on the processes that control the progression and resolution of a normal inflammatory reaction. For example, inflammation may become chronic because of the persistence of the etiologic agent, such as when an intracellular parasite of low virulence survives and replicates, producing sustained inflammation. Other scenarios that lead to lung injury and influence the process of repair are discussed in Chapter 6.

CONCLUSIONS

The importance of an anatomically normal respiratory tract as well as intact humoral and cellular mechanisms for effective defense of the lung is readily apparent.[1,2,106] The pulmonary sequelae of an impaired or absent cough reflex (see Chapters 25 and 26), abnormalities of ciliary function (see Chapter 67), Ig deficiencies (see Chapters 36 and 51), and defects in oxidative metabolism in the neutrophil (see Chapter 51) all attest to the importance of these mechanisms in defending the lung against invading organisms. In general, the body is well equipped to handle challenges from the environment with a built-in redundancy in lung defense that helps ensure the integrity of the organ.

An important part of lung defense is the inflammatory reaction that can be initiated by both antigen-specific and nonspecific mechanisms. Pulmonary inflammation is generally beneficial to the host and resolves without significant sequelae because of an extensive array of checks and balances. However, it is also important to realize that when part of the checks and balances is lacking (e.g., deficiency of α-proteinase inhibitor), inflammation may eventually harm the host (see Chapter 71). In addition, if this programmed response goes awry (see Chapter 44), is prolonged, or is inappropriate in magnitude (see Chapter 57), lung dysfunction and irreversible injury are produced. Given the variety of environmental insults to which the lung is continuously exposed and the complexities of the processes that defend the respiratory tract, it is remarkable that lung disease is the exception. Indeed, most children never experience significant pulmonary disease because of the efficiency of these elaborate and complementary systems of defense.

CHAPTER 6

Mechanisms of Acute Lung Injury and Repair

Kevin C. Doerschug and Gary W. Hunninghake

TEACHING POINTS

- Acute lung injury represents a common pathway of cellular and chemical processes despite a wide array of underlying causes.
- Inflammation causes alveolar permeability and leads to extravasation of protein-rich fluid into the alveolar space.
- Leukocytes, endothelium, and epithelium all actively contribute to the injury process.
- Mediators of injury are also mediators of host defense, which makes physiologic studies (and treatment) complex.

BACKGROUND

The term *acute lung injury* (ALI) refers to a syndrome of diffuse pulmonary inflammation and increased capillary permeability that manifests in acute refractory hypoxemia and lung infiltrates. Although references date through the last century, the first formal description of the syndrome is attributed to Ashbaugh in 1967.[1] Historically, reports of the syndrome have included terms such as *adult respiratory distress syndrome* and *shock lung*, thus emphasizing specific patient populations or predisposing conditions. More recently, hyaline membrane disease of newborns has been recognized as sharing the same radiographic and histologic findings, and being mediated by the same cellular and soluble factors, as the syndrome seen in adults with septic shock. To incorporate all continuums of patient populations and the vast variety of primary insults that lead to the final common pathway of diffuse pulmonary parenchymal damage, the more inclusive terms acute lung injury (ALI) and *acute respiratory distress syndrome* (ARDS) are now favored. The first American European Consensus Conference[2] defined ALI as (1) acute onset of bilateral infiltrates consistent with pulmonary edema; (2) the absence of evidence for left atrial hypertension; and (3) reduced ratio of arterial oxygen tension (PaO_2) to the fraction of inspired oxygen (FIO_2), PaO_2/FIO_2. The syndrome is called ALI when PaO_2/FIO_2 >300 and ARDS when this ratio falls below 200. The consensus definitions of ALI/ARDS have allowed for extensive clinical and translational research into the mechanisms of lung injury and repair.

STRUCTURE AND FUNCTION

Radiographic and Pathologic Aspects

Acute lung injury's hallmark finding of noncardiac pulmonary edema from alveolar capillary disruption usually appears several hours after an initial predisposing insult, but may not be detected for up to 72 hours. Clinical aspects of ALI are covered in more detail in Chapter 19. The syndrome of ALI has been attributed to an extensive and broad list of inciting causes that are frequently divided into direct (or primary pulmonary insult) and indirect (extrathoracic insult with systemic involvement) insults. A direct insult to the lung stimulates alveolar macrophages to produce a cascade of cytokines including tumor necrosis factor-alpha (TNF-α) and interleukins (IL),[3-5] which in turn recruit further cellular and biochemical responses that characterize the clinical effects of acute lung injury including fever, epithelial injury, and increased endothelial permeability.[6] The pulmonary response to an indirect insult is commonly considered to be part of the so-called *systemic inflammatory response syndrome* (SIRS), and mediated by migration of proinflammatory cytokines[7,8] and microbes[9-11] through the systemic circulation. Many of the local and systemic mediators of ALI are included in Table 6-1. Regardless of the nature and anatomic location of the initial insult, the clinical physiology and pathologic findings within the lungs are remarkably similar, indicating a common final pathway of injury.

The acute phase of lung injury is also characterized by reduced respiratory system compliance and pulmonary hypertension. The latter, in conjunction with increased capillary permeability, leads to pulmonary edema, which is contrasted to congestive heart failure by the finding of protein-rich fluid in the alveoli of those with ALI.[12] Despite vast differences in the molecular characteristics of noncardiogenic edema fluid, chest radiograph findings are indistinguishable from those depicting cardiogenic pulmonary edema[13]—ranging from asymmetrical patchy infiltrates to dense consolidation and may also include pleural effusions.[14,15] Chest computed tomography indicates heterogeneous involvement of injured lungs with a dependent gradient of consolidation that results in reduced effective alveolar surface area.[16] This consolidation relates to prognosis in that the percentage of lung units that can be recruited by increasing ventilatory support correlates with mortality.[17] In parallel, measure-

Table 6-1
Mediators of Acute Lung Injury

Factor	Class	Main Cell of Origin	Major Effects
Tumor necrosis factor-alpha (TNF-α)	Cytokine	Macrophage	Activate endothelium Induce nitric oxide synthesis Stimulate IL-1 production Fever, mobilize metabolites
Interleukin-1β (IL-1β)	Cytokine	Neutrophil, endothelial cell	Activate endothelium Stimulate IL-6 production Local tissue destruction Fever, mobilize metabolites
IL-6	Cytokine	Macrophage, endothelial cell	Activate lymphocytes Stimulate antibody production Fever
IL-8	Cytokine	Many	Stimulate neutrophil transmigration Degranulate neutrophil (oxidative burst)
IL-10	Cytokine	Many	Suppress proinflammatory cytokine expression
Vascular endothelial growth factor (VEGF)	Soluble protein	Many	Activate endothelium Induce permeability Stimulate adhesion molecules
Intracellular adhesion molecule (ICAM)	Adhesion molecule	Endothelial cell	Attract leukocytes to injured endothelium
Vascular adhesion molecule (VCAM)	Adhesion molecule	Endothelial cell	Attract leukocytes to injured endothelium
Nuclear factor kappa-B (NF-κB)	Transcription factor	Many	Increase transcription of proinflammatory mediators
CD14	Cell surface receptor	Macrophage	Bind bacterial endotoxin Activate macrophage
Toll-like receptor (TLR)	Cell surface receptor	Macrophage	Bind bacterial endotoxin Activate macrophage

ments of physiologic dead space correlate inversely with the prognosis of patients with acute lung injury.[18] It is important to note that lung areas that appear radiographically normal exhibit significant biochemical abnormalities on analysis of bronchoalveolar lavage fluid.[19]

Post-mortem examination of lungs from ALI patients reveals heavy, congested, and atelectatic lungs. The majority of autopsy organs show evidence of infection[20] even though pre-mortem studies reveal pneumonia at a much lower rate[21-23]; whether this is due to sampling errors or antibiotic effects on clinical evaluation is not clear. During the acute or exudative phase of ALI, biopsies display hyperemia and evidence of both epithelial and endothelial cell injury.[24,25] Endothelial cells are swollen, with decreased cell-cell adhesion leading to extravasation of microthrombi and polymorphonuclear neutrophils (PMNs) into the interstitium. Denudation of the alveolar epithelium leads to flooding of the alveoli with proteinaceous fluid, immune cells (largely PMNs) and red blood cells. Alveoli may be atelectatic and hyaline membranes are seen on the epithelial side of the basement membrane. The exudative phase of ALI usually persists for several days, after which many patients have rapid clinical improvement with resolution of parenchymal injury. This resolution is marked by a return of macrophages as the prominent luminal cell,[26] whereas type II pneumocytes re-epithelialize the alveolus, differentiate into type I pneumocytes, and restore epithelial barrier function. Other patients develop a prolonged fibroproliferative phase characterized by the absence of type II pneumocytes and the proliferation of myofibroblasts, fibronectin, and collagen within the alveoli.[27] It is not clear what triggers this prolonged recovery phase in some individuals with ALI, but these findings on lung biopsy signal an ominous prognosis. Attempts at reducing or reversing the fibroproliferative phase with corticosteroids showed initially promising results,[28,29] but ultimately corticosteroids have yet to be proven beneficial in larger studies of patients with ALI.

CELL-MEDIATED LUNG INJURY

Neutrophils

Biopsy and bronchoalveolar lavage specimens from patients with ALI are dominated by neutrophils, and intense investigations into the function of these cells during clinical illness have uncovered numerous processes mediated by PMNs. Neutrophils are recruited to injured sites by the expression of adhesion molecules including intracellular adhesion molecule (ICAM)-1 and E-selectin on activated endothelial cells, and plasma levels of these adhesion molecules correlate with the degree of organ dysfunction.[30] Once recruited to the alveolus, neutrophils in patients with ALI demonstrate activation of the transcriptional regulatory unit nuclear factor kappa-B (NF-κB), which in turn increases neutrophil expression of IL-1β and other proinflammatory mediators implicated in tissue injury. Accordingly, both the persistence of alveolar neutrophils and the activation of NF-κB within neutrophils[31] correlate inversely with survival. Following activation, neutrophils orchestrate a process of oxidative burst which generates hydrogen peroxide and other reactive oxygen and nitrogen species that destroy invading pathogens. This free-radical stress also culminates in oxidized host phospholipid membranes that alter mitochondrial and cellular function and compound tissue injury. Neutrophils may play a key role in the apoptosis (or programmed cell death) of immune cells in the lung through regulation of phosphatidylinositol-3 kinase (PI-3K) pathways.[32]

The association of neutrophil number and activation with outcome provides strong evidence of the involvement of these leukocytes in the injury pathways, yet tremendous controversy persists regarding the importance of PMNs in the pathophysiology of ALI. Attempts to mediate neutrophil

activation have led to conflicting results, raising questions regarding PMN function. This controversy is at least in part due to the recognition that these processes contribute to organ injury but are also key mediators of host defense. For these reasons, clinical and translational research continues in this important area.

Macrophages

The predominance of neutrophils in lung specimens obtained during ALI has drawn attention away from monocytic cell lines, including the macrophage. Alveolar macrophages are the resident immune cell in the lung, and represent the innate host defense system and as such initiate many of the processes leading to the intense inflammatory response of ALI (Fig. 6-1). Importantly, key macrophage activity may precede the clinical recognition of the disease. Alveolar macrophages recognize pathogens or their products through various cell surface receptors. In the most well-characterized system, pathogens or their products initially bind to CD14 which in turn recruits Toll-like receptor (TLR) subtypes that are specific for the toxin.[33-35] Together, toxin binding to CD14/TLR leads to activation of the macrophage and a subsequent intense inflammatory response. In addition to CD14 on the cell surface, macrophages release a soluble form of the receptor, sCD14, which activates cells that do not express CD14 (most notably endothelial and epithelial cells). The importance of sCD14 is demonstrated by the finding that the concentration of this protein in alveolar fluid is highly associated with the number of neutrophils in the lung.[36]

Once stimulated, macrophages display mobilization of NF-κB to the cell nucleus.[37] In contrast to neutrophil activation, macrophage activation is more characterized by the production of TNF-α[38] although certainly IL-1β is secreted as well. Like the macrophages themselves, TNF-α levels peak[38] and wane early in the disease process, making investigations, or manipulations, of TNF-α-mediated processes in humans difficult. In addition to TNF-α, the secretory products of activated macrophages form a list that is extensive,[39] redundant, and interactive in function, and summate to sequester and stimulate neutrophils in the lung early in ALI.[38]

The return of macrophages as the dominant alveolar cell line signals resolution of ALI,[26] supporting the notion that macrophages are also involved in the regulation of tissue injury. Further support is garnered by findings that alveolar macrophages possess surface receptors for neutrophil proteases,[40] and can scavenge hydrogen peroxide and limit oxidant-mediated injury.[41] Finally, macrophages phagocytose neutrophils in vitro in a time-dependent manner that corresponds to the clinical time course of resolution.[42] Taken together, these observations lend credence to the importance of alveolar macrophages in the resolution of ALI.

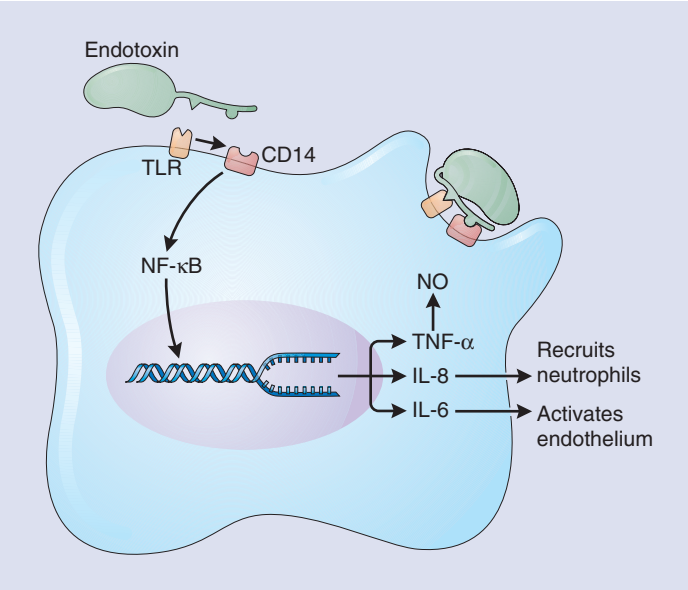

Figure 6-1 The alveolar macrophage in acute lung injury. Pathogenic bacteria are recognized by a family of Toll-like receptors (TLRs) which present the pathogen to the cell surface receptor CD14. Together, these receptors mobilize NF-κB to the nucleus where it facilitates gene transcription of several proinflammatory factors. Tumor necrosis factor-alpha (TNF-α) stimulates other immune cells and leads to the production of nitric oxide, which promotes both killing of engulfed bacteria as well as tissue injury. Stimulated macrophages also produce interleukin (IL)-6, which activates endothelial cells, and IL-8, which recruits neutrophils to the site of injury.

Endothelial Cells

The histology of ALI clearly documents altered capillary endothelial cells, and some consider ALI as a continuum of "panendothelial disease" resulting from the systemic inflammatory response syndrome.[43] This not only pertains to indirect, but also direct causes of ALI, as alveolar TNF-α affects the adjacent endothelium.[44] Once considered a relatively static cell line, the endothelium is now recognized as an active tissue that regulates blood flow, immune function, and solute transport. Whether the noted changes represent an injury to the endothelial cell or an activation of this cell line is controversial. Most likely, there is a continuum of altered endothelial processes that, if allowed to persist unabated, lead to irreversible loss of normal function. Because endothelial cell changes in ALI involve a loss of normal cell function and the extent of endothelial changes is related to the severity of disease, the term *endothelial injury* will be used throughout this chapter. This view is exemplified by findings that von Willebrand factor antigen (vWf, normally found in large concentrations only within endothelial cells) is released from injured cells into the vessel lumen and into the alveolar space. The extracellular concentrations of vWf are predictive of the development of ALI in those at risk,[45] and of outcome in patients with established ALI.[46,47]

Systemic inflammation leads to the secretion of vascular endothelial growth factor (VEGF) from many different cell lines. VEGF, also known as *vascular permeability factor*, induces many of the endothelial changes seen in ALI. Once injured, the endothelium transforms from a flat monolayer with tight intracellular junctions to an irregular surface of rounded endothelial cells and a loss of cell-cell interactions. This state creates a permeable surface such that fluid can escape capillaries into the interstitium and ultimately the alveoli. Extravascular lung water is clearly deleterious to gas exchange, but the injured endothelium also allows plasma proteases to exit the vessel and impair alveolar surfactant function and contribute to atelectasis.[48]

The role of endothelial cells in lung injury extends beyond a passive loss of barrier function leading to extravasation of vessel contents into the alveoli. VEGF stimulates the expres-

sion of several adhesion molecules on the luminal surface of endothelial cells, particularly intracellular adhesion molecule (ICAM), vascular adhesion molecule (VCAM), and the selectin family of glycoproteins. Together, these adhesion molecules function to slow neutrophil transport within the vessel and initiate rolling and adhesion of neutrophils on the endothelial surface (Fig. 6-2). Additional chemotactic molecules on the basolateral surface and beyond then promote transmigration through the permeable endothelium. VEGF is downregulated by endothelial-derived factors and this function is lost during sepsis; hence, the loss of normal endothelial function contributes to further endothelial injury. Importantly, manipulations to decrease expression of VEGF lead to decreased organ injury and improved mortality in live-infection models of sepsis, demonstrating the importance of VEGF and the related adhesion molecules in the progression of disease.[49] Consistent with these findings, the concentrations of endothelial-neutrophil adhesion molecules are more strongly associated with mortality in humans than are measures of neutrophil activation.[30]

Beyond neutrophil recruitment, endothelial cells propagate the inflammatory response by secreting cytokines, including IL-1 and IL-6. These inflammatory mediators further stimulate endothelial cells to decrease tissue-type plasminogen activator and increase plasminogen activator inhibitor activities[50] as well as decrease thrombomodulin secretion,[50] and thus induce the procoagulant state found in the alveolar fluid of patients with ALI.[51] Injured endothelial cells have diminished capacity to secrete endogenous vasoconstrictors and vasodilators necessary to regulate blood flow.[52] Endothelial cells exhibit injury that is evident on pathologic studies, but they clearly mediate the injury pattern and contribute to the morbidity and mortality of ALI.

Epithelial Cells

Histologic analysis shows diffuse alveolar damage during clinical ALI, and altered epithelial structure is evident. The lung epithelium has many functions during health, and many of these functions are lost during acute inflammatory processes. Epithelial damage clearly contributes to the pathogenesis and morbidity of ALI.

Increased capillary permeability may present a conduit for vascular contents to extravasate into alveoli, but there is a growing body of evidence describing ineffective clearance of alveolar fluid by epithelial cells leading to the clinical findings of noncardiogenic pulmonary edema. The epithelial surface is lined mainly with type I pneumocytes that maintain the structural integrity of the alveolus through barrier function. The remaining cells in the lung epithelium are type II pneumocytes, whose diverse functions include ion transport regulation, surfactant production, and regeneration of type I pneumocytes. Defects in epithelial function lead to alveolar fluid accumulation in two ways—increased permeability and decreased fluid transport out of the alveoli. However, the epithelial barrier is less permeable than the endothelium, even after injurious exposure,[53] suggesting that defects in alveolar liquid clearance play a large role in the accumulation of extravascular lung water. Indeed, the rate of alveolar fluid clearance is impaired in patients with ALI, and inversely related to prognosis.[54] Transepithelial transport of fluid occurs in several fashions, the best described being along an osmotic gradient formed by active transport of sodium via a Na^+/K^+-ATPase on the basolateral surface of type II pneumocytes.[55] Experimental evidence shows that hypoxia leads to displacement of the Na^+/K^+-ATPase from the basolateral surface—a condition that is rapidly reversible with alveolar instillation of the beta-adrenergic agonist, terbutaline.[56] Although the role of Na^+/K^+-ATPase in human ALI is still unclear, beta-agonist administration decreases total lung water in ALI patients, lending support to this hypothesis. Alveolar fluid clearance is impaired by several factors in addition to hypoxia. The generation of reactive oxygen and nitrogen species, possibly caused by free-radical deactivation of transport proteins, diminishes epithelial fluid transport.[57,58] Epithelial function is likely impaired through a loss of epithelial cells through the process of apoptosis.[58]

With the progression of ALI and loss of epithelial integrity, inflammatory mediators and bacteria normally contained by

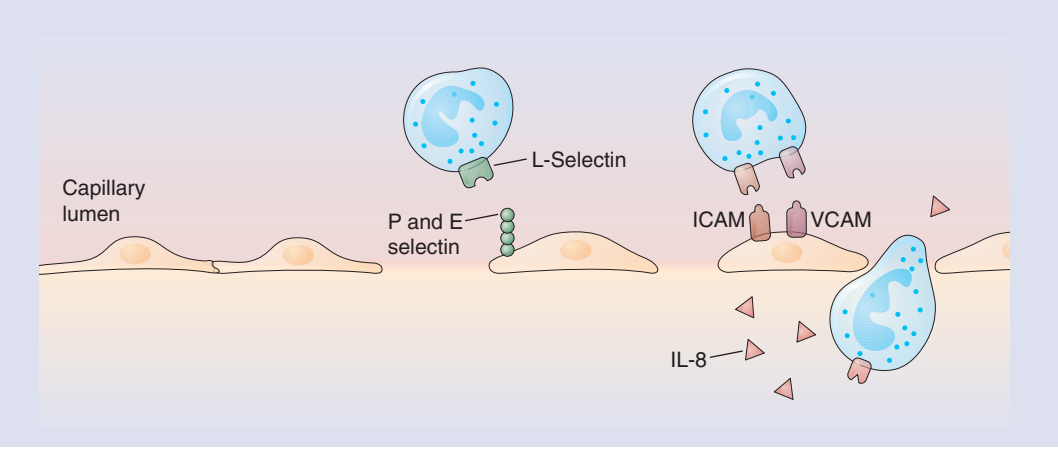

Figure 6-2 Endothelial-neutrophil interactions in acute lung injury. Endothelial cells become activated through a variety of factors, including tumor necrosis factor-alpha, angiotensin II, and vascular endothelial growth factor. Once activated, endothelial cells lose cell-cell interactions and the monolayer is permeable. Activated endothelial cells express P- and E-selectins which form weak interactions with passing neutrophils (via L-selectin) and initiate leukocyte rolling. Stronger interactions with intracellular adhesion molecule (ICAM) and vascular adhesion molecule (VCAM) function to adhere leukocytes to the monolayer, where chemokines such as interleukin-8 (IL-8) stimulate transmigration into the tissue.

the intact epithelium can enter the lung parenchyma and circulation.[59] The importance of this phenomenon is highlighted by a study showing that mortality-lowering ventilator strategies reduce the incidence of bacteremia in animal models.[60] However, compelling data of translocation across human lung epithelia are lacking. In contrast, there is a significant body of evidence that surfactant, a secretory product of the epithelium, is altered in composition and function in human ALI. Normal lung surfactant is composed of phospholipids, neutral lipids, apoproteins, and the surfactant proteins (SP)-A, B, C, and D. During ALI, the total amount of surfactant phospholipids is reduced, with marked decreases in phosphatidylcholine and phosphatidylglycerol[61,62]; these changes are associated with increased surface tension of surfactant liquid[61] and the severity of respiratory failure.[63] In addition to deficiencies in phospholipids, there is marked depletion of SP-A and SP-B during ALI. The net deficiency of proteins and phospholipids is due to decreased production by type II pneumocytes as a result of inflammation[64] and increased destruction by oxidant stress[65] and proteolytic cleavage.[66] The findings of abnormal surfactant composition and function have led to more than 200 clinical evaluations of exogenous surfactant,[67] yet no trial has provided a convincing mortality benefit. Several variables in previous trials of exogenous surfactant therapy include issues of dose, timing, and composition of the applied therapy—leading to continued debate regarding the future of this mode of treatment.

Soluble Mediators of Inflammation

CYTOKINE-MEDIATED LUNG INJURY

Cytokines are low-molecular-weight soluble proteins that transmit signals within cells; therefore they mediate many of the interactions between immune cells and lung tissue in the pathogenesis of ALI. Despite the intense effort spent in researching the role of cytokines in the pathogenesis of ALI, criticism of human studies has evolved and some consideration of sampling techniques must be mentioned. In most instances, cytokines participate in cell signaling through interaction with cell surface receptors and in this regard may have very localized effects. In parallel, because various anatomic barriers compartmentalize the immune response,[68] cytokine concentrations may be quite different in the serum, alveolar space, or lung parenchyma. Furthermore, systemic cytokines may represent "the tip of the iceberg"[69] or overflow of cytokines from various sources,[70] making interpretation of these factors complex. There is evidence, however, that the alveolar compartment is disrupted during intense inflammation and airway sampling yields cytokine concentrations that are similar to more invasive sampling.[71] With this in mind, as well as the capacity to perform repeated measurements in patients safely and easily, most regard bronchoscopic sampling of alveolar fluids as the best method available to assess the role of cytokines in ALI.[72]

Investigations into the role of cytokines in ALI initially focused on TNF-α and IL-1β—primarily because bacteria stimulate production of these molecules, whereas in the absence of bacteria, these cytokines are capable of initiating an inflammatory response identical to ALI. TNF-α has been identified in BAL fluid in some, but not all, studies of human ALI. This discrepancy may be related in part to timing of samples because this cytokine may be prevalent in the airway fluid for less than 24 hours. TNF-α exerts its effects through interaction with TNF receptors I and II on the surface of macrophages and other immune cells,[73] or is shed as a soluble receptor. TNF-α interactions with these soluble receptors are complex because the receptors may either potentiate TNF-α effects by stabilizing the cytokine, or attenuate TNF-α effects by interfering with TNF-α binding to active receptors.[74] The local effects of TNF-α collectively function to increase inflammation within the tissue by activating endothelial cells, thereby increasing vascular permeability and allowing the passage of immune cells, immunoglobulin, and complement into the tissue. In addition to these effects, TNF-α also stimulates the production of itself and IL-1β and thus further stimulates inflammation.

Like TNF-α, IL-1β has been identified in lavage fluid obtained during ALI, and through binding to the interleukin-1 receptor (IL-1r)—a potent stimulator of vascular endothelium. This cytokine also activates lymphocytes and as such has many of the same effects as TNF-α. However, IL-1β is commonly thought to be more responsible for tissue destruction than is TNF-α, as evidenced in a study that showed that inhibition of IL-1β decreased endothelial activation caused by BAL fluid from ALI patients, whereas inhibition of TNF-α had no effect.[75] In addition to the effects on tissue injury, IL-1β stimulates the production of IL-6. It has been proposed that IL-6 integrates the inflammatory response through diverse actions including differentiation of lymphocytes, induction of immunoglobulin production, and induction of many proteins found during the acute phase of inflammation.[76] Unlike TNF-α and IL-1β, IL-6 is found in the BAL of patients throughout the course of ALI, but the concentrations of the latter cytokine also inconsistently predict outcome.[72,77] All three of these early cytokines can be detected in the blood of patients with ALI, and may be responsible for systemic disease.

While TNF-α, IL-1β, and IL-6 have local and systemic effects, the effects of the chemotactic cytokine IL-8 are largely local in nature. This cytokine is the most abundant product secreted by alveolar macrophages followed by bacterial toxin stimulation, and it is the predominant neutrophil chemoattractant in BAL fluid.[78,79] It is worth noting, however, that although IL-8 concentrations correlate with BAL neutrophil concentrations, this strength of relationship varies over time, and IL-8 concentrations at any time are poor predictors of outcome. This observation clearly indicates that additional neutrophil chemoattractants are involved in the pathogenesis of ALI.

Immune cells also secrete a number of anti-inflammatory cytokines that regulate inflammation. In keeping with its role as an integrative cytokine, IL-6 reduces the effects of TNF-α and IL-1β by inhibiting their production[80] and stimulating their natural antagonists.[81] However, the most widely described anti-inflammatory cytokine is IL-10. This counter-regulatory protein is synthesized in lymphocytes and monocytic cells in response to bacteria and inflammatory cytokines, and inhibits inflammatory cytokines, inhibits class II major histocompatibility protein expression, and suppresses monocyte procoagulant activity in experimental systems. IL-10 is found in BAL fluid during ALI, and lower levels of this cytokine are associated with a poor prognosis.[82] Although this suggests that failure to decrease inflammation leads to

increased injury, increasing IL-10 in pneumonia models leads to impaired bacterial clearance and increased mortality.[83]

Tremendous efforts have been made to identify which cytokines may be primary mediators of inflammation during ALI. Although these studies provide irrefutable evidence of the involvement of many biochemical and cytologic processes, none has clearly prevailed as primary mediators amenable to therapy in human disease. Attempts at blocking or reversing suspected agents in patients have been generally unsuccessful and, at times, lethal. At least four issues may explain this apparent inconsistency. First, ALI induces a complex and redundant inflammatory milieu, and ameliorating any one factor is unlikely to stop the cascade of events. Second, inflammation and organ injury likely begin hours or days prior to the clinical recognition of the disease such that the primary mediators are no longer actively involved at the time of therapy. Third, the inflammatory process is, in fact, a reaction to a primary inciting event; a reduction in inflammation impairs host defense mechanisms. Fourth, and related to the latter issue, the host response is a tightly controlled response involving an initial proinflammatory response rapidly followed by an exuberant anti-inflammatory response. Both responses are increased during the first days of lung injury; however inflammatory antagonists predominate in the alveoli within 24 hours of disease onset.[84] It is becoming clear that the balance of inflammatory agonists and antagonists in patients at risk for lung injury may be more important than any one factor.[85,86] Further, exogenous attempts at altering inflammation may disrupt this balance and lead to either excessive inflammation or impaired host defenses, both of which may increase mortality.[87]

In summary, cytokine measurements in the BAL fluid of patients with ALI have provided insight into the complexity of interactions between lung epithelium, endothelium, and immune cells. However, despite intense research we have yet to discover a consistent pattern of cytokine regulation in ALI. Further research into cohesive groups of cytokines, coupled with markers of epithelial and endothelial barrier injury, is needed to provide a more comprehensive understanding of immune regulation in ALI.

RENIN-ANGIOTENSIN MEDIATED INJURY

The emergence of the severe acute respiratory syndrome (SARS) and the subsequent identification of an angiotensin converting enzyme (ACE) subtype as the receptor for the causative coronavirus have increased our understanding of the role of the renin-angiotensin-system (RAS) in the pathogenesis of ALI. Briefly, renin is produced by a variety of stimuli, including decreased glomerular pressure as encountered during shock. Renin cleaves angiotensinogen to angiotensin, which is subsequently transformed to angiotensin II (Ang II) by ACE subtype I (ACE-1). Ang II then exerts multiple effects through interactions with the AT1 receptor, including vasoconstriction and sodium resorption, that counteract the hemodynamic state during shock.

The association of the lung and RAS was first recognized anatomically and may be traced to findings that ACE-1 is produced extensively on the luminal surface of pulmonary capillary endothelial cells, and thus the lungs are a major source of systemic Ang II.[88] Furthermore, ACE-1 is found in lung lavage fluid during experimental lung injury[89] and as well as in serum from patients with lung diseases not typically associated with shock. These findings were initially explained as a demonstration of shedding of ACE-1 from injured endothelium, but there has been gradual acceptance that RAS is actively involved in the process of acute lung injury. Certainly RAS is upregulated in critical illness and patients have increased concentrations of Ang II in serum. It is also clear that this peptide mediates many of the pathogenic processes implicated in lung injury. Ang II promotes inflammation through activation of the NF-κB pathways,[90] as well as through the recruitment of immune cells via increased expression of VEGF[91] and of intercellular adhesion markers.[92] Furthermore, through the AT-1 receptor, Ang II promotes collagen formation in lung fibroblasts[93] and apoptosis in epithelial cells[94] and hence is responsible for features seen during the fibroproliferative phase of ALI. Most strikingly, AT-1 receptor blockers may decrease neutrophil infiltration, improve oxygenation, and prolong survival in an animal model of ALI.[95]

The lungs are a significant source of Ang II during critical illness as evidenced by increased concentrations found in arterial compared to mixed venous blood[96-98]; presumably this is related to an increase in ACE-1 activity within the lungs. In fact, patients with ACE-1 polymorphisms associated with increased ACE-1 activity appear to have an increased risk of both the development of ALI as well as mortality from the syndrome.[99] ACE-1 activity is not limited to pulmonary endothelial cells as previously thought—alveolar macrophages, neutrophils, and alveolar epithelial cells also produce ACE-1. These additional sources of Ang-II may, in fact, be more clinically relevant during critical illness because endothelium-bound ACE-1 activity is actually decreased in patients with ALI.[100] Because inhibition of ACE-1 attenuates endothelial activation[101] in patients at risk of ALI and decreases TNF-α activation in animal models,[102] persistent expression of angiotensin I is likely to contribute to the pathogenesis of ALI.

Recently, a homologue of ACE-1, or ACE-2, was discovered. This subtype of ACE cleaves Ang I and Ang II to additional angiotensin species that do not act through the AT-1 receptor. In so doing, ACE-2 appears to be protective in ALI; loss of ACE-2 activity via genetic manipulation of experimental sepsis leads to increased vascular permeability, lung edema, and neutrophil accumulation.[103] The finding that ACE-2 is an essential receptor to the coronavirus responsible for SARS, a severe demonstration of clinical ALI, lends clinical credence to the protective function of this enzyme.

CLINICAL APPLICATIONS

Decades of research have provided insight into many mechanisms of the pathogenesis of ALI, but have failed to identify disease-specific mechanisms that are amenable to therapy. As such, therapy is considered supportive, and most patients require some form of mechanical ventilation, parenteral fluids and nutrition, and intensive monitoring. The largest clinical trials of ALI[104-106] have described excessive mortality and morbidity because of the supportive care that allows patients to survive beyond the first several hours of disease. Patterns of injury related to ICU therapy should, therefore, be discussed.

Ventilator-Associated Lung Injury

Soon after the initial description of ALI and its pathology, many animal models of positive-pressure mechanical ventilation have demonstrated that high peak inspiratory pressures induce injury in previously normal lungs, including changes in pulmonary mechanics,[107] alveolar integrity,[108] and histology[109] that are identical to those seen in ALI. Subsequently, investigators found that limiting chest wall excursion during high pressure ventilation reduced the magnitude of this injury, demonstrating that the high lung volumes induced by high inspiratory pressures are responsible for this injury.[110] Furthermore, low tidal volume strategies decrease the translocation of bacteria[60] and toxins[111] from the lungs to the systemic circulation, showing that high tidal volumes contribute to a loss of epithelial barrier function. Edema and atelectasis in ALI could culminate in a significant decrease in effective alveoli, the so-called "baby lung,"[112,113] such that standard tidal volumes produce overdistention and alveolar wall shear stress and injury of the remaining functional lung.[114]

Clinical investigations of patients with ALI demonstrate that those ventilated with lung-protective strategies that included limited tidal volumes had lower concentrations of neutrophils and inflammatory cytokines in BAL fluid and decreased systemic inflammatory cytokines compared to those ventilated with traditional settings.[115] An early study of lung-protective ventilation strategies showed mortality lower than that predicted by severity of illness scoring,[116] but the initial randomized controlled trials of lung-protective ventilatory strategies that followed were small and produced conflicting results.[117-120] However, in the largest clinical trial of ventilator strategies in ALI, the group of patients ventilated with small tidal volumes (6 mL/kg) experienced lower mortality than those ventilated with higher tidal volumes (12 to 15 mL/kg).[105] Although there is controversy regarding both the choice of control group strategy and whether a tidal volume between the two strategies would be even more effective, experimental and clinical evidence clearly shows that mechanical ventilation with high tidal volumes contributes to lung injury and mortality.

Extravascular lung water is a hallmark finding in ALI, and as mentioned, indicates both increased alveolar-capillary permeability and impaired resorption of alveolar edema. In addition, hydrostatic pressure[121] and loss of capillary oncotic pressure owing to hypoproteinemia[122] contribute to non-cardiogenic pulmonary edema. Logically, decreasing capillary hydrostatic pressure may decrease edema and improve outcomes. Conversely, impaired left ventricular stroke volume from inadequate filling pressures may contribute to the inflammatory state resulting from inadequate organ perfusion.

Several studies have examined the relation between extravascular lung water and outcomes in ALI. An early study showed that patients managed with attempts to decrease extravascular lung water had more ventilator-free days than those whose fluid management was based on pulmonary capillary wedge pressures[123]—whether this was an effect of net fluid management or of the monitoring techniques was unclear. Increasing plasma oncotic pressure while decreasing total body water by co-infusing furosemide and albumin may also improve ICU-related outcomes.[124] The large ARDSnet Fluid and Catheter Treatment Trial utilized a 2 × 2 factorial design including conservative or liberal fluid treatment strategies guided by either central or pulmonary artery catheters.[104,106] Patients who were randomized to conservative fluid management experienced more ventilator-free days and fewer ICU days—this effect was true regardless of how fluid management was monitored. Although mortality did not differ between the two catheter groups, those managed with pulmonary artery catheters experienced more complications, illustrating the potential for iatrogenic complications in ALI. Taken together, multiple trials have shown that minimizing hydrostatic pressure improves physiology and ICU-related outcomes; the assuredness of this conservative fluid management is likely more important than the methods used to achieve it. These findings add support to the significance and complexity of pathology leading to the accumulation of non-cardiogenic pulmonary edema fluid in ALI.

CONCLUSION

Acute lung injury is a syndrome resulting from a variety of causes that involves diffuse inflammation leading to proteinaceous alveolar edema. The mechanisms involved in the injury are remarkably similar regardless of the underlying etiology, leading to damage of both epithelial and endothelial surfaces. These surfaces are not only passively injured, however, and along with leukocytes contribute to the pathogenesis of the syndrome. Considerable overlap exists between mediators of injury and mediators of host defense and repair such that attempts at intervening in the injury pathway have been troublesome.

CHAPTER 7

Applied Clinical Respiratory Physiology

Peter D. Sly and Rachel A. Collins

TEACHING POINTS

- Lung volume is actively maintained by muscle activity, glottic "braking," or increases in respiratory rate in the presence of lung disease.
- Hyperinflation comes at the cost of an increase in work of breathing and putting respiratory muscles at a mechanical disadvantage.
- The presence of wheeze implies that expiratory flow limitation exists.
- Cough is a natural forced expiration and its characterization is an essential component of examining the respiratory system.
- The functional anatomy of the respiratory tract largely determines the physiology.
- An understanding of basic respiratory physiology aids understanding of the alterations of normal function that occur in diseases.

BACKGROUND: BASIC PHYSIOLOGIC PRINCIPLES

Functional Anatomy of the Respiratory System

RIB CAGE

The rib cage is formed by the 12 thoracic vertebrae, the 12 pairs of ribs, the sternum, and the costal cartilages. Posteriorly, the ribs articulate with the vertebral bodies. The head of the first, tenth, eleventh, and twelfth ribs each articulate with a single vertebra. The other ribs articulate with two vertebrae across the intervertebral disk. There is an articular surface on the tubercle of ribs 1 through 10, through which the ribs articulate with the transverse process of the vertebra to which it corresponds numerically.

Anteriorly, the first seven ribs are connected directly to the sternum via the costal cartilages and are called *true ribs*. The remaining five ribs are called *false ribs* because they are not attached directly to the sternum. The cartilages of ribs 8, 9, and 10 are joined to the cartilage of the rib above, and ribs 11 and 12 are free anteriorly. These are often called *floating ribs*.

The axis of rotation of the rib changes progressively down the thoracic cage (Fig. 7-1). The upper ribs have a pump-handle movement, with the anterior end swinging upward and outward. The lower ribs have a bucket-handle movement, with the ribs moving laterally and upward; the lowest ribs have a caliper movement, with the entire rib swinging laterally. These combinations of movements lift the rib cage as well as expand it in the anteroposterior and lateral directions. Such movement increases the transverse diameter of the rib cage, particularly at its lower end, and increases its volume. An understanding of how the ribs move is fundamental to understanding how the muscles of respiration expand the rib cage during breathing. This point is highlighted in sections discussing the individual muscle groups. The consequences of abnormalities in the rib cage are dealt with in Chapter 66.

MUSCLES OF RESPIRATION

The basic contractile unit of the skeletal muscle fiber is the *sarcomere*, consisting of thin actin filaments anchored at one end to the Z disk and thick myosin filaments that overlap between adjacent sets of actin filaments (Fig. 7-2). Contraction of the muscle is thought to occur when cross-bridges form between the actin and myosin filaments and the actin filaments slide progressively along the myosin filaments. Muscle shortening is thought to be limited when the Z disks limit further sliding of the filaments. Myofibrils are made up of multiple sarcomeres, and form the contractile apparatus of muscle fibers. Each muscle fiber is covered in a fine tubular sheath known as the *sarcolemma*.

When muscle excitation occurs, a propagated action potential is initiated across the sarcolemmal membrane of the muscle fibers, which travels in both directions away from the centrally located myoneural junction. The action potential is an ionic current flow resulting from sequential increases in membrane sodium and potassium conductance. The action potential also spreads inward along the transverse tubular system (which is an extension of the sarcolemmal membrane). The action potential causes calcium ions to be liberated into the tubular space. During rest, muscle interaction between actin and myosin is inhibited by the troponin-tropomyosin complex, thus preventing muscle contraction. The influx of calcium ions is thought to initiate muscle contraction by combining with troponin, releasing actin and myosin from the inhibitory influence of the troponin-tropomyosin complex. The sliding filament paradigm, which has been proposed to explain skeletal muscle, explains muscle contraction in terms of the thick (myosin) and thin (actin) filaments sliding over one another, forming attachments known as *cross-bridges*. During this process, adenosine triphosphate is converted to adenosine diphosphate, with the accompanying release of energy. The cross-bridges are not

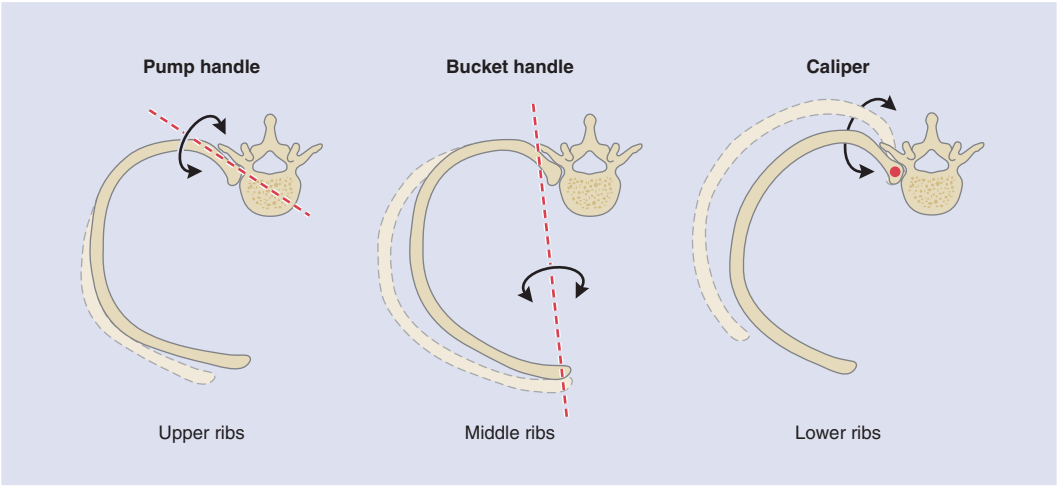

Figure 7-1 Schematic representation of rib motion around its axis. The *dotted lines* represent the upper and middle ribs, and the *red dot* represents the lower ribs.

static connections but actively cycle (attaching, detaching, and reattaching) during a contraction. Relaxation occurs as a result of the active transport of calcium ions into longitudinally oriented elements of the sarcoplasmic reticulum and a reversing of this process. Skeletal muscle cells typically bridge their attachment points on the skeleton. As a result, each cell is independent; the force of contraction can be increased by recruiting more cells for contraction.

The muscle fibers supplied by a single nerve fiber are known as a *motor unit*. A muscle is made up of many individual motor units, each unit consisting of many different muscle fibers. The number of muscle fibers in a motor unit varies widely among different muscles but can be as low as 2 to 10 fibers in small muscles used for delicate movements (e.g., laryngeal and extraocular muscles) and as many as 2000 fibers for large muscles such as the gastrocnemius muscle. Fibers from a single motor unit are not packed into one region of the muscle but are scattered throughout the muscle.

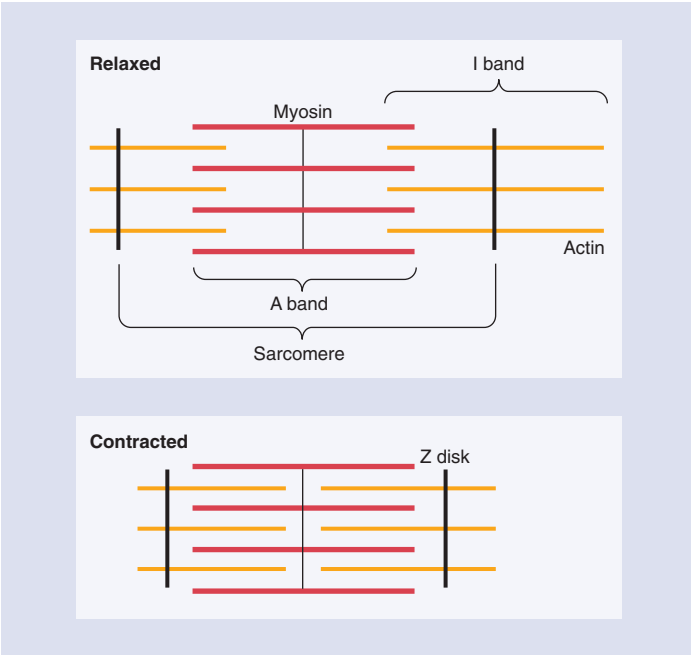

Figure 7-2 The sarcomere in the relaxed and contracted state. Sarcomeric shortening occurs by sliding of actin over myosin filaments.

Muscles of Inspiration

Diaphragm. The diaphragm is the most important inspiratory muscle. It consists of three main parts: the costal diaphragm originating from the costal margin and inserting into the central tendon, the crural diaphragm originating mainly from the vertebral column and also inserting into the central tendon, and the central tendon itself. The fibers of both muscular parts are directed axially; the costal part is apposed directly to the inner surface of the rib cage (zone of apposition).

Stimulation of the costal fibers causes a fall in pleural pressure and inflation of the lungs. Abdominal pressure rises, and the abdomen is displaced outward. The rib cage is also displaced outward. The force generated by the costal diaphragm is partly transmitted to the rib cage through the zone of apposition. This results in the rib cage being "pushed" upward and outward because of the axis of rotation of the ribs. Stimulation of the crural fibers also causes a fall in pleural pressure, a rise in abdominal pressure, and outward displacement of the abdominal wall, but there is no displacement of the rib cage.

External Intercostal Muscles. The external intercostal muscles connect adjacent ribs and slope downward and forward. When they contract, the ribs are pulled upward and forward, resulting in an increase in both the anteroposterior and lateral diameters of the thorax.

Accessory Muscles. The major accessory muscles are the scalene muscles, which elevate the first two ribs, and the sternocleidomastoid muscles, which elevate the sternum. These muscles play only a minor role in normal quiet breathing but contribute significantly at times of increased ventilatory requirements, such as during exercise or with obstructive diseases of the respiratory system (e.g., asthma). Other

muscles may also help inspiration; for example, the muscles of the alae nasi flare the nostrils and reduce nasal resistance, the small muscles of the head and neck can help raise the first rib, and the pectoralis major can be used to stabilize the rib cage.

Muscles of Expiration

Quiet expiration is usually passive, but at times of increased ventilatory requirement, expiration may become an active process.

Muscles of the Anterior Abdominal Wall. Contraction of the rectus abdominis muscle, internal and external oblique muscles, and transversus abdominis muscle causes the abdominal pressure to rise and the anterior abdominal wall to be displaced inward. This pushes the diaphragm upward and aids expiration. These muscles also contract forcefully during coughing, vomiting, and defecation.

Internal Intercostal Muscles. The internal intercostal muscles aid active expiration by pulling the ribs downward and inward. The muscles also stiffen the intercostal spaces and prevent them from bulging outward.

PLEURA

Each lung is covered by a serous membrane arranged in the form of a closed sac called the *pleura*. A part of this serous membrane (the visceral pleura) covers the surface of the lung and lines the fissures between its lobes. The rest of the membrane (the parietal pleura) lines the inner surface of the corresponding half of the chest wall, covers a large part of the diaphragm, and is reflected over the mediastinum. Between the two layers of the pleura is a potential space called the *pleural space*. The pleural space is 10 to 15 μ wide and contains a small amount of liquid. The lymphatic system opens directly onto the parietal pleura. Active transport of pleural liquid occurs from top to bottom and from costal to mediastinal surfaces. The pleural space "couples" the chest wall to the lungs; without the intact pleural space the lungs would collapse away from the chest wall (a pneumothorax).

LUNGS

Airways. The airways consist of a series of branching tubes that become narrower, shorter, and more numerous as they penetrate deeper into the lung. The trachea divides into the right and left main bronchi, which in turn divide into lobar bronchi, segmental bronchi, subsegmental bronchi, small bronchi, bronchioles, terminal bronchioles, respiratory bronchioles, alveolar ducts, and finally, alveoli (Fig. 7-3). At each division, or generation, the total cross-sectional area of the tracheobronchial tree increases. The division of airways does not occur symmetrically. The tracheobronchial tree is generally divided into two parts. The airways from the trachea (generation 0) to the terminal bronchioles (generation 16) are generally known as the *conducting airways* because they have no alveoli arising from them.

The airways from the respiratory bronchioles (generations 17 through 19) and the alveolar ducts (generations 20 through 22) have increasing numbers of alveoli budding from their wall and are known collectively as the *transitional* and *respiratory zones*. The portion of lung distal to a terminal bronchus forms an anatomic unit called the *primary lobule* or *acinus*.

Gas exchange occurs only within the acini and not in the conducting airways. The total volume of the conducting airways is approximately 150 mL in adults. During expiration, 500 mL of air is forced out of the acini and through the airways. Approximately 350 mL of this air is exhaled through the nose or mouth (together with the 150 mL of air in the conducting airways), but about 150 mL remains in the conducting airways. With the next inspiration, 500 mL of air enters the alveoli, but the first 150 mL is not atmospheric air but the 150 mL left in the conducting airways at the end of

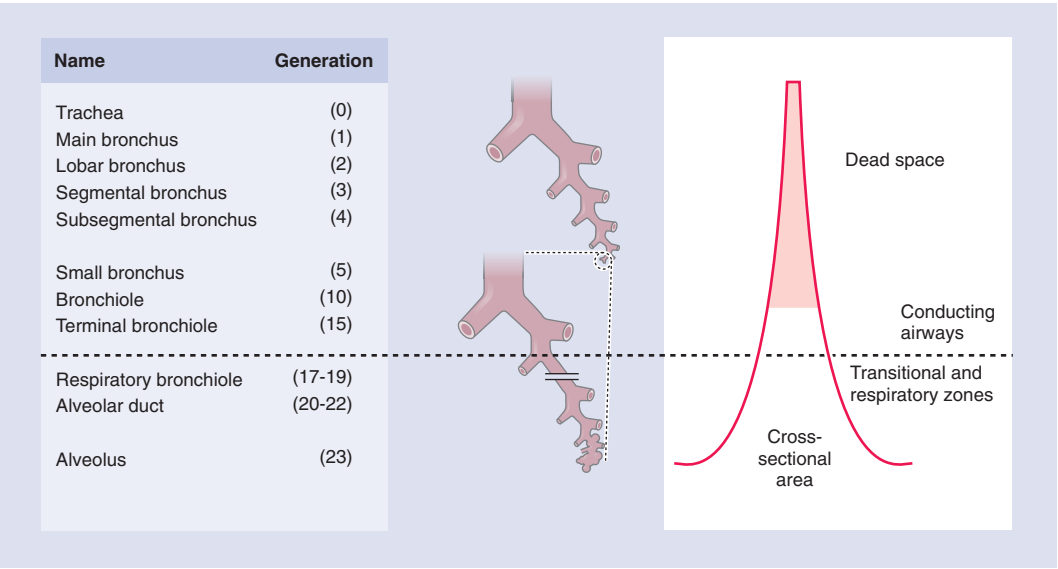

Figure 7-3 Airway generations. Individual airway size decreases with increasing generations but the total cross-sectional area increases. The conducting airways (generations 0 to 16) have no gas exchange and contribute to the amount of dead space *(shaded area)*.

the previous expiration. Thus, only 350 mL of new atmospheric air enters the alveoli during one inspiration. At the end of inspiration, 150 mL of fresh air also fills the conducting airways but cannot participate in gas exchange. The volume of the conducting airways is known as the *anatomic dead space*. The ratio of dead space volume to tidal volume (V_{DS}/V_T), together with the breathing frequency, determines the alveolar ventilation. It is the alveolar ventilation that is important for gas exchange. A decrease in V_T without a corresponding increase in breathing frequency, as may occur with central respiratory depression, leads to a decrease in alveolar ventilation. Similarly, an increase in V_{DS}, such as can occur in conditions that make the conducting airways more compliant (e.g., bronchiectasis), can also lead to alveolar hypoventilation. The cross-sectional area of the tracheobronchial tree increases with each division. This increase in area becomes very rapid in the respiratory zone (see Fig. 7-3).

During respiration, gas flows through the conducting airways by bulk flow, like water through a hose. Beyond that point, the cross-sectional area of the airways is so large that the forward velocity of the gas becomes very small. Diffusion of gas takes over as the dominant mechanism of ventilation in the respiratory zone.

Airway Smooth Muscle. In contrast to skeletal muscle cells, which are mechanically independent, smooth muscle cells must be mechanically coupled and their activation coordinated. Increases in force are produced by increases in the activation of all the coupled cells. The "tone" maintained in airway smooth muscle is an example of continuous partial activation.

There are similarities in ultrastructure, subcellular mechanisms, and contractile and regulatory proteins in striated and smooth muscle. However, there are differences in the way muscle function is regulated. For example, in smooth muscle, a calcium-sensitive regulation of contraction is mediated not via a tropomyosin-troponin system but by a calmodulin-mediated, myosin-linked light-chain phosphorylation mechanism. Smooth muscle has a random organization of filaments giving it a smooth appearance under electron microscopy. Smooth muscle thin filaments are anchored in dense bodies, in a similar fashion to the Z disks of skeletal muscle. Smooth muscle contraction is achieved by cross-bridge formation and interaction between actin and myosin.

Smooth muscle exists in the walls of airways, where it is oriented in a spiral fashion rather than a circular fashion around the airway. The smooth muscle has been reported to make an angle of approximately 30 degrees with the cross-sectional plane.[1] Thus, smooth muscle contraction results in both narrowing and shortening of the airways. The orientation of the smooth muscle could be important in determining airway responsiveness to various stimuli[2] (see Part 10).

Alveoli. The lung can be considered a collection of hundreds of millions of bubbles, each approximately 0.3 mm in diameter. The alveoli bring the air and blood into proximity to each other to facilitate gas exchange. The alveolar walls are thin and contain numerous capillaries. The alveolar-capillary membrane consists of four layers: the capillary endothelium and its basement membrane; a thin connective tissue layer; the alveolar epithelium and its basement membrane; and a surfactant lining. The alveolar epithelium consists of two types of cells: Type 1 cells, or squamous pneumocytes, are large, mature cells that do not divide, cover most of the alveolar surface, and are vulnerable to injury, and type 2 cells, or granular pneumocytes, are small, cuboidal cells packed with granules that store and synthesize surfactant. Type 2 cells differentiate into type 1 cells during growth and repair after injury.

The alveoli are inherently unstable. Because of the surface tension of the liquid lining the alveoli, relatively large forces develop that tend to collapse alveoli. The surfactant secreted by the type 2 cells profoundly lowers the surface tension of the alveolar lining fluid. This increases the compliance of the lung and reduces the work of expanding it with each breath. It also makes the alveoli more stable and less likely to collapse. Because the surface tension forces are greater within bubbles with a larger radius of curvature, there is a tendency for smaller bubbles to empty into larger ones (Fig. 7-4). This results in a reduction of alveolar surface area and a decreased ability for gas exchange. Surfactant reduces the surface tension more in smaller bubbles and prevents the collapse of smaller alveoli. Surfactant also helps keep the alveoli dry. Surface tension forces tend to suck fluid into the alveolar spaces from the capillaries. By reducing these forces, surfactant prevents the transudation of fluid.

Infants born prematurely may suffer from a condition known as *respiratory distress syndrome*. This syndrome is thought to result from a lack of surfactant and is characterized by stiff lungs (low compliance), areas of collapsed alveoli (atelectasis), and alveoli filled with transudate. The result is a decreased capability for gas exchange (see Chapters 28 and 29).

Connective Tissues. In addition to the airways and blood vessels, the lungs consist of a network of collagen and elastin fibers within a proteoglycan matrix. These fibers form a supportive network connecting adjacent airways and alveoli. They are partly responsible for the elastic recoil of the lung, help prevent the collapse of the alveoli and airways, and promote homogeneous emptying of the lungs. The elastin

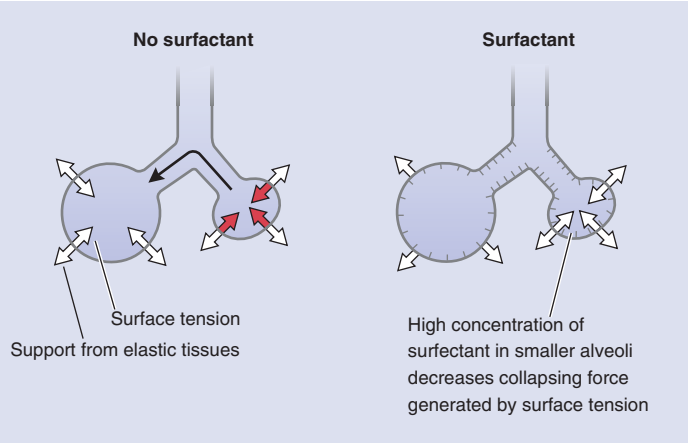

Figure 7-4 The presence of surfactant in the alveoli decreases surface tension and prevents alveoli with a high radius of curvature (small size) from emptying into larger alveoli. (Arrow size represents the magnitude of force.)

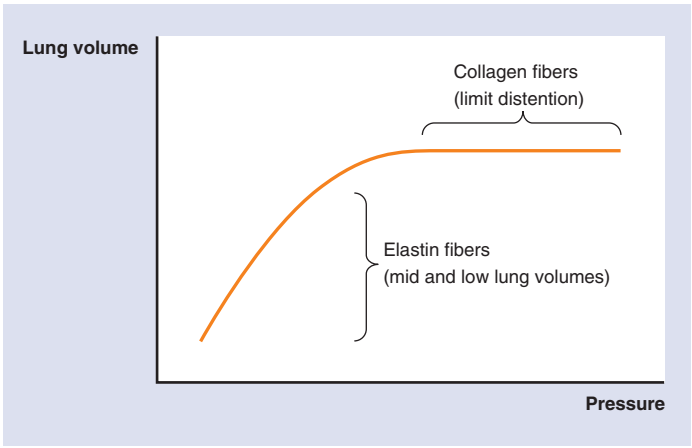

Figure 7-5 Pressure-volume relationship of the lungs. The influence of connective tissues at different lung volumes is demonstrated.

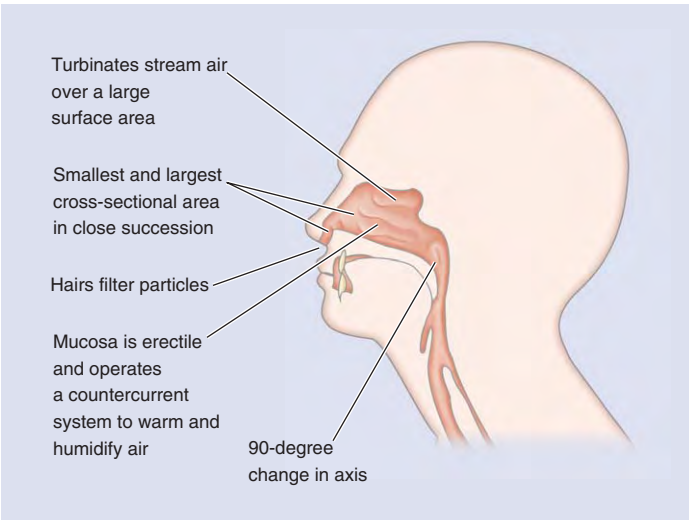

Figure 7-6 Air filtration and conditioning factors of the upper airway.

fibers are thought to be largely responsible for the distensibility of the lungs at volumes in the low to middle ranges. This distensibility is reflected in the slope of the static pressure-volume curve (a reflection of the compliance of the lungs). The collagen fibers are thought to be more involved in limiting distention of the lungs, which is reflected by the plateau in the static pressure-volume curve (Fig. 7-5). Proteoglycans act to stabilize the collagen-elastin network within the connective tissue matrix and contribute to lung elasticity and alveolar stability at low to medium lung volumes.[3] Alterations in proteoglycan content have been shown to alter the distensibility of the lung parenchyma in animal models. The collapse of alveoli or airways in one area tends to pull on adjacent alveoli and airways. The adjacent structures resist this pull, which in turn tends to resist the tendency for the alveoli or airways to collapse. This relationship is known as *mechanical interdependence*.

PULMONARY CIRCULATION

The pulmonary circulation begins at the main pulmonary artery, which receives the mixed venous blood pumped by the right ventricle. The pulmonary artery divides in a manner corresponding to the division of the tracheobronchial tree. Pulmonary arteries accompany the bronchi as far as the terminal bronchioles. Beyond that, they break up to supply the capillary bed, which lies in the walls of the alveoli, where gas exchange occurs. The oxygenated blood is collected by the small pulmonary veins that run between the lobules and eventually unite to form four large veins that drain into the left atrium. The blood supply to the lungs comes from the bronchial circulation, which is formed by systemic arteries and veins and is separate from the pulmonary circulation. The pulmonary circulation is a low-pressure system, and the arteries have thin walls containing little smooth muscle. This lessens the work of the right side of the heart as much as is feasible for efficient gas exchange to occur in the lung. If the pulmonary arteries are subjected to chronic hypoxia, the muscle in the wall hypertrophies and narrows the lumen. This increases the resistance to blood flow through the pulmonary system and results in increased pulmonary artery pressures and an increased strain on the right side of the heart (see Part 9).

UPPER AIRWAY

The upper airway consists of the passages for airflow between the larynx and the airway opening. Ordinarily it is composed of the nasal passages (from the nostrils to the posterior termination of the nasal septum), the nasopharynx (from the end of the nasal septum to the lower border of the soft palate), and the pharynx (from the palate to the larynx). When a person breathes through the mouth, it also includes the mouth. The nasal airway consists of two passages, each with turbinates projecting from the lateral wall into the lumen. In adults, the surface area of the functional (turbinated) portion of the nasal mucosa is around 120 cm^2, approximately double that of the trachea. The blood vessels in the nasal mucosa, especially that covering the turbinates, are arranged to provide an erectile capacity comparable to that of the male genitalia.

The following are the main anatomic features that allow the nasal passages to perform their specialized function:

1. The axis of the nasal airway is oriented at 90 degrees to that of the trachea.
2. The cross-sectional area increases from the smallest area in the respiratory tract (anterior nares) to the relatively large turbinated airway and then decreases again in the nasopharynx.
3. The anatomic arrangement of the turbinates concentrates the airflow into a relatively small stream.
4. The surface area of the turbinated airway is large.
5. The extensive vascular network gives the body the ability to vary the width of the nasal airway.

All of these features allow the nasal airway to function as an efficient air filtering and conditioning unit (Fig. 7-6).

Air Conditioning. Blood flow in the nasal mucosa is arranged in a countercurrent fashion such that air entering the nose is progressively brought to body temperature and humidity. This usually means that the air is warmed to 37° C and fully saturated with water. The transfer of heat (by turbulent convection) and water (by evaporation) to the air cools the mucosa. During expiration, some of the heat and water vapor return to the mucosa from the alveolar gas. If the nasal

airway is bypassed, the mouth and pharynx can perform these air-conditioning functions almost as well as the nose. The trachea and bronchi cannot. During strenuous exercise, the nasal airway is usually bypassed, and increased minute ventilation may exceed the conditioning capacity of the mouth and pharynx. This causes drying and cooling of the lower airways and may provoke exercise-induced asthma in susceptible individuals.

Filtration and Cleansing. Hairs in the anterior nares block the passage of very large particles into the nose. Once inside the nose, the air is forced to pass in narrow streams close to the mucosa. The turbulent flow through the nasal airway and the changes of air stream direction force many particles to become trapped in the mucus lining the nasal mucosa. Particles with diameters greater than 10 μ are almost completely removed from the inspired air in the nose. The nasal mucosa is also capable of removing some toxic gases, especially those that are water soluble; for example, sulfur dioxide in concentrations up to 25 ppm can be removed by the nasal mucosa.

Mechanics of the Upper Airway. The nose accounts for approximately one half the total respiratory resistance to airflow, but the absolute value shows marked variation among subjects. Nasal resistance varies with changes in nasal vascular congestion, posture, exercise, ambient air conditions, pharmacologic agents, and disease.

Almost all of the nasal resistance is contributed by the first 2 to 3 cm of the nasal passage (i.e., the anterior constriction [the nares and the tip of the inferior turbinate]). The turbinated passage contributes little to resistance under normal circumstances. However, if the nasal mucosa is engorged with blood, the turbinated passages can make a significant contribution to the total resistance.

The nasal vasculature is under autonomic control, reflexively responding to changing ambient air conditions. Small fluctuations occur in response to the temperature of inspired air; there is a significant increase in nasal resistance resulting from vascular engorgement when the temperature of inspired air falls below 7° C. Changes in body posture alter resistance through hydrostatic effects on the vasculature. Changing from a standing or sitting to a recumbent position increases nasal resistance. Nasal resistance is often higher through one nasal passage than the other because of differences in the degree of vascular engorgement. The high-resistance changes from one side of the nose to the other occurs in 3- to 4-hour cycles. This cycle may allow one nasal passage to recover from injury suffered in filtering and conditioning inspired air.

The most compliant region of the upper airway is the pharynx. The negative pressures generated during inspiration tend to collapse the pharynx. This region is usually protected from collapsing by the tone of the upper airway muscles, which also contract during inspiration. During rapid-eye-movement sleep, this tone can be markedly decreased, making the upper airway vulnerable to collapse during inspiration. If other factors combine to make the upper airway more prone to collapse, the syndrome of obstructive sleep apnea may be seen (see Chapter 65). Some infants are born with relatively small upper airways. This may be part of a recognized syndrome or may be a familial trait. A small upper airway has a higher resistance and may necessitate the generation of greater negative pressures to produce sufficient inspiratory flow. This results in a greater tendency for the upper airway to collapse. The same syndrome is seen in adults, especially those who are grossly obese. These people probably have deposits of fat around the upper airway that effectively "load" the upper airway and make it more likely to collapse during inspiration. Heavy alcohol use can also precipitate upper airway obstruction during inspiration, probably by decreasing the tone of the upper airway muscles that are responsible for stabilizing the upper airway.

ELASTIC PROPERTIES OF THE RESPIRATORY SYSTEM

The respiratory system is composed of a collection of elastic structures. When a force is applied to an elastic structure, the structure resists deformation by producing an opposing force to return the structure to its relaxed state. This opposing force is known as *elastic recoil*. In the respiratory system the pressure generated by the elastic recoil is known as the *elastic recoil pressure* (P_{el}). The force required to stretch an elastic structure depends on how far it is stretched, not on how rapidly it is being stretched. Similarly, the pressure required to overcome the elastic recoil of the lung depends on the lung volume above or below the elastic equilibrium volume (EEV) (i.e., the volume at which the outward recoil of the chest wall balances the inward recoil of the lungs [see later section]). The P_{el} divided by the lung volume gives a measure of the elastic properties of the respiratory system and is called *elastance*, as follows:

$$E = Pel/V \qquad \text{Eq 7.1}$$

When lung volume is plotted on the ordinate and P_{el} is plotted on the abscissa, the slope of the static pressure-volume curve is equivalent to the reciprocal of elastance, called *compliance*. Elastance and compliance are discussed more fully in Chapters 12 and 13.

HYSTERESIS

The static pressure-volume curves of the respiratory system, lungs, and chest wall are not the same during inspiration and expiration. This phenomenon is called *hysteresis* (Fig. 7-7). Hysteresis is the failure of a system to follow identical paths of response on application and withdrawal of a forcing agent. Hysteresis in the respiratory system depends on viscoelasticity, such as stress adaptation (i.e., a rate-dependent phenomenon) and on plasticity (i.e., a rate-independent phenomenon). In the lungs, hysteresis is due mainly to surface properties and alveolar recruitment-derecruitment, whereas in the chest wall, it seems mainly related to muscles and ligaments because both skeletal muscles and elastic fibers exhibit hysteresis. Hysteresis is negligible for volume changes such as those occurring during quiet breathing. This is functionally desirable because the area of the hysteresis loop represents energy lost from the system.

Muscles of the Respiratory System

BASIC CONCEPTS OF SKELETAL MUSCLE MECHANICS

Muscle Fiber Type. The three basic types of muscle fibers are distinguished by their histochemical and morphologic

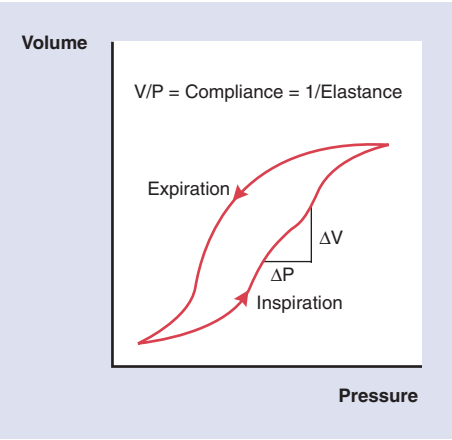

Figure 7-7 Hysteresis in the pressure-volume curve of the lung. The area contained within the curve represents energy lost in the system. P, pressure; ΔP, change in pressure; V, volume; ΔV, change in volume.

Table 7-1
Properties of Muscle Fiber Types

Properties	FOG	FG	SO
Synonym	Fast-twitch red	Fast-twitch white	Slow-twitch red
Presence of myoglobin	Positive	Negative	Positive
Isometric-twitch contraction time	Short	Short	Long
Myosin adenosine triphosphatase activity	High	High	Low
Glycolytic enzyme system	Reasonable	Good	Poor
Mitochondrial oxidative system	Good	Poor	Good
Resistance to fatigue	Good	Poor	Very good
Movements	Sustained, phasic	Brief, rapid, powerful	Sustained, tonic

FG, fast-twitch, glycolytic; FOG, fast-twitch, oxidative, glycolytic; SO, slow-twitch, oxidative.

properties and their time course of contraction: fast-twitch, oxidative, glycolytic (FOG); fast-twitch, glycolytic (FG); and slow-twitch, oxidative (SO). The concentration of myoglobin in the FOG and SO fibers makes them red, so these fibers are also known as *fast-twitch red* and *slow-twitch red fibers*, respectively (Table 7-1). The FG fibers have minimal myoglobin and are known as *fast-twitch white fibers*.

Within a species, white fibers are frequently larger in diameter than fast red fibers, with slow red fibers intermediate in size. FG fibers are used for short-term, fast, powerful activity in which endurance and resistance to fatigue are not required. FOG fibers are used for sustained phasic activity in which resistance to fatigue is desirable. The SO fibers are sluggish but are economical contractile units most suitable for sustained tonic activity (such as the maintenance of posture, in which resistance to fatigue is of prime importance).

Most mammalian muscles contain a mixture of the three types of muscle fibers. Each motor unit of a mixed muscle is composed of a single fiber type. The contractile properties of a mixed muscle are determined by the predominant fiber type. Although three types of muscle fiber are recognized, classification of muscle based on their mechanical properties alone yields two types of muscle: fast-twitch, including both FOG and FG fibers; and slow-twitch muscle, composed of predominantly SO fibers.

The following factors are important in determining the twitch characteristics of muscles:

1. The speed of sarcomere shortening, which is proportional to the specific activity of myosin adenosine triphosphatase (ATPase) activity (which varies with myosin isotype).
2. The neural supply to the muscle: If a motor nerve that normally innervates a slow muscle is transplanted into a fast muscle and time is allowed for nerve regeneration, the muscle changes its properties from those of a fast muscle to those of a slow muscle, and vice versa.
3. The stage of muscle development: Differentiation into fast and slow fibers takes place somewhat late in development. In species in which the young are born mature (e.g., guinea pig), the differentiation occurs before birth, whereas in species in which the young are born immature (e.g., mouse, rat, human), the differentiation occurs after birth. The differentiation seems to involve changes in the biochemical and morphologic properties of the sarcoplasmic reticulum and transverse tubular system, which effect changes in the excitation-contraction coupling.
4. Training: Any training, particularly endurance training, can alter fiber composition and characteristics.

Thus, the composition of a muscle is a dynamic property that can be altered to suit the requirements of the muscle at the time.

Muscle Mechanics. Skeletal muscle has been most successfully modeled as the following interacting components (Fig. 7-8):

1. A contractile component responsible for force generation and muscle shortening
2. A lightly damped series-elastic component representing an internal load that the muscle must overcome
3. A parallel-elastic component responsible for the passive tension produced as the muscle is stretched

During contraction, the actin and myosin filaments slide over one another, shortening the sarcomere. The force generated is a function of the degree of sarcomere shortening. As the filaments slide over one other, cross-bridges form between the fibers. These cross-bridges are independent, force-generating elements, and the force produced is a function of the number of active cross-bridges.

Length-Tension Relationship. Measurement of the force developed with activation over a range of lengths provides information about the ability of the muscle to stiffen and support loads. The "resting tension" curve is the tension produced when the muscle is passively stretched. The shape of this curve is typical of noncontractile biological tissues and results primarily from the presence of elastin and collagen. With activation of the muscle at a given length, the tension rises to a level shown by the "total tension" curve. The difference in tension between the total and resting tension

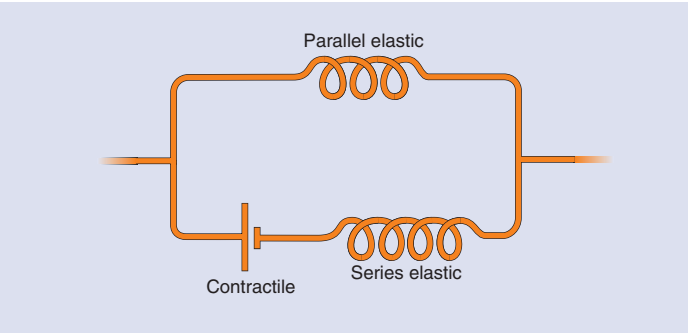

Figure 7-8 Circuit diagram representing the mechanical properties of skeletal muscle.

curves represents the activity of the contractile element or force generator of the muscle and is known as the *active tension.* The length at which the active tension is maximal is defined as the optimal length of the muscle. The resting length of the muscle is defined as the maximal length the muscle can be stretched before passive tension develops. This length generally corresponds to the muscle's resting length in the body. When the resting muscle is stretched beyond optimal length, it exerts a passive tension that increases exponentially as a function of increasing muscle length. When the muscle is maximally stimulated at varying lengths, an isometric length-tension curve can be drawn. The *active tension* of the muscle is defined as the difference between the total tension measured and the passive tension at that length. There is an optimal muscle length, usually between 100% and 120% of the length at which isometric tension is maximal during tetanic stimulation. Comparing the tension-generating capacity of one muscle with another muscle of a different size requires expression of tension in relationship to the amount of contractile material active in parallel with the muscle. This is usually done by expressing tension in terms of force per unit of a cross-sectional area of the muscle. The cross-sectional area is only roughly related to the amount of contractile material acting in parallel because it ignores variations in the density with which myofibrils are packed within individual fibers and it ignores differences in extracellular space that occupies 8% to 25% of the cross-sectional area in different muscles. When expressed this way, fast and slow muscles show no major differences in the intrinsic strength of their contractile material.

Force-Velocity Relationship. A light weight can be moved very rapidly by a muscle, whereas a heavy weight must be moved slowly. This fundamental property of muscle is known as the *force-velocity relationship.* There is an inverse curvilinear relationship between the force produced by a muscle and the velocity with which the muscle can shorten while producing that force. This can be expressed by Hill's equation, which describes a hyperbolic relationship between force and velocity, as follows:

Eq 7.2
$$(P + a)(V + b) = (P_0 + a)b$$

where P is the instantaneous force of contraction, V is the velocity of shortening, P_0 is the force of contraction at zero velocity (i.e., the isometric force of contraction), and a and b are constants. The position of the force-velocity curve depends on the initial length of the muscle.

The shortening velocity of a muscle (appropriately normalized for fiber cross-sectional area and so on) reflects the average cross-bridge cycling rates, which in turn are functions of the load and the isoform of myosin expressed in that particular muscle cell.[5,6]

BASIC CONCEPTS OF SMOOTH MUSCLE MECHANICS

Although smooth muscle does not have the same anatomic structure as skeletal muscle, biochemical and biophysical studies in the 1970s indicated that smooth muscles contract in a manner similar to skeletal muscle. The "sliding filament" paradigm in which the active cycling of cross-bridges is responsible for the amount of force developed (number of cross-bridges) and the force-velocity relationship (cycling rate) of muscle, however, cannot adequately explain the "force maintenance" properties of smooth muscle. This leads to the description of "latchbridges." *Latch* refers to a state in which force is maintained, despite a reduced cross-bridge cycling rate, by calcium-dependent cross-bridge phosphorylation.[5] Although the term *latchbridge* tends to imply that the actin and myosin filaments are locked together, this is not the case.

In a review of the regulation of smooth muscle contraction, Murphy[5] suggested that the unique properties of smooth muscle derive from a covalent regulatory mechanism whereby phosphorylation of cross-bridges is obligatory for attachment and cycling and that the fundamental myosin "motor" whose behavior is described by the sliding filament/cross-bridge hypothesis is the same in smooth and striated muscle. Murphy presented evidence suggesting that covalent regulation in smooth muscle allows four rather than two cross-bridge states: free, attached, phosphorylated, and dephosphorylated. This hypothesis seems to explain the special properties of smooth muscle.

Length-Tension Relationship. Although skeletal muscle usually has a resting length approximating the optimal length, it has not been established whether this is also true for airway smooth muscle. Some investigators have found that airway smooth muscle is close to optimal length at the end of tidal expiration. The contractile elements of smooth muscle can develop approximately the same force as those of skeletal muscle. Skeletal muscle can shorten to approximately 65% of optimal length, whereas tracheal smooth muscle can shorten to about 10% of optimal length. The reason for this difference is not known. The ratio of myosin to actin is less in smooth muscle than in striated muscle, and well-defined sarcomeres are not present. It has been speculated that the lack of limiting Z bands allows the myosin filaments to "crawl" farther along a set of relatively long actin filaments.

Force-Velocity Relationship. Measurements of force at various velocities of contraction provide information regarding the ability of the muscle to not only support loads but also to shorten and thus do work. They also provide an index of power generation. Smooth muscle force-velocity curves are also hyperbolic and can be fitted by Hill's equation, as previously described. Force-velocity studies show that the force of contraction at zero velocity for smooth muscle is

similar to the force of contraction for striated muscle but that maximum velocity values are much smaller. The maximum velocity is a convenient index of the contractility of smooth muscle as long as the shortening is limited to less than 25% of optimal length.

When a muscle is forcibly lengthened, the load may exceed the force of contraction at zero velocity. This may be the case for airway smooth muscle during inspiration. Thus a muscle that is being actively elongated may be stronger than the same muscle that is shortening. An elongating muscle also consumes less energy than the shortening muscle at equivalent velocities.

Influence of Breathing Movements on Smooth Muscle Mechanics. As diameters of airways change with inspiration and expiration, it is important to know how the smooth muscle behaves when its length is externally forced. When the muscle length is changed with amplitudes and frequencies similar to those occurring during respiration, considerable force-length hysteresis occurs. The tension in the muscle depends not only on the pattern of the imposed length cycles but also on their timing. During repeated muscle stretching, increased time between cycles equates to greater initial tension in the muscle.

INDIVIDUAL RESPIRATORY MUSCLES

The mechanical task of the respiratory muscles differs from that of a typical limb muscle because the respiratory muscle must overcome primarily elastic and resistive impedances, whereas limb muscles contend principally with inertial impedances. Usually, respiratory muscles must repeatedly perform relatively sustained tension-generating and shortening actions, whereas limb muscles are usually required to generate short bursts of tension and shortening in executing the usual rhythmic motions of the limbs. This difference can be a determining factor for the contractile and endurance properties of the respiratory muscles. The changes in lung volume that occur during breathing indicate that different muscles are asked to begin contracting from different lengths.

Diaphragm. The diaphragm is a mixed muscle made up of approximately 21% FOG, 55% SO, and 24% FG fibers. The number of fatigue-resistant SO fibers increases in the diaphragm during infancy and has been reported to be approximately 10% in premature infants, 25% in full-term infants, and reaching the adult level (around 55%) by 2 years of age. In all species studied, including humans, the diaphragm is functionally intermediate in its rate of tension generated between fast and slow muscles. The diaphragm fibers are thought to be at optimal length at supine functional residual capacity (FRC), although maximal tension seems to occur at somewhat longer lengths.

Intercostal Muscles. The composition of the intercostal muscles is similar to that of the diaphragm. Also, the percentage of fatigue-resistant fibers is substantially reduced in premature infants and, to a lesser extent, full-term neonates, reaching adult levels by 2 years of age.

Scalenus Muscles. The scalenus muscles insert into the first rib, and contraction elevates the first rib during inspiration. These muscles have generally been regarded as accessory muscles of respiration, but they appear to contract, as indicated by the presence of action potentials, during resting breathing and should be regarded as primary respiratory muscles. There are no published data about their fiber type distribution or contractile properties.

Sternocleidomastoid Muscle. The sternocleidomastoid muscle is clearly an accessory muscle of respiration because it usually does not contract unless breaths are considerably deeper than resting tidal breaths. It appears to be made up of 65% fast-twitch and 35% slow-twitch fibers.

Abdominal Muscles. The respiratory actions of the abdominal muscles are twofold. They are primary expiratory muscles because of their direct action on the rib cage and their ability to compress the abdominal contents, forcing the diaphragm upward. They also appear to facilitate the inspiratory action of the diaphragm by contracting toward the end of expiration, pushing the diaphragm upward and optimizing its fiber length for generating tension during the subsequent inspiration. This action of the abdominal muscles occurs during the postural change from supine to upright, during voluntary hyperventilation, and during exercise.

Dynamics of Breathing

Ventilation of the lungs involves motion of the respiratory system, which is produced by the forces required to overcome the flow-resistive, inertial, and elastic properties of the lungs and chest wall. Under normal circumstances, these forces are produced by the respiratory muscles.

FLOW RESISTANCE

The force required to move a block of wood over a surface is determined by the friction between the block of wood and the surface and by the speed with which the block is moving. It is not, however, determined by the position of the block. Similarly, the pressure required to produce flow between the atmosphere and alveoli and thus to overcome the frictional resistance *(fr)* of the airways is proportional to flow $\dot{V}$ (i.e., the rate at which volume is changing), as follows:

$$P_{mouth} - P_{alv} = P_{fr} = \alpha\dot{V} \qquad \text{Eq 7.3}$$

The pressure required to produce a unit of flow is known as the *flow resistance (R)*, as shown by the following:

$$R = P_{fr}/\dot{V} \qquad \text{Eq 7.4}$$

If the respiratory system is modeled as a single compartment with a single constant elastance *(E)* and a single constant resistance *(R)*, then the equation of motion describing the balance of forces acting on the system is as follows:

$$P = EV + R\dot{V} + I\dot{V} \qquad \text{Eq 7.5}$$

The inertance *(I)* is usually negligible and therefore ignored. During tidal respiration, approximately 90% of the pressure produced is required to overcome the elastic forces,

and approximately 10% is required to overcome the flow-resistant forces.

Traditionally, it was thought that the majority of the force developed during breathing was required to move gas through the airways and that little energy was dissipated by the tissues of the respiratory system. In recent years, however, it has become increasingly apparent that the viscoelastic properties of the respiratory system contribute significantly to the behavior of that system. The energy expended moving the tissues has been called *tissue viscance* or *resistance*, although it is a non-newtonian resistance. The anatomic structures responsible for the viscoelastic behavior of lung tissue are not known. Candidates likely to contribute to viscoelasticity include the air-liquid interface, collagen and elastin fibers, actin/myosin cross-bridges, contractile (Kapanci) cells within the interstitium, and smooth muscle in the alveolar ducts. Experimental evidence is consistent with the involvement of "contractile" elements because the stress adaptation seen after an airflow interruption (a manifestation of viscoelastic behavior) increases after "constrictor" stimuli[4,7-10] and decreases after "relaxant" stimuli. Alternatively, the viscoelasticity demonstrated in many animal studies may be a reflection of the immense complexity of the lungs, with no single structure responsible.[11]

Studies in animals have demonstrated that when measured during inspiration, tissue resistance increases and airway resistance falls with increasing lung volume. Tissue resistance contributes approximately 65% of respiratory system resistance at FRC in mechanically ventilated animals and increases to as much as 95% at higher lung volumes.[12] The contribution of tissue resistance to respiratory system resistance in humans, under the same conditions, is not known, but the overall behavior of the respiratory system appears to be similar.

DRIVING PRESSURES FOR RESPIRATION

Inspiration occurs when the respiratory muscles cause the alveolar pressure to be less than atmospheric pressure. Air then moves along this pressure gradient, and the lungs inflate, thus storing potential energy in the elastic structures. At the end of inspiration, the respiratory muscles relax, and the elastic recoil of the respiratory system causes the alveolar pressure to be positive relative to atmospheric pressure, and expiration occurs. Under resting conditions, expiration is usually passive. At times of increased ventilatory requirements, such as during exercise, contraction of the abdominal and internal intercostal muscles can aid expiration.

TIME CONSTANT OF EMPTYING

When the respiratory system is allowed to empty passively the time taken for the initial volume to be reduced by 63% is known as the *time constant* (τ) of the respiratory system (Fig. 7-9). If the respiratory system is modeled as a single compartment with a single, constant elastance and a single, constant resistance, then the following occurs:

Eq 7.6

$$\tau = R/E$$

Under these conditions, the volume-time profile can be represented by a single exponential decay.

In healthy adults the time constant of the passive respiratory system is approximately 0.5 second, which allows the lungs to empty to the EEV at the end of each expiration; the FRC and EEV are equal. This means that the respiratory system is relaxed at the end of expiration and that inspiration can begin as soon as inspiratory muscle activity commences. In obstructive airway diseases, such as asthma and chronic bronchitis, resistance is increased, and the expiratory time constant is longer. Therefore, a longer time is required for the lungs to empty and return the respiratory system to EEV. Patients with these diseases frequently have carbon dioxide retention and an increased respiratory drive. This results in an increased respiratory rate with a decrease in the time available for expiration. Thus, the respiratory system frequently does not have time to return to EEV before the next inspiration starts. This means that FRC occurs at a volume higher than EEV and that the respiratory system is not relaxed at the end of expiration but that there is a positive recoil pressure. This pressure has been called *intrinsic positive end-expiratory pressure*, or PEEPi. Before inspiratory flow can begin, the inspiratory muscle must produce enough force to overcome the PEEPi; thus this force is "lost" to producing inspiratory flow and represents a load that must be overcome by the inspiratory muscle. In patients with severe airway obstruction this pressure can be as high as 15 to 20 cm H_2O. The expiratory time constant is shorter in children, with values approximating 0.3 second reported in infants with normal lungs.[10] Infants with hyaline membrane disease have stiffer-than-normal lungs, with expiratory time constants reported to be as low as 0.1 second.[13]

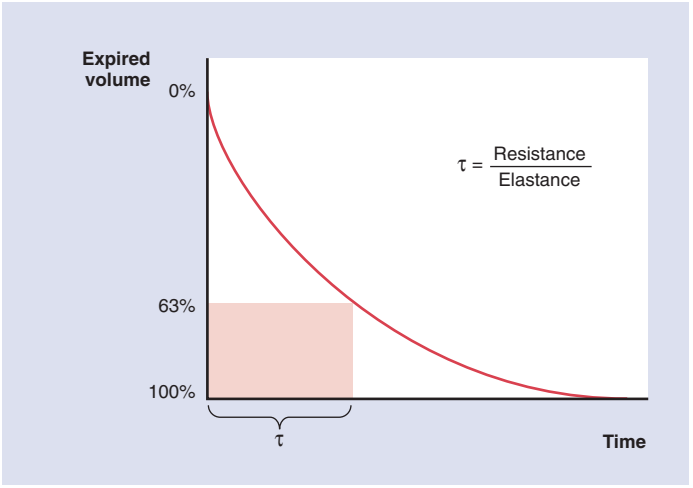

Figure 7-9 Time constant of lung emptying.

DYNAMIC CHANGE IN AIRWAY CALIBER DURING RESPIRATION

Airway caliber is partially dependent on the transmural pressure (Fig. 7-10). The external airway wall is subjected to interstitial pressure, which is approximately equal to pleural pressure for all intrathoracic airways. The external walls of extrathoracic airways are subjected to atmospheric pressure. The pressure inside the airway depends on the generation of the airway. During inspiration, pleural pressure is negative relative to atmospheric pressure. Alveolar pressure is approximately equal to pleural pressure, and pressure at the mouth is atmospheric. Thus, there is a pressure gradient from the

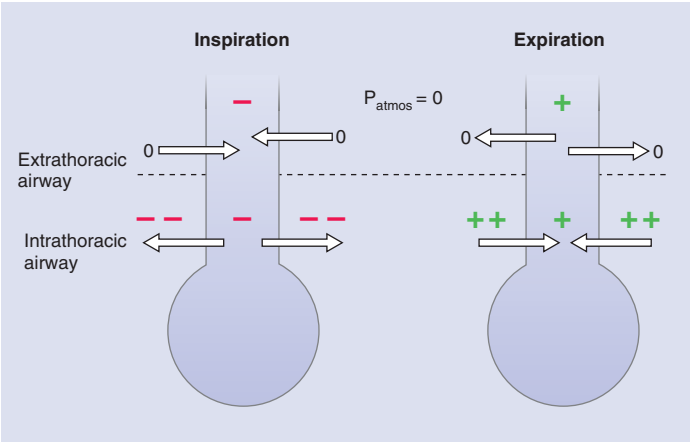

Figure 7-10 Transmural airway pressures during inspiration and expiration, with net forces illustrating one factor leading to extrathoracic narrowing on inspiration and intrathoracic narrowing on expiration. *Arrows* indicate net force on airway; plus and minus signs indicate pressure relative to atmospheric pressure (0).

mouth to the alveoli. Transmural pressure for the extrathoracic airways is positive, and there is a tendency for these airways to narrow during inspiration. The transmural pressure is negative for the intrathoracic airways, causing a tendency for these airways to dilate during inspiration. The degree of change in airway caliber depends on the magnitude of the transmural pressure and the airway wall compliance. At the end of inspiration, the inspiratory muscles relax, and the elastic recoil of the respiratory system produces positive pleural and alveolar pressures (relative to atmospheric pressure). Thus, there is a tendency for intrathoracic airways to narrow and extrathoracic airways to dilate during expiration.

Gas Exchange

The basic respiratory function of the respiratory system is to supply oxygen to the body and to remove excess carbon dioxide. The following are the basic steps involved in this process:

1. Ventilation, the exchange of gas between the atmosphere and the alveoli
2. Diffusion across the alveolar-capillary membranes
3. Transport of gases in the blood
4. Diffusion from the capillaries of the systemic circulation to the cells of the body
5. Use of oxygen and production of carbon dioxide within the cells (i.e., internal respiration)

VENTILATION

Ventilation is the process whereby fresh, oxygen-rich gas is delivered to the alveoli and carbon dioxide is removed. As discussed earlier, the volume of gas reaching the alveoli per unit time—not the volume of gas entering and leaving the respiratory system—is the important parameter for gas exchange.

GAS DIFFUSION

Gas diffusion is a passive process: Gases diffuse from a site of high partial pressure to a site of low partial pressure. The flux is proportional to the area available for diffusion and to the difference in partial pressure per unit length of the diffusion pathway. Conditions that thicken the alveolar wall, the main blood-gas barrier, can interfere with diffusion.

GAS TRANSPORT

Gas is transported in the blood via two primary methods: dissolved in plasma or combined with hemoglobin. Approximately 98% of oxygen transported in the blood is bound to hemoglobin. When oxygen combines loosely with the heme portion of hemoglobin in the lung, where the oxygen partial pressure is high, it forms oxyhemoglobin. When the oxyhemoglobin reaches the tissues, where oxygen partial pressure is low, the oxygen is released and diffuses to the cells. The binding of oxygen to hemoglobin is a nonlinear process, as demonstrated by the sigmoid oxygen-hemoglobin dissociation curve (see Chapter 14 for a more detailed discussion). When hemoglobin is 100% saturated with oxygen, large changes in the partial pressure of oxygen (Pa_{O_2}) are required before the arterial oxygen saturation (Sa_{O_2}) falls much. However, below a Sa_{O_2} of about 90%, the relationship between the fall in Pa_{O_2} and that in Sa_{O_2} becomes steeper. Increases in both body temperature and arterial pH shift the oxygen-hemoglobin dissociation curve to the right, facilitating the peripheral unloading of oxygen. Normal lungs have sufficient reserve capacity to overcome the increased difficulty in loading oxygen under these circumstances. However, in the presence of a marked $\dot{V}/\dot{Q}$ imbalance, rightward shifts in the oxygen-hemoglobin dissociation curve may become more significant.

Carbon dioxide is transported more readily in the blood than oxygen because carbon dioxide, being a nonpolar molecule, is highly lipid soluble. Carbon dioxide is transported in the blood in the following ways, all of which begin with the gas being dissolved in the plasma after it has diffused into the systemic capillaries from the tissues:

1. As bicarbonate ions (60% to 70%)
2. Combined with hemoglobin to form carbaminohemoglobin (15% to 30%)
3. Dissolved in plasma and red blood cells (7% to 10%)

Carbon dioxide does not bind to hemoglobin at the same site as oxygen; instead it binds directly with some of the amino groups that form the hemoglobin molecule. The carbon dioxide-hemoglobin dissociation curve is less curvilinear.

VENTILATION/PERFUSION IMBALANCE

Inhomogeneity of the ventilation/perfusion ($\dot{V}/\dot{Q}$) balance in the lungs most commonly occurs in conditions that produce ventilatory inhomogeneity, such as obstructive airway diseases (e.g., asthma). $\dot{V}/\dot{Q}$ mismatch results in a decrease in the transfer of oxygen to arterial blood and a decrease in carbon dioxide elimination. However, the result is a lowering of Pa_{O_2}, with a lesser increase in Pa_{CO_2}. Several factors contribute to this phenomenon. The gas tension in an individual alveolar-capillary unit depends on the ratio of ventilation to perfusion in that unit. Well-ventilated units tend to raise the oxygen tension toward that of the inspired gas (about 150 mm Hg when breathing air), whereas well-perfused units tend to lower oxygen tension toward that of the mixed venous blood (normally about 40 mm Hg). For the same reasons, the

	A	B	A+B
Alveolar ventilation (L/min)	2.0	2.0	4.0
Pulmonary blood flow (L/min)	2.5	2.5	5.0

Arterial O_2 tension (mm Hg)	104.0	104.0	104.0

	A	B	A+B
Alveolar ventilation (L/min)	3.2	0.8	4.0
Pulmonary blood flow (L/min)	1.3	2.5	5.0
Ventilation/blood flow ratio	75.0	0.3	0.0
Mixed venous O_2 saturation (%)	98.2	75.0	75.0
Arterial O_2 saturation (%)	40.0	91.7	95.0
Mixed venous O_2 tension (mm Hg)	116.0	40.0	40.0
Alveolar O_2 tension (mm Hg)	116.0	66.0	106.0
Arterial O_2 tension (mm Hg)		66.0	84.0

Figure 7-11 *Left,* Ideal $\dot{V}/\dot{Q}$ matching. *Right,* Nonuniform ventilation with uniform blood flow leading to mismatch. MV, respiratory minute volume; $\dot{V}_A$, alveolar ventilation. (From Comroe JH Jr, et al: The Lung: Clinical Physiology and Pulmonary Function Tests, 2nd ed. St Louis, Mosby, 1962.)

P_{CO_2} is higher in overperfused units and lower in overventilated units. The extreme case of overventilation and underperfusion results in an increase in dead space, whereas the converse results in an intrapulmonary shunt (Fig. 7-11). Mixing of the blood from units with different $\dot{V}/\dot{Q}$ balances does not compensate for the different oxygen and carbon dioxide tensions because, by definition, relatively more blood comes from the underventilated, overperfused units. This results in a difference between the gas tensions in the mixed pulmonary venous blood (which becomes the arterial gas tension) and the mixed alveolar gas (in reality the average tension) and is expressed as an alveolar-arterial difference. The alveolar-arterial difference is greater for oxygen than for carbon dioxide.

A lowering of the P_{aO_2} or an increase of P_{aO_2} results in an increase in respiratory rate via chemoreceptor stimulation. This increase can lower the P_{aCO_2} but cannot raise the P_{aO_2} to the same extent. This is because of the different shapes of the blood gas content-tension curves. Because the oxygen-hemoglobin dissociation curve is almost flat at high blood oxygen contents, increasing ventilation to well-ventilated units cannot increase the blood oxygen content but does remove extra carbon dioxide from the blood passing through the well-ventilated units. This means that increasing ventilation, in the face of $\dot{V}/\dot{Q}$ inhomogeneity, reduces the P_{aCO_2} toward or below normal but does not increase the P_{aO_2} to normal values.

Control of Breathing

The primary function of the respiratory system is gas exchange. This requires a precise regulation of blood gas concentrations, which allows for the varying requirements imposed by the different levels of demand encountered with differing levels of activity. This control system can be thought of as having two parts: a "feed-forward" component, which is related to the ventilatory requirements, and a "feedback" component, which tells the system how well it is performing. The feed-forward system includes factors such as cardiac output, carbon dioxide production, oxygen consumption,

input from muscle afferents, and input from higher brain centers. The feedback system consists of the partial pressures of carbon dioxide and oxygen and the hydrogen ion concentration reaching the respiratory centers. The feed-forward system is important because it allows the respiratory centers to "anticipate" the increased ventilatory requirements (e.g., during exercise). Without this anticipation, the ability to cope with the increased ventilatory demands is substantially reduced. This concept is expanded more fully in an article by Cunningham and colleagues.[14]

Although much of the knowledge about the interaction of changes in blood gases through control of breathing has come from studies in which the influences of carbon dioxide and oxygen have been studied separately, in the real world, these variables almost always change together. Changes in blood gas tensions are sensed by chemoreceptors located in the carotid bodies and central respiratory centers. The carotid body receptors respond to a change in either blood carbon dioxide or oxygen levels by a change in output. The impulses that reach the central respiratory control centers are identical, whether they are produced by changes in oxygen or carbon dioxide tensions. The carotid body chemoreceptors respond to a fall in PaO_2 or an increase in $PaCO_2$ with an increase in output, stimulating an increased respiratory rate. Changes in $PaCO_2$ also result in changes in hydrogen ion concentration, which also influences chemoreceptor output. The central chemoreceptors are influenced by the pH and carbon dioxide tensions in the cerebrospinal fluid. The output from the central chemoreceptors is thought to act independently on the respiratory control centers.

The relationship between ventilation $(\dot{V})$ and alveolar carbon dioxide partial pressure ($PaCO_2$) can be described as:

Eq 7.7

$$\dot{V} = S(PaCO_2 - B)$$

where S is the slope of the line or sensitivity of the relationship and B is the intercept with the $PaCO_2$ axis (Fig. 7-12).

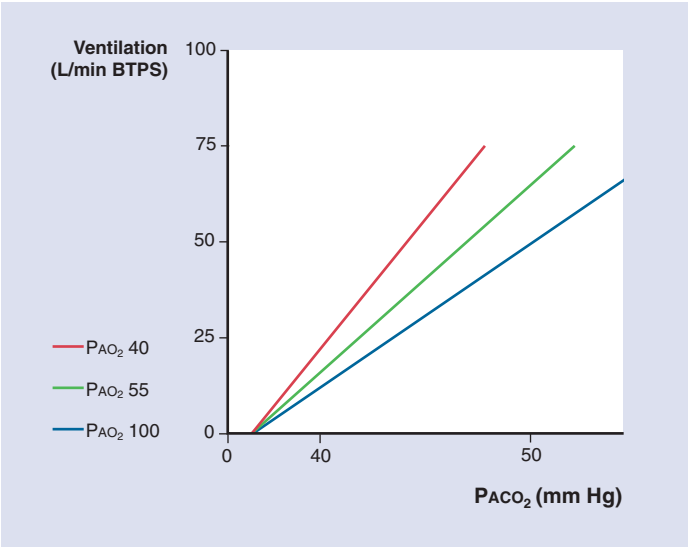

Figure 7-12 Carbon dioxide response curves at various fixed values for PaO_2. BTPS, Body temperature, pressure, saturated. (From Ganong WF: Review of Medical Physiology, 16th ed. Norwalk, Conn, Appleton & Lange, 1993.)

Hypoxia increases the sensitivity without altering the intercept. At very high levels of $PaCO_2$ and very low levels of PaO_2, respiratory depression occurs.

Studies investigating the control of breathing in infants have reported conflicting results, largely because of the methodologic difficulties inherent in studying infants. The major difference in the control of breathing between adults and infants is in the infants' ventilatory response to hypoxia. Despite the difficulties in using appropriate methodology, it is now generally agreed that the slope of the ventilatory response to carbon dioxide, when appropriately corrected for size in infants, is the same as that in the adult.

When exposed to low oxygen mixtures, newborns respond with a brief period of hyperpnea, followed by ventilatory depression. If the neonate has been allowed to cool (or is not in a neutral thermal environment), the period of hyperpnea is not seen. The ventilatory depression in response to hypoxia persists for about a week in full-term infants and for several weeks in infants born prematurely. The mechanism for this paradoxical response remains obscure. Recent evidence favors an immaturity of the central controlling centers rather than an immaturity of the peripheral chemoreceptors. Sleep state also seems to modify the ventilatory response to hypoxia, with the paradoxical response absent during rapid-eye-movement sleep. For an in-depth discussion of control of breathing in the fetus and newborn, see Bryan and coworkers.[15]

The state of the respiratory system is important in the translation of the signals from the respiratory center to alveolar ventilation and gas exchange. Diseases of the various components of the respiratory system are characteristically associated with increased mechanical loads. These loads may be elastic, resistive, inertive, or a combination thereof.

Diseases that increase the resistance against which the patient must breathe impose resistive loads. Increased intrinsic resistive loading occurs when the peribronchial forces that act to keep the airways patent are overwhelmed, resulting in airway narrowing; when gas flow becomes turbulent, increasing energy dissipation; or when high-viscosity or high-density gases are breathed. The most common example of increased intrinsic resistive loading seen in children is asthma, although this also occurs in other lung diseases such as chronic suppurative bronchitis and emphysema. The primary ventilatory response to these disorders is usually an alteration in V_T and respiratory timing indices, although many patients with severe disease appear to tolerate a chronic increase in $PaCO_2$ rather than respond appropriately, thereby conserving work of breathing. A breathing pattern with a prolonged expiratory phase is optimal for lung emptying and avoiding increases in lung volume (which would impose an increased elastic load), although a shortened inspiratory time would require higher inspiratory flows, adding to the increased resistive load.

Increased elastic loading occurs when the respiratory system is stiffer than usual; this occurs with hyaline membrane disease and interstitial lung diseases (increased lung stiffness); severe cases of obesity, ankylosing spondylitis, or kyphoscoliosis (increased chest wall stiffness); or conditions of decreased muscle performance (e.g., high quadriplegia, Guillain-Barré syndrome, botulism, muscular dystrophies). In these conditions, the ability to expand the thorax is decreased. The primary ventilatory response to these disor-

ders is usually tachypnea; hypoxia, and a relatively normal or even low $PaCO_2$ result. Rapid, shallow breathing, which minimizes the elastic load, may be seen.

STRUCTURE AND FUNCTION: APPLIED PHYSIOLOGY

Maintenance of Lung Volume

In healthy subjects at rest, FRC occurs at the volume at which the elastic recoil of the respiratory system is zero. This volume is known as the *EEV*, or the relaxation volume. The lungs and chest wall both contribute to the elastic properties of the respiratory system. The chest wall and the lungs are mechanically in series; thus the algebraic sum of the pressure exerted by the chest wall and lungs equals the pressure of the respiratory system. The EEV of the respiratory system occurs where the elastic recoil of the chest wall is equal and opposite to that of the lungs (Fig. 7-13). In isolation the relaxation volume of the lungs is zero; that is, there is always a tendency for the lungs to empty when there is gas in them. However, in practice, the lungs can never empty fully because small airways collapse before the lung volume becomes zero, thus trapping gas in the lungs. In healthy people the relaxation volume of the respiratory system is well above the volume at which the small airways close. Newborns have a more compliant (less stiff) chest wall. The chest wall thus has less elastic recoil to balance that of the lungs. This moves the static pressure-volume curve to the right, thus decreasing the relaxation volume of the respiratory system. Infants born prematurely also have stiff lungs. Thus at any given volume the P_{el} of the lungs is increased. This moves the static pressure-volume curve of the lungs, and hence that of the respiratory system, to the right, further reducing the EEV. This reduction may be marked enough so that the relaxation volume is less than the "closing volume" for small airways. This situation cannot be tolerated, and the infant remedies the situation by breathing at a higher volume than the relaxation volume. Thus FRC and relaxation volume are not necessarily interchangeable because they may not always be equivalent.

Hyperinflation

Hyperinflation refers to an increase in lung volume above that usually seen at rest. As previously discussed, the end-expiratory lung volume coincides with the EEV of the respiratory system in adults and older children with normal lungs. Hyperinflation occurs naturally in two primary settings: (1) in the presence of a significant increase in resistance and (2) in the presence of a significant decrease in elastic recoil. Both of these conditions result in an increase in the time constant of emptying of the respiratory system. If the respiratory rate required to satisfy ventilatory demands does not allow sufficient expiratory time, hyperinflation occurs. Another setting in which hyperinflation may develop is during mechanical ventilation. On theoretical grounds, an expiratory time equal to three times the expiratory time constant allows emptying of 95% of the end-inspiratory volume, whereas an expiratory time equal to five times the expiratory time constant allows emptying of 99% of the volume. In practice, if the expiratory time constant was less than three times the expiratory time constant, hyperinflation (manifested as the development of PEEPi) develops in ventilated infants.[13]

Hyperinflation does serve a useful purpose. The increase in lung volume is associated with an increase in airway caliber secondary to mechanical interdependence. The increase in lung volume also increases the tissue viscance.[16,17] The degree to which resistance and, therefore, the time constant of emptying depends on the balance between these opposing influences. A patient with severe airflow obstruction may have so

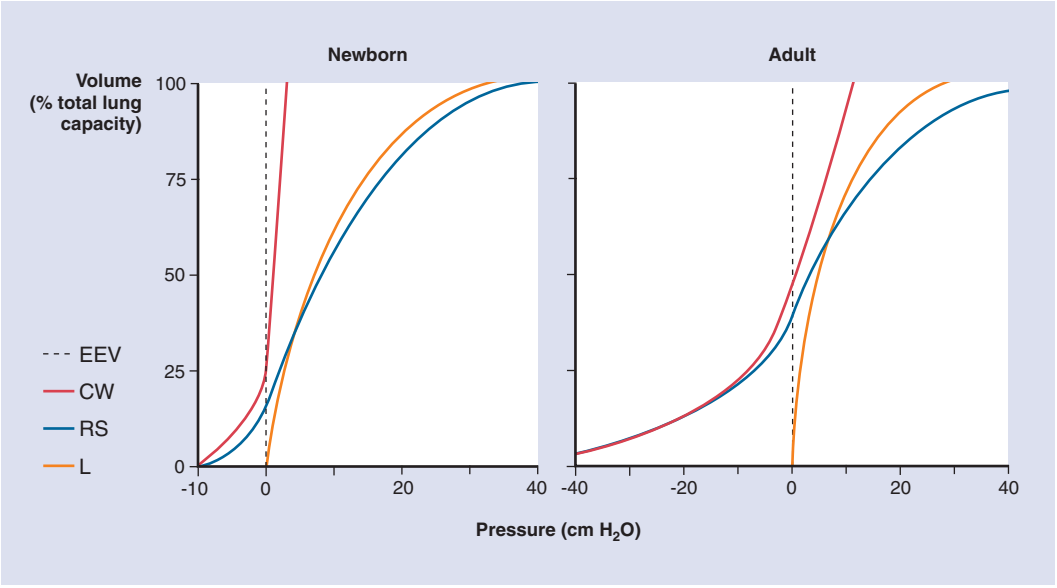

Figure 7-13 Pressure-volume curves of the newborn and adult respiratory system (RS) demonstrating the effect of lung (L) and chest wall (CW) compliance on elastic equilibrium volume (EEV). (From Agostini E: Volume-pressure relationships of the thorax and lung in the newborn. J Appl Physiol 14:909-913, 1959.)

much expiratory flow limitation that these values are, in fact, flow-limited during tidal breathing at rest. The only way that the expiratory flows can be increased at times of increased ventilatory demand, such as during exercise or febrile illnesses, is to increase lung volume, thus moving tidal breathing to a more advantageous part of the expiratory flow-volume curve. It is not surprising that hyperinflation has been found to be, at least partly, an active phenomenon.[18-20] Hyperinflation is achieved by tonic contraction of inspiratory muscles[19] and by expiratory "braking" by adduction of the vocal cords.[21]

The increase in expiratory flows made possible by hyperinflation does come at a cost. Hyperinflation puts the inspiratory muscles at a mechanical disadvantage, placing them at an inefficient part of their length-tension relationships. Under these conditions, the muscle excitation must increase to produce the same external work. This results in an increase in energy consumption and a decrease in efficiency. The work of breathing also increases because although the resistive work decreases and the total resistance is less, the elastic work increases and more than offsets any gain in resistive work. In addition, actively contracting muscles run the risk of limiting their own energy supply by narrowing the feeding arteries. These factors place the inspiratory muscles at risk of developing inspiratory muscle fatigue.

Two compensatory processes have been reported that have the potential to decrease the load on the inspiratory muscles. In patients with severe chronic airflow limitation, end-expiratory lung volume has been reported to increase during exercise, whereas the anteroposterior dimensions of the abdomen decrease because of expiratory recruitment of the abdominal muscles.[22] End-expiratory cephalad displacement of the diaphragm, secondary to contraction of abdominal muscles toward the end of expiration,[23] aids inspiration in at least two ways: It puts the muscle fibers of the diaphragm on a more favorable part of their length-tension relationship, and it stores elastic and gravitational energy in the abdominal compartment and releases it during the subsequent inspiration, performing inspiratory work and contributing to minute ventilation without increasing the activation of the diaphragm.

The expiratory braking, grunting, achieved by partial glottic adduction, "unloads" the inspiratory muscles by allowing hyperinflation to be maintained with less tonic activation of inspiratory muscles.

Forced Expiration

EXPIRATORY FLOW LIMITATION

Measurements during forced expiration are useful in detecting obstructive lung disease because during a forced expiration, expiratory flow is independent of the force driving the flow over most of the expired vital capacity as long as reasonable effort is made. This observation was made by plotting the pressure-flow relationships at isovolume points measured during expirations made with increasing effort (Fig. 7-14). This observation led directly to the description of the maximal expiratory flow volume curve, which emphasized that at most lung volumes, there was a limit to maximal expiratory flow. The peak flow depends largely on effort, and the flows near the residual volume may be effort-dependent because some people may not be able to maintain sufficient force to maintain flow limitation at this low lung volume.

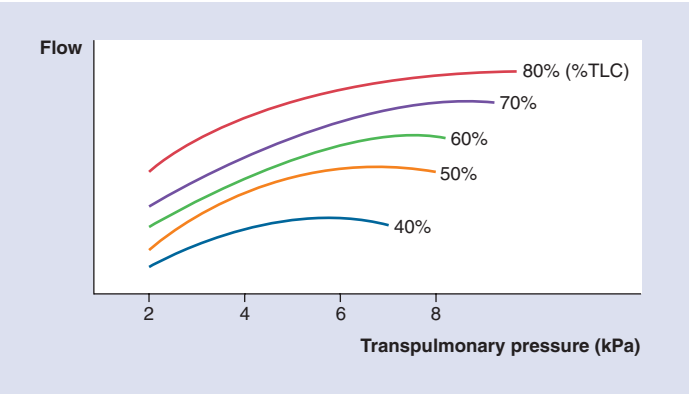

Figure 7-14 Isovolume pressure-flow curves in a normal adult at different proportions of total lung capacity (TLC). (From Tammeling GJ, et al: Contours of Breathing, 2nd ed. Burlington, Ontario, Canada, Boehringer Ingelheim Pharmaceuticals, 1985.)

The mechanism for expiratory flow limitation is complex. In fluid dynamic terms, a system cannot carry a greater flow than the flow for which the fluid velocity equals wave speed at some point in the system. The wave speed is the speed at which a small disturbance travels in a compliant tube filled with fluid. In the arteries, this is the speed at which the pulse propagates. In the airway, the speed is higher than this—mainly because the fluid density is lower. The wave speed *(c)* in a compliant tube with an area *(A)* that depends on lateral pressure *(P)* filled with a fluid of density *(ρ)*, is given by the following:

$$c = (A\delta P/\rho\delta A)^{1/2} \qquad \text{Eq 7.8}$$

where $\delta P/\delta A$ is the slope of the pressure-area curve for the airway. Maximal flow is the product of the fluid velocity at wave speed and airway area, as follows:

$$\dot{V}_{max} = cA \qquad \text{Eq 7.9}$$

At high lung volumes the flow-limiting site in the human airways is typically in the second and third airway generations. As lung volume decreases, flow decreases, and the flow-limiting site moves peripherally. At low lung volumes the density dependence of maximal flow is small, and the viscosity dependence is large and becomes the predominant mechanism limiting expiratory flow.

PHYSIOLOGY OF WHEEZING

Flow limitation in a compliant tube is accompanied by the "flutter" of the walls at the site of flow limitation. This flutter occurs to conserve the energy in the system because the driving pressure in excess of that required to produce $\dot{V}_{max}$ is dissipated in causing the flutter.[24,25] In the presence of airway obstruction, this flutter may become large enough to generate sound. This sound is heard as wheezing. Thus expiratory wheezing is a sign of expiratory flow limitation. However, although wheezing implies the presence of expiratory flow limitation, flow limitation can occur in the absence of

detectable wheezing.[24] Gavriely and associates[26] demonstrated that the transpulmonary pressures (as an indication of the effort required for breathing) required to produce wheezing were substantially greater than those required to achieve flow limitation. They concluded that this extra pressure was required to "induce flattening of the intrathoracic airways downstream from the choke point" and to induce oscillations in the airway walls.[26]

COUGH

Cough is the most common natural forced expiration. Most of the forced expirations measured by clinicians are artificially produced to satisfy the clinician's desires. Cough has several practical functions. It can be stimulated by various receptors in the respiratory tract; that is, irritant receptors in the large airways stimulate cough in response to mechanical irritation (e.g., inhalation of dust, cigarette smoke, aspirated material) or respiratory infections to help clear material from the respiratory tract; irritant receptors in the larynx prevent or minimize aspiration of foreign materials into the airways; or stretch receptors in the lung parenchyma, stimulated by application of high distention pressures to the lung, limit maximal inspiration, presumably protecting the lung from overdistention and mechanical disruption. Cough can also be initiated voluntarily.

Whether cough is initiated by voluntary means or by stimulation of receptors, the first action is usually inspiration of a variable volume of air. Next, the glottis is closed simultaneously with or just after the onset of forceful expiratory muscle activity that quickly raises thoracoabdominal pressures to 100 cm H_2O or more above ambient pressure. About 0.2 second after the glottis closes, it is actively opened; subglottic pressure falls, and expiratory flow begins. Intrathoracic pressures, however, usually continue to rise; thus peak pressure usually occurs after peak flow. Expiratory flow quickly rises to "maximal" flow as central intrathoracic airways collapse. Their narrowed cross-section is associated with high gas linear velocities and therefore with high shearing forces at airway walls and high kinetic energies. These conditions are probably important in suspending and clearing materials adherent to the walls. After a widely variable volume of air is expired, expiratory muscle activity diminishes abruptly, perhaps with the onset of antagonist activity of the diaphragm and other muscles; alveolar pressure falls toward ambient pressure, and flow drops toward zero, sometimes interrupted finally by glottic closure. Several coughs may follow in immediate series from high to low lung volume without intervening inspirations. This has the effect of "squeezing" secretions in the smaller airways more centrally to airways with high enough linear velocities to clear the secretions.

CHAPTER 8

Exercise Physiology

Alan R. Morton

TEACHING POINTS

- Exercise physiology is a branch of applied physiology concerned with the patient's responses to both acute and chronic exercise (training).
- Humans require regular physical activity to achieve optimal growth, optimal development of the heart and lungs, and optimal strength of bones, ligaments, tendons, and muscles.
- A sedentary lifestyle during adulthood, which is often the result of a childhood with restricted physical activity, may contribute to the development of various illnesses collectively classified as *hypokinetic diseases*. These diseases include coronary heart disease, obesity, diabetes, hypertension, colon cancer, and low back problems.
- Adenosine triphosphate (ATP), often referred to as the *universal energy currency*. is a molecule that contains adenosine plus three phosphate groups. Energy is provided by the phosphagen system, the lactic acid system (anaerobic glycolysis), or the oxygen (aerobic) system.
- The number of muscle fibers is determined at birth; however, the thickness of the fibers grows about fivefold from birth to adulthood. The increase in muscle girth is due almost entirely to hypertrophy or continued growth of existing muscle fibers and not by hyperplasia.
- When the body changes from a resting state to one of maximal exercise intensity, its energy expenditure may increase more than 23 to 26 times the resting value, and the metabolic demands of the most active skeletal muscles may increase by as much as 130 to 200 times the resting value.
- During exercise, the body's rate of oxygen consumption ($\dot{V}O_2$) may increase by more than 20-fold, exhibiting a linear relationship between $\dot{V}O_2$ and the intensity of exercise or rate of work.
- The child is not a miniature adult, and because there are important differences in physiologic responses to muscular activity, children should not be expected to perform in a manner similar to adults.
- During training and competition, repetitive stress on a muscle, bone, or joint produces adaptations, some of which may be undesirable.
- In sports, the different levels of performance at a given age are often the result of different levels of maturity rather than of skill.

The trend is for children to become involved with serious sports training at progressively younger ages, with some beginning as early as 6 years of age, and teenagers are performing at world championship level in many sports, particularly swimming, tennis, and gymnastics. It is important, therefore, that the clinician have a good understanding of the physiologic, psychologic, and sociologic responses of children to vigorous exercise, with emphasis on the benefits and possible detrimental outcomes.

Exercise physiology is a branch of applied physiology concerned with the patient's responses to both acute and chronic exercise (training). It is concerned with these responses under various climatic, hyperbaric, and hypobaric conditions as they differ between genders and among people of different ages. In a chapter of this size, it is impossible to describe all of the physiologic changes accompanying acute and chronic exercise; therefore the major metabolic and cardiorespiratory factors are discussed only briefly.

Unfortunately, most of the research in this relatively new discipline has been performed on adults, and as a result, many of the pediatric exercise physiology questions are either unanswered or only partly answered. The reason for the lack of evidence concerning children can be explained by the reluctance of parents and ethics committees to provide consent for many of the required invasive and noninvasive procedures, such as muscle biopsies and arterial and venous blood sampling (especially when performed on a serial basis), and exposure to harsh environmental conditions and prolonged or severe exercise for what is often misconstrued as "athletic curiosity." When cross-sectional studies are performed in an effort to compare athletic children with sedentary children, it is difficult to separate training effects from genetic endowment. Nevertheless, this chapter examines the general responses to exercise and, when information is available, compares the responses of adults to those of children. This comparison will indicate any advantages that the mature child, who more closely resembles the adult, has over the immature child. This maturity difference is often evident in children of the same chronologic age who are expected to compete against one another in sports.

Humans require regular physical activity to achieve optimal growth,[1] optimal development of the heart and lungs, and optimal strength of bones, ligaments, tendons, and muscles. The child needs to play and be on the move constantly and, until a generation ago, considered *rest* a four-letter word; however, this no longer appears to be true. For instance, studies in England[2,3] and Singapore[4] have indicated that the daily activity level of children today, as determined by continuous heart rate monitoring, is very low and that many children seldom undertake enough physical activity to appropriately stress the cardiopulmonary system. A sedentary lifestyle during adulthood, which is often the result of a childhood

with restricted physical activity, may contribute to the development of various illnesses collectively classified as *hypokinetic diseases*. These diseases include coronary heart disease, obesity, and low back problems.[5] In 1996 the Surgeon General of the United States published a most comprehensive review of the research on physical activity and health and the implications. This 278 page document, based on a vast number of studies, showed that a lifelong regimen of regular, moderate amounts of moderate or vigorous physical activity, will provide substantial health gains. Physical activity also reduces the risks of developing coronary heart disease, hypertension, colon cancer, and diabetes as well as maintaining a high quality of life.[6] Regular and frequent exercise is an important component in the prevention and treatment of obesity, a problem that has reached epidemic proportions among children and adults in the Western world. Many obese children and adolescents become obese adults.[7] Weight-bearing physical activity during childhood and adolescence is required to develop peak bone mass. This helps to prevent osteoporosis in later life. Sallis[8] suggests that improved psychological health may be one of the strongest health benefits of physical activity for young people. It is generally accepted that the foundation for the lifelong regular exercise habit should be laid down during childhood and depends on a competent school physical education program emphasizing motor skills, improvement and maintenance of fitness components, and the pleasure of participation in physical activities.[6]

It is impossible in this chapter to fully discuss the role of exercise in the prevention, management, and treatment of the various diseases. The reader is referred to the excellent text by Bar-Or.[7]

METABOLIC RESPONSES TO ACUTE EXERCISE

Energy Systems

The muscular system, as with other systems of the body, has one source of energy for metabolism (Fig. 8-1): adenosine triphosphate (ATP), often referred to as the *universal energy currency*. ATP is a molecule that contains adenosine plus three phosphate groups in the following format:

$$\text{ADENOSINE} - \text{Pi}^{-} \sim \text{Pi}^{-} \sim \text{Pi}^{-2} \qquad \text{Eq 8.1}$$

The last two phosphate radicals are attached by two high-energy bonds (.010), each of which releases 30.7 kJ (7.3 kcal) per mole of ATP when the bond is broken to change ATP to adenosine diphosphate (ADP) or ADP to adenosine monophosphate. The provision of ATP for metabolism occurs by at least one of three metabolic systems: the phosphagen

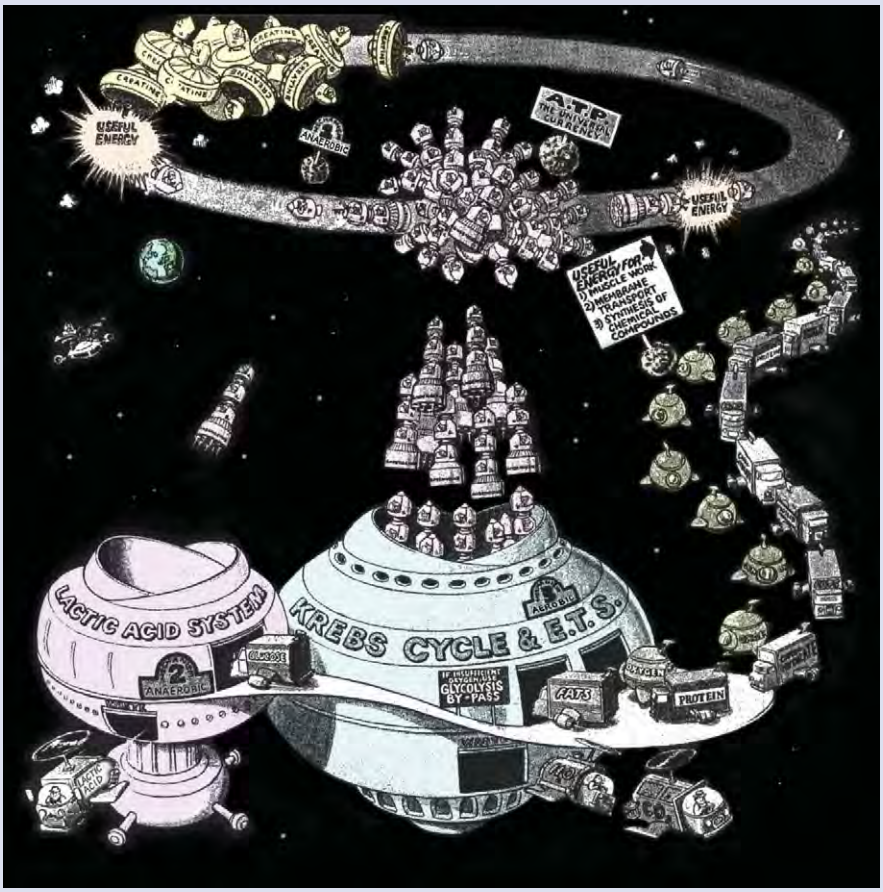

Figure 8-1 Representation of the body's energy sources.

system, the lactic acid system, and the oxygen (aerobic) system.

PHOSPHAGEN SYSTEM

The phosphagen system consists of the ATP store and the phosphocreatine (PC) (also called *creatine phosphate*) store (see upper section of Fig. 8-1). The ATP store in the body is small and is sufficient to allow maximal effort for about 1 to 2 seconds, but there are ways of providing more ATP to replace that being used during metabolism. Muscles cannot obtain ATP from the blood or other tissues, so they must manufacture it. To do this, they need ADP, inorganic phosphate (Pi), and energy from other chemical sources to reconstruct the ATP molecules by rephosphorylation of ADP, as follows:

Eq 8.2 $$\text{ADP} + \text{Pi (plus energy)} \rightarrow \text{ATP}$$

One method of providing more ATP is to break down another stored chemical containing a high-energy phosphate bond so that the energy released by its breakdown can be used to reconstitute ATP from ADP and Pi: PC (creatine .010 PO_3^-) decomposes to creatine plus a phosphate ion plus energy. The breaking of the PC bond releases 43.3 kJ (10.3 kcal) per mole, which is considerably more than that seen in the breakdown of the high-energy bonds in ATP, indicating that there is more than enough energy to reconstitute ATP. Unfortunately, the energy available from the store of PC is also limited and is enough for only about another 5 to 8 seconds of maximal effort. That is, the ATP and PC activity combined, referred to as the *phosphagen system*, can provide energy for less than 10 seconds of maximal activity. This phosphagen system is the most rapidly available source of energy and is often termed the *immediate energy source*. It is extremely important in explosive type efforts such as throwing, hitting, jumping, and sprinting.

The system is rapidly replenished during recovery; in fact, it requires about 30 seconds to replenish about 70% of the phosphagens and 3 to 5 minutes to replenish 100%. This means that during intermittent work (short periods of activity followed by rest periods), much of the phosphagen can be replenished during the recovery period and thus be used over and over again.

LACTIC ACID SYSTEM (ANAEROBIC GLYCOLYSIS)

Because the ATP-PC system can sustain intense activity for less than 10 seconds, other means of reconstituting the ATP molecule must be available. This is accomplished by the use of the other two energy systems, the lactic acid system and the oxygen system, both of which use the breakdown products of the foods ingested.

During the initial stages of exercise and during high-intensity effort, the body cannot provide sufficient oxygen to regenerate the ATP required. To allow for this, the ATP-PC and another system termed the *anaerobic glycolysis system* or *lactic acid system* provides the ATP.

The lactic acid system, also referred to as the *short-term energy source*, uses glucose or glycogen (carbohydrates), which break down to pyruvic acid; then if insufficient oxygen is available, the pyruvic acid breaks down to lactic acid. During the breakdown of glucose to lactic acid, a small amount of ATP is produced (see lower left section of Fig. 8-1). If this system is overworked, the hydrogen ions from the dissociation of lactic acid and the subsequent decrease in pH are associated with fatigue, and when the hydrogen ion concentration becomes high enough, it can decrease the contractile capacity of muscle. This system can sustain another 40 seconds of maximal work over and above that of the ATP-PC system. During glycolysis, which occurs in the cytoplasm of the cell, a complex series of enzymatic reactions occur to provide ATP. This is a slower process than in the phosphagen system. The lactic acid system results in two or three ATP molecules being made available, depending on whether glucose or glycogen is used. This system is inefficient compared to the oxygen system, which can provide 38 molecules of ATP; however, the lactic acid system can provide these two or three ATP molecules even when the supply of oxygen to the muscle is absent.

Lactic acid can be removed during rest periods, but this is a slow process compared to the replenishment of the phosphagen stores. In fact, a large accumulation of lactate may take at least an hour to be removed.

The lactic acid system provides the majority of energy during bursts of vigorous activity that can be maintained for only 1 to 2 minutes; for example, people doing long sprints (200-, 400-, and 800-meter runs) rely largely on the lactic acid system, although during these events, some energy would be provided by all three systems. Neither the ATP-PC system nor the lactic acid system requires oxygen to be present, so they are classified as *anaerobic energy systems*.

OXYGEN (AEROBIC) SYSTEM

If the level of activity is light enough to be performed for a considerable length of time, sufficient oxygen will be available to prevent pyruvic acid from breaking down to lactic acid after glycolysis. Instead, the pyruvic acid breaks down to acetylcoenzyme A, which enters the Krebs cycle and the electron transport system and is eventually processed to form water plus carbon dioxide plus a large amount of ATP. Oxygen is required in this process, and the carbon dioxide produced is then transported to the lungs for removal from the body. Fat and protein can also be used aerobically to provide ATP (see lower section of Fig. 8-1). The aerobic system, also termed the *long-term energy source*, is the important energy system for activities lasting longer than 2 minutes (all-out efforts lasting 2 minutes receive one half of their energy aerobically and one half anaerobically). The higher the maximal oxygen uptake (aerobic power) by the muscles, the higher the work rate that can be sustained.

The contribution of the various energy sources during a given event or sport can be gauged by the duration of the event or effort phases in the sport. For instance, events lasting less than 6 to 10 seconds rely almost exclusively on energy provided by the ATP-PC system. In events lasting 10 to 60 seconds, most of the energy is provided via the anaerobic glycolytic pathway (lactic acid system). As the event increases to about 2 to 4 minutes, the reliance on the anaerobic pathways becomes less important, and aerobic (oxygen system) metabolism increases in importance. Events performed at a low level of intensity for prolonged periods of time, such as a marathon, use the oxygen system almost completely because

the ability to provide oxygen is adequate to cover the oxygen requirements.

SUMMARY OF ENERGY SOURCES

During glycolysis, four molecules of ATP are formed from a molecule of glucose; however, two of these are expended to initiate the process by the phosphorylation of glucose, leaving a net gain of two ATP molecules. During the use of the oxygen system, there is a maximal gain of 38 molecules of ATP: 2 via glycolysis and 36 via the Krebs cycle and electron transport system.

Although most of this discussion concerns carbohydrate use, fat and protein can also be used to provide ATP aerobically; however, only carbohydrate can be used anaerobically. Triglycerides are digested to fatty acids; fatty acids are activated in a process called β-*oxidation,* which prepares fatty acids for entrance into the Krebs cycle by modifying them to acetylcoenzyme A. Protein is used as a substrate only in small amounts, unless the available carbohydrates and fats are seriously depleted.

The use of a gram of fat as the energy substrate produces $2^1/_4$ times as much energy (37.7 kJ or 9 kcal) as 1 g of carbohydrate (16.7 kJ or 4 kcal). However, about 8% less oxygen is required to produce a given amount of energy when using carbohydrate compared to fat.

MUSCULAR SYSTEM

It appears that the number of muscle fibers is determined at birth; however, the thickness of the fibers grows about fivefold from birth and adulthood.[8] The increase in muscle girth is due almost entirely to hypertrophy or continued growth of existing muscle fibers and not by hyperplasia. In male patients, this increase is facilitated by the secretion of testosterone after sexual maturation.[9]

At birth, about 20% of the muscle fibers are type IIc (undifferentiated), whereas by the age of 6, the distribution of types I, IIa, and IIb fibers is identical to that of adults.[10] There are almost no type IIc fibers found after a child has reached 1 year of age.

Muscular strength, or the ability to exert force, is highly related to the cross-sectional area of the muscle and to lean body mass. According to Malina,[11] muscle strength increases linearly with chronologic age from early childhood to about 13 to 14 years in boys. This is followed by a period until about 20 years of age, during which there is considerable acceleration of the increase in muscular strength. The muscular strength of girls increases linearly until about 15 years of age, after which it tends to plateau with very little additional increase.

CARDIORESPIRATORY RESPONSES TO ACUTE EXERCISE

The cardiorespiratory system plays an important role during exercise because its response to the exercise-induced increase in metabolic rate allows the muscles to be supplied with increased oxygen, glucose, and free fatty acids to support the increase in metabolism and to remove waste products (particularly carbon dioxide and heat). This system also transports hormones, vitamins, and amino acids to their target areas so that they can help regulate the body's activities during performance at an increased metabolic rate. When the body changes from a resting state to one of maximal exercise intensity, its energy expenditure may increase more than 23 to 26 times the resting value, and the metabolic demands of the most active skeletal muscles may increase by as much as 130 to 200 times the resting value. That is, the body's rate of oxygen consumption ($\dot{V}O_2$) may increase by more than 20-fold, exhibiting a linear relation between $\dot{V}O_2$ and the intensity of exercise or rate of work. The increase in $\dot{V}O_2$ is accomplished by the following:

1. An increase in cardiac output ($\dot{Q}$)
2. An increase in the oxygen extraction rate by the muscles ($a - \bar{v}O_2\Delta$)
3. A redistribution of the $\dot{Q}$ so that more blood is channeled to the active tissues (skeletal and cardiac muscle) and to the skin for heat dissipation, and so that reduced amounts are channeled to organs such as the gut and kidneys while maintaining the absolute flow rate to the brain (although decreased relative to the increased $\dot{Q}$)
4. An increase in ventilation
5. An increase in the lung diffusion capacity resulting from an increase in blood flow to the lungs (particularly to the upper portion) and the opening of closed alveoli
6. An increase in hematocrit because of the redistribution of fluid from the plasma to the interstitial space (hemoconcentration), thus increasing the oxygen-carrying capacity of the circulating blood

The magnitude of many of these responses changes as a result of regular, frequent, endurance-overload training sessions (chronic exercise). These changes in responses result in an increase in the maximal work capacity and a decrease in the myocardial oxygen demand for a given level of submaximal work.

Cardiovascular Responses to Acute Exercise

The increase in $\dot{Q}$ during maximal work may be as much as four to five times the resting $\dot{Q}$, is linearly related to the increase in the $\dot{V}O_2$ and therefore to the work rate, and is a result of an increase in both the heart rate and the stroke volume. When the body changes from rest to a given level of submaximal exercise, the heart rate and oxygen consumption increase rapidly and reach a steady state in about 3 or 4 minutes; with cessation of exercise the heart rate decreases rapidly at first and then more gradually until the resting level is reached (Fig. 8-2A and C). The steady-state heart rate increases linearly, $2^1/_2$-fold to 3-fold, with an increase in $\dot{V}O_2$ from the resting level to the maximal heart rate. Maximal heart rate has for many years been estimated at 220 minus the age of the individual, but more recently it has been more accurately estimated by the formula HRmax = 208 − (0.7 × age).[14]

Stroke volume increases rapidly with an increase in work rate but usually plateaus at about 40% to 60% of the maximal oxygen consumption ($\dot{V}O_2$max) and represents approximately a twofold increase. This is assuming that the exercise is performed in an upright position because the maximal stroke volume during upright exercise is very similar to the resting stroke volume in the supine position. When the body changes

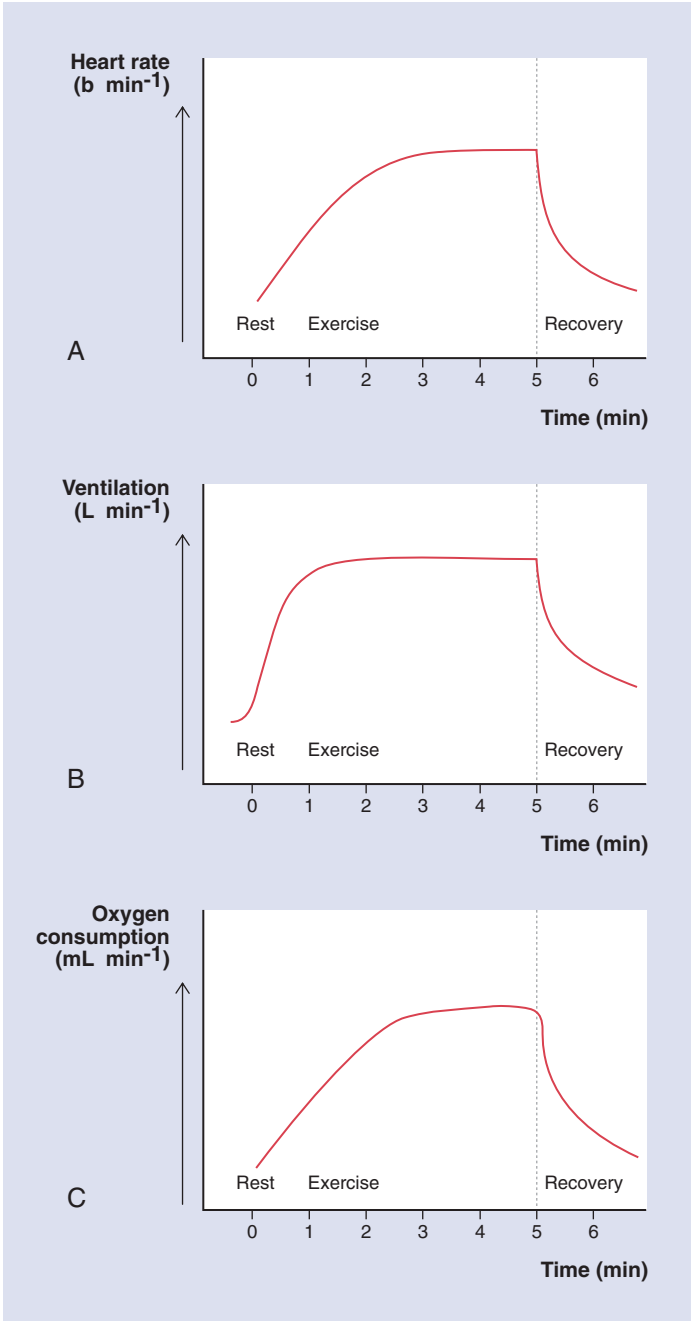

Figure 8-2 Responses of selected cardiorespiratory parameters when the body changes from rest to a given level of submaximal exercise followed by a recovery period.

from resting to maximal exercise while in the supine position, there is little increase in the stroke volume. At rest, a change from supine to standing results in a drop in stroke volume resulting from the effects of gravity, which tends to cause the blood to pool in the legs. This pooling decreases the central blood volume and venous return, thus reducing stroke volume.

The approximately threefold increase in $a - \bar{v}O_2\Delta$ from resting to maximal exercise is attained by increasing the number of patent capillaries, by increasing the oxygen partial pressure gradient between blood and active tissues (which results from the use of oxygen by active cells in accordance with the characteristics of the oxygen-hemoglobin dissociation curve), and by metabolically inducing an increase in blood temperature and acidity (the Bohr effect).

The blood pressure increases during exercise to ensure an adequate blood flow to critical areas such as the brain and the heart and to meet the increased requirements of the skeletal muscles. This increase occurs as a result of an increased $\dot{Q}$ value and the vasoconstriction in inactive tissues. It also occurs despite a large decrease in peripheral resistance.

The blood pressure during a given submaximal workload reaches a steady state within 3 to 4 minutes. When the steady-state blood pressure is plotted against $\dot{V}O_2max$ or the increasing workload, it follows a pattern indicating that the systolic blood pressure increases linearly, reaching a value about 1.5 to 1.6 times the resting level. Meanwhile, the diastolic pressure remains fairly constant or increases to about 1.1 times the resting value; under some conditions, it even decreases slightly. The mean arterial blood pressure, which is equal to the diastolic blood pressure plus one third of the pulse pressure, increases linearly to about 1.3 times the resting level.

The relatively small increases in arterial blood pressure caused by the large increase in $\dot{Q}$ is explained by the curvilinear decrease in the total peripheral resistance caused by the increasing workload. The total peripheral resistance can be reduced by about $4^1/_2$-fold. This decrease in total peripheral resistance results primarily from vasodilation of the arterial vascular beds in the active muscles as a result of the metabolites released during the increased metabolism of these muscles. These metabolites override the sympathetic vasoconstrictor effects.

The myocardial oxygen consumption ($M\dot{V}O_2$), like the heart rate, increases linearly with increasing workload. The $M\dot{V}O_2$ may increase fourfold to fivefold from rest to maximal exercise because of an increase in coronary blood flow and the $a - \bar{v}O_2\Delta$ of the cardiac muscle. The myocardial $a - \bar{v}O_2\Delta$ is very high at rest and increases only slightly during exercise, whereas the coronary blood flow increases about fourfold during maximal exercise. The heart, which is only about 0.5% of the weight of the body, receives about 5% of the $\dot{Q}$.

Ventilatory Responses to Acute Exercise

The increase in the ventilatory rate from rest to a given level of submaximal exercise is very rapid at first and then becomes more gradual until a steady state is attained. Similarly, when exercise is terminated, a rapid decrease is followed by a more gradual decline until the resting ventilatory value is reached (see Fig. 8-2B).

When exercise is increased from resting until maximal levels are attained, the minute ventilation increases linearly with the increase in workload up to approximately 50% to 60% of the $\dot{V}O_2max$, after which it becomes curvilinearly related, with the increase in ventilation being greater than the increase in workload. The increase in minute ventilation results from an increase in the breathing frequency, which varies from 10 to 15 breaths/min at rest to 45 to 70 breaths/min at maximal work (depending on age), and an increase in tidal volume, which may reach values as high as 50% to 60% of the vital capacity during maximal work. Both breathing frequency and tidal volume tend to increase linearly when

there is an increase in workload and $\dot{V}O_2$ during light to moderate work, whereas at heavier workloads and higher $\dot{V}O_2$, the tidal volume tends to level off, and the increases in ventilation become dependent primarily on an increase in breathing frequency. The increase in ventilation increases the elastic and flow-resistive work of breathing, which increases the energy required for breathing. The energy required by the muscles of breathing is very low at rest but may increase 50-fold during maximal exercise.[15]

The point on the ventilation-$\dot{V}O_2$ curve at which the relationship suddenly changes from linear to curvilinear is often referred to as the *respiratory compensation threshold*[16] or *ventilatory anaerobic threshold*.[17]

The ventilatory response during exercise, which increases the provision of oxygen for transport to muscle cells, also includes a threefold increase in the lung diffusion capacity. This is due primarily to an increase in the amount of blood flowing through the lung, particularly to the upper sections, as a result of more of the pulmonary capillaries becoming patent; thus the total surface area available for pulmonary gas exchange is increased. (Diffusion capacity is measured in milliliters of oxygen diffused for each millimeter of mercury of partial pressure difference between the alveolus and pulmonary blood.)

CARDIORESPIRATORY RESPONSES TO CHRONIC EXERCISE

Exercise sessions repeated every 2 or 3 days for weeks or months (endurance training) result in physiologic and morphologic adjustments that modify physical performance. Training increases the maximal work capacity, and the best measure of this capacity is the $\dot{V}O_2$. The $\dot{V}O_2$ depends on the ability of the body to take in oxygen from the environment, transport it to the active muscles, extract it from the blood, and use it for muscular work. That is, the $\dot{V}O_2$ is the maximum $\dot{Q}$ multiplied by the maximal arteriovenous oxygen difference ($a - \bar{v}O_2\Delta$).

The responses of the trained and sedentary individual differ in the parameters that modify maximal work capacity. The person in training has a higher maximal work capacity, higher $\dot{V}O_2max$, and greater maximum $\dot{Q}$; however, both the $\dot{V}O_2$ and the $\dot{Q}$ at rest and at any given level of submaximal work is essentially the same for both the trained and the sedentary individual.

The increased maximum $\dot{Q}$ is a result of an increased maximal stroke volume because the maximum heart rate is changed very little and, in fact, may decrease as a result of endurance training. The stroke volume at rest or at any given submaximal work rate is also higher in the trained person, and because the $\dot{Q}$ is essentially the same, it is evident that the heart rate at that workload must be considerably lower.

The pattern of response for $M\dot{V}O_2$ for the trained and sedentary individual is similar to that for the heart rate responses. That is, $M\dot{V}O_2$, which is highly related to the double product (heart rate multiplied by systolic blood pressure), which in turn reflects the work of the heart, is considerably lower in the trained individual at rest and at any given level of submaximal work, whereas the maximal attainable $M\dot{V}O_2$ is very similar for the trained and sedentary individual. This indicates that the trained heart is more efficient.

The $a - \bar{v}O_2\Delta$ and oxygen use in the trained and the sedentary individual is essentially the same at rest and for given levels of submaximal work; however, the maximal ability to extract and use oxygen from a given amount of blood is greater in the trained individual. This response pattern is similar to that of $\dot{Q}$ and $\dot{V}O_2$.

Systolic, diastolic, and mean blood pressures all tend to be reduced at rest or at submaximal work intensities after endurance training. The values at maximal work capacity are similar for the trained and the sedentary individual. There is a greater reduction in the peripheral resistance in trained versus sedentary individuals at rest and at all levels of exercise intensity.

The changes in ventilation with increasing workload after endurance training has a pattern similar to those in the sedentary individual; however, at any submaximal workload the ventilatory rate is reduced in trained individuals. The ventilatory rate is very similar at rest, whereas the maximal ventilatory rate is greater in the trained individual. The pattern of response for pulmonary diffusion capacity is similar in the trained and the sedentary individual except that the value is greater in the trained person at rest at any given submaximal workload and at maximal work capacity.

COMPARISON OF CHILDREN AND ADULTS

An examination of sports programs for children indicates that boys and girls are, for the most part, participating in games and events designed by and for adults. This is particularly true in school sports programs. The child is an "immature working machine," not a miniature adult, and because there are important differences in physiologic responses to muscular activity, children should not be expected to perform in a manner similar to adults.

Anaerobic Metabolism

ALACTIC ENERGY COMPONENT

The contribution of the phosphagen system to the energy used during the performance of a given physical activity is termed the alactic energy component. The concentration of the phosphagens (ATP and CP) are similar in children and adults. The rate of use of both phosphagens at workloads eliciting a given percentage of $\dot{V}O_2max$ is also similar in children and adults. Thus the alactic anaerobic processes do not differ significantly.[18-22]

LACTACID ENERGY COMPONENT

The contribution of the lactic acid system to the energy used during the performance of a given physical activity is termed the lactacid energy component. A child possesses lower concentrations of phosphofructokinase, the rate-limiting enzyme in glycolysis, than adults.[22] Furthermore, the child exhibits a lower maximal lactic acid level in both blood and muscle after maximal work and lower lactic acid levels at all submaximal workloads when compared to adults. This suggests that the child has a lower lactacid anaerobic capacity and is at a disadvantage in events requiring maximal use of this energy source.[19,23] Furthermore, development of this lactacid energy capacity and thus success in events dependent on this energy source are closely related to maturity level.

Aerobic Metabolism

The child's heart and lungs are smaller than the adult's when expressed in absolute terms, but the sizes are very similar if expressed relative to body size.[24] Aerobic capacity ($\dot{V}O_2max$), the usual index of endurance capacity and cardiorespiratory fitness,[25] depends on the $\dot{Q}$ and the $a - \bar{v}O_2\Delta$. The stroke volume of the heart is similar in children and adults when corrections are made for the difference in body size,[20] whereas the maximal attainable heart rate is slightly higher in children.[26,27] Because these are the components of $\dot{Q}$, it is evident that adaptation of the $\dot{Q}$ to aerobic work in the child is at least equivalent to that of the adult.

At any given level of submaximal exercise and at maximal exercise $\dot{V}O_2$ ($L\,min^{-1}$), $\dot{Q}$, stroke volume, lactate concentration, tidal volume, ventilation, respiratory exchange ratio (RER), and blood pressure are lower in children than in adults; however, $\dot{V}O_2$ ($mL{\cdot}kg^{-1}{\cdot}min^{-1}$), heart rate and ventilatory equivalent $\dot{V}E/\dot{V}O_2$) are higher.[28] The $a - \bar{v}O_2\Delta$ is higher in children at submaximal but not at maximal exercise. Blood flow to the exercising muscle is greater in children.[29]

Despite the fact that maximal $a - \bar{v}O_2\Delta$ normally depends on the hemoglobin concentration in the blood and that children have a lower hemoglobin concentration than adults, the maximal $a - \bar{v}O_2\Delta$ is similar for both adults and children.[20,26,27] Eriksson[19,30] claims that this is because the child's maximal $a - \bar{v}O_2\Delta$ comes closer to the blood's oxygen-carrying capacity as a result of more active enzyme systems.[31] Children also have the ability to shunt a greater percentage of the $\dot{Q}$ through the active tissues during exercise, thus exhibiting a lower $\dot{Q}$ at any given submaximal level of oxygen uptake. This may result from a decrease in the amount of oxygen demanded by the child's smaller viscera or a decreased need for blood flow to the skin which is caused by a more ready elimination of the body's heat.[31] Systolic, mean, and even diastolic arterial blood pressures are relatively lower in children than in adults.[32,33]

In absolute terms, the pulmonary diffusion capacity is smaller in children than adults because it is dependent on the area of the alveolar membrane available for gaseous diffusion. This changes, as do lung volumes, with body size, particularly with height.

The question of the equality of aerobic capabilities between adults and children, however, is one in which there is not complete agreement. For instance, Astrand[34] claims that the $\dot{V}O_2max$ in children is not as high as expected for their size and they do not have the aerobic power to handle their weight compared to adults. However, the 16- to 18-year-old boys in his study had a mean $\dot{V}O_2max$ of $3.68\ L{\cdot}min^{-1}$, which translated into $57.6\ mL{\cdot}kg^{-1}\ min^{-1}$, whereas 7- to 9-year-old boys had values of $1.75\ L{\cdot}min^{-1}$ and $57\ mL{\cdot}kg^{-1}\ min^{-1}$. This indicates that the oxygen uptake expressed relative to body weight was the same, although the adult did have a higher aerobic power reserve. This was indicated by the adult's ability to increase the basal metabolic rate 13.5-fold, whereas the 8-year-old children demonstrated a maximal increase of only 9.4-fold.

Bar-Or[10] plotted data from a large number of studies and showed that the maximal aerobic power for boys, when expressed in liters per minute, increased continually from age 5 to 18 years, whereas for girls the values, although always slightly lower than boys, increased at about the same rate until about 14 years of age, after which it leveled off and increased no further. Because $\dot{V}O_2max$ is related not only to maturity but also to body size, Bar-Or[10] also compared the maximal aerobic power of individuals of different body mass and showed that it remained fairly constant for boys 5 to 18 years when expressed relative to body weight, whereas for girls the values were similar but lower up to age 10 years, after which there was a continual decline with age. Bar-Or[10] suggested that this decline may reflect an increase in body adiposity of girls during adolescence. Somewhat similar results have been reported by Andersen and coworkers[35] and Kemper and Verschuur.[36]

The child requires a greater stride frequency than the adult when running at the same speed, and because this results in a more expensive use of energy per unit of time, the child requires a greater oxygen uptake per kilogram of body weight than the adult.[34] Providing that the child is competing only against those of similar maturity, the sporting implications are minimal.

However, the most recent view is that the aerobic capacity of children is at least equivalent to that of the adult. As Eriksson[30] claims, when participating in an aerobic activity lasting less than 1 hour, the child, like the adult, must carry and transport his or her own body weight; therefore the child is not at any real disadvantage compared to the adult.

In aerobic events requiring a work level of 70% $\dot{V}O_2max$ for longer than 1 hour, the child is at a disadvantage because of the smaller absolute and relative storage capacity for muscle glycogen.[19,20,22,37] Muscle glycogen depletion is associated with fatigue.

The mean maximal accumulated oxygen deficit, a measure of anaerobic capacity, is 58.5 and 39 mL $O_2{\cdot}kg^{-1}$, respectively, for men and women.[38] These values are higher than those found for boys ($35\ mL\ O_2{\cdot}kg^{-1}$) and girls ($40\ mL\ O_2{\cdot}kg^{-1}$).[39] Carlson and Naughton[39] express concern over the accuracy of the values that they obtained for girls because they indicated that the reliability of the data was poorer.

The ventilation required per liter of oxygen consumed (oxygen ventilatory equivalent) at maximal exercise decreases from 6 to 18 years. In children under 10 years of age the values for ventilatory equivalent are about 30 L/L O_2 consumed during light work and up to 40 L/L O_2 during maximal exercise. The resting adult ventilatory equivalent is 20 to 25 L/L O_2 and increases to 30 to 35 L/L O_2 during moderately heavy exercise and to 40 L/L O_2 during maximal exercise. This seems to indicate that the ventilatory system is less efficient in children—this inefficiency being more pronounced in younger children because they use smaller amounts of oxygen from given amounts of inspired air.

The respiratory frequency during maximal exercise is about 70 breaths/min in 5-year-old children. The respiratory frequency drops to 55 breaths/min and 40 to 45 breaths/min in 12-year-olds and adults, respectively.[13] The young child has a shallower breathing pattern with a tidal volume/vital capacity ratio lower than that in older children and adults.

Strength

Children are at a disadvantage in events relying largely on strength because not only are children weaker than adults but

they are also weaker relative to their body dimensions. According to Paterson,[40] this indicates the involvement of biological factors that modify muscular dynamics. Astrand[34] lists three factors that affect muscle strength in aging children: (1) the increase in size of the muscles; (2) the aging process itself, which may reflect maturation of the central nervous system; and (3) the development of sexual maturity, which probably plays a dominant role for boys. For this reason, it is not very productive to include weight training for the prepubertal boy or girl because the strength gains are small until the androgenic hormones are produced in amounts sufficient to permit muscle hypertrophy.[41] It is, therefore, more beneficial to spend the extra time on practicing skills.[42] However, there are few detrimental effects if performed correctly, and those using weight training will certainly become stronger.[43-47] Also, learning the correct techniques of lifting is valuable in performing activities of daily living. The value of weight training in children's training programs is still not completely resolved, and many questions remain. For instance, it may be that those who commence weight training early may develop greater strength as an adult. Based on a recent review, Tanner[48] has claimed that most children and adolescents, provided that they adhere to a well-supervised, progressive strength-training program, can improve performance in other sports. This view is supported in a comprehensive review of the risks and benefits of resistance training in children by Blimkie.[49]

Thermoregulation

The human body is about 20% to 25% efficient under the best conditions; therefore most of the metabolic activity is eventually converted to heat. During vigorous exercise, a considerable heat load is imposed on the body, and bodily mechanisms, including sweating, shunting of blood through the arteriovenous anastomosis in the skin, and cutaneous vasodilation, are initiated to increase the rate of heat dissipation by evaporation, conduction, convection, and radiation.

Vigorous prolonged exercise in high temperatures and humidity can increase body core temperatures to levels high enough to cause cell and tissue destruction, which are manifested as heat illnesses such as heat cramps, heat exhaustion, and heat stroke. To prevent heat illness, people exercising in the heat should drink plenty of fluids (remembering that thirst is not an adequate guide to fluid needs); select appropriate, loose-fitting, light clothing; and cease exercise if any of the early symptoms of heat illness occur. People organizing and administering sporting events should cancel endurance events if the environmental conditions are such that the wet bulb globe temperature exceeds 28° C.[50]

The child has a larger skin surface area/body mass ratio than the adult and is more susceptible to heat loss or heat gain from the environment. The child also has less mature sweat glands and is at a disadvantage and in possible danger when performing heavy, long-term activities in the heat and high humidity. Children are also at a disadvantage when competing in endurance swimming events in cold water. That is, children are disadvantaged when performing exercise under environmental extremes of heat or cold. Inbar and colleagues[51] have also postulated that children are prevented from deriving the full effect of exercise-in-heat acclimatization because of some as-yet-undefined age-related factors associated with the thermoregulatory system.

Application

The differences between children and adults are important in sporting events. For example, there is a need to modify adult equipment, adult facilities, the duration of events, the number of players per team, and the rules—and to use a physiologic basis for selecting the most appropriate activities for the various age groups.

For instance, when the type of activities most suitable for children are selected, evidence suggests that the child can handle short, intense (alactic) sprints or aerobic work of less than 1 hour's duration without undue stress. However, compared to adults, children perform poorly in lactacid sprint-type events lasting $1^1/_2$ minutes (e.g., 200- or 400-meter track events). Success in these events depends on the child's level of maturity, so children who mature late may suffer psychologically as a result of continual failure. There is no apparent reason to suggest that the child should not attempt to train this energy system.

Although the available scientific data are meager and inconclusive, the American Academy of Pediatrics has issued a position statement on children lifting weights.[52] It claims that an athlete should not attempt maximal lifts until growth is complete at about age 16 or 17; thus weight-lifting and power-lifting are contraindicated before this age. The position statement admits that a well-supervised weight training program involving submaximal resistance can enhance performance in most sports, especially after puberty. The Academy warns of the tendency for weight-lifting to result in a transient elevation of blood pressure and that lifting very heavy weights may cause epiphysial damage in preadolescents.

The recognition of these differences between children and adults has been responsible (at last) for the realization that adult equipment and playing fields and adult game rules are not suitable for small children. As a result, some sporting associations have introduced modifications. The fields have been reduced in size, as have goal posts, balls, bats, and other playing equipment, and the duration of play and rest periods has been modified to better suit the physiologic development of the players. A study by Elliott[53] showed the need to modify the size of tennis racquets to suit the size and strength of the child. He found that children approximately 8 years of age, because they are smaller in stature and have less strength, could not handle the increases in the moment of inertia involved with the use of a larger racquet, so performance deteriorated, primarily in the strokes such as the serve requiring greater total racquet movement.

EFFECTS OF TRAINING

General Outcomes

One of the common questions related to the training of children concerns the suggestion that if training occurs during the period of rapid growth (prepuberty and puberty), there is a more marked improvement in components, such as aerobic power, than can be attained in training during adulthood. Certainly some animal studies have shown that this occurs, at least with the rat.[54]

Although some human studies[18,20,55,56] indicate that training before and during puberty produces a greater increase in the size of organs of the cardiorespiratory system than training later in life, Eriksson[20] claims that the changes in $\dot{V}O_2$max are similar. He found that in 11-year-old boys training for running, $\dot{V}O_2$max expressed in $mL \cdot kg^{-1} \cdot min^{-1}$ improved 16%, which is similar to the increase found by Saltin and associates[57] for sedentary adults. However, improvement is easier the more unfit the subject is initially, and sedentary adults are probably more unfit than sedentary children. A review by Bar-Or[58] has shown that $\dot{V}O_2$max can be increased in children with training; however, the improvement in prepubescent children is not as great as it is in adults. This conflicts with the view of Shephard,[59] who claims that there is no immediate evidence that the training response of the prepubescent child is less than that in an older person. However, after reviewing Malina and colleagues[60] and Payne and colleagues,[61] it appears that whereas prepubescent children do improve aerobic performance, that improvement is less than in older children.

Another question that is frequently asked, particularly by parents, is whether hard training has any deleterious effect on the growing child. A study by Astrand and coworkers[55] showed that in 30 Swedish girl swimmers aged 12 to 16 years, who trained intensively up to 65 km/week over a number of years, the $\dot{V}O_2$max improved to a mean value of 52 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$. This training also increased the size of the organs involved in the oxygen transport system, and there was no indication of any detrimental effects.

These same girls were studied for 10 years, during which time all ceased regular training and most regressed to a sedentary lifestyle. As a result, their $\dot{V}O_2$max decreased from a mean of 52 to 37 mL $O_2 \cdot kg^{-1} \cdot min^{-1}$ (29% decrease); however, the dimensions of the lungs and heart were relatively unchanged.[56] The implication of retaining the larger heart and lungs is unknown, but others[62] have reported increased heart volumes in former top-rated endurance athletes without any accompanying medical problems. It does suggest, however, that the functional capacity of the cardiovascular system declines more markedly than its dimensions after training is ceased. This hypokinetically induced drop in $\dot{V}O_2$max to levels lower than those of the average nonathlete creates concern regarding the long-term effects on attitude toward physical activity after participation in a demanding training program at an early age.

A representative sample of 16 of the original 30 girls then embarked, at a mean age of 23.9 years, on a 12-week retraining program to determine whether the $\dot{V}O_2$max could be improved in this now-sedentary group of former swimmers to a greater extent than the average sedentary woman.[63] The study showed that the 12-week program increased $\dot{V}O_2$max by 14% without an increase in heart volume and yet almost restored stroke volume to that computed for the girls during their competitive swimming period 10 years earlier. This suggests that the training effect on the pumping function of the heart may be more pronounced in former top athletes than in previously sedentary people. Although these increases in $\dot{V}O_2$max and stroke volume are larger in other studies,[64] the studies are not quite comparable, so it is still difficult to claim that previous training in early life is of definite advantage. In fact, Pollock[65] has reviewed a large number of training studies, and his summary table indicates that a 14% gain represents an average increase in $\dot{V}O_2$max.

Because the training participation by these girls was not as good as expected and because no control group was used, Eriksson and colleagues[66] repeated the study using the most elite girls from the 1961 study ($N = 4$). This study used a control group of women each of whom lived in the same neighborhood and was age-matched to one of the former swimmers.[66] After retraining, the former girl swimmers had a 19% increase in $\dot{V}O_2$max when expressed in liters per minute, whereas $\dot{V}O_2$max in the control group increased 12.5%. When $\dot{V}O_2$max was expressed relative to body weight, the former swimmers' increase was still 19% compared to 10% for the controls. Stroke volume of the heart increased in both groups, exhibiting a 33% and 26% increase for the former swimmers and the control group, respectively. This study gives some support to the hypothesis that a former athlete has a greater capability to increase aerobic power with training.

Another longitudinal study of 29 girl swimmers who started vigorous swimming at ages 8.6 and 13.7 years has been reported.[56,67] These girls were followed annually to age 16 years. At 15 years of age, 15 of the 29 were still training, thus allowing comparisons between those still in training and the 14 who had dropped out. The data showed that heart volume increased with growth in both groups; however, the girls who continued to train had larger hearts at each age. A similar pattern was evident for maximal oxygen uptake in which absolute values (in liters per minute) increased with age for both groups. However, when these values were corrected for growth, the training group again showed a slightly greater value than the nontraining group. Static lung volumes were larger than normal after only a few years of training and increased further only in relation to the increase in height.

Early training does not necessarily guarantee sporting success later in life. Nor is it a prerequisite for success. One of the conclusions drawn from the Medford Boys' Growth Study[68] was that outstanding elementary school athletes may not be outstanding in junior high school and outstanding junior high school athletes may not have been outstanding in elementary school. He found that 45% of those outstanding athletes in junior high school were not considered such in elementary school. Research has yet to provide clear evidence as to the effects of sport training on the growth of children.[69]

Possible Detrimental Outcomes

During training and competition, repetitive stress on a muscle, bone, or joint produces adaptations, some of which may be undesirable.[70] Extreme overuse may lead to bony and muscular hypertrophy[71] and create problems such as Little Leaguer's elbow, tennis arm, swimmer's shoulder, Osgood-Schlatter disease, Sever's disease, and stress fractures.[72] In the child, ligaments are stronger than the epiphyses, so injuries are more likely to involve epiphyseal problems rather than be simple sprains. This type of injury then will require a more definitive treatment, such as protection, until the epiphysis heals, but more importantly, epiphysial injuries are often undetected.

To prevent problems caused by overuse, many sporting associations limit the amount of time a player uses particular

muscle groups; for instance, U.S. Little League baseball limits the number of innings that young players can pitch to six per week. To be successful, this system still relies on the coach placing the child's welfare above everything else, limiting the number of pitches allowed during a training session, and educating the child so that he or she restricts throwing activities when not under supervision. Similarly, restrictions have been advocated to prevent the frequent back injuries in young "fast bowlers" in cricket[73] and to prevent running injuries by limiting competitive race distances for children of various ages.[74]

Larson and McMahon[75] reported on 1338 athletic injuries in the area around Eugene, Oregon; 20% of these injuries occurred in the age groups 14 years and younger, which consisted of 60% of the participants, whereas 40% occurred in the group 15 to 18 years old, which constituted only 15% of the participants. This study indicated that the 15- to 18-year-old group is the most vulnerable to athletic injury. They found that 1.67% (23) were epiphysial injuries but claimed that although growth deformity can occur afterward, this type of injury is the exception rather than the rule. Most cases of epiphysial displacement were easily reduced with traction and gentle manual pressure, and only rarely was open reduction necessary.

Australian studies by Davidson and coworkers[76] and Sugarman, reported by the Australian Football Schools Union,[77] also indicate the low incidence of injury in the younger children, even in collision sports such as rugby. It is only as the boys become mature, and develop the muscle bulk and speed which contribute to greater momentum and coordination and the desire to "hit" rather than tackle, that the incidence of injury becomes a real concern.

However, even if the number of injuries is less than once believed and even if, as Larson and McMahon claim, they can be successfully treated medically, prevention should be the aim. Prevention efforts will involve an adequate level of preseason conditioning and emphasis on skills to ensure correct mechanics. Tennis elbow in adults is certainly related to overuse and faulty stroke mechanics.[78] Thus all coaches should modify an activity (such as by using two-handed backhand) or reduce the number of repetitions of an activity that places too much stress on young bones and joints.

Based on reports on heel cord injuries, epiphysial growth plate injuries, and other chronic joint trauma as a result of long-distance running, the American Academy of Pediatrics[79] has, in the interest of prevention, issued the following statement:

> Long distance competitive running events primarily designed for adults are not recommended for children prior to physical maturation. Under no circumstances should a full marathon be attempted by immature youths (less than Tanner Stage 5 sexual maturity rating). After pubertal development is complete, guidelines for adult distance running are appropriate.

The Australian Sports Medicine Federation[74] recommended that the maximal permitted competitive running distances for children under 12 years, 12 to 15 years, 15 to 16 years, and 16 to 17 years of age be 5 km, 10 km, a half marathon, and 30 km, respectively. Those 18 years of age and older should be permitted to run a full marathon race. The Federation also recommended that the maximal weekly training distance be no more than three times the recommended race distances.[74]

There is not enough evidence to prove or disprove the need to limit the amount and intensity of vigorous training; however, it appears prudent to err on the side of caution until such studies are performed. After reviewing the injury risks to children in sports, Larson and McMahon[75] drew the following conclusion:

> A more vigorous type of life will produce more wear and tear on joint surfaces than a sedentary one. However, the benefits derived by children participating in athletics, such as physical fitness, learning to meet competition, and the discipline of an organized athletic program outweigh such an indefinite potential.

LEVEL OF MATURITY AND SPORTS PERFORMANCE

In sports, the different levels of performance at a given age are often the result of different levels of maturity rather than of skill. For instance, Cumming and associates[80] showed that the level of performance in track-and-field events was more closely related to skeletal age than chronologic age, height, or weight. Mero and colleagues[81] have also shown that endurance capacity and strength were greater in an athletic group than in a control group and that the athletic group demonstrated an advanced biological maturity. Clarke[68] found that the skeletal age of children who were aged 13 years chronologically varied from 8 years, 10 months to 15 years, 11 months.

Advanced maturity imparts not only an increased body size, lactacid anaerobic ability, increased ability to store glycogen, and increased strength and muscle bulk, but also an increase in speed and power. Speed, which increases with age at least to the age of 18 for boys and 14 for girls, is probably due to the maturation of the nervous system.[34] Speed is related more closely to maturity level than height because at any given age, the running speed is usually not different in children of different heights, except for boys around the age of puberty. Boys around 14 and 15 years of age have increased running speed with increased height, probably because the taller boys are more mature.

The rate of growth and development is as individual as physique, eye color, and other personal characteristics.[82] Therefore, because junior sports programs should try to provide optimal participation and fair competition with a minimal risk of injury, classification on the basis of chronologic age is not satisfactory. This is especially true in events in which speed, size, and strength are important for successful performance. Probably the best criteria for matching competitors in sports should include maturity, age, height, weight, skill, and, where indicated, gender. The five stages of genital development or pubic hair development as described by Tanner[83] are adequate means of scoring maturity, and certainly no one classified in stages 1 or 2 should compete against anyone classified in stages 4 or 5, regardless of chronologic age. Shaffer[82] suggests estimating maturity level simply by observing secondary sexual development, namely the axillary and pubic hair, rather than organ development. He also suggests that girls' date of menarche is often adequate for determining maturity level.

Although the early maturers may have a distinct advantage in sports at an early age, they may suffer long-term disadvantages compared to the late maturers. Late maturers who do not become "sporting dropouts" because of discouragement from continual failure often spend a great deal of time acquiring skill so that they may compete. Many of the early maturers, however, because they are bigger and stronger, spend little time developing skill. They are content to use bulk rather than finesse, and unfortunately this practice is encouraged by many so-called coaches, especially in collision sports. As a result, these early maturers often become relegated to the second team when the late maturers eventually reach a similar size and develop similar speed and strength. Because success usually promotes continued interest and effort, lack of success often leads to hatred of the specific sport and often all forms of physical activity; as a result, many early maturers terminate their sporting careers before reaching their 20s.

CONCLUSION

If the effects of regular frequent exercise are plotted on the y-axis against the amount of exercise on the x-axis, the graph would take the shape of an inverted U. That is, little or no regular exercise has detrimental effects on the child and may be associated with some of the hypokinetic diseases such as heart disease and obesity in later life. As the volume of regular exercise is increased, there are increasing benefits, including increased capacity and efficiency of the cardiorespiratory, muscular, and metabolic systems, leading to greater work capacity. If, however, the volume and intensity of regular exercise become excessive, detrimental effects, especially stress fractures, overuse injuries, and even chronic fatigue syndrome, are likely.

All children require regular exercise for normal growth and development and for the development of minimal levels of health and fitness. Although many children today have far too little exercise, there are others who begin very intensive physical training for sports at an early age. Many children in age-group sports participate in unfair competition because chronologic age alone is used as the means of classification. In collision sports, this can be dangerous for the late maturer.

The physiologic responses to acute exercise and to training are similar in children and adults, and for the most part, these responses are beneficial. The pediatrician must understand these responses and be aware of the role of exercise in the possible prevention and management of many diseases such as asthma, cystic fibrosis, diabetes mellitus, hypertension, obesity, and cerebral palsy. The pediatrician must realize that although no sport is risk free, sports-related injuries can be minimized with proper preparticipation medical screening, with supervision, and with the use of protective equipment. Activities such as weight training, weight-lifting, and long-distance running are becoming popular with children and teenagers; therefore the advice of pediatricians to parents, sport administrators, and participants concerning what is safe and what can be hazardous at various ages can be very effective in minimizing detrimental outcomes. The desirability of regular, appropriate, supervised physical training is not in question and should be recommended on the basis of improved health, fitness, and performance capabilities.

CHAPTER 9

Breathing in Unusual Environments

Michael A. Wall

TEACHING POINTS

- Ambient pressure increases most rapidly during the first 10 m of a dive. Thus pulmonary barotrauma can occur on ascent from relatively shallow depths.
- Children with obstructive lung diseases such as cystic fibrosis or bronchiectasis as well as children with any cystic lung pathology should not scuba dive.
- Children with asthma should be cautious about scuba diving. In general, children with current asthma, an exacerbation of asthma in the last 2 years, or a history of cold air induced bronchospasm should not dive. Others should be counseled on an individual basis.
- Most children with chronic lung disease who do not need supplemental oxygen on a daily basis will be able to take commercial flights without oxygen.
- Children with unilateral pulmonary hypoplasia are especially prone to the development of high altitude pulmonary edema.
- Children with CO poisoning may have extreme levels of tissue hypoxia yet will not be cyanotic. Thus, all children who are fire victims should be assumed to have CO poisoning until proven otherwise.

DIVING

A large number of medical conditions have been associated with breath-holding and scuba diving, and many texts and review articles on the subject are available as well as excellent websites.[1-5] This section concentrates on risk factors for injury that may be especially applicable to children with lung disease.

Diving Physics

The major health risks to divers (other than drowning) are related to the behavior of gases in conditions of changing ambient pressure. In essence, there are three ways that a human being can descend in the water (Fig. 9-1). In a submarine the hull resists compression, and the pressure inside the hull (and lungs) stays at about 1 atm. Thus for the crew, the situation is no different than breathing at sea level. During a breath-hold dive, the chest wall and lungs are compressed by ambient water pressure, pressure in the lungs increases to ambient pressure, and the volume of gas in the thorax decreases according to Boyle's law (in a closed system under conditions of constant temperature, the volume of gas is inversely proportional to the pressure applied to the system). On ascent, the ambient pressure around the thorax decreases, and the lungs re-expand to approximately their original volume when the diver reaches the surface. Thus, a breath-hold dive does not expose a diver to the risks associated with having the pressure in the lungs exceed ambient pressure. During scuba diving, however, one breathes compressed air at the ambient pressure of the water at any given depth and maintains relatively normal thoracic gas volume. The breathing of air at ambient pressure is made possible by the special features of scuba equipment. Typically this involves a two-stage regulator system. The first-stage regulator sits on top of the high-pressure tank and reduces the pressure in the scuba system from several thousand pounds per square inch to about 100 psi above ambient pressure. A second-stage regulator is located at the mouthpiece and reduces the gas pressure to ambient. This allows the diver to make a comfortable inhalation. At the end of inspiration, the pressure inside the lungs is equal to ambient as seen in Figure 9-1.

As a diver descends from sea level, the ambient pressure increases by 1 atm for every 10 m. Figure 9-2 depicts the relative changes in gas pressure and volume in a closed system as depth increases in increments of 10 m. For instance, as one goes from the surface to a depth of 10 m the absolute ambient pressure doubles and gas volume in a closed system will decrease by 50%. Gas volume does not decrease by another 50% until the diver reaches a depth of 30 m. Inspection of Figure 9-2 demonstrates that on a relative basis, the most change in ambient pressure occurs at the shallowest depths. This is why barotrauma caused by rapid expansion of gas often occurs as a diver ascends from relatively shallow depths.

The general principle to be understood is that local rupture is a risk if gas can get into an area under high pressure but cannot escape rapidly as it expands during ascent. Such conditions can arise if a diver holds his/her breath and ascends rapidly or if gas can get into a space but its egress is partially blocked (e.g., a partially blocked airway, a narrowed sinus opening, a partially blocked eustachian tube).

Another gas law particularly relevant to scuba divers is Henry's law. Henry's law states that the amount of gas dissolved in a liquid at a constant temperature is proportional to the partial pressure of that gas. Henry's law explains that as ambient pressure in the lungs increases during scuba descent, more and more oxygen and nitrogen (the major components of room air) dissolve into the blood. As long as the diver stays down, this is not a problem in regard to the risk for decompression illness. However, as the diver ascends

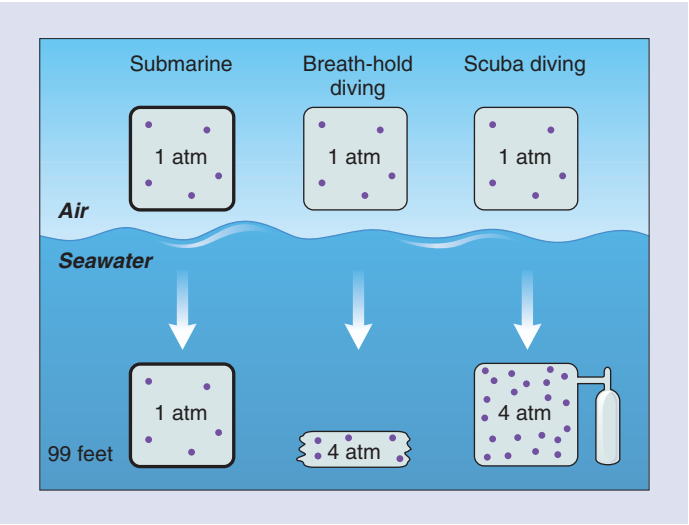

Figure 9-1 Impact of the three methods of submersion on intrapulmonary pressure and thoracic gas volume. Atm, atmosphere. (Redrawn with permission from Strauss RH [ed]: Diving Medicine, New York, Grune & Stratton, 1976.)

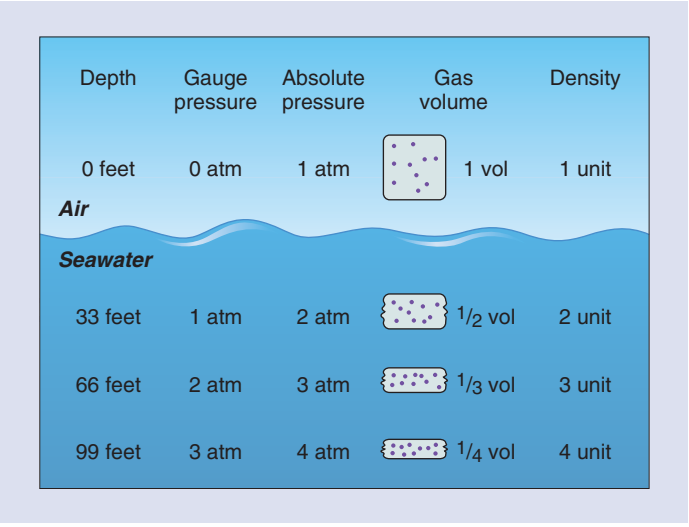

Figure 9-2 Effect of increasing depth on relative ambient pressure and gas volume. Atm, atmosphere. (Redrawn with permission from Strauss RH [ed]: Diving Medicine, New York, Grune & Stratton, 1976.)

and ambient pressure decreases, the gas that dissolved in the blood during descent is going to reverse direction and come out of solution (especially the inert nitrogen; most of the oxygen is metabolized). If ascent is too rapid, the gas coming out of solution will form small bubbles in the bloodstream that can lodge in crucial blood vessels and cause localized ischemia.

Pulmonary Barotrauma

CAUSE

Boyle's law explains one of the most potentially dangerous medical aspects of scuba diving: barotrauma associated with rapid ascent. Assume that a scuba diver is breathing tidally at a lung volume of 50% of total lung capacity (i.e., around functional residual capacity) at a depth of 30 m. The gas pressure in the lungs will be 4 atm (same as ambient). The diver then ascends to 10 m with the glottis and mouth tightly closed so that no gas can escape. At the new depth, the pressure in the lungs is still 4 atm, whereas the ambient pressure is 2 atm, and the thoracic gas volume doubles to total lung capacity. If the diver then continues to ascend with the mouth closed, the lung volume cannot expand to any significant degree and transpulmonary pressure increases. At total lung capacity, the transpulmonary pressure is usually 40 to 50 cm H_2O. When it reaches 80 to 100 cm H_2O, lung rupture ensues, leading to pneumothorax, pneumomediastinum, or air embolism. If a diver starts a closed-mouth rapid ascent at total lung capacity, which commonly occurs in panic situations, lung rupture occurs much sooner than if the ascent started at functional residual capacity. In fact, a rapid ascent from 2 m below the surface can cause lung rupture if one starts at total lung capacity.

For these reasons, scuba divers are instructed to ascend in one of two fashions. The usual ascent is made slowly while breathing in and out. During such an ascent lung pressure will equal ambient, so lung rupture is avoided. If an emergency ascent is required, divers are instructed to exhale actively or keep the mouth and glottis open all the way to the surface.

The same principles that cause pulmonary barotrauma can cause medical problems in other air-containing spaces. Rapid ascent can cause middle ear or sinus rupture if the diver ascends too quickly. This is especially true for children who have a history of recent middle ear or sinus disease.

SIGNS AND SYMPTOMS

Lung rupture may cause mediastinal emphysema, pneumothorax, air embolism, or any combination thereof. The signs and symptoms of mediastinal rupture include chest pain, dyspnea, subcutaneous crepitus, dysphagia, and voice changes. Pneumothorax presents initially as sudden chest pain with dyspnea. Because air in the pleural cavity continues to expand until one reaches the surface, tension pneumothorax with decreased cardiac output is common. Air embolism is thought to result from rupture into the pulmonary veins with subsequent carriage of air bubbles into the arterial system. The bubbles lodge in small arteries virtually anywhere in the body, with the cerebral and coronary systems being the common sites. Thus, air embolism may manifest as a sudden stroke with focal or global consequences or as a myocardial infarction.

TREATMENT

Mild mediastinal emphysema usually requires no treatment, although administration of oxygen may hasten its resolution. Divers thought to have a pneumothorax should be given oxygen in high concentration and transported to the nearest hospital for appropriate treatment, which may range from administration of oxygen to placement of a chest tube. Emergency, on-site relief of pressure from a tension pneumothorax may be required if cardiac output is severely impaired. Victims of suspected air embolism should be given high-concentration oxygen and transported in an emergent fashion to the nearest hyperbaric facility. In the United States, one can call the Divers Alert Network *(www.diversalertnetwork.org)* 24 hours a day for advice and consultation (1-919-684-8111).

Decompression Sickness

CAUSE

During descent, nitrogen and oxygen are breathed at ambient pressure and dissolve into the bloodstream and tissues. Much of the oxygen is consumed by metabolic demands, but the bulk of the nitrogen remains dissolved in a supersaturated fashion. The total amount of nitrogen dissolved in blood and tissues increases as a function of both depth and bottom time. Decompression sickness (the bends or caisson disease) is caused by the release of nitrogen bubbles into the tissues and arterial system on ascent. These bubbles may lodge anywhere and cause local ischemia. They have a particular predilection to lodge in cerebral, myocardial, and bone locations.

SIGNS AND SYMPTOMS

The signs and symptoms of decompression sickness may include pruritus, back and joint pain, neurological dysfunction such as spinal cord paralysis and stroke, and chest pain caused by myocardial infarction.

TREATMENT

As with barotrauma, prevention is of utmost concern. Detailed tables are available to advise divers of their safe bottom time at any depth. This is the time a diver can stay at any given depth and safely ascend to the surface without making stops to decompress along the way. The tables will also inform divers of the time they must stay on the surface before another dive. Treatment includes the immediate administration of oxygen, stabilization on return to shore, and transport to a hyperbaric chamber facility.

Recommendations for Children with Lung Disease

Patients with obstructive lung disease may be especially prone to lung rupture during ascent from scuba diving. The reason is that areas of the lung communicating only poorly with the airways may not have enough time to empty before regional transpulmonary pressure rises to a level that causes rupture. This phenomenon depends on the time constant of the area in question, the relative volume in the area before ascent, and the rate of ascent. Examples of lung diseases that could predispose a diver to lung rupture include cystic fibrosis, bronchopulmonary dysplasia, and current asthma. An additional group of patients who should avoid scuba diving are those who have had a previous spontaneous pneumothorax or who have a condition that might predispose to pneumothorax (e.g., Marfan syndrome, Ehlers-Danlos syndrome). Although these patients do not have obstructive lung disease, they are thought to be at risk because lung rupture may occur at a lower transpulmonary pressure than in people without such risk factors.

The most frequent question asked of pediatric pulmonologists in regard to scuba diving is whether to allow a child with current or past asthma to participate in the sport. The medical problems related to asthma and diving in adults have been reviewed.[6-8] About 8% to 10% of recreational divers claim a current and/or past history of asthma, which is no different than the general population. The consensus of the literature indicates that the odds ratio related to asthma for a diving related medical emergency (arterial gas embolism) is elevated to about 1.5 to 2.0; this did not reach statistical significance.[6-8] Scuba diving exposes the diver to the inhalation of cool, relatively dry gas. In addition, the diver may hyperventilate because of excitement, exercise, or panic. Divers often inhale small amounts of hypertonic water because of issues with their mask or a small leak around the mouthpiece. Thus, scuba diving certainly exposes the diver to an environment that is well known to stimulate asthma exacerbations in some children. An additional risk factor for a few children is latex in the rubber tubing of scuba equipment. Various medical and diving societies have different recommendations for allowing asthmatics to dive. It should be noted that there are no data pertaining to whether pretreatment with a beta-2 agonist before diving will prevent an asthma exacerbation during scuba diving. Given this information and the current state of the literature regarding asthma and scuba diving the following recommendations seem reasonable:

1. Preteens with a history of asthma should not scuba dive. There are no universally accepted laws concerning the age at which a child may be certified to dive. In general, most diving societies will allow children to begin to learn to dive at about age 10 to 12 years and will allow certification at about age 15. A major limitation for any child learning to dive is their response to panic and fear. Brief episodes of panic/fear are common for inexperienced divers and are caused by factors such as claustrophobia, inhaling some water, bumping into coral, seeing a predator fish, and so on. The issue is that divers need to have the mental capacity to recognize when panic is setting in and to remain in control. This mental maturity is lacking in most young children (and some adults). If a child adds hyperventilation or cold air-induced bronchoconstriction to a panic situation it can only make things worse. In addition, some children cannot recognize the early onset of airway constriction or may feel compelled to continue a dive for social reasons.
2. Children with current asthma or who have had a significant exacerbation in the past 2 years should not dive.
3. Children with a past history of asthma with current abnormal lung function should not dive. All asthmatic children should at least have spirometry performed prior to starting scuba training.
4. Children with a history of exercise, cold air, or hyperventilation-induced asthma should undergo a cold air challenge. If positive, they should not dive.
5. A child who requires controller medications to remain asymptomatic and who has a history of noncompliance should not be allowed to dive.
6. Children with a history of mild asthma who have had no exacerbations in the past 2 years, who have normal spirometry and cold air challenge if indicated, and who are compliant with medications, may be allowed to dive under strictly supervised conditions. This author would not sign a child's permission prior to a personal medical evaluation, an evaluation of the child's maturity and understanding of asthma, pulmonary function testing, and an in-depth discussion with the parents.

Other Medical Problems Associated with Diving

Patients with sinus disease may develop barotrauma on ascent in a fashion similar to pulmonary barotrauma. This usually manifests as pain over the frontal sinuses with epistaxis and responds to conservative therapy with decongestants.[2] Recurrent otitis or serous otitis is another contraindication to breath-hold or scuba diving because barotrauma may occur during descent or ascent. The signs and symptoms range from a feeling of pressure and pain to tympanic rupture, hematotympanum, conductive hearing loss, and vertigo.[3] The etiology is an inability to equalize middle ear pressure with ambient pressure, which is usually caused by blockage or swelling of the eustachian tube. Treatment ranges from decongestants to surgery—depending on the extent of injury.

ALTITUDE AND AIR TRAVEL

Air is much less dense than water, and a person must ascend to an altitude of about 5450 m (18,000 ft) before the ambient pressure decreases to 0.5 atm. The major potential problem of ascent above sea level for children with lung disease is hypoxemia. Barometric pressure decreases in an exponential fashion with altitude (Fig. 9-3), although from sea level to 4000 m the relationship is for all practical purposes linear. The most frequent questions concerning children with lung disease and altitude are about air travel during which the cabin is pressurized to an altitude of 1500 to 2400 m. The author has also been asked to give recommendations concerning hang gliding, skiing, and the feasibility of obtaining a pilot's license.

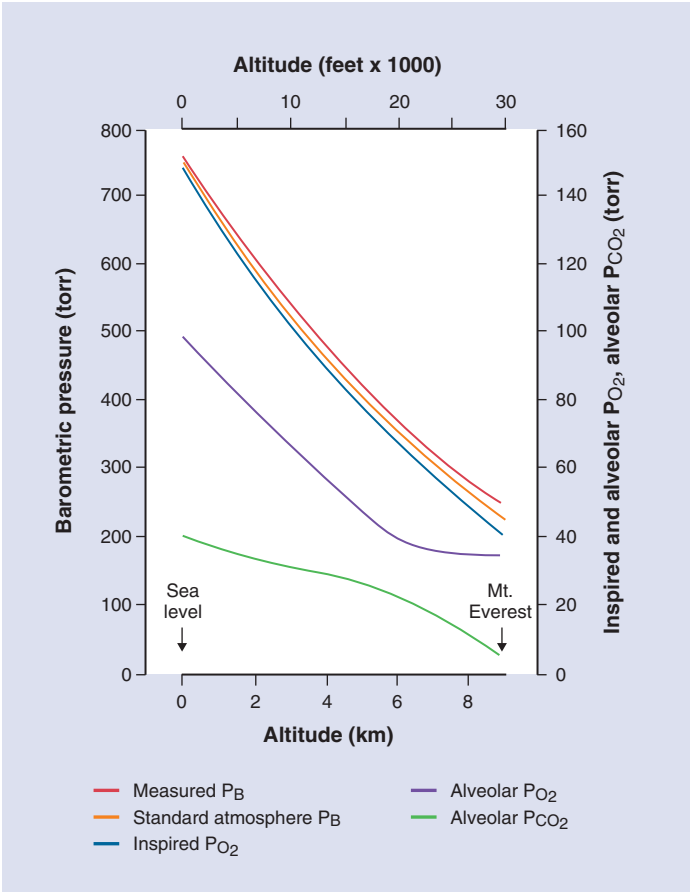

Figure 9-3 Effect of altitude on barometric pressure (Pb), the fraction of inspired oxygen, and alveolar P_{O_2}. (Redrawn with permission from West JB. In Crystal RG, West JB [eds]: The Lung. New York, Raven, 1991, pp 2093-2108.)

At 1500 m the alveolar oxygen partial pressure (P_{aO_2}) in a normal person will be about 74 mm Hg; at 2400 m, it will be about 60 mm Hg. Assuming a normal alveolar-arterial oxygen gradient, arterial P_{aO_2} should be in the range of 67 to 55 mm Hg. However, normal people hyperventilate somewhat at this range of P_{aO_2}, so the actual arterial P_{aO_2} is usually slightly higher. For any patient with chronic lung disease, a precise prediction of arterial P_{aO_2} when going from sea level to altitude is difficult because there is considerable variation in terms of ventilatory control mechanisms and mechanical ability to hyperventilate. Nonetheless, many patients with a sea level arterial P_{aO_2} of 55 to 75 mm Hg will show decreases in P_{O_2} to the range of 38 to 50 mm Hg as they ascend to 2400 m. Regression equations have been published relating ground-level arterial P_{aO_2} and the 1-second forced expiratory volume to P_{aO_2} at altitude that can serve as guidelines for clinical decision making.[9]

Several papers have been published reporting the effect of transient, altitude-related hypoxemia in adults with chronic obstructive pulmonary disease (COPD). The majority of these patients were elderly, and many had cardiovascular conditions that would not be present in children. In one study, 18% of adults with COPD who flew in commercial aircraft without supplemental oxygen had transient symptoms, but none had a serious medical incident.[10] In another study the same research group showed that 12 of 18 COPD patients exposed to hypobaric pressure simulating an altitude of 2400 m had a P_{aO_2} of less than 50 mm Hg, but none developed serious medical problems.[11] In an experimental setting, patients with cystic fibrosis have the same decrease in P_{aO_2} as adults with COPD.[12]

Patients already requiring preflight oxygen therapy will need at least the same amount of oxygen during air travel and perhaps more. For patients who do not require preflight oxygen, the situation is not as clear. The majority of young patients whose P_{aO_2} is greater than 55 mm Hg can tolerate the cabin altitude of air travel without supplemental oxygen with minimal discomfort. Patients whose P_{aO_2} is less than 55 mm Hg may need to arrange for in-flight oxygen.

In the United States, there are no standard policies or procedures for obtaining oxygen from an airline or for the delivery system to be used. Passengers are generally not allowed to use their own delivery systems but exceptions are made especially for those patients using ventilators. At this point, the best suggestion is to contact the particular airline in question well in advance of the flight to determine its rules. Many of the airlines have their oxygen regulations posted on their website. Virtually all airlines charge a fee for oxygen. A physician's prescription will be required and must state the flow to be maintained. It should be noted that airlines will not provide oxygen in the terminal. Other suggestions for travelers needing oxygen include: arrange for wheelchair assistance in advance; try to get an aisle seat; bring extra long cannula tubing; and make sure the vendor is set to deliver oxygen at the destination.

Barotrauma may be a concern for patients who have cystic lung disease or areas of the lung that communicate

poorly with the airways. The latter is almost purely theoretical because it would take a very rapid ascent to overcome even a very slowly emptying time constant. If a patient had a noncommunicating cyst at sea level that was fully expanded with a regional transpulmonary pressure of 40 to 50 mm Hg, then rupture would theoretically be possible on ascent to cabin altitudes of 4000 to 8000 ft. Reports of such events are exceedingly rare but the author reminds patients with advanced cystic fibrosis or other cystic lung diseases about the symptoms of pneumothorax as they prepare for air travel.

The author has received many questions from teenagers and young adults with cystic fibrosis concerning the potential altitude-associated risks of snow skiing. The summits of many resorts in the western United States are at altitudes where even sedentary patients may experience some discomfort, and with exercise, such patients may become quite dyspneic. The author advises patients with moderate to severe obstructive lung disease that they may become somewhat uncomfortable skiing at high altitudes but note that many have chosen to ski anyway with no long-lasting consequences. Teenagers and young adults with cystic fibrosis have also asked the author whether they would be able to obtain a private pilot's license. In the United States, all people who wish to obtain a pilot's license must pass a physical examination administered by a Federal Aviation Administration–approved physician. In the guide for examiners, no specific statements disqualify someone with a childhood lung disease, although moderate to severe asthma and bronchiectasis are both listed as relative contraindicators.[13] Each case is considered on an individual basis by the examiners. It has become the author's policy to advise hypoxemic patients that they probably would not pass the medical examination and that their medical history and laboratory results will be forwarded on request.

Acute Altitude-Related Problems

At altitudes above approximately 2500 m, even young, well-conditioned athletes may begin to experience altitude-related problems. Above 4000 m the incidence increases to about 40% to 50%. Acute mountain sickness is a syndrome in which headache is a universal feature; other signs and symptoms include lassitude, nausea, anorexia, and palpitations.[14] Acute mountain sickness may be accompanied by all the features of acute cerebral edema. The etiology of acute mountain sickness has not been completely elucidated but appears to include factors related to hypoxia, increased cerebral blood flow, fluid retention, and capillary leak.[14] Slow acclimatization is the best preventive measure and the best "treatment" for acute mountain sickness is descent. Various medications can help in prevention and treatment and have been recently reviewed.[14]

Acute high-altitude pulmonary edema is noncardiogenic in origin and may manifest in the context of acute mountain sickness or as an isolated phenomenon. Slow acclimatization can help reduce the incidence of high-altitude pulmonary edema but does not eliminate it. Unilateral pulmonary hypoplasia may be a particular risk factor for children.[15] The signs and symptoms usually start with dry cough and proceed to dyspnea; orthopnea; diffuse crackles; pink, frothy sputum; and cyanosis. The only definitive treatment is rapid descent, although administration of oxygen and continuous positive airway pressure will help. Nifedipine may be efficacious for prevention and treatment.[14]

CARBON MONOXIDE POISONING

Carbon monoxide (CO) is an odorless, colorless gas present in minute quantities in the atmosphere. CO is produced by incomplete combustion of carbon-containing compounds such as wood, hydrocarbons, and coal. Lethal concentrations of CO can be found in the blood of 50% of fire victims, and all burn victims should be assumed to have CO poisoning until it is proved otherwise. In addition to house fires, children can be exposed to high levels of CO via indoor heaters, wood stoves, indoor grills, automobile exhaust, and other sources.

Disease Mechanisms

Traditionally CO has been thought to cause poisoning by producing a functional anemia and by decreasing tissue oxygen availability. CO has a binding affinity for hemoglobin 240 times that of oxygen, so the competition for binding sites is heavily weighted toward CO. Thus, CO poisoning causes a functional anemia because any hemoglobin site bound by CO is virtually unavailable for oxygen binding. CO poisoning leads to tissue hypoxia because the presence of carboxyhemoglobin in the blood causes a leftward shift in the oxyhemoglobin dissociation curve (Fig. 9-4). This leads to increased binding of oxygen to hemoglobin so that at any given Pa_{O_2} the amount of oxygen released to tissues is decreased. However, current evidence suggests that the pathophysiology of CO poisoning is much more complex than initially thought. For instance, carboxyhemoglobin levels in the blood correlate

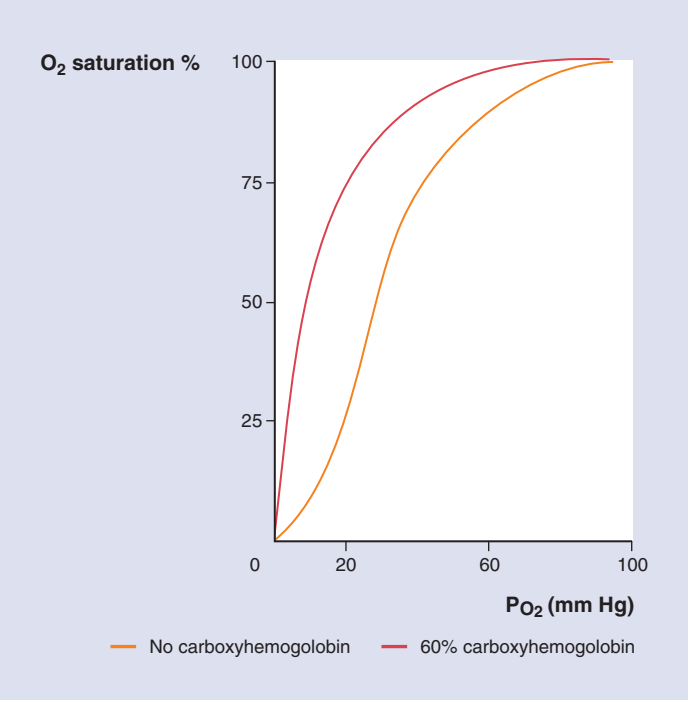

Figure 9-4 Effect of carboxyhemoglobin on the shape of the oxygen-hemoglobin dissociation curve. Note that at an arterial Pa_{O_2} of 20 mm Hg, 75% of the bound oxygen has been released to tissues in curve A versus only 25% in curve B.

poorly with clinical symptoms,[16] and in cross-transfusion experiments the presence of moderate levels of carboxyhemoglobin does not lead to toxicity.[17] CO binds to the cytochrome oxidases and other proteins involved in the intracellular oxygen-transport system, and the weight of evidence suggests that CO toxicity is probably mostly due to disruption of intracellular oxidative mechanisms.[16]

Clinical Manifestations

The initial signs and symptoms of CO poisoning are diverse and may be confused with viral illness. The first symptoms often include headache, nausea, dizziness, and blurred vision. As toxicity increases neurologic and cardiovascular symptoms predominate and include confusion, syncope, seizures, dyspnea, and hypotension. In the end stages, signs and symptoms include myocardial infarction, coma, and cardiopulmonary arrest.

Assessment

As noted earlier, all fire victims should be assumed to be suffering from CO poisoning until proved otherwise. Because the early symptoms are nonspecific, a high degree of suspicion is required. A history of potential exposure should be obtained for children presenting with viral-like symptoms but no fever. Because carboxyhemoglobin is well known to be "cherry red," cyanosis is not a reliable physical finding. Spectrophotometric measurement of carboxyhemoglobin concentration is the most reliable method of diagnosis. Co-oximetry is required to measure "true" oxygen saturation in the setting of CO poisoning. The standard measures of oxygenation used in most emergency rooms and intensive care units are of limited use in determining CO poisoning. Arterial P_{O_2} is usually normal in CO poisoning because this test measures only oxygen dissolved in the plasma. Oxygen saturation as determined by a pulse oximeter also needs to be interpreted with caution. The standard pulse oximeter uses only the wavelengths required to measure levels of oxyhemoglobin. However, the critical wavelength for carboxyhemoglobin is very close to that of oxyhemoglobin and thus, standard pulse oximetry measures the percent saturation of both molecules. In fact, the gap between oxygen saturation measured by co-oximetry and pulse oximetry will be very close to the carboxyhemoglobin level.[16]

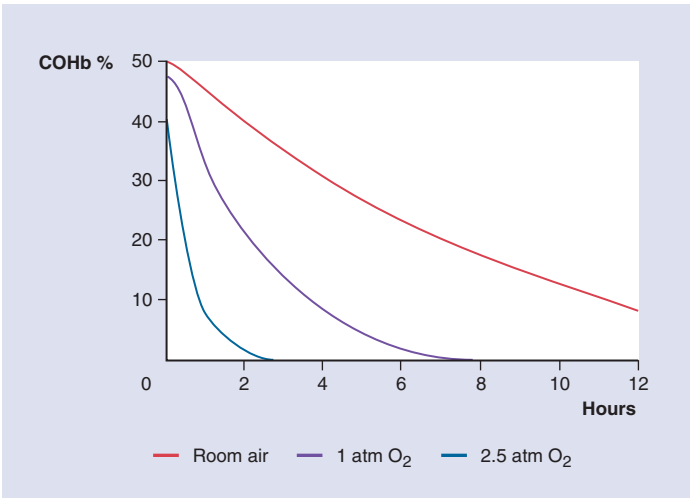

Figure 9-5 Effect of oxygen at varying concentrations and ambient pressure on the elimination of carboxyhemoglobin. (Redrawn with permission from Winter PM, Miller JN: Carbon monoxide poisoning. JAMA 236:1502-1504, 1976.)

Therapy

The only definitive therapy for CO poisoning is administration of oxygen. Oxygen significantly reduces the biological half-life of CO and should be administered in high concentration via a nonrebreathing mask to all burn victims until a carboxyhemoglobin level is obtained. Hyperbaric oxygen therapy offers two theoretical advantages. As seen in Figure 9-5, increasing the pressure at which oxygen is administered further reduces the half-life of carboxyhemoglobin. In addition, hyperbaric therapy increases the amount of oxygen dissolved in the plasma to levels that can almost sustain life even in the absence of hemoglobin. However, a recent Cochrane review concluded that there is no good evidence to support its use in reducing adverse neurologic outcomes.[18] In addition, hyperbaric oxygen is available only in a few locales, and bedside intensive care is virtually impossible in a hyperbaric chamber, so for most patients, such therapy is impractical.

CHAPTER 10 Clinical Assessment and Diagnostic Approach to Common Problems

Mark A. Brown, Erika von Mutius, and Wayne J. Morgan

TEACHING POINTS

- Adapting the mnemonic device PQRST (provocation/palliation; quality; radiation or associated symptoms; severity; timing) may be helpful in systematically characterizing respiratory symptoms.
- The respiratory examination involves thorough inspection, palpation, percussion, and auscultation of the chest, as well as the relevant components of several other body areas, including the upper airway. It is not sufficient to merely listen to the chest.
- Frequent cough without colds should not be seen in healthy, normal children and thus deserves further evaluation.
- Extrathoracic airway obstruction leads to worsened obstruction on inspiration. Progression of upper airway obstruction to biphasic (inspiratory and expiratory) obstruction is a sign that critical airway obstruction is developing.
- In the absence of palpitation and/or syncopy, chest pain in children is rarely due to a cardiac etiology.
- The diagnosis of chronic bronchitis should occur in two phases. The first is consideration and identification of several well-defined respiratory disorders according to a staged management protocol. The second but simultaneous phase is elimination or modification of exogenous factors that produce or maintain the child's illness.

For millennia, the mark of the healer or physician was the ability to discern the nature of a patient's illness through careful questioning, observation, and examination. However, over the past half century or more, practitioners have for a variety of reasons come to rely more and more on technologic means of diagnosis. Although always important, the art of physical diagnosis will likely reassume greater importance in clinical practice in the future because of the growing emphasis on cost containment and the likelihood of limited access to certain technologies. This chapter focuses on clinical assessment of the respiratory system in children. There is much overlap between the respiratory examination and that of other systems, and it is assumed that the reader has mastered basic physical examination skills. Several excellent resources for the general physical examination are listed in the references.[1,2]

HISTORY

The extent and focus of the history (and physical examination) are dictated by the patient's pressing complaint. With few exceptions, there is no such thing as a "routine history and physical," both those activities being tailored to fit the particular complaint that the patient has. An extended history may not be necessary in every case. For example, it would not be necessary to inquire into the stool characteristics of a patient presenting for evaluation of snoring. Careful attention should be paid to the patient's narrative, followed by probing, nonleading questioning and clarification of key points. The exact order of elicitation is not as important as a consistent general routine covering all aspects pertinent to the patient's complaint.

Most physicians begin with the history of present illness, although in younger pediatric patients, it may be appropriate to begin with the antenatal and birth histories. Often the first step is to elicit the chief complaint with an open-ended statement or question. It is generally better not to accept a diagnosis as the reason for seeking consultation. The clinician should insist on hearing the symptoms that promoted concern in the patient's own words. Obviously, information such as the circumstances at onset, frequency, duration, and severity is important. Adapting the mnemonic device PQRST (provocation/palliation; quality; radiation; severity; timing) may be helpful in systematically characterizing a symptom. Associated symptoms such as fatigue, exercise induction or intolerance, and viral syndrome are important to note as well. The results of prior evaluations should be solicited and every effort made to obtain the actual reports or images of previous procedures, including those from pulmonary function tests. Information about previous therapies used and the response or lack thereof can provide important clues as to possible etiologies and may allow an assessment of adherence as well.

The antenatal, birth, and neonatal histories in general should be reviewed; the detail that is necessary depends on the individual. The duration of the pregnancy, together with any complications, including maternal medications and substance use or abuse (including tobacco), should be noted.

Previous respiratory problems, including respiratory illnesses, hospitalizations, and pulmonary injuries (e.g., chest trauma or surgery, smoke inhalation), should be explored in

detail, especially as they relate to airway instrumentation (e.g., endotracheal intubation, bronchoscopy). A history of recurrent pneumonia may suggest immunodeficiency, cystic fibrosis, anatomic abnormality, dysfunctional swallowing, or bronchiectasis. The child with a history of tracheoesophageal fistula repair is prone to tracheomalacia and gastroesophageal reflux–related disease.[3] Survivors of adult respiratory distress syndrome initially have restrictive lung disease, followed later by peripheral airway obstructive disease.[4,5] Evidence of atopy, such as eczema, atopic dermatitis, hay fever, or known allergies, may be important in the child with chronic cough or recalcitrant asthma. A history of frequent infections, blood product transfusion, parental substance abuse, or poor growth may be a clue to an underlying immunodeficiency. Risk factors for human immunodeficiency virus infection, both iatrogenic and behavioral, should be carefully explored because this is the most common cause of immunodeficiency in many countries.

The family history may provide valuable information. It is often fruitful to probe using a variety of terms; for example, *chronic bronchitis*, *wheezy bronchitis*, and *asthmatic bronchitis* are all frequently used to describe asthma. There may be terms in the local vernacular, especially in areas where segments of the population use traditional healers, with which the practitioner should become familiar. It is also important to elicit a family history of illnesses unlikely in the child, such as a parent or grandparent with recent lung cancer, because this may disclose a cause of undue anxiety about a cough or another respiratory symptom.

The social history is always important, if for no other reason than because it provides a better understanding of the patient's circumstances, potentially yielding information helpful in both making a diagnosis and planning therapy (e.g., assessing the likelihood of adherence problems). Specific items to be elicited include the makeup (number, age) of the household unit and the family's living arrangements (house, trailer, apartment). School or day-care attendance or child care arrangements should be reviewed, with attention paid to the environment there as well (see later section). Hobbies may also be important, especially those involving exposure to dusts, paints, and other fumes. Even hairspray use can be clinically relevant. In a setting that preserves confidentiality, the clinician should discretely ask older children and adolescents about inhaled substances of abuse, such as tobacco, marijuana, and solvents (e.g., paint, glue, correction fluid). Of course, contact with ill individuals and a travel history are also pertinent.

A careful environmental history is important. The type of heating and cooling system in place should be noted. Other information such as the age of the dwelling, the presence of a basement, and recent renovations may also be useful. The number and type of animals present should be established. Many families do not consider animals kept outside, such as farm animals or birds, to be pets, so it may be better to ask about "animals" rather than "pets." It is important to inquire about exposure to potential irritants. The most common of these is smoke, either from tobacco use or use of wood for heating, cooking, or both. New composite furniture (manufactured from particle board and veneers), waterbeds, carpets, and ceiling tiles may contain volatile aldehydes that can incite asthma.

Often neglected in the pediatric patient, a review of systems can provide important information. Headache may be a sign of sinus disease or, especially if occurring in the early morning, a result of obstructive sleep apnea. Ocular symptoms such as conjunctivitis and blepharitis, as well as nasal symptoms, may indicate an atopic predisposition or in the young infant a chlamydial infection. Recurrent mouth ulcers or thrush can be associated with immunodeficiency, as may chronic or recurrent ear drainage. Poor feeding, edema, shortness of breath, and exercise tolerance can be clues to the presence of congestive heart failure. Stool characteristics, abdominal bloating, and fatty food intolerance are important features of cystic fibrosis. Neurologic symptoms such as seizures or developmental delay are important in evaluating the child with apparent life-threatening events or suspected chronic or recurrent aspiration.

PHYSICAL EXAMINATION

This section focuses on the chest and respiratory system, with pertinent findings in other systems included as appropriate. For examination of other systems, the reader is referred to one of the general physical examination texts listed in the references.[1,2] It is best to establish a consistent pattern for the physical examination so that part of it is not omitted. The order in which the components of the examination are presented here is arbitrary. At all times, the privacy of the patient should be respected, the examination being conducted out of view and out of hearing of other patients. In the case of adolescents, the use of another staff member, the same gender as the patient, as a chaperon may be appropriate.

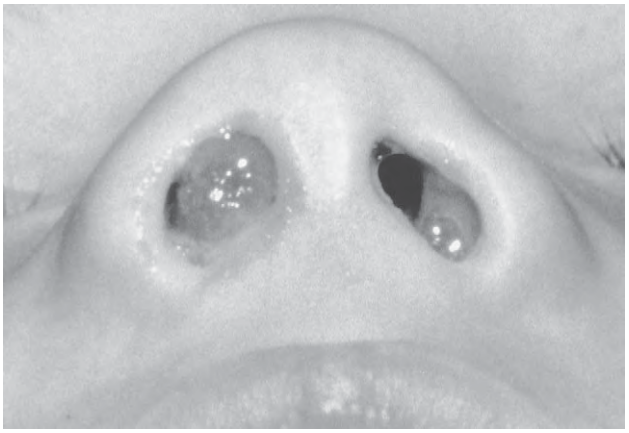
Upper Airway

Although not truly an airway or gas-exchanging tissue, the ear is considered part of the respiratory tract for several reasons. The middle ear and eustachian tube develop embryologically from the first pharyngeal pouch and share a contiguous mucosal surface with the respiratory tract.[6] The lining of the eustachian tube consists of ciliated pseudostratified columnar epithelium identical to the remainder of the respiratory tract.[7] Although the middle ear is lined predominantly with simple squamous or cuboidal epithelium, patches of ciliated pseudostratified columnar epithelium have been described there as well.[7] There are also cough receptors located in the external auditory canal. Thus, it is important to examine the ears for foreign bodies and for signs of middle ear infection or another abnormality as a source of chronic cough.

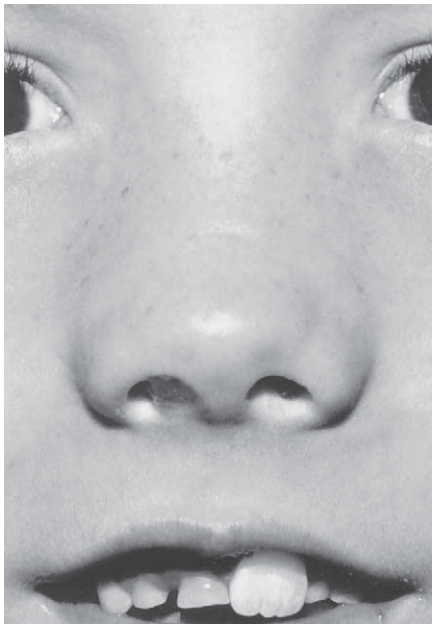
The nasal passages are uniquely configured to perform their role as the portal for inspired air. The turbinates and, to some degree, the paranasal sinuses warm and humidify inspired air from ambient temperature and humidity to roughly body temperature and 100% relative humidity. Careful inspection of the nose can identify subtle changes indicative of local and sometimes systemic disorders. Children with inhalant allergies frequently develop a transverse nasal crease, the result of repetitive up-and-down rubbing to relieve itching and discomfort. This may be accompanied by other signs associated with allergic disease, such as dark circles under the eyes ("allergic shiners") and Dennie sign,

skin creases radiating from the inner canthus of the eye to approximately two-thirds the length of the lower lid margin. The nasal bridge is normally straight. A deviation of the bridge may indicate a congenital abnormality or previous trauma and should prompt careful inspection of the septum for deviation and obstruction. Widening of the nasal bridge can be seen in individuals with extensive nasal polyps (Fig. 10-1). The relative patency of the passages can be assessed by asking the child to sniff (or simply listening in the younger child) while manually occluding one naris. A question of complete obstruction can be clarified by passage of a feeding tube or red rubber catheter. With congenital or acquired absence of the alar cartilage, the nares may collapse with each inspiration.

The nasal passages themselves can often be visualized through the use of an otoscope and a large (4- to 5-mm) ear speculum by placing the free hand on the top of the patient's head and, with the thumb, gently lifting the tip of the patient's nose. Alternatively, a nasal speculum can be used.



A



B

Figure 10-1 **A,** Child with cystic fibrosis and large nasal polyp. **B,** Note the widening of the nasal bridge and the polyp projecting from the right naris.

The nasal mucosa, normally pink and glistening, should be inspected for edema and changes in color (inflamed or pale, boggy or gray), and the color, consistency, and odor of any secretions are noted. Inflamed mucosa suggests infection, whereas pale, boggy mucosa is frequently seen in allergic rhinitis. With chronic rhinitis, the mucosa may take on a grayish appearance. Foul-smelling and sometimes bloody secretions suggest a foreign body or chronic sinus disease, whereas clear secretions may occur in allergic rhinitis or early in the course of an uncomplicated upper respiratory infection. A smear of nasal secretions, stained with Hansel's stain, may be helpful, a predominance of eosinophils suggesting allergic disease and a predominance of polymorphonuclear leukocytes (especially when accompanied by a single bacterial morphology) suggesting bacterial sinus disease. No conclusions regarding the causative organism should be drawn from these results, however. The septum should be inspected for deviations, perforations, and sites of bleeding. (Bleeding in the nasopharynx is a common source of perceived hemoptysis.) Foreign bodies, polyps (see Fig. 10-1), and masses within the nares should be carefully sought out and inspected.

Examination of the paranasal sinuses is difficult in children younger than 10 years. Techniques such as transillumination and percussion not only are impeded by lack of cooperation but also may be difficult to interpret because of the relative thickness and density of the overlying soft tissues. However, it may be possible to localize the source of purulent secretions in the nose by direct inspection. Most commonly, this is the middle meatus, which is located between the middle and inferior turbinates; the middle meatus drains the frontal, maxillary, and anterior ethmoid sinuses. The confluence of these three meatuses is called the *osteomeatal complex*. Obstruction from edema, a foreign body, or a polyp in this region is a frequent cause of chronic sinus disease. However, this may not be readily identified on examination; computed tomography (CT) is a more reliable means of diagnosis.

The profile of the mandible should be inspected carefully for the presence of retrognathia or micrognathia, either of which may lead to airway obstruction, especially during sleep. The state of oral hygiene, including not only of the teeth but also of the oral mucosa, should be noted. The integrity of the palate should be ensured either by visualization or preferably by gentle palpation because a submucous cleft palate can easily be missed on simple inspection. The size and shape of the uvula are noted. A long uvula may cause chronic cough, whereas a bifid uvula may be a clue to an occult submucous cleft palate. The motion of the uvula and soft palate during phonation and gagging is important to note, especially in children with known neurologic abnormalities. Poor or abnormal motion may suggest palatal insufficiency or cranial nerve palsy that may be associated with dysfunctional swallowing and an increased risk of aspiration. The clinician should also note the presence and size of the tonsils as well as any other masses, especially unilateral enlargement, which can be seen in retropharyngeal or tonsillar abscess or lymphoma. Adenoidal tissue visible on the posterior pharyngeal wall ("cobblestoning") is abnormal and implies hypertrophy in association with allergic disease.

The presence or absence of foul breath should be noted. Fetid breath may indicate poor dental hygiene, a nasal foreign body, anaerobic infection, or even pneumonia.

The position of the trachea is important to note during examination of the neck. Deviation to one side may be associated with pneumothorax, neck mass, unilateral pulmonary agenesis or hypoplasia, or unilateral hyperinflation such as with foreign body or congenital cystic lung disorders. With the exception of unilateral pulmonary agenesis or hypoplasia and large areas of atelectasis, which cause deviation toward the involved side, the trachea is deviated away from the abnormality. The neck should be palpated for masses, thyromegaly, and adenopathy.

The character of the voice often provides important information as well. Hoarseness with or without stridor suggests an abnormality of the vocal cords such as edema, dysfunction (e.g., paresis, paralysis), or injury. A weak voice accompanied by high-pitched inspiratory stridor but no hoarseness can result from a subglottic obstruction, whereas a muffled voice associated with a low-pitched stridor but no hoarseness suggests a supraglottic obstruction. Narrowing of the glottis itself results in hoarseness with high-pitched stridor only on inspiration. Hoarseness or a muffled cry in a newborn is very suggestive of a congenital glottic or subglottic abnormality and should prompt further investigation, especially in infants at risk for laryngeal papillomatosis because of maternal genital papillomatosis.

Chest

INSPECTION

Examination of the chest, as with other areas, should begin with inspection. The general shape of the chest and the presence of any deformities are noted. The circumference of the chest, as measured at the nipple line, should be roughly equal to the head circumference in infants and is larger in older children. Barrel chest deformity, an increase in the anteroposterior dimension of the chest, is associated with obstructive lung disease. There is a good correlation between the degree of severity of this deformity and both increased lung volumes (functional residual capacity, residual volume, total lung capacity, functional residual capacity/total lung capacity ratio, and residual volume/total lung capacity ratio) and radiographic findings of hyperinflation in children with poorly controlled asthma.[8]

Asymmetry of the chest can be seen in children with cardiomegaly (especially with right-sided ventricular hypertrophy), pneumothorax, and scoliosis. Pectus carinatum ("pigeon breast") or pectus excavatum ("funnel chest") can be present to a variable degree. The latter may falsely accentuate the severity or even mimic the presence of sternal retractions. Harrison's groove or sulcus, a horizontal depression in the lower thoracic cage at the site of anterior diaphragmatic attachment, may be seen in patients who have chronically increased work of breathing, as in pulmonary fibrosis, cystic fibrosis, or poorly controlled asthma.

Work of breathing is assessed mainly through inspection. The respiratory rate, preferably noted with the child at rest or asleep, is a fairly sensitive clinical indicator of pulmonary health (Table 10-1). However, fever and metabolic acidosis can lead to an increased respiratory rate in the absence of pulmonary disease. Nasal flaring, an attempt to reduce nasal resistance to airflow, is a manifestation of increased work of breathing, as is the use of accessory muscles of respiration such as the sternocleidomastoid muscles. Retractions or indrawing of the skin of the neck and chest is a sign of increased work of breathing as well. Areas of retraction include the suprasternal notch (suprasternal retractions), the subxiphoid region (infrasternal retractions), and the costal interspaces (intercostal retractions). In infants and toddlers, the sternum itself draws in during inspiration, a manifestation of the increased chest wall compliance in this age group. Because of this, other sites of retraction may be absent in this age group, whereas in the older child, suprasternal and intercostal retractions predominate.

Adapted from Waring WW: The history and physical examination. In Kendig EL (ed): Disorders of the Respiratory Tract in Children. Philadelphia, WB Saunders, 1972, pp 71-97; and Iliff A, Lee VA: Child Dev 23:237-245, 1952.

Children with evidence of increased work of breathing are said to have dyspnea, although complaints of shortness of breath are subjective and may not be related to a true respiratory pathologic condition. Children with neuromuscular disease, quadriplegia, paralyzed hemidiaphragm, and other such conditions may complain of dyspnea associated with metabolic acidosis or fever because of their inability to effectively increase their minute ventilation, the normal response in such a setting. The degree of dyspnea may be estimated by noting the number of words a child is able to speak before having to take a breath or by asking the child to count and noting the highest number reached. Both the use of accessory muscles and dyspnea correlate closely with lung function as measured by the 1-second forced expiratory volume and oxyhemoglobin saturation in children with acute exacerbations of asthma.[9]

The respiratory pattern may also provide valuable information. It is important to remember that the respiratory pattern is set by the respiratory centers in the brain stem.

Changes in the pattern can reflect responses to oxygenation state, acidosis, or alkalosis or can indicate a primary abnormality of the respiratory centers themselves. The depth of respiration should also be noted. One author has suggested that each physician establish informal "norms" for depth of respiration in children of various ages by noting the distance from the nose at which the breath can be felt on the hand.[10]

Individuals with restrictive lung disease may have shallow, rapid respirations. Hyperpnea, rapid and deep respiration, can be associated with a number of underlying problems, including hypoxia and metabolic acidosis. Alkalosis may result in slow, shallow breaths. Biot respiration, a pattern of very irregular respirations with alternating periods of hyperpnea and apnea, can be seen in meningitis, encephalitis, and other central nervous lesions involving the respiratory centers. Cheyne-Stokes respirations are a repetitive pattern of gradually increasing and decreasing respirations over 30 seconds to 1 minute and are generally associated with coma. The relative length of the respiratory phases (the inspiratory/expiratory ratio) is significant, with the inspiratory and expiratory phases normally being approximately equal. Prolonged expiration is seen in obstructive diseases such as bronchiolitis, acute exacerbations of asthma, and cystic fibrosis. Some degree of paradoxical respiration, or abdominal ("belly") breathing, may be normal, especially in children up to 6 or 7 years of age. Prominent respirations of this type in any child, however, generally reflect a pulmonary abnormality such as pneumonia, upper airway obstruction, obstructive lung disease, or respiratory muscle weakness.

PALPATION

Although more generally thought of in terms of the abdominal examination, palpation is important in the respiratory examination as well. It is used to confirm the visual observations of chest wall shape and excursion. Palpation is performed by placing the entire hand on the chest and feeling with the palm and fingertips. Friction rubs may be felt as high-frequency vibrations in synchrony with the respiratory pattern. Tactile fremitus, the transmission of vibrations associated with vocalization, is at times difficult to assess in children because of a lack of cooperation and a higher-pitched voice; lower-pitched vocalization is more effectively transmitted. It is best felt with the palmar aspects of the metacarpal and phalangeal joints on the costal interspaces. Decreased fremitus suggests airway obstruction, pleural fluid, or pleural thickening, whereas increased fremitus is associated with parenchymal consolidation. Occasionally a "thud" can be felt high in the chest or in the neck, a finding suggestive of a free tracheal foreign body. One can also assess chest excursion by placing the hands with the fingertips anterior and thumbs posterior and noting the degree of chest wall movement, comparing excursion of one side with the other by noting the movement of the thumbs away from the midline (the spinous processes). The point of maximal impulse, frequently shifted to the left in cardiac disease, may be shifted inferiorly and to the right in severe asthma, a large left-sided pleural effusion, or a tension pneumothorax. With massive left-sided atelectasis, it may be shifted to the left.

PERCUSSION

Much like its counterpart in the musical world, percussion of the chest relies on differences in vibratory characteristics, in this case using various tissues, to produce characteristic sounds. First described by Leopold Auenbrugger in Vienna in 1761, the technique was largely ignored by the medical community until around the turn of the next century, when it was revived by Napoleon's personal physician, Corvisant. It is widely thought that Auenbrugger adapted the technique from that used by his innkeeper father to determine the level of wine in barrels, though it is not known for certain how Auenbrugger developed the idea. There are two different methods of performing percussion: direct (or immediate), in which the chest is struck directly with the finger, and indirect (or mediate), in which sound is generated by striking a finger laid on the chest. This discussion involves the indirect method only. A discussion of direct percussion can be found elsewhere.[11]

Correct technique is critical in both performing and interpreting percussion of the chest, especially in small children. Percussion is best performed with the child upright with the head in a neutral position. A single finger from one hand (the pleximeter) is placed on an interspace; care is taken to avoid contact of the other fingers and palm with the chest because contact between the chest and any other part of the nonstriking hand dampens the sound generated and leads to erroneous interpretation. The finger is then struck with a single finger from the other hand (the plexor) by holding the hand fixed and pivoting at the wrist, quickly removing the striking finger, again to avoid dampening the sound. Many examiners find it comfortable to use the long fingers of each hand for this technique. Generally, the clinician strikes two or three times in each position. The force used should be consistent with each strike and should not be too strong. Excessive force may lead to an erroneous impression of hyperresonance, especially in a small child. Some have suggested the use of a reflex hammer as the plexor; this should not be done in children because it may lead to the false impression of increased resonance. Sounds commonly elicited by percussion of the chest are listed in Table 10-2.

The clinician can delineate the level of the diaphragmatic leaves anteriorly and posteriorly by carefully percussing along the lower thoracic cage (Table 10-3). This can be helpful in guiding auscultation. The clinician may even be able to assess diaphragmatic excursion in older children and adults with suspected diaphragmatic dysfunction by percussing during inspiration and expiration; in adults this is normally 5 to 6 cm. The extent of the mediastinal structures can also be delineated by percussion.

AUSCULTATION

With the development of the stethoscope by René Laënnec in 1816 and its improvement by Piorry, Williams, Cammann, and others, physicians had the capability to recognize changes in sound characteristics in the chest and to correlate these changes with specific pathophysiologic events in health and disease. (An excellent review of the history and physics of the stethoscope is available.[12]) Although the standard stethoscope does not amplify sound, by excluding extraneous environmental sounds and to some degree localizing sounds, it allows the clinician to assess gas movement within the lungs

Table 10-2
Sounds Elicited by Percussion of the Chest

Term	Definition
Tympany	A low- to medium-pitched sound with a musical quality, this sound is usually heard only with percussion of the abdomen; massive pneumothorax is suggested if it is heard in the chest.
Hyperresonance	Somewhat similar to tympany, this is an accentuation of the sound heard when percussing the chest of a normal individual. This sound is associated with hyperinflation as with emphysema, asthma, or free intrapleural air.
Bell-metal resonance	Also called the *coin test,* this is a clearly transmitted metallic sound heard with a stethoscope when tapping a coin that is held flat against the chest with another coin; it indicates a pneumothorax.
Skodiac resonance	This peculiar, high-pitched sound is obtained by percussion just above the level of a pleural effusion.
Resonance	This is the normal state in the chest; it is sometimes called *vesicular resonance.*
Dullness	A flat, thud-like sound, this sound is associated with pleural fluid or parenchymal consolidation.
Flatness	This sound can be mimicked by percussing over muscle; its presence in the chest suggests massive pleural effusion.

and relate changes to known associations with specific abnormalities. Thus, developing expertise in interpreting auscultatory findings is very much an experiential process, and as such, there is no substitute for having listened to a large number of patients, both with and without lung disease. Audio programs, such as one available from the American College of Chest Physicians,[13] can be helpful in establishing a base on which to build this skill.

For most physicians, the standard binaural stethoscope is adequate as long as it is in good repair. The earpieces should fit well to exclude environmental sounds. The tubing should not be cracked or kinked and ideally should be no longer than 30 cm (12 inches), although many physicians accept longer lengths for ease and comfort in examining patients. The bell should be fitted with a rubber ring, and the diaphragm should be intact. Pulmonologists may find it more convenient to use a differential stethoscope, a stethoscope with two chest pieces, one connected to each earpiece, allowing simultaneous auscultation and direct comparison of sounds in different locations. However, use of the differential stethoscope requires even more practice than the standard binaural stethoscope for effective use, so it is probably not practical for the general pediatrician or family physician.

The diaphragm, which filters out low-pitched sounds, thereby isolating high-pitched sound, should be pressed tightly against the skin. In contrast, the bell should be placed lightly on the skin to preferentially isolate low-pitched sounds.

Table 10-3
Usual Level of Diaphragm as Assessed by Percussion

Term	Left	Right
Anterior	Ribs 8-10	Rib 6 (midaxillary line)
Posterior	Ribs 8-10	Ribs 8-10

If excessive pressure is applied when using the bell, the skin below the bell may be stretched taut, thereby functioning as a diaphragm and filtering out the low-pitched sounds being sought. A loud, roaring sound generally indicates inadequate contact between the chest piece and skin, especially when the bell is used. This can be especially problematic when examining an infant or small child unless a stethoscope with appropriate-sized chest pieces is used. Instruments with chest pieces appropriate for premature infants, infants, children, and adolescents and adults are available. The clinician should avoid listening through clothing or bedclothes and should listen (if possible) with the patient breathing slowly and deeply through the mouth in a neutral position, either upright, prone or supine.

As always, it is best to develop a consistently used pattern of examination to avoid missing areas (Fig. 10-2). The upper lobes are best heard by listening anteriorly in the infraclavicular regions, the lower lobes by listening posteriorly below the scapulae, and the right middle lobe and lingula by listening anteriorly lateral to the lower third of the sternum. All lobes can be heard in the axillae.

When auscultating, the clinician should note the amplitude of the sounds produced. It is also important to specify the timing (continuous, early, or late), pitch (high, medium, or low), and character (fine, medium, or coarse) of sounds. These sounds can be divided into breath sounds (produced by the movement of gas through the airways), voice sounds (modifications of phonation not heard distinctly in the normal state), and adventitious sounds (neither breath or voice sounds). Table 10-4 lists the most commonly heard sounds.

Breath Sounds

Vesicular breath sounds are the sounds heard during respiration in a healthy individual. They have a low-pitched, "whishing" quality with a relatively longer inspiratory phase and a shorter expiratory phase and are louder on inspiration. These sounds emanate from the lobar and segmental airways and are then transmitted through normal parenchyma.[14]

Bronchial breath sounds are usually louder than vesicular sounds and have short inspiratory and long expiratory phases. They are higher pitched and louder during expiration. They may be the result of consolidation or compression (i.e., airlessness) of the underlying parenchyma. A similar sound can be heard by listening directly over the trachea.

Bronchovesicular breath sounds, as the name implies, are intermediate between vesicular and bronchial sounds. The respiratory phases are roughly equal in length. This sound is felt to be indicative of a lesser degree of consolidation or compression (airlessness) than bronchial sounds. Bronchovesicular (and sometimes bronchial) breath sounds can occasionally be heard in normal individuals in the auscultatory triangle (the area in the back bound by the lower border of the trapezius, the latissimus dorsi, and the rhomboideus major muscles) and the right upper lobe.

Wheezes are continuous musical sounds, more commonly expiratory in nature, and usually associated with short inspiratory and prolonged expiratory phases. They can be of single (monophonic) or multiple (polyphonic) pitches, which are higher pitched than vesicular sounds. These can often be very

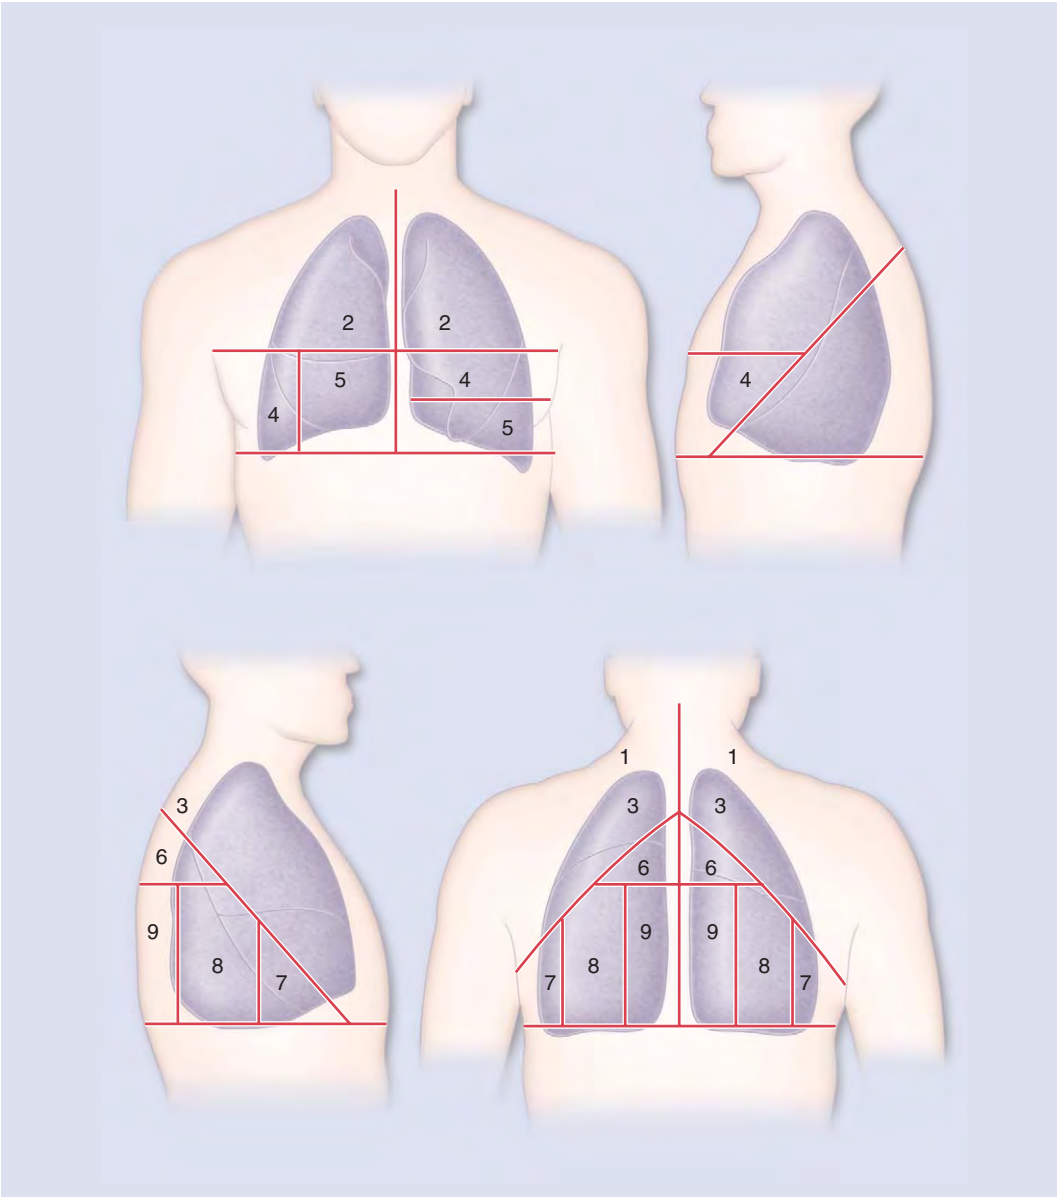

Figure 10-2 Projections of the lobar/segmental pattern on the surface of the chest. *1*, Apical segment of the upper lobes; *2*, anterior segment of the upper lobes; *3*, posterior segment of the upper lobes; *4*, superior lingular *(left)* and lateral *(right)* segments of the middle lobe; *5*, inferior lingular *(left)* and medial *(right)* segments of the middle lobe; *6*, superior segment of the lower lobes; *7*, anterior basal segment of the lower lobes; *8*, lateral basal segment of the lower lobes; *9*, posterior basal segment of the lower lobes.

difficult to distinguish from snoring and upper airway sounds such as stridor.

Stridor is a musical, monophonic, often high-pitched sound, usually thought of as inspiratory in nature; it can be expiratory as well, such as when produced by partial obstruction of a central, typically extrathoracic airway. Its presence in both inspiration and expiration suggests severe, fixed airway obstruction.

A cardiorespiratory murmur is a localized vesicular sound that appears to be synchronized with the heartbeat, mimicking a cardiac murmur or bruit. It can be heard anywhere in the chest but is frequently very dependent on body position, often disappearing with position change. It may be heard in systole, diastole, or both during quiet respiration.

Voice Sounds

The normal lung parenchyma filters vocalization so that whispered sounds are not usually heard during auscultation and normally spoken syllables are indistinct. Bronchophony is the distinct transmission of spoken syllables as the result of an underlying consolidation or compression. More severe consolidation or compression results in the transmission of whispered sounds or whispered pectoriloquy. Egophony is very similar to bronchophony but has a nasal quality as well. It may reflect an underlying effusion, consolidation or compression, or both conditions.

Adventitious Sounds

The nomenclature for adventitious sounds is perhaps the least standardized of all physical findings and therefore is prone to

Table 10-4
Pulmonary Auscultatory Sounds*

confusion. Synonymous terms such as *rales* and *crackles*, *subcrepitant* and *fine*, and *crepitant* and *coarse* are widely used in a variety of combinations. Because past attempts at standardization have met with variable success,[15] the authors have chosen to identify these sounds using several descriptors, allowing the reader to choose which to use and hopefully allowing him or her to recognize others when used by colleagues.

Fine (subcrepitant) crackles are thought to be the result of the explosive reopening of alveoli that closed during the previous exhalation or exhalations.[16] These occur exclusively during inspiration and are associated with conditions such as bronchitis, pneumonia, pulmonary infarction, and atelectasis. They can also be normal when heard in the posterior lung bases during the first few breaths on awakening. They may be imitated by rolling several strands of hair between the thumb and forefinger in front of the ear or by pulling apart Velcro. Hamman's sign, also called a *mediastinal crunch*, is the finding of crackles associated with systole and is suggestive of pneumomediastinum.

Coarse (crepitant) crackles are popping sounds likely produced by the movement of thin fluids in bronchi or bronchioles.[16] They occur early in inspiration and occasionally in expiration as well, may be audible at the mouth, and may clear or change pattern after a cough. They can sometimes be heard in the anterior lung bases during exhalation to residual volume. An example of these sounds is the crackles typically heard in patients with cystic fibrosis.

Rhonchi (sometimes more descriptively called *large airway sounds*) are gurgling or bubbling sounds usually heard during exhalation. These sounds are the result of movement of fluid within larger airways.

A squawk is a short inspiratory wheeze often heard in association with fine crackles. It is thought to result from the explosive opening and fluttering of a large airway.

In individuals with pleural inflammation, a pleural friction rub may be heard. This loud, grating sound may come and go over a short period of time. It is usually associated with a subpleural parenchymal inflammatory process.

Finally, peristalsis may sometimes be heard within the thorax, especially over the left lung base because of the proximity of the stomach and large bowel. The clinician must be alert to the possibility of acquired or congenital diaphragmatic hernia.

OTHER SIGNS AND SYMPTOMS

Occasionally, pulmonary disease is manifest by changes or signs in other organ systems. An example is digital clubbing, the broadening and thickening of the ends of the fingers and toes that occur as the result of connective tissue hypertrophy and hyperplasia[17] and increased vascularity[18] in the distal phalanges (Fig. 10-3). It may be quite subtle but can be confirmed clinically by checking for Schamroth's sign (Table 10-5). Although clubbing can be a primary finding (either idiopathic or inherited), it is usually seen in association with lung disease, heart disease, or liver or other gastrointestinal diseases as well (Box 10-1). The degree of clubbing can be quantitated by several methods as a way of following the progression of lung disease.[19,20] Clubbing may occur acutely (e.g., with a bout of severe pneumonia) but may also regress if the underlying cause is corrected. When associated with a usually painful periostosis, clubbing is one component of hypertrophic osteoarthropathy.

The pathophysiology of clubbing associated with lung disease is unclear. It may be the result of the lungs' failure to remove or inactivate a circulating fibroblast growth factor,[21] although the arachidonic acid metabolites prostaglandins $F_{2\alpha}$ and E have been implicated in patients with cystic fibrosis.[22] Still another theory proposes that clubbing is the result of peripheral impaction of megakaryocytes and platelets in the digits, with subsequent release of platelet-derived growth factor, which induces the histologic and anatomic changes associated with clubbing.[23]

BOX 10-1 Digital Clubbing

Intrapulmonary shunting and inflammation
- Bronchiectasis
- Severe pneumonia, lung abscess, or empyema
- Interstitial lung disease (autoimmune and infectious)
- Pulmonary arteriovenous malformation
- Hepatopulmonary syndrome
- Pulmonary malignancy

Cardiac and cardiovascular causes
- Cyanotic congenital heart disease
- Bacterial endocarditis

Noncardiopulmonary causes
- Inflammatory bowel disease
- Thyrotoxicosis

Familial

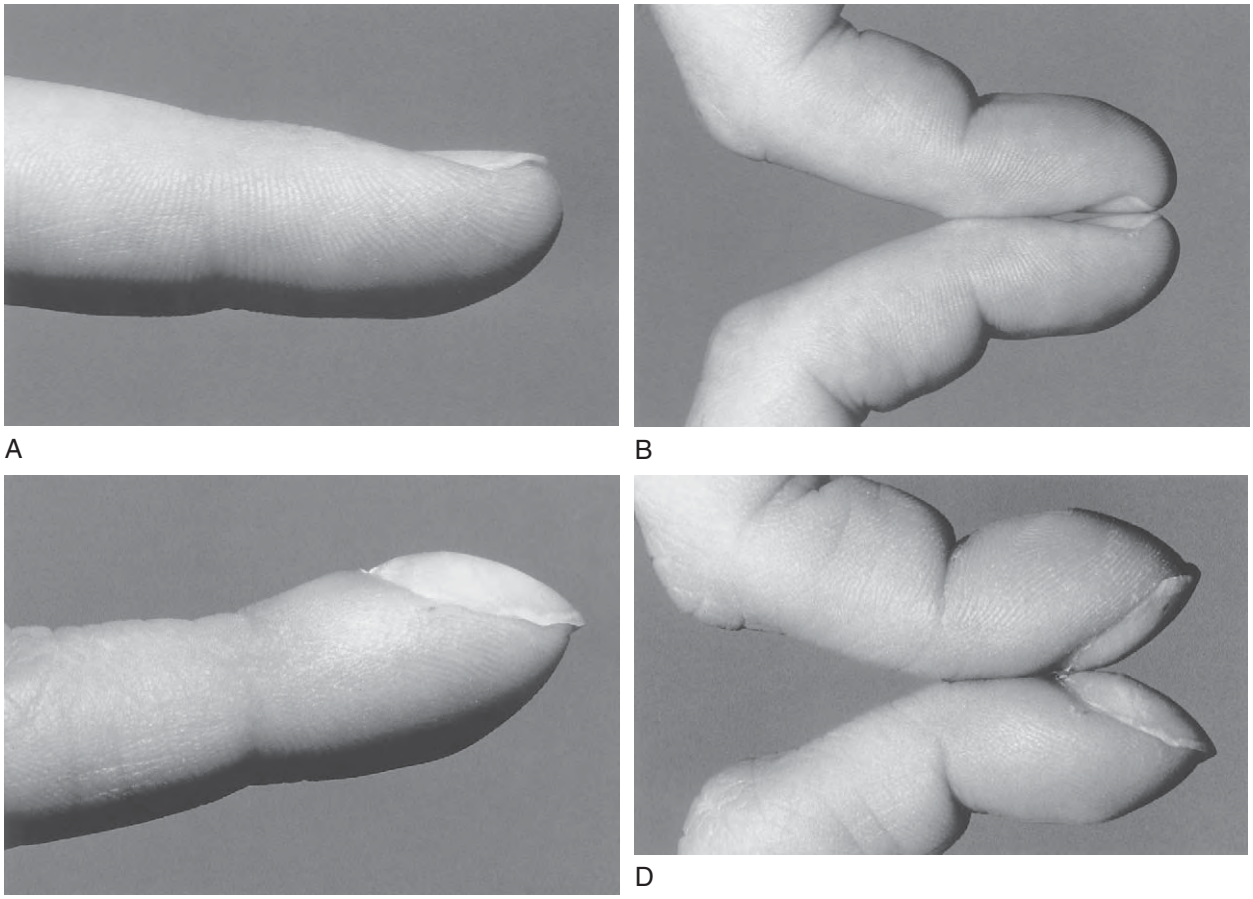

Figure 10-3 Lateral views of the index finger and Schamroth's sign in a healthy individual (**A** and **B**) and in an individual with severe clubbing (**C** and **D**).

Table 10-5
Pulmonary "Signs"

Sign	Definition
Abrahams	Rales and other adventitious sounds, changes in respiratory murmurs, and an increase in whispered sounds can be heard on auscultation over the acromial end of the clavicle for some time before they become audible at the apex.
Aufrecht	Diminished breath sounds occur in the trachea just above the jugular notch in cases of tracheal stenosis.
Baccelli	There is good conduction of a whisper in nonpurulent pleural effusions.
Bird	There is a zone of dullness on percussion with the absence of respiratory signs in the presence of a hydatid cyst of the lung.
di'Espine	In pulmonary tuberculosis, bronchophony over the spinous processes is heard at a lower level than in healthy people.
Ewart	In large pericardial effusions, an area of dullness with bronchial breathing and bronchophony is found below the angle of the left scapula.
Ewing	Dullness on percussion to the inner side of the angle of the left scapula denotes an accumulation of fluid in the pericardium behind the heart.
Fischer	In a case of tuberculosis of the bronchial glands, if one bends the child's head as far back as possible, auscultation of the manubrium sterni sometimes reveals a continuous loud murmur caused by the pressure of the enlarged glands on the vena anonyma.
Hamman	Crackles associated with systole is suggestive of pneumomediastinum; this sign is also called the *mediastinal crunch.*
Hoover	A modification in the movement of the costal margins during respiration is caused by flattening of the diaphragm; this sign suggests emphysema or another intrathoracic condition causing a change in the contour of the diaphragm.
Jackson	During quiet respiration, the movement of the paralyzed side of the chest may be greater than that of the opposite side, whereas in forced respiration, the paralyzed side moves less than the other.
Lorenz	This sign is stiffness of the thoracic spine in early pulmonary tuberculosis.
Perez	Rales are audible over the upper part of the chest when the arms are alternately raised and lowered; it is a common occurrence in cases of fibrous mediastinitis and aneurysm of the aortic arch.
Rotch	Percussion dullness occurs in the fifth intercostal space on the right side in cases of pericardial effusion.
Schamroth	In patients with clubbing, there are loss of the normal diamond-shaped aperture at the base of the nails and an increased angle at the nail tips when the dorsal surfaces of the terminal phalanges are approximated.
Skoda	High-pitched percussion sound just above a pleuritic effusion.

BOX 10-2 Cyanosis

Central Cyanosis

Arterial hypoxemia

Normal levels of arterial oxygen

- Hematologic causes
  - Methemoglobin
  - Other hemoglobinopathies
- Vascular cause
  - Superior vena caval obstruction

Peripheral Cyanosis

Vascular causes
- Peripheral cyanosis resulting from vasomotor instability or hypothermia
- Venous obstruction
- Shock or hypoperfusion with venous stasis

Hematologic cause
- Polycythemia

Cyanosis, another abnormality that may be associated with lung disease, is the bluish discoloration of tissues caused by increased concentrations of reduced (unoxygenated) hemoglobin, which is purple (Box 10-2). It occurs more readily in tissues with low blood flow or higher oxygen extraction than tissues with higher flow or lower oxygen extraction. This accounts for the traditional interpretation that peripheral cyanosis (or acrocyanosis) reflects less severe hypoxemia than central cyanosis.

The use of cyanosis as a clinical indicator of hypoxemia is confounded by a number of factors. Simply identifying the cyanotic patient can be problematic because of variations in skin pigmentation, poor lighting, the presence of nail polish, or temperature extremes (especially cold). Even when cyanosis is unequivocally present or absent, inferences made regarding the oxygenation state of the patient may not be correct. Cyanosis occurs when the concentration of reduced arterial hemoglobin exceeds 3 g/dL. At this level the concentration of reduced hemoglobin in the capillary beds is generally 4 to 6 g/dL. However, the blood's oxygen-carrying capacity, and therefore blood oxygen content, depends primarily on total hemoglobin concentration. Thus, the actual oxygen content may be normal in a cyanotic patient with polycythemia, but an anemic patient may have an abnormally low oxygen content in the absence of cyanosis. Clinical impressions of oxygenation, such as cyanosis, should therefore be verified by arterial blood gas analysis or pulse oximetry.

Pulsus paradoxus is another physical sign sometimes associated with pulmonary disease, particularly obstructive lung disease. Pulsus paradoxus is the fluctuation in arterial systolic blood pressure with the respiratory cycle, the pressure falling during inspiration and rising with exhalation. It is quantified as the difference between the systolic pressures measured during inspiration and expiration. It can be measured a number of ways, most easily by using a sphygmomanometer. It can also be qualitatively identified by observing the pressure tracing of an intraarterial catheter or the pulse tracing of a pulse oximeter. It may also be detected by palpation in patients with pulsus paradoxus greater than 20 mm Hg, signifying more severe obstructive lung disease (see later section).

The pathophysiology of pulsus paradoxus is likely multifactorial.[24] With wider swings in intrathoracic pressure associated with airway obstruction, there is a wider gradient between pressure within the intrathoracic and extrathoracic arterial vessels. Thus, the left ventricle must generate increased force to keep the arterial pressure relatively constant. Because the ventricle does not do so in an instantaneous fashion, there is a drop in arterial pressure. The wider swing in intrathoracic pressure also results in greater right ventricular filling pressure, leading to increased right ventricular end-diastolic volume and displacement of the ventricular septum leftward. This reduces left ventricular filling, thereby reducing stroke volume and further decreasing arterial pressure during and immediately after inspiration.

Pulsus paradoxus is useful in evaluating children with cystic fibrosis[25] and asthma, in which pulsus paradoxus of more than 15 mm Hg has been found to correlate with a 1-second forced expiratory volume of less than 60% of the predicted value.[26] It should be noted that the levels of pulsus paradoxus commonly seen with obstructive lung disease are much higher than those seen in individuals in whom cardiac tamponade is the etiology of pulsus paradoxus.

EVALUATION OF THE CHILD WITH CHRONIC COUGH

Physiology

Cough is an extremely important component of pulmonary host defense. When functioning effectively, it clears bulk material from the airway. In patients with impaired mucociliary clearance either from acquired or congenital abnormalities of ciliary function or other mechanical factors, cough may be the only airway clearance mechanism available. The loss of effective cough in patients with advanced neuromuscular or neurologic disease is a critical factor in the morbidity and mortality of those disorders.

Although a seemingly simple action, cough is actually a very complex reflex involving afferent pathways in the vagus and efferent pathways in the somatic nervous system. Cough can be produced or suppressed volitionally, although it is not always completely suppressible. Although their existence has not yet been confirmed histologically (only inferred by physiology and suggested by electron micrographic studies), cough receptors are thought to be fairly widely distributed in the respiratory tract. They are found predominantly in the extrapulmonary airways (larynx, trachea, mainstem bronchi) but are also present in the external auditory canals, tympanic membranes, upper airway, pleura, pericardium, and diaphragm. Few, if any, are found in the lung parenchyma itself.

The sequence of events associated with a cough are well described. The initial phase consists of opening of the glottis and a short inspiration, which increases lung volume for the next phases. The glottis then closes, and the chest wall, abdominal, and perineal muscles contract, generating high

intrathoracic and transpulmonary pressures. With the sudden opening of the glottis, there is rapid decompression of the airway with a high-velocity expulsion of gas and movement of airway contents (e.g., secretions and other solid material) proximally. In smaller airways the intrathoracic pressure generated may lead to airway closure, trapping some material distally. Thus, cough primarily clears the larger, more central airways. Recognition of this phenomenon has led to alternative methods of airway clearance, such as autogenic drainage[27] and the use of positive expiratory pressure and flutter valve devices,[27,28] which are thought to be more effective at clearing the smaller, more distal airways.

Movement of material as the result of coughing occurs by three mechanisms. First, the high-velocity airflow results in a wavelike gas or liquid pumping of the mucous blanket and movement of loose mucus and other material. The increase in intrathoracic pressure causes airway compression, which squeezes some material proximally into larger airways. This is especially important peripherally, where gas velocities are insufficient to propel mucus. Finally, the vibration of the airway walls and the shearing force of the high-velocity gas flow dislodge mucus from the walls. The sounds produced by coughing are the result of the vibration of secretions and nonrigid respiratory structures.

In contrast to the beneficial airway clearing effects of cough, there are a number of potential deleterious effects as well. Extremely forceful coughing may induce bronchospasm in some individuals. With extremely forceful coughing, there may be injury to the larynx or development of an air leak such as a pneumothorax, a pneumomediastinum, or interstitial emphysema. The high intrathoracic pressures generated during coughing impede venous return to the heart, may result in transient systemic hypertension, or may induce arrhythmias. Syncope can occur because of strenuous coughing. With very forceful coughing, rib fractures may occur. Other complications include rupture of the rectus abdominis muscles, urinary incontinence, pulmonary emboli, and kinking and knotting of venous catheters. An excellent in-depth review of cough is available.[29]

Evaluation

There are many etiologies of chronic cough in childhood (Box 10-3). Without some guidance in tailoring it to the individual, evaluation of this complaint could consume a tremendous amount of time and medical resources. The guidance needed can usually be provided by a careful history.

Onset of cough in the neonatal period is suggestive of a congenital airway malformation. In the perinatal period, abnormalities such as tracheal stenosis, laryngeal web, and tracheosophageal fistula may present with cough, whereas tracheomalacia typically results in cough later in the neonatal period. There may be an association with infectious symptoms such as TORCH (toxoplasmosis, other agents, rubella, cytomegalovirus, herpes simplex) syndrome, chlamydial infection, or pertussis; in older children, there may be an association with tuberculosis or sinusitis. The character of the cough can also provide important clues to the etiology. A continual cough, perhaps worse at night, may be found in asthma, cystic fibrosis, or other forms of bronchiectasis (especially if the cough is productive). Features suggestive of asthma (such as prolonged cough after upper respiratory tract infections, exercise, or exposure to environmental irritants) or the presence of risk factors for asthma (family history, history of prematurity) should prompt a careful evaluation for asthma or cough-variant asthma as a cause. A loud, honking cough absent during sleep is highly suggestive of a psychogenic cough, habit cough, or cough tic. History of a choking or gagging spell followed by chronic cough may promote concern over a possible aspirated foreign body, although there may be no such history, even in cases of documented foreign body aspiration. Chronic aspiration or gastroesophageal reflux as the cause of cough may be elicited by a careful neurologic and feeding history. Obviously, signs or symptoms of chronic illness, such as poor growth, recurrent fevers, and purulent sputum, should prompt a search for more severe pulmonary or systemic disease. Finally, the social history often provides information vital to elucidation of the cause. Factors such as exposure to environmental tobacco smoke, wood stoves, solvents, and dusts can explain chronic respiratory symptoms. The presence of family or school conflicts may support a suspicion of psychogenic cough.

The physical examination must be complete and carefully performed, with emphasis placed on the head and neck (transverse nasal crease, allergic shiners, boggy nasal mucosa, polyps, ear disease, foreign body in ear or nose, postnasal drip, long uvula, cobblestoning of posterior pharynx), chest (hyperinflation, wheezes, crackle, stridor), and heart (murmurs, gallops, signs of heart failure). The laboratory evaluation, which could easily be exhaustive, should be directed by findings elicited in the history and examination. Common tests include pulmonary function testing, including bronchoprovocation (pharmacologic, exercise, cold air); chest radiograph (two views, occasionally inspiratory and expiratory or lateral decubitus) and other imaging studies (CT, magnetic resonance imaging [MRI], sinus series and CT); barium esophagogram; esophageal pH monitoring; and bronchoscopy. The use of flexible versus rigid bronchoscopy in evaluating pediatric patients has been reviewed[30] and bronchoscopy may be appropriate in selected patients. Unless foreign body aspiration is considered likely, flexible fiberoptic bronchoscopy is generally the procedure of choice. Laboratory studies that may be helpful include a complete blood count with differential (evaluating for leukocytosis, eosinophilia), total immunoglobulin E assay, purified protein derivative and control skin tests, sweat test, sputum culture (including culture for acid-fast bacillus and fungus), ciliary biopsy, and limited allergy skin testing (limited to locally common aeroallergens and animals and foods known to be in the child's environment). It may also be reasonable to perform an empiric trial of bronchodilators or a short course of systemic corticosteroids.

EVALUATION OF THE CHILD WITH AIRWAY OBSTRUCTION

Regardless of the etiology of the obstruction, wheezing and stridor with increased work of breathing are the cardinal manifestations of clinically significant airway obstruction. Usually the term *stridor* refers to a vibratory sound that is loudest on inspiration and is predominantly due to dynamic extrathoracic airway obstruction. In contrast, wheezing is

BOX 10-3 Persistent Cough*

Congenital Anomalies

Connection of the airway to the esophagus
- Laryngeal cleft
- Tracheoesophageal fistula

Laryngotracheomalacia
- Primary laryngotracheomalacia
- Laryngotracheomalacia secondary to gastroesophageal reflux disease, vascular or other compression

Bronchopulmonary foregut malformation

Congenital mediastinal tumors
- Congenital heart disease with pulmonary congestion or vascular airway compression

Infection

Recurrent viral infection (infants and toddlers)

Chlamydial infection (infants)

Whooping coughlike syndrome
- *Bordetella pertussis* infection
- Chlamydial infection
- *Mycoplasma* infection
- Cystic fibrosis (infants and toddlers)

Granulomatous infection
- Mycobacterial infection
- Fungal infection

Suppurative Lung Disease (Bronchiectasis and Lung Abscess)

Cystic fibrosis

Foreign body aspiration with secondary suppuration

Cilia dyskinesia

Immunodeficiency
- Primary immunodeficiency
- Secondary immunodeficiency (especially human immunodeficiency virus and acquired immunodeficiency syndrome)

Paranasal sinus infection

Allergy and Asthma

Asthma and cough-variant asthma

Allergic or vasomotor rhinitis and postnasal drip

Aspiration (Fluid Material)

Dyskinetic swallowing with aspiration
- General neurodevelopmental problems
- Möbius syndrome

Bottle-propping and bottle in bed (infants and toddlers)

Gastroesophageal reflux

Foreign body aspiration (solid material)
- Upper airway aspiration (tonsillar, pharyngeal, laryngeal)
- Tracheobronchial aspiration
- Esophageal aspiration with an obstruction or aspiration resulting from dysphagia

Physical and Chemical Irritation

Smoke from tobacco products (active and passive)

Wood smoke from stoves and fireplaces

Dry, dusty environment (hobbies and employment)

Volatile chemicals (hobbies and employment)

Psychogenic or habit cough

Iatrogenic

Angiotensin-converting enzyme inhibitors

*Longer than 3 weeks.

usually produced by intrathoracic obstruction that worsens on expiration. At times, it can be difficult to distinguish between wheezing and stridor, and it should be remembered that critical airway obstruction can lead to stridor or wheeze in both phases of respiration (Box 10-4). A monophonic wheeze suggests obstruction of a large central airway, whereas a polyphonic wheeze reflects peripheral airway obstruction.

Although asthma is certainly the most common disorder associated with wheezing, not every child with wheezing has asthma, nor does every child with asthma wheeze. The differential diagnosis of wheezing varies significantly with the age of the child. Congenital anatomic abnormalities that produce wheezing, like those associated with cough, are generally more likely to present in early infancy rather than later. Laryngotracheomalacia is an exception, usually presenting at several weeks of age or later. Laryngomalacia and extrathoracic tracheomalacia typically present as inspiratory stridor, whereas intrathoracic tracheomalacia and bronchomalacia are associated with low-pitched expiratory wheezing. Asthma, bronchiolitis, and bronchopulmonary dysplasia all may be associated with wheezing in infancy but can generally be distinguished on historical grounds. Along with asthma, cystic fibrosis and chronic aspiration (secondary to gastroesophageal reflux or a neurologic abnormality with dysfunctional swallowing) may present as wheezing at any age. Foreign body aspiration, most commonly pulmonary but also esophageal, classically presents as a monophonic, unilateral wheeze and is unusual before 6 months of age. This diagnosis, however, should be considered regardless of history (or lack thereof). Congestive heart failure may lead to wheezing secondary to lymphatic engorgement and resultant compression of the airway within the peribronchovascular sheath. Finally, wheezing may be produced by vocal cord opposition, either volitionally (often subconsciously) or because of vocal cord dysfunction.[31]

BOX 10-4 Airway Obstruction: Wheeze and Stridor

Inspiratory Obstruction = Extrathoracic

The vibratory sound produced by inspiratory obstruction is heard during inspiration, is usually monophonic, and may be high pitched as in croup or low to medium pitched as in snoring resulting from adenotonsillar hypertrophy.

- Congenital malformations
  - Nasal, nasopharyngeal, and oropharyngeal malformations
    - Retrognathia (Pierre Robin syndrome)
    - Nasal, choanal, or nasopharyngeal stenosis; tumor; mass
    - Anterior encephalocele
    - Teratoma
  - Adenotonsillar hypertrophy
  - Obesity or redundant pharyngeal tissue
  - Hypotonia (e.g., Down syndrome)
  - Oral cavity or pharyngeal tumor
  - Lingual tumor
    - Lingual thyroid tumor
      - Hemangioma
    - Neck masses
      - Bronchial cleft cyst
      - Cystic hygroma
- Laryngeal or subglottic airway malformations
  - Laryngomalacia
  - Paralyzed vocal cords
  - Laryngeal or subglottic cysts
  - Laryngocele
  - Subglottic stenosis
  - Subglottic hemangioma
- Infection
  - Nasal, nasopharyngeal, and oropharyngeal infection
    - Tonsillitis and peritonsillar abscess
    - Sublingual abscess (Ludwig's angina)
    - Retropharyngeal abscess
  - Laryngeal and subglottic infection
    - Epiglottitis
    - Croup (spasmodic)
    - Bacterial tracheitis (usually some expiratory wheeze)
    - Juvenile respiratory papillomatosis (early)
    - Tetanus with laryngospasm
- Foreign body or aspiration
  - Gastroesophageal reflux with edema, laryngospasm
  - Foreign body aspiration in pharynx, larynx, or subglottis
- Trauma
  - Laryngeal hematoma
  - Laryngeal burns or scalds
  - Stenosis secondary to instrumentation
  - Vocal cord paralysis after surgery
- Allergy and asthma
  - Anaphylactoid reaction to food or inhalant
- Psychogenic
  - Vocal cord dysfunction
- Metabolic problem
  - Hypocalcemia or hypomagnesemia
- Acquired tumor (rare)

Expiratory Obstruction = Intrathoracic

The vibratory sound produced by this obstruction is best heard on expiration and may be focal or monophonic and of low to medium pitch or may be diffuse or polyphonic and of medium to high pitch

- Congenital malformations
  - Tracheobronchial tree malformations
    - Tracheobronchomalacia
    - Primary (focal or diffuse) tracheobronchomalacia
    - Tracheobronchomalacia secondary to compression by tumor (focal)
    - Tracheostenosis
      - VATER (vertebral defects, imperforate anus, tracheoesophageal fistula, radial and renal dysplasia) association
      - Complete tracheal rings
  - Vascular compression (ring or sling)
    - Aberrant subclavian vein
    - Pulmonary artery sling (aberrant left pulmonary artery)
    - Right-sided thoracic aorta with left ductus arteriosus
    - Left-sided thoracic aorta with right ductus arteriosus
    - Double aortic arch
  - Dilated cardiac chamber or dilated pulmonary artery with compression
- Infection
  - Intrinsic airway narrowing
    - Bronchitis
    - Bronchiolitis
    - Laryngotracheobronchitis
    - Bacterial tracheitis
    - Bronchiectasis
    - Cystic fibrosis
    - Juvenile respiratory papillomatosis (late)
  - Extrinsic airway compression
    - Mycobacterial or fungal infection with lymph node enlargement
    - Infection of congenital foregut malformations, cysts
    - Lung abscess
- Foreign body or aspiration
  - Gastroesophageal reflux with bronchitis
  - Foreign body in airway
  - Foreign body in esophagus
- Trauma
  - Tracheobronchial burns or scalds
  - Tracheobronchial injury (blunt or penetrating)
- Allergy and asthma
  - Anaphylactoid reaction to food or inhalant
  - Asthma with inflammation or bronchospasm
- Autoimmune disease
  - Bronchiolitis obliterans after lung or bone marrow transplant
  - Idiopathic bronchiolitis obliterans

- Pulmonary edema

Inspiratory and Expiratory Obstruction

When obstruction is evident in both phases of breathing, the obstruction may be variable and may simultaneously occur in both the intrathoracic and extrathoracic airways (e.g., croup with laryngotracheobronchitis). If this has not occurred, the obstruction may have become critical in nature. This is particularly the case in extrathoracic airway obstruction in which the development of obstruction during expiration is particularly worrisome. In contrast, with severe intrathoracic airway obstruction resulting from asthma or bronchitis, wheezing may occur in both phases of respiration but can usually be localized to the chest as opposed to the upper airway.

Evaluation of the child with wheezing starts with a careful history followed by thorough examination. When present, signs and symptoms of increased work of breathing or distress may dictate swift intervention before etiologic evaluation can take place. Depending on the age of the patient and the suspected etiology, ancillary tests may be helpful. These could include imaging studies (chest radiograph, CT, MRI, esophagogram, swallowing study), pulmonary function testing with bronchoprovocation or bronchodilator response, microbiologic studies (especially for respiratory syncytial virus in infants), and an empiric trial of bronchodilators. Bronchoscopic evaluation may also be helpful.

EVALUATION OF THE CHILD WITH EXERCISE INTOLERANCE

The majority of patients with chronic lung or cardiac disease and exercise intolerance usually have a clear reason for the inability to exercise; this may include deconditioning secondary to the primary illness. Instead of deconditioning, this section addresses the apparently normal child who has a difficult time exercising and develops dyspnea with a normal workload. These patients are commonly brought to their physician because they are unable to complete physical education at school or have a difficult time on sports teams. The approach to the apparently normal child with exercise intolerance involves delineating whether the child has a cardiorespiratory problem or is simply deconditioned (Box 10-5). The history is critical in this assessment. Data regarding symptoms compatible with asthma, cystic fibrosis, or another lung condition such as preexisting bronchopulmonary dysplasia need to be obtained. Similarly, a history of congenital or acquired cardiac disease needs to be reviewed.

Other than deconditioning, the leading cause of exercise intolerance is a variant of asthma, exercise-induced bronchospasm (EIB).[32] Children with EIB usually complain of a tightening or pain in the chest or submental triangle after vigorous exercise. This pain may be associated with frank wheezing or cough. Usually, patients complain of difficulty breathing that does not improve on stopping the exercise, but instead worsens after they sit down to rest. The symptoms then usually subside spontaneously. On cold or dry days, the tightness and cough are worse with exercise involving free running, such as soccer, football, and hockey. Swimming and cycling seem less prone to inducing bronchospasm. Some athletes notice that they can "run through" their bronchospasm or even prevent it by doing brief sprints before competing to obtain the protective effect of exercise on further EIB. Children with EIB may also have a history of spontaneous or prolonged wheezing and cough with colds. Collateral allergic symptoms should also be sought. The physical examination may be normal, but signs of allergy and asthma should be sought. Occasionally, wheezing or hyperinflation may be found; however, in children with these signs, usually asthma has already been diagnosed. Laboratory studies such as an exercise or cold-air challenge test, or eucapnic voluntary

BOX 10-5 Exercise Intolerance

- Chronic lung disease
  - Asthma
    - Exercise-induced bronchospasm
    - Vocal cord dysfunction
    - Deconditioning resulting from exercise-induced bronchospasm
  - Other pulmonary conditions
    - Bronchopulmonary dysplasia
    - Cystic fibrosis
    - Pulmonary fibrosis/interstitial lung disease
    - Other
- Congenital or acquired cardiac disease
- Deconditioning with or without obesity
- Myopathy or muscular dystrophy
- Endocrine abnormalities
  - Thyroid dysfunction
  - Cortisol insufficiency
  - Diabetes mellitus
- Other chronic illnesses

hyperventilation may be conducted both to demonstrate airway hyperreactivity and to reproduce the symptoms so that the child can confirm their nature (see Chapter 58). In contrast, a trial of a β-agonist such as albuterol before exercise may be effective in diagnosing EIB, as well as assessing a treatment modality.

Cardiovascular disease leading to exercise intolerance in an apparently normal child is uncommon and is usually diagnosed based on a history of diaphoresis and dyspnea with initiation of exercise. Furthermore, dyspnea resolves with resting compared to the persistence or worsening of EIB. A history of ankle edema, palpitations, fainting, chest pain, and nocturnal symptoms such as orthopnea or paroxysmal nocturnal dyspnea should be obtained but is positive only in children with relatively severe disease. Physical examination may reveal weight loss and fatigue, a hyperactive precordium, pathologic murmurs, and evidence of hypervolemia such as hepatomegaly and peripheral edema. Electrocardiography, chest radiography and echocardography are central to the laboratory assessment; however, a child with dyspnea and signs of cardiac disease should be referred to a pediatric cardiologist for clinical assessment and management.

It is relatively common for the pulmonary specialist to be asked to assess a child for exercise intolerance who has neither EIB nor heart disease. These children are commonly mildly to moderately obese, have a sedentary lifestyle, and do not readily engage in sports. They are commonly assessed because of an inability to keep up with school exercise programs. Their dyspnea and fatigue usually occur during exercise such as running laps. They usually do not have chest pain or cough and do not complain of any dysphoria or tightness in the submental region. They may complain of headache, leg pain, and cramping with exercise. Lacking the symptom complexes and findings previously noted, this group may most benefit from exercise testing. The clinician can use the test to reproduce the symptoms and demonstrate that the child does not have bronchospasm. Furthermore, the child may be unable to exercise vigorously enough to successfully complete an exercise challenge test. These clinical and laboratory findings combined can be useful to reassure the family that cardiorespiratory disease is not present and that deconditioning is the main problem. An exercise program and weight-control program can then be prescribed to help the child return to an active lifestyle.

EVALUATION OF THE CHILD WITH CHEST PAIN

The child with chest pain can present a challenge for the practitioner; parental anxiety is usually high because of the concern that the child may have heart disease (Box 10-6). In fact, the majority of children with chest pain have either EIB or a musculoskeletal cause that will respond to anti-inflammatory medication or nonspecific therapies.[33,34] Chest pain resulting from cardiac disease is uncommon in an apparently healthy child without other cardiac symptoms. However, chest pain associated with syncope should prompt urgent cardiac evaluation. The history should be focused after the clinician determines that the child is generally well. The pain should be characterized using the PQRST approach (see History). The pain is described as sharp, burning, or dull and aching. It is localized, and any radiation such as from the spine through an intercostal space should be noted. Radiation to the shoulder suggests diaphragmatic irritation. Worsening of the pain with breathing or movement should be noted, as should other provocative factors. The history should include a survey of activities compatible with muscular strain such as recent trauma, contact sports, and sports such as weight training. Surprisingly, many children do not associate anterior parasternal chest pain with the fact that they just began weight training to increase their pectoral muscle bulk. Also, many children carry schoolbooks in a pack or bag slung over one shoulder, leading to shoulder girdle strain. Patients with asthma, pertussis, and cystic fibrosis may develop chest pain associated with chronic cough and repetitive trauma to the ribs and muscles of the chest wall. The history should also review recent symptoms of lung infection, allergies, asthma, and EIB. Symptoms of arthritis or joint disease should be assessed, as should any recent skin changes or weight loss. Gastroesophageal reflux with esophagitis can also present as chest pain. A history of reflux after meals or on lying down with heartburn, a bitter taste in the mouth, water brash, and

BOX 10-6 Chest Pain

Musculoskeletal or soft tissue problems (most common)
- Chronic cough (asthma, cystic fibrosis, pertussis) with muscle injury
- Sports or weight training that caused muscle or joint strain
- Blunt trauma to the ribs or joints
- Costochondritis
- Tietze's syndrome
- Rheumatoid arthritis
- Breath development, inflammation
- Diaphragmatic pain
- Slipping rib syndrome

Asthma
- Acute bronchospasm, especially with exercise
- Pneumomediastinum
- Pneumothorax

Pleural inflammation
- Viral inflammation: Bornholm disease or pleurodynia
- Bacterial, mycobacterial, or fungal infection with pleurisy

Gastrointestinal or abdominal problems
- Gastroesophageal reflux
- Gastric or duodenal ulcer
- Diaphragmatic irritation caused by an intra-abdominal process

Cardiac problems (uncommon)
- Aberrant coronary problems
- Pericarditis, myocarditis, or myopathy
- Palpitations or arrhythmias that are confused with pain

Pulmonary vasculature
- Pulmonary embolus
- Sickle cell pulmonary crisis

Psychogenic or psychophysiologic problems

sensitivity to acid, high-fat foods, or coffee can be helpful. The physical examination should be relatively complete and include an assessment of general well-being and the respiratory, cardiovascular, gastrointestinal, and musculoskeletal systems. Changes on the chest wall with swelling or any mass, particularly over the costochondral and clavicular joints, should be specifically noted. Tenderness over the site of chest pain strongly implicates a musculoskeletal process. Although acute infection such as pneumococcal pneumonia with pleurisy is usually a clear diagnosis, other infections such as histoplasmosis, coccidioidomycosis, and tuberculosis may have a slow course and present with pleuritic pain. Thus, a careful chest examination for reduced air entry, crackles, or a friction rub is important. The results of chest radiography are usually normal in musculoskeletal chest pain but may be reassuring to both the parent and practitioner. Electrocardiography or stress testing is only occasionally useful in cases without additional cardiac symptoms or signs.

EVALUATION OF THE CHILD WITH HEMOPTYSIS

The approach to diagnosing hemoptysis in a child depends on whether there is a known preexisting disease such as cystic fibrosis.[35,36] In the previously well child with hemoptysis, the history is critical (Box 10-7). Care should be taken to ensure that the red or purple material expectorated was actually blood and not coloring from food. Afterward, the most important point is to try to determine that the bleeding truly represents respiratory bleeding from the lower respiratory tract and is not due to nasal, pharyngeal, or gastrointestinal bleeding (Table 10-6). A history of recent epistaxis, acute or recurrent tonsillitis, or throat trauma focuses attention on the upper respiratory tract. Indeed, examination of the nasopharynx by a specialist is sometimes important in ruling out a bleeding site in the upper respiratory tract. A history of gastroesophageal reflux, vomiting, liver disease, or portal hypertension focuses concern on the gastrointestinal tract as the source of the bleeding.

Although some streaking of the sputum in bacterial bronchitis or pneumonia is relatively common, true hemoptysis in the previously well child is rare. The hemoptysis should be characterized by the volume of blood (i.e., streaking versus submassive [<240 mL] versus massive [≥240 mL]). Whether the blood was a bright red liquid that clotted or simply old purple-brown clots should be noted. In the case of submassive and massive hemoptysis the patient may have a warm, bubbling feeling over the affected segment. The history

BOX 10-7 Hemoptysis

Pulmonary Origin of Bleeding

- Infection
  - Acute tracheobronchitis or severe pneumonia
  - Bronchiectasis
  - Erosion by an infected lymph node (mycobacteria, fungi)
  - Lung abscess
  - Fungal infection, including secondary mycetoma
  - Parasitic infection
  - Pulmonary hemorrhage in severe viral pneumonia
- Foreign body aspiration
- Bronchial tumor
  - Primary tumor
  - Secondary tumor
- Autoimmune lung disease
  - Idiopathic pulmonary hemosiderosis
  - Goodpasture syndrome
  - Milk allergy (Heiner syndrome)
  - Wegener's granulomatosis
  - Other vasculitis (e.g., Churg-Strauss)
- Pulmonary vascular conditions
  - Pulmonary embolism
  - Primary pulmonary hypertension
  - Obstructed pulmonary veins
  - Raised left atrial pressure
    - Congestive heart failure or pulmonary edema
    - Mitral valve stenosis
    - Aortic valvular stenosis or obstruction
  - Arteriovenous malformations
  - Osler-Weber-Rendu disease
  - Sickle cell pulmonary crisis
  - Pulmonary hemorrhage in acute respiratory distress syndrome
- Bronchopulmonary foregut malformations
- Trauma
  - Blunt trauma with pulmonary contusion or airway disruption
  - Penetrating trauma

Nonpulmonary Origin of Bleeding

- Upper airway conditions
  - Epistaxis
  - Sinusitis
  - Adenoidal or tonsillar bleeding
  - Severe pharyngitis or pharyngeal trauma
  - Coagulopathy with trauma to the mouth or pharynx
- Gastrointestinal conditions
  - Esophagitis with gastroesophageal reflux
  - Esophageal varices secondary to portal hypertension
  - Gastric or duodenal ulcer
  - Mallory-Weiss syndrome or esophageal erosion with severe vomiting or bulimia
  - Munchausen or Munchausen by proxy syndrome

Fictitious Bleeding

- Natural and artificial coloring in food
- Dyes in medicines
- Nasal foreign body with dye (e.g., crayon)

Table 10-6
Differential Features of Hemoptysis and Hematemesis

Hemoptysis	*Hematemesis*
Blood is coughed up, not vomited. Retching and nausea may come from pharyngeal irritation from blood.	Blood is vomited.
A portion of the blood should be frothy.	Blood is never frothy.
Blood is usually, but not always, bright red in color.	Blood is dark red in color.
Blood is alkaline in reaction.	Blood is acid in reaction.
Hemoptysis is preceded by a gurgling noise or a sensation stimulating a cough reflex. This may be absent in massive hemoptysis.	Hematemesis is preceded by nausea and vomiting.
There is sometimes a history of past cough.	There may be history of alcoholism and/or gastric disturbances, plus clinical findings of liver disease.
There is continued blood-tinged sputum, which lasts for several days.	Blood-tinged sputum is usually absent.
Blood is mixed with pus, organisms, or macrophages; some of the macrophages may contain hemosiderin particles.	Vomited blood may contain food particles.
Anemia may or may not be present.	There are often clinical and laboratory findings of blood loss before the actual hematemesis.

From Lyons HA: Basics of RD. ATS news, New York, American Lung Association, 1976.

BOX 10-8 Tissue Hypoxia

- Hypoxemic hypoxia: low arterial partial pressure of oxygen
  - Low inspired oxygen concentration (low inspired oxygen partial pressure)
    - Low barometric pressure (high altitude)
    - Low inspired oxygen concentration (low fraction of inspired oxygen)
  - Cardiorespiratory disease
  - Hypoventilation
  - Diffusion block
  - Ventilation-perfusion imbalance
  - Shunting
    - Intrapulmonary shunting
    - Extrapulmonary shunting
- Anemic hypoxia
  - Anemia
  - Carbon monoxide poisoning
  - Hemoglobinopathy
- Circulatory hypoxia
  - Shock or hypoperfusion
    - Hypovolemic shock
    - Obstructive shock
    - Cardiogenic shock
    - Distributive shock
  - Local vascular obstruction
- Histotoxic hypoxia
  - Sepsis with poor oxygen use
  - Cyanide poisoning

should rigorously assess the possibility of foreign body aspiration. This may not have been a recent event because foreign bodies leading to bleeding must usually be in the respiratory tree long enough to cause chronic infection or irritation with mucosal erosion. Past respiratory illness such as remote foreign body aspiration, pertussis, and severe pneumonia can also be associated with hemoptysis related to bronchiectasis formation. A history of heart disease should be obtained because increased left atrial pressures or obstructed pulmonary veins can lead to bleeding. Usually, however, the cardiovascular history is negative. Physical examination is usually negative in the absence of acute lung infection or chronic lung problems such as cystic fibrosis. Focal lung changes such as reduced or lagged air entry and focal hyperinflation may suggest foreign body aspiration. Coarse crackles and reduced air entry may lead to the consideration of infection and, if accompanied by clubbing, bronchiectasis. Chest radiography is used to rule out pneumonia, gross bronchiectasis, and cavitary disease. Evidence of focal hyperaeration or atelectasis may suggest focal airway obstruction resulting from a foreign body, infected lymph node, or tumor. If the diagnosis of bronchiectasis is considered, a thin-section, high-resolution CT scan rapidly identifies the presence of these lesions. Bronchoscopy can also be used, but the site may be obscured in the presence of moderate bleeding. Bronchoscopy may be most useful after the bleeding has quieted, when lesions such as bronchial adenomas, lymph nodes eroding the mucosa, and foreign bodies can be better seen. Angiography may be used and echocardiography and cardiac catheterization may have a role in diagnosing recurrent hemoptysis with no apparent lesion. In this case the hemoptysis may result from an obstructed pulmonary vein. Studies to evaluate possible vasculitis are particularly relevant when there is significant air space involvement on chest roentgenogram or associated hematuria.

EVALUATION OF THE CHILD WITH HYPOXIA

The approach to evaluating the child with evidence of tissue hypoxia requires the determination of whether the hypoxia is due to a failure of oxygen delivery or an inability of the tissues to use oxygen (Box 10-8). Failure of oxygen delivery or use may be evidenced by an alteration in global metabolism, resulting in anaerobic glycolysis with the production of a lactic acidosis, or an end-organ dysfunction (e.g., confusion secondary to cerebral hypoperfusion). A common approach has been to classify tissue hypoxia as occurring in one of four manners. The first two abnormalities lead to reduced oxygen content in the blood. The most common cause in patients with lung disease, hypoxemic hypoxia, is due to a reduced arterial partial pressure of oxygen, leading to an inadequate saturation of hemoglobin (see later section). The second is anemic hypoxia. Even with a normal arterial partial pressure of oxygen and hemoglobin saturation, anemia (reduced functional hemoglobin) leads to reduced oxygen delivery resulting from reduced oxygen capacity in the blood. This occurs in carbon monoxide poisoning, in which the hemoglobin is bound with the carbon monoxide, reducing the amount available to carry oxygen. In addition, carbon monoxide poisoning increases the affinity of hemoglobin for oxygen, further

reducing oxygen delivery to the tissues. If oxygen content is adequate but signs of tissue hypoxia are present, there are two possibilities. Either the oxygen is not being delivered to the tissues, or the tissues are unable to use oxygen in aerobic metabolism. The former is called *circulatory hypoxia* and may occur globally as in shock or locally as in vascular obstruction with ischemia. The latter, *histotoxic hypoxia*, occurs in sepsis and cyanide poisoning of aerobic metabolism when the cells are unable to conduct aerobic glycolysis.

The approach to hypoxemic hypoxia (see Box 10-8) is to divide potential causes into five categories. As in assessing tissue hypoxia, the clinician simply needs to work through the steps of the oxygenation of blood in the lung to delineate potential problems. First, a reduced inspired oxygen partial pressure leads to hypoxemia in the absence of compensatory hyperventilation. This may result from a reduced fractional concentration of oxygen secondary to oxygen consumption by combustion or of other gases in the environment. It may also occur with a reduced barometric pressure caused by increases in altitude. Hypoventilation with an increase in the level of alveolar carbon dioxide and decrease in the level of alveolar oxygen causes hypoxemia as a result of a failure to ventilate adequate oxygen into the lungs to meet the body's metabolic demands. These first two causes of hypoxemia are associated with a normal alveolar-arterial oxygen difference. Thickening of the alveolar-capillary membrane may cause the normal perfusion limitation of oxygen transfer to become diffusion limited and lead to hypoxemia. Increased cardiac output and reduced alveolar oxygen levels exacerbate this diffusion block. Areas of local hypoventilation in the lung resulting from either airway or airspace disease lead to hypoxemia secondary to a ventilation-perfusion imbalance, with incomplete saturation of blood passing through these regions of the lung. Finally, blood from the systemic venous system may bypass the ventilation entirely, either because of intrapulmonary shunting with lung disease or arteriovenous fistulae or because of extrapulmonary shunting with congenital heart or great vessel malformation (cyanotic congenital heart disease). The arterial carbon dioxide level may be normal in all of these conditions except hypoventilation. This is because the healthy, well-ventilated lung can compensate for the dysfunctional lung by clearing excess carbon dioxide. Unfortunately, blood that is normally ventilated is already nearly completely saturated with oxygen, and thus healthy units cannot return arterial oxygen to normal by overcompensating for units with diffusion block, ventilation-perfusion imbalance, or shunt. Finally, shunt is commonly separated from the other causes of hypoxia because it does not respond to the administration of supplemental oxygen with a significant increase in arterial oxygen levels.

EVALUATION OF THE CHILD WITH HYPOVENTILATION

The definition of *hypoventilation* is an increase in the arterial carbon dioxide level above 45 mm Hg; it is, by definition, a respiratory acidosis. It may differ with the apparent minute ventilation, tidal volume, or respiratory rate. *Hyperpnea* and *hypopnea* refer to an apparent increase or decrease in overall breathing; however, *hyperventilation* and *hypoventilation* refer specifically to the level of arterial carbon dioxide achieved. The first step in assessing the child with hypoventilation is to try to determine whether the respiratory pump is functioning as well as expected in response to substantive lung disease or whether it is a primary or adjunctive cause of the increased arterial carbon dioxide (Box 10-9). Second, the pump may be functioning properly and delivering adequate minute ventilation; however, there may be an increased ventilation of physiologic dead space with reduced alveolar ventilation. This may result either from a reduction in tidal volume with a fixed physiologic dead space or from an increase in physiologic dead space that is not matched by an increase in tidal volume. In either case, the dead space/tidal volume ratio increases, and alveolar ventilation is compromised, leading to carbon dioxide retention.

The differential diagnosis of airspace or airway disease that can lead to carbon dioxide retention is broad and is not addressed further here. The differential diagnosis of a failure of the respiratory pump is considered here because it may apply even in patients in whom lung disease is paramount. A useful approach is to work through the steps necessary for the maintenance of minute ventilation, starting centrally with respiratory control and ending with the respiratory muscles and chest wall (see Box 10-9). Failure may result from central controller failure or disruption of upper motor neuron function, such as in sedation or cervical cord damage. Lower motor neuron disease may occur at a cellular level, such as in poliomyelitis, or may be more peripheral resulting from damage to the phrenic nerves caused by trauma or demyelinating diseases. The neuromuscular junction may inadequately conduct the neural impulse, such as in botulism, or the muscle may be unable to respond, such as in profound hypokalemia. Finally, even if the controller/feedback system is functioning and the respiratory muscles are able to respond, the chest wall itself must be able to function as a pump without reduced motion or inappropriate paradoxical motion.

EVALUATION OF THE CHILD WITH BRONCHITIS

Bronchitis is a clinical respiratory problem that is common in childhood. It occurs as an acute illness generally secondary to a viral upper respiratory tract infection, as well as a chronic component of underlying asthma, cystic fibrosis, foreign body aspiration, immunodeficiency, immotile cilia syndrome, and other conditions. Low-grade airway inflammation occurs secondary to inhalable noxious agents such as passive smoke or various environmental pollutants. In children, unlike in adults, chronic bronchitis per se is not considered a final diagnosis.

Because of its frequent occurrence, it would seem that bronchitis should be easily characterized and defined. However, the primary and at times exclusive manifestation of the disease is cough, a symptom of little diagnostic specificity. Other than viral studies, no noninvasive laboratory tests are available to specifically diagnose bronchitis in young children. The self-limited course of acute bronchitis as well as the lack of a consistent definition of *chronic bronchitis* in childhood have limited pathologic investigation and characterization of the disease in childhood. In adults, *chronic bronchitis* is defined as a condition of chronic or recurrent productive cough that is present on most days for 3 months in a year for 2 years.[37] Whether this definition can be applied

BOX 10-9 Hypoventilation

Reduced Minute Ventilation

- Respiratory pump failure as a primary cause
  - Central controller failures
    - Encephalopathy or brain stem dysfunction
      - Infection
      - Intoxication
      - Metabolic dysfunction or seizure
      - Tumor
      - Trauma, concussion, or hemorrhage
      - Malformation (Arnold-Chiari malformation)
    - Central hypoventilation syndrome
    - Metabolic alkalosis
  - Cervical spinal cord disruption (upper motor neuron)
    - Infection
    - Tumor
    - Trauma, concussion, or hemorrhage
    - Inflammation (transverse myelitis)
    - Compression (achondroplasia, Down syndrome)
    - Multiple sclerosis
  - Cervical spinal cord (lower motor neuron: cell)
    - Infection (poliomyelitis)
    - Inflammation or degeneration (transverse myelitis)
    - Vasculitis or vascular accident
    - Werdnig-Hoffman disease
  - Phrenic or intercostal nerves (lower motor neuron: axon)
    - Trauma (thoracic surgery or penetrating injury)
    - Demyelinating neuropathies (Guillain-Barré syndrome)
    - Tumor
  - Neuromuscular junction failure
    - Myasthenia gravis
    - Botulism
    - Aminoglycosides
    - Pseudocholinesterase deficiency
  - Respiratory muscle failure
    - Muscular dystrophies
    - Extreme electrolyte abnormalities
    - Extreme starvation or metabolic imbalance
    - Familial paralysis syndromes (e.g., hypokalemia)
  - Chest wall disease or disruption
    - Flail chest
    - Restrictive chest wall disease
      - Kyphoscoliosis
      - Congenital chest wall malformation or dystrophy
      - Ankylosing spondylitis
    - Prune-belly syndrome (infancy)
- Increased elastic and resistive work with muscle fatigue
  - Increased elastic work
    - Pulmonary fibrosis
    - Pulmonary edema
      - Cardiogenic edema
      - Noncardiogenic edema (adult respiratory distress syndrome)
    - Diffuse pneumonia
  - Increased resistive work
    - Upper airway obstruction
    - Lower airway obstruction
  - Mixed increase in elastic and resistive work

Increased Physiologic Dead Space

- Increased physiologic dead space
  - Increased anatomic dead space
    - Severe bronchiectasis
  - Increased alveolar dead space
    - Alveolar distention or overexpansion
      - Intrathoracic airway obstructive airway disease
      - Mechanical ventilation with inadvertent positive end-expiratory pressure
    - Shock with reduced pulmonary perfusion pressures
    - Pulmonary embolus
- Reduced tidal volume with normal physiologic dead space

to childhood bronchitis remains unclear. Thus, no generally agreed-on definition of *acute*, *chronic*, *recurrent*, or *wheezy bronchitis* in childhood exists.[38] Furthermore, the clinical presentation of children with asthma, wheezy bronchitis, and recurrent and chronic bronchitis overlaps considerably. A diagnosis of bronchitis should therefore cautiously be considered.[39] It has the potential to divert the pediatrician from detecting a more specific respiratory condition.

Several studies have demonstrated the importance of childhood respiratory problems in the development of chronic pulmonary disease in adulthood.[40-43] Despite these limitations, it seems important to understand bronchitis in its various forms.

ACUTE BRONCHITIS

Acute Viral Bronchitis

Viruses produce most attacks of acute bronchitis.[44] Rhinovirus, respiratory syncytial virus, influenza virus, parainfluenza virus, adenovirus, rubeola virus, and the paramyxoviruses all have been identified as etiologic agents.[45,46] Attacks of acute bronchitis can occur at any time during the year but are most common in the winter, when the respiratory virus season peaks.[47] A knowledge of which pathogens are currently endemic is helpful but not conclusive etiologic evidence.

Because acute bronchitis is usually a mild and self-limited condition, the pathology is ill defined because of the lack of tissue to study. Mucous gland activity increases, and desquamation of the ciliated epithelium occurs. Infiltration of polymorphonuclear leukocytes into the airway walls and lumen contributes to a purulent appearance of the secretions. Because this leukocytic migration is a nonspecific response to airway damage, purulent sputum does not necessarily imply bacterial superinfection.[48]

Acute bronchitis usually follows symptoms of upper respiratory tract infection such as serous rhinitis and pharyngitis. The cough usually appears 3 to 4 days after the rhinitis. The

cough is initially harsh and dry but frequently evolves into a loose cough with significant sputum production. Because young children do not expectorate but generally swallow the mucus, vomiting associated with cough paroxysms can occur. Chest pain secondary to a progressive severity and production of sputum with cough may be a prominent complaint in older children.

Auscultation of the chest is usually unremarkable in the early stages. As the cough progresses, variable rhonchi, harsh breath sounds, wheezes, or a combination thereof may be heard. Crackles are infrequent. Chest radiographs are normal or may have increased bronchial markings. Generally, the symptoms resolve within 10 to 14 days. If the clinical signs persist beyond 2 to 3 weeks, a chronic condition should be suspected. Occasionally, a secondary bacterial infection occurs.

Acute Bacterial Bronchitis

Mycoplasma pneumoniae has occasionally been identified as an organism producing acute bronchitis in school-age children and adolescents.[46,49] There are no characteristic clinical findings. Positive cold hemagglutination titers associated with a concomitant rise in specific *Mycoplasma* titers confirm the diagnosis. Treatment with a macrolide antibiotic or tetracycline in children over 9 years of age can be effective.

In unimmunized children, infections with *Bordetella pertussis* and *Corynebacterium diphtheriae* are associated with a characteristic tracheobronchitis. During the catarrhal stage of pertussis, symptoms of upper respiratory tract infection, such as rhinitis, conjunctivitis, low-grade fever, and cough, predominate. As the paroxysmal stage develops, episodes of coughing increase in number and severity. Characteristically, repetitive series of forceful coughs during a single expiration are followed by a sudden massive inspiratory effort, which produces the whoop. This cough eventually dislodges thick, tenacious mucus. Posttussive emesis associated with the paroxysms is a characteristic symptom even in the child without whoop. The pathologic findings of pertussis bronchitis include infiltration of the mucosa with lymphocytes and polymorphonuclear leukocytes. Furthermore, necrosis of the midzonal and basilar layers of the mucosa has been observed. Leukocytosis with an absolute lymphocytosis occurs characteristically at the end of the catarrhal stage and the beginning of the paroxysmal stage. Culture and fluorescent antibody tests of secretions can confirm the diagnosis. Treatment of pertussis is largely supportive. Erythromycin may eliminate pertussis organisms from the nasopharynx within 3 to 4 days, thereby decreasing spread of the disease. Given within 14 days of the onset of illness, erythromycin may abort pertussis. However, once paroxysms of cough develop, this medication has little effect on the course of the illness.[50]

Progressive cough and lung disease starting at a few weeks of age in conjunction with conjunctivitis or blepharitis is highly suggestive of chlamydial infection. Diagnosis can be made by culture, fluorescent antibody, or serology studies, and therapy with erythromycin is usually effective. Infection with *Ureaplasma* organisms may closely mimic chlamydial disease.[51] Although difficult to diagnose, these infections may respond to a therapeutic trial with erythromycin.

CHRONIC, RECURRENT, AND WHEEZY BRONCHITIS

The persistence of signs and symptoms of acute bronchitis or frequent recurrences should initiate an attempt to identify an underlying illness. Clinicians do not generally agree on a definition of chronic or recurrent bronchitis in childhood. Factors that must be defined are where the isolated, recurrent episodes end and the chronic state begins and how many episodes are "too many." For the purpose of this discussion, *chronic bronchitis* is defined as the symptom complex of chronic (greater than 1 month) or recurrent (at least four) episodes of productive cough per year that may be associated with wheezing or crackles on auscultation.

The chronicity and recurrence of the condition suggests either that an endogenous susceptibility or increased response to acute airway injury exists or that continuing exposure to noxious environmental agents produces the symptoms. Host factors include a variety of underlying illnesses, whereas exogenous factors affect susceptible and normal airways as well. An airway that suffers an insult responds in a limited number of ways.[39] Inflammation, edema, increased sputum production, and disordered mucus clearance occur in varying degrees and produce cough. Depending on the severity of the airway damage and the resulting increase in airflow resistance, wheezing may also be present. In subjects with bronchial hyperresponsiveness, acute airway injury may furthermore trigger bronchial obstruction, also leading to cough and wheeze. Thus, cough and wheezing are nonspecific symptoms that reflect airway damage and narrowing without regard to mechanism and etiology.

This overlap of syndromes has created considerable confusion in clinical as well as in epidemiologic studies of chronic bronchitis in childhood and has limited assessment of its prevalence. When restricting the definition of *chronic bronchitis* to a productive cough that received medical therapy and lasted more than 2 weeks, Peat and associates[52] found an overall prevalence of 14% to 24% in Australian children. Other definitions of *chronic* or *recurrent bronchitis* have led to widely different estimates of its prevalence (Table 10-7). The overlap of syndromes and the lack of tissue studied have furthermore hampered pathologic investigation of chronic bronchitis in childhood.

Table 10-7
Prevalence of Childhood Bronchitis

Reference	Study	Prevalence	Asthma/ Bronchitis Ratio
Burrows et al[41]	1977: Arizona children (chronic)	46.4%	1 : 1.6

CLINICAL ASSESSMENT AND DIFFERENTIAL DIAGNOSIS

The diagnosis of chronic bronchitis should occur in two phases (Box 10-10). The first is consideration and identification of several well-defined respiratory disorders according to a staged management protocol (Box 10-11). The second but simultaneous phase is elimination or modification of exogenous factors that produce or maintain the child's illness. Diagnostic tests selected on the bases of the child's history, the incidence of the suspected disease, the morbidity to the patient, and the costs are performed. At the same time, the parents are encouraged to avoid exposing the child to irritants such as cigarette smoke or recurrent viral respiratory tract infections in daycare centers.

Phase I: Differential Diagnosis

ASTHMA

Asthma is the most likely diagnosis in a child with recurrent or chronic bronchitis. Burrows and Lebowitz[53] showed in an epidemiologic survey in the United States that 74% of children with a diagnosis of chronic bronchitis were wheezing. Moreover, skin test reactivity was associated with symptoms of bronchitis. When subjects in whom asthma was first diagnosed between the ages of 10 and 20 years were prospec-

BOX 10-10 Differential Diagnosis of Chronic and Recurrent Bronchitis

Phase I: Specific Etiologies

- Asthma
- Preexisting lung disease
  - Respiratory distress syndrome and bronchopulmonary dysplasia
  - Postinfectious bronchiectasis
- Cystic fibrosis
- Foreign body aspiration
  - Intrathoracic or extrathoracic airway
  - Esophagus
- Aspiration syndromes
  - Abnormal enteropulmonary communications (e.g., laryngeal cleft)
  - Dysfunction of swallowing
  - Gastroesophageal reflux
- Airway compression
  - Weakened wall (e.g., tracheomalacia)
  - Extrinsic compression (e.g., vascular ring)
- Congenital heart disease
- Immunodeficiency
- Primary cilia abnormalities

Phase II: Nonspecific Airway Irritation

- Exposure to recurrent respiratory tract infections in daycare centers
- Cigarette smoke
  - Passive smoke exposure
  - Active smoking
- Air pollution
  - Outdoor secondary to particulate matter, automobile exhaust, and other pollutants
  - Indoor secondary to wood burning, irritants, and chemicals

BOX 10-11 Diagnostic Evaluation of Bronchitis

Initial Assessment

History
- Assessment of the presence of cough, wheezing, and lower respiratory tract infections
- Identification of specific symptoms of possibly underlying respiratory conditions

Physical examination
- Assessment of general well-being, height, weight, chest circumference, and signs of chronic airway disease
- Notice of worrisome signs such as clubbing

Laboratory
- No tests in acute bronchitis
- Complete blood count and differential, immunoglobulin E level, sweat chloride test, and chest radiograph
- Skin prick tests to assess atopy and specific allergens
- Skin tests for tuberculosis and fungal infection
- Baseline pulmonary function testing and response to bronchodilators or bronchial challenge
- Chlamydial culture, serology, or both tests in infants younger than 6 months of age

Therapy
- Bronchodilators
- Chest physiotherapy and management of gastroesophageal reflux
- Trial of erythromycin in infants and school-age children

Follow-up

Interim history
- Response to therapeutic trial
- Repeat of questions about specific symptoms of possible underlying respiratory conditions

Interim physical examination
- Improvement of findings after therapeutic trial
- Unexpected changes in pulmonary status

Laboratory
- Barium swallow, high-kilovolt airway films
- Measurement of levels of immunoglobulin G and its subclasses
- Assessment of cilia

Therapy
- If patient is doing well, continuation of bronchodilators and physiotherapy for 1 month and then consideration of trial off medication
- If patient is not doing well, consideration of parental compliance by starting theophylline and measuring the medication level
- If patient is not doing well, consideration of a trial of antibiotics

tively investigated, a prior diagnosis of chronic bronchitis was found to be an independent risk factor for asthma, more reflecting the natural history of the disease than estimating the risk for developing it.[54] Boule et al[55] found decreased dynamic compliance with evidence of air trapping and increased airway reactivity in 29 children with recurrent bronchitis. Conversely, chronic cough in children without any clinical evidence of asthma or another respiratory disease has been associated with exercise-induced airway hyperreactivity.[56] Both the cough and airway hyperreactivity were relieved by oral theophylline therapy. This overlap of the clinical presentations of asthma and chronic bronchitis has made the distinction between these conditions very difficult.

Wheeze in relation to viral infections has commonly been labeled *wheezy bronchitis* or *wheezing associated respiratory illness* (WARI) to differentiate it from asthma because of additional precipitating factors and different age distributions of the disease.[57] Evidence suggests that in many children with recurrent wheeze, WARI is simply the first presentation of what will later become diagnosed as asthma. In an Australian study, both children with wheezy bronchitis (wheeze with viral infections only) and children with asthma differed from a control population in several atopic markers.[58] Furthermore, no difference in the genetic backgrounds of either condition could be found.[59] Finally, the clear demonstration that asthma was both underdiagnosed and undertreated[60,61] was in part held to be attributable to the use of terms such as *wheezy* or *asthmatoid bronchitis*. The prognosis and pathophysiologic features of each condition may differ, however. The outcome of childhood wheeze after 25 years was significantly worse for adults with a diagnosis of childhood asthma compared with those with a diagnosis of wheezy bronchitis.[62] Lower levels of lung function in the first months of life precede and predict the development of wheezing respiratory illnesses during the first 3 years of life.[63-65] Thus, in some infants, wheezing respiratory illnesses may be driven by anatomic abnormalities such as initial lower airway diameters and lengths or alterations of the lung parenchyma and may disappear with lung maturation. The challenge for the clinician is to assess the likelihood that recurrent wheeze in an infant or toddler actually represents a nascent asthma phenotype and not either non-atopic wheeze or other pathologic condition.

The recognition of the variability in obstructive airway disease presentation and course in children led to the description by Martinez and associates[66] of distinct wheezing phenotypes in childhood, namely, transient early wheeze (present in the first year of life, resolving by early school years), late-onset ("non-atopic") wheeze (onset in the first 3 years of life, resolving in early adolescence), and persistent ("atopic") wheeze (onset in mid-preschool years with persistence into adolescence) (Fig. 10-4). Presented a slightly different way, Figure 10-5 combines the phenotypes to allow estimation of the proportion of each phenotype at any given age. Early in life transient wheeze predominates, whereas in the early school years, the non-atopic wheeze group makes up about two thirds of children with wheeze. However, after ages 9 to 12, atopic wheeze and persistent asthma account for most of the wheezing children, highlighting the role of atopy in preventing remission of wheezing illness.

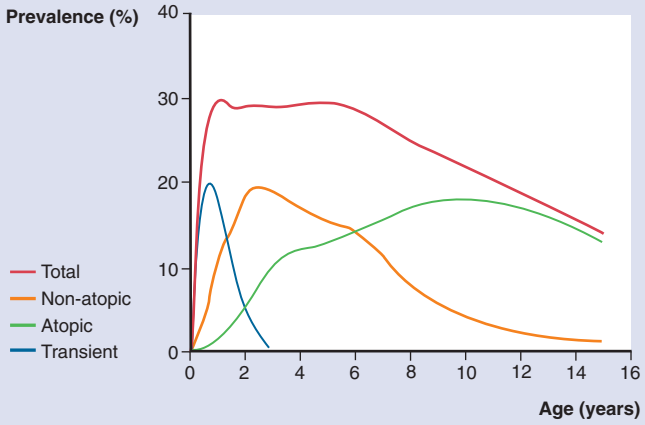

Figure 10-4 Schematic representation of the incidence of asthma phenotypes in childhood. (Redrawn with permission from Martinez FD, Godfrey S: Wheezing Disorders in the Preschool Child. New York, Martin Dunitz, Taylor & Francis Group, 2003, p 15.)

Wheezing illnesses continuing beyond infancy and the development of asthma may be determined by a child's susceptibility to become atopic.[67] For clinical practice, infants with recurrent wheezing illnesses and atopic stigmata such as eczema, elevated immunoglobulin E (IgE) levels, or a family history of atopy may be more likely to develop asthma in later years, whereas non-atopic wheezing infants who have been exposed to environmental noxious agents such as maternal smoking may have a better prognosis. However, a diagnosis of wheezy bronchitis should not prevent the pediatrician from initiating a therapeutic trial of bronchodilators.

A history of wheezing in children with recurrent or chronic bronchitis that responds to bronchodilator therapy or occurs with exercise, cold air, laughter, or exposure to allergens should be considered evidence of asthma. Nocturnal cough apart from colds or cough with exercise is suggestive of airway hyperreactivity. A family history of asthma or allergy may further add to the diagnosis of asthma. Evidence of

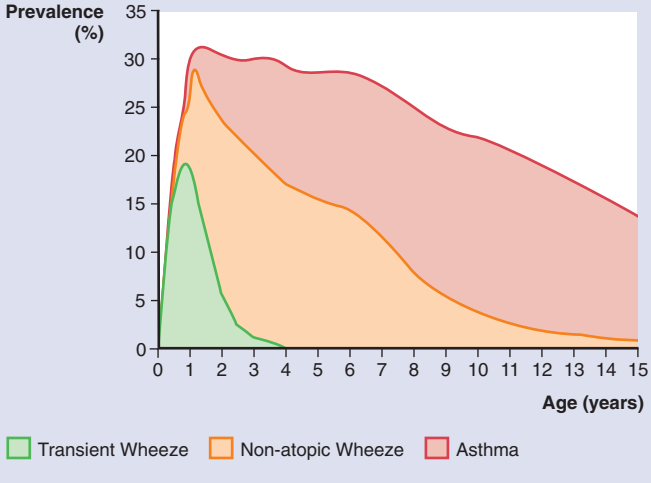

Figure 10-5 Relative proportion of childhood wheezing attributable to various phenotypes.

BOX 10-12 Asthma Predictive Index

Child with ≥3 Episodes of Wheeze by 3 Years of Age

Major Criteria	Minor Criteria
Parental asthma (physician diagnosed)	Allergic rhinitis (physician diagnosed)
Eczema (physician diagnosed)	Wheezing apart from colds
	Peripheral eosinophilia (≥4%)

Adapted from Castro-Rodriguez JA, Holberg CJ, Wright AL, et al: A clinical index to define risk of asthma in young children with recurrent wheeze. Am J Respir Crit Care Med 162:1403-1406, 2000.

allergy such as positive skin prick tests, elevated serum IgE levels, blood eosinophilia, or more than 20% eosinophils in sputum examined with Hansell stain can support the diagnosis of asthma. However, airway hyperreactivity can exist without concomitant allergy. Thus, the absence of atopy should not obviate a therapeutic trial of bronchodilators.

Castro-Rodriguez and associates[68] found an index composed of some of these characteristics to be helpful in predicting continued wheezing in young children with recurrent wheezing (Box 10-12). In a child with three or more episodes of wheezing by 3 years of age, the index is considered to be "positive" if a child has one major criterion or two minor criteria. A positive index is associated with an increased risk of continued frequent wheezing at ages 6, 8, 11, and 13 years. Thus, it may be more reasonable to institute anti-inflammatory therapy earlier in children with a positive asthma predictive index than in those whose index is negative. While doing so may result in better symptom control, early anti-inflammatory therapy has recently been shown to not influence subsequent outcome in terms of development of asthma in later childhood.[69]

Pulmonary function tests can be reliably performed in children as young as 5 years. Measurement with spirometry allows the baseline assessment of airway obstruction. A significant bronchodilator response aids in the diagnosis. Furthermore, airway reactivity to different physical stimuli such as exercise or cold air or to pharmacologic agents such as methacholine or histamine can be determined. The availability of relatively inexpensive spirometers should make the measurement of pulmonary function an integral part of the assessment of every child with chronic airway disease.

A trial of bronchodilator therapy is useful in both the diagnosis and management of children with asthma. However, long-term therapy should be aimed at reducing airway inflammation by administering medications such as cromolyn, nedocromil, and inhaled steroids.

PREEXISTING PULMONARY DISEASE

Congenital abnormalities and airway injury acquired early in life can predispose children to subsequent pulmonary disease. Considering and identifying such early pulmonary insults may be crucial in understanding the clinical course of some chronic airway diseases. Infants who survive neonatal respiratory distress syndrome are at higher risk for developing respiratory illnesses in the first year of life and beyond.[70-73] The risk is highest for children who require mechanical ventilation and subsequently develop bronchopulmonary dysplasia, but it is also increased in children who have a history of respiratory distress syndrome but no bronchopulmonary dysplasia. In a significant number of these children, airway hyperreactivity, exercise-associated desaturation, cough, and wheezing can be demonstrated.[71,72,74,75]

Early lung injury by chlamydial, viral, or *B. pertussis* infection is associated with long-term pulmonary sequelae[76,77] and may leave a child vulnerable to repeated lower respiratory tract infections. This increased susceptibility may be attributable to the induction of airway hyperreactivity, preexisting small airways, or a fixed small airway obstruction. In some cases, pneumonia caused by adenovirus, respiratory syncytial virus, measles virus, or *B. pertussis* may lead to the development of bronchiectasis. This condition should be suspected in a child who has a history of sustained productive cough exacerbated by a postural change or who has digital clubbing.

CYSTIC FIBROSIS

Cough is the most constant symptom of pulmonary involvement in cystic fibrosis. At first, the cough may be dry and hacking, but eventually, it becomes loose and productive. Sometimes the disease remains asymptomatic for long periods, or the infant seems to have prolonged acute respiratory infections. Accompanying symptoms of gastrointestinal malabsorption, such as bulky, greasy stools, and failure to gain weight despite a large food intake, should alert the pediatrician to the diagnosis of cystic fibrosis. Thus, serial documentation of weight and height measurements should be part of every follow-up of children with chronic respiratory conditions. Furthermore, a diagnosis of cystic fibrosis should be considered in children with increased anteroposterior diameters of the chest, generalized hyperresonance, digital clubbing, and bronchiectasis. Cystic fibrosis is the diagnosis most tragic to miss in children with chronic or recurrent bronchitis because early initiation of therapy may alter the course of the illness and early diagnosis can alert the parents to the risk of having other children with the same disease. Thus, a sweat chloride determination should be obtained in every child with chronic or recurrent bronchitis.

The sweat test should be performed using quantitative pilocarpine iontophoresis to collect sweat and to analyze its chloride content. Because this method requires care and accuracy, it should be performed by a center that frequently performs these tests.[78] The amount of sweat collected should be measured and reported. For reliable results, at least 75 mg, preferably 100 mg, of sweat should be collected. Because of low sweat rates, accurate testing may be difficult in the first weeks of life. More than 60 mEq/L chloride in sweat is diagnostic of cystic fibrosis.

FOREIGN BODY ASPIRATION

Foreign bodies aspirated into and retained in the tracheobronchial tree should always be considered in the differential diagnosis of chronic bronchitis.[79] A careful history and a high index of suspicion are important for the identification of this

condition. Sudden violent cough, wheezing, and gagging may occur, but after the aspiration of small foreign bodies, the onset may be insidious or overlooked, and a persistent cough and wheezing may be the only presenting signs. Occasionally, persistent or recurrent pneumonia that does not completely clear with adequate antibiotic therapy may lead to the diagnosis. Unsuspected foreign bodies have been identified as the cause of chronic respiratory illness in a significant number of children. They may produce chronic airway inflammation, distal atelectasis, bronchiectasis, and severe lung damage and may thus distract from an accurate diagnosis. Physical examination, especially differential auscultation with a binaural stethoscope, can be helpful.[39] Decreased breath sounds are found over the affected side; delayed air entry into the involved lobe, regional prolongation of exhalation, and a louder wheezing can be heard. Inspiratory-expiratory and decubitus chest radiographs confirm the physical findings and may show unilateral obstructive emphysema or atelectasis. Bronchoscopy should always be performed if the possibility of a foreign body aspiration exists.

ASPIRATION SYNDROMES

A history of cough with feeding is suggestive of conditions associated with recurrent aspiration of feedings or gastric contents after reflux. "Bottle propping" (i.e., propping the bottle up in the crib so that the infant can drink while falling asleep) can cause chronic cough and wheezing in infants and toddlers and is associated with later persistence of asthma or recurrent wheezing into the school years.[80] Furthermore, chronic irritation of the airway subsequent to feeding can occur in conditions such as an H-type tracheoesophageal fistula, a laryngeal cleft, and dysfunctional swallowing mechanisms such as familial dysautonomia, submucous cleft palate, cerebral palsy, and muscular dystrophy.[81] If very small amounts of material are aspirated or aspiration occurs primarily during sleep, chronic cough, wheezing, and rattling breathing may be the only presenting signs. The extent of pulmonary injury after aspiration is in part determined by the pH, the amount, and the particulate content (milk or other foods) of the aspirate.[82] Wolfe and colleagues[83] have proposed that chronic aspiration produces airway erythema with disruption of the normal tracheal clearance. Increased mucus production and a subsequent "wet" cough could then mimic the clinical appearance of chronic bronchitis.

Nocturnal cough may indicate the presence of gastroesophageal reflux. The pathophysiologic changes in chronic pulmonary disease subsequent to reflux may be attributable to microaspirations of refluxed material into the lungs or to reflex bronchoconstriction when acid is present in the lower esophagus. Chronic respiratory illness may also be seen in patients who have undergone repair of esophageal atresia. The prevalence of annual bouts of bronchitis was 74% in children under 15 years of age in an Australian center.[84] Multiple factors, including recurrent inhalation of gastric or esophageal contents, structural instability of the major airways, and abnormal airway epithelium, may contribute to these problems.

Swallowing as well as esophageal anatomy and function can be assessed with a barium swallow and esophagram. The documentation of gastroesophageal reflux may require prolonged pH monitoring.

AIRWAY COMPRESSION

Chronic airway compression can lead to a chronic, dry, irritative cough. Extrathoracic lesions such as laryngomalacia and subglottic hemangioma lead to collapse during inspiration, with a resulting characteristic inspiratory stridor. These conditions are rarely mistaken for chronic bronchitis. Tracheomalacia and intrathoracic airway compression, however, result in collapse on expiration with wheezing. Functional or structural abnormalities of the tracheal cartilages have been reported in primary tracheomalacia, whereas vascular rings or slings as well as perihilar adenopathy and mediastinal tumors account for intrathoracic airway compression. Irrespective of the underlying condition, the wheezing is most obvious with forced exhalation during cough and laughing. In addition, lower respiratory tract infections worsen both the cough and the wheezing because of increased airway resistance upstream of the obstruction, resulting in a more dynamic collapse.

Physical examination may demonstrate a wheeze and prolonged expiration. Differential auscultation with a binaural stethoscope can be helpful in further localizing the abnormality, and the findings on auscultation are similar to those of a foreign body aspiration. Airway compression by an abnormal vessel may be seen on an esophagram, and echocardiography may confirm the diagnosis of an aberrant vessel such as a double aortic arch. Chest CT scanning, particularly spiral CT, can be useful in delineating vascular and other compressions of the central airways. The ease with which flexible fiberoptic bronchoscopy can now be conducted by skilled and experienced bronchoscopists makes this a most useful study in assessing children with suspected extrinsic airway compression.[85] Before surgical correction, MRI can be used to definitely outline the vascular anatomic structures without requiring intravascular contrast medium or x-ray exposure.[86]

CONGENITAL HEART DISEASE

Wheezing and chronic airway obstruction can be major manifestations of pulmonary edema. Narrowing of both large and small airways may underlie this condition. Although peribronchiolar cuffs of fluid would be expected to lead to increases in airway closure and resistance, morphometric studies provide no support for the notion that interstitial lung edema compresses airways.[87] They suggest that alveolar or airway luminal edema may be responsible for the increase in resistance with edema. Small airways contribute a relatively greater proportion of the total airway resistance in infants. This becomes important in the assessment of young children with known "mild" heart disease such as ventricular septal defect or patent ductus arteriosus and left-to-right-shunts. A trial of diuretics and more aggressive management of the pulmonary congestion may relieve symptoms. However, Hordof and associates[88] found no improvement until repair of the lesion was carried out despite vigorous cardiotonic therapy. In addition, some children with interstitial edema as a result of left-sided heart failure with a variety of underlying diseases, such as cor triatriatum, mitral stenosis, and congenital hypoplastic left heart syndrome, have also had recurrent wheezy attacks. The differentiation between primary and secondary lung disease in this situation requires effective communication among the cardiologist, pulmonologist, and child's pediatrician.

INFECTIONS

An additional factor important for the recurrence or maintenance of airway inflammation is the frequency of lower respiratory tract infections. A prospective study of 108 children found protracted bacterial bronchitis to be the most common cause of chronic cough.[89] The average number of infections in the infant and preschool child varies but can be as high as 8 to 10 per year. Children with frequent infections of the upper and lower respiratory tract are prone to subsequent respiratory viral infections, predominantly of the lower respiratory tract.[90] Whether this increased susceptibility is attributable to minor abnormalities in immune response mechanisms, small airway size, or altered airway reactivity remains to be elucidated. Repeated and prolonged episodes of lower respiratory tract infections should always alert the pediatrician to consider an underlying cause, most frequently airway hyperreactivity.

Other infectious agents may cause chronic bronchitis. Infections with *Chlamydia* or *Ureaplasma* organisms can lead to progressive cough and lung disease in infants. *B. pertussis* can cause airway damage and an unremitting chronic cough in infants and preschool children. *M. pneumoniae* should be considered a possible causative agent in school-age children. Furthermore, mycobacterial or fungal infection must be ruled out as a cause of chronic cough and wheezing. Delayed hypersensitivity skin testing and fungal serologies can aid in the diagnosis. The chest radiographs may reveal enlarged hilar nodes or parenchymal infiltrates.

IMMUNODEFICIENCY

Recurrent respiratory disease represents the main clinical expression in children with humoral immunodeficiency syndromes such as common variable hypogammaglobulinemia, common variable immunodeficiency, or X-linked infantile (Bruton's) agammaglobulinemia.[91] Bronchitis is often not the sole manifestation of these conditions, but there are also associated recurrent episodes of pneumonia, sinusitis, and otitis media. Therefore a thorough evaluation of the child's history and a careful physical examination provide important clues for the diagnosis.

In addition, minor abnormalities in humoral defense mechanisms such as isolated and combined IgG subclass deficiencies, in particular IgG_2 subclass deficiency, have been described in children with recurrent bronchitis.[92-94] Antibodies against polysaccharide antigens, the main determinants of encapsulated bacteria, are found mainly in the IgG_2 subclass. It has been reported that children with recurrent bronchitis and recurrent infections show a decreased humoral immune response to *Haemophilus influenzae* type b and to pneumococcal type 3 polysaccharide antigen.[95,96] The significance of selective IgA deficiency remains unknown.

PRIMARY ABNORMALITIES OF CILIA

Chronic airway disease may be produced by cilia defects. Cilia and their supporting structures contain several proteins. A great variety of genetic abnormalities can therefore lead to some form of ciliary dyskinesis. Abnormal mucociliary clearance results in chronic bronchitis and eventually in bronchiectasis as a late complication. In addition, the absence of ciliary clearance from the middle ears, eustachian tubes, and sinus cavities results in an increased incidence and greater severity of chronic otitis media and sinusitis.[97] A positive family history and situs inversus (Kartagener syndrome) may add to the diagnosis. Electron microscopy of cilia obtained from nasal or bronchial biopsy can detect structural abnormalities of the cilia. Functional abnormalities can be observed by examining the beating of cilia with a phase-contrast microscope in fresh specimens of mucosa.[98]

Phase II: Exogenous Factors Contributing to the Development of Chronic or Recurrent Bronchitis

Having ruled out the diagnoses previously discussed, it is important to identify other factors that may produce chronic or recurrent bronchitis. Moreover, these factors not only contribute to the development of bronchitis but may also maintain symptoms of bronchitis in other, better-defined conditions such as asthma. Exogenous factors such as increased exposure to infectious diseases in daycare centers, passive smoke, or air pollution may need other endogenous predisposing factors to produce bronchitis in certain affected children. Most of these factors are theoretically amenable to therapy by avoiding the exposure.

CHILD CARE SETTING

The frequency of infection in a particular child relates to his or her susceptibility regarding the degree of exposure to viral infections. The risk of developing lower respiratory tract infections has been reported to increase up to twofold or more for children between 4 months and 3 years of age who are in child care situations involving the presence of three or more unrelated children.[99] In the same study, the presence of siblings was also associated with risks of lower respiratory tract infections of a magnitude similar to the risks of exposure to unrelated children, but only in the first 6 months of life. Another case-control study has furthermore shown a similar risk for the development of lower respiratory tract infections requiring hospitalization in children younger than 2 years of age whose care situations involved the presence of more than six children.[100] These findings underline the importance of including epidemiologic aspects in the evaluation of a child with chronic or recurrent bronchitis. Also, they suggest that children with a known susceptibility to chronic airway disease such as chronic or recurrent bronchitis, asthma, bronchopulmonary dysplasia, or cystic fibrosis should avoid exposure to repeated respiratory infections in large daycare settings.

CIGARETTE SMOKE

Cigarette smoking has been identified as the major cause of obstructive lung disease among adults in the United States. In children and in young adults who have recently taken up smoking, increases in the prevalence of respiratory symptoms such as cough, phlegm production, and shortness of breath have been reported.[101,102] Among young teenagers, functional impairment attributable to smoking may be found after as little as 1 year of smoking 10 or more cigarettes a week.[103]

Passive smoke exposure may produce effects similar to those elicited by active smoking. However, several differences both between active and passive forms of exposure and among the individuals exposed need to be considered.

Approximately half of the smoke produced by a cigarette is sidestream smoke. Compared with the concentration of mainstream smoke inhaled, the concentration of smoke components inhaled by a passively exposed subject is small. However, the mean diameter of particles from sidestream smoke is smaller than that of mainstream smoke. Furthermore, the level of respirable particulate substance in an "average" indoor smoking environment is greater than the levels of total particulates considered safe in outdoor pollution monitoring.[104]

Individual susceptibility may be an important determinant of the possible adverse effects of passive smoke exposure on respiratory morbidity. Among adults a self-selection process occurs, whereby those more susceptible to the irritant effects of tobacco smoke either never start or quit smoking. Passively exposed infants and children may include a disproportionate number of subjects prone to developing chronic airway disease subsequent to exposure.

Several studies have noted that children exposed to environmental tobacco smoke are at considerably higher risk of having acute lower respiratory tract illnesses and chronic respiratory symptoms, such as cough, phlegm, and wheezing, than unexposed children.[105-110] The majority of studies found that the effect was stronger among children whose mothers smoked than among those whose fathers smoked.[105-109] In addition, several studies also reported a dose-response relationship between degree of exposure (number of cigarettes smoked) and the risk of acute and chronic respiratory illness.[109] These findings support the existence of a causal explanation for the association. There is also convincing evidence that the risk inversely correlates with age; infants no older than 3 months of age are reported to be 3.3 times more likely to have lower respiratory illnesses if their mothers smoke 20 or more cigarettes per day than infants of nonsmoking mothers.[109] A relative risk of 1.5 to 2.0 has been reported in older infants and young children. This decrease in risk may be attributed to a decrease in illness frequency, maturation of the respiratory tract and immune system, or decreased contact between mother and child with age.

Smoking caregivers in a child-care setting can add to the risk of developing lower respiratory tract infections regardless of maternal smoking status. An increased risk for wheezing lower respiratory tract infections of up to threefold or more has been demonstrated in young children who were in a child-care setting with a smoking caregiver after controlling for maternal smoking and other risk factors.[99] These findings illustrate the potential interaction of environmental factors in eliciting airway irritation and acute and chronic respiratory disease.

In the adolescent, active smoking becomes a significant problem. A study of Irish teens found that bronchitis symptoms were more common among active smokers than nonsmokers (odds ratio, 3.02, 95% confidence interval, 2.34 to 3.88; $p < 0.0001$) and in passive smokers than in nonexposed teens (odds ratio, 1.82, 95% confidence interval, 1.32 to 2.52; $p < 0.0001$).[111] Determinants of the initiation of smoking seem to be related to parental smoking, peer and sibling smoking, and personality. Every child and young adult with symptoms of chronic and recurrent bronchitis should be asked about personal smoking habits in a confidential setting; the clinician should realize that the history is of questionable validity if parents or siblings are present. The impact of passive smoke exposure on the development of the presenting symptoms can thus be assessed. In addition, preventing initiation of smoking in children at risk for chronic lung disease may be possible. The clinician should vigorously discourage any smoking in the child's environment.

AIR POLLUTION

Air pollution with high levels of sulfur dioxide and particulate matter has long been associated with respiratory morbidity in children and adults.[112-115] Studies of school children in England and Germany found increased rates of respiratory illness among children living in areas with high pollution levels, including sulfur dioxide and particulate matters.[113,116,117] Follow-up studies of these children 3 to 4 years later, after the introduction of clean-air programs, demonstrated major reductions in air concentrations of particulate matter and a decline in respiratory morbidity among the school children.[110,118] The American Six Cities Study reported a positive correlation of the prevalence of bronchitis and chronic cough with exposure to particulate matter in relatively small concentrations.[112] A twofold increased prevalence of recurrent bronchitis was furthermore demonstrated in an area with high air pollution from sulfur dioxide and particulate matter in East Germany compared with a less polluted region in West Germany.[119,120] Increased prevalence of respiratory symptoms has also been reported in children exposed to heavy automobile traffic.[121] The reasons for such an increase are unknown. Findings of an association among high concentrations of sulfur dioxide, particulate matter, and nitrogen dioxide with upper respiratory tract infections suggest that air pollutants may not only produce irritative symptoms but also enhance susceptibility to common infections and subsequent lower respiratory tract infections.[122]

In addition to outdoor pollutants, the indoor environment should be assessed for every child with symptoms of chronic and recurrent bronchitis. In particular, wood-burning stoves have been associated with acute respiratory illnesses.[123] Chronic airway irritation by noxious agents may furthermore be found with formaldehyde emissions from chipboards[124] and with activities such as house cleaning, artistic pursuits, and hobbies.

CHAPTER 11 Imaging of the Respiratory System

Eric Crotty and Alan S. Brody

TEACHING POINTS

- Multiple modalities are available for imaging the respiratory system.
- Spiral and high-resolution computed tomography have different applications.
- Controlled ventilation technique improves the quality of high-resolution computed tomography scanning.
- Use computed tomography for airways and lungs; consider magnetic resonance imaging for mediastinal masses and vascular structives.
- Nasal and paranasal structures are best imaged with computed tomography and magnetic resonance imaging.
- Complex pleural effusions are best evaluated with ultrasonography.
- Be conscious of the ALARA (As Low As Reasonably Achievable) principle.

Diagnostic imaging is an often-used discipline in the evaluation of the respiratory system in the pediatric population. It is a continuously changing area of medicine, highlighted by rapid developments of new imaging technology. However, the judicious use of this technology remains of the utmost importance, especially in the pediatric population in whom there is ongoing concern regarding the long-term effects of even low-dose radiation exposure.

This chapter discusses the various modalities available in modern imaging and their use in investigating disorders of the respiratory tract, with some advice on the appropriate use of diagnostic imaging.

PHYSICAL PRINCIPLES OF IMAGING MODALITIES

Radiography

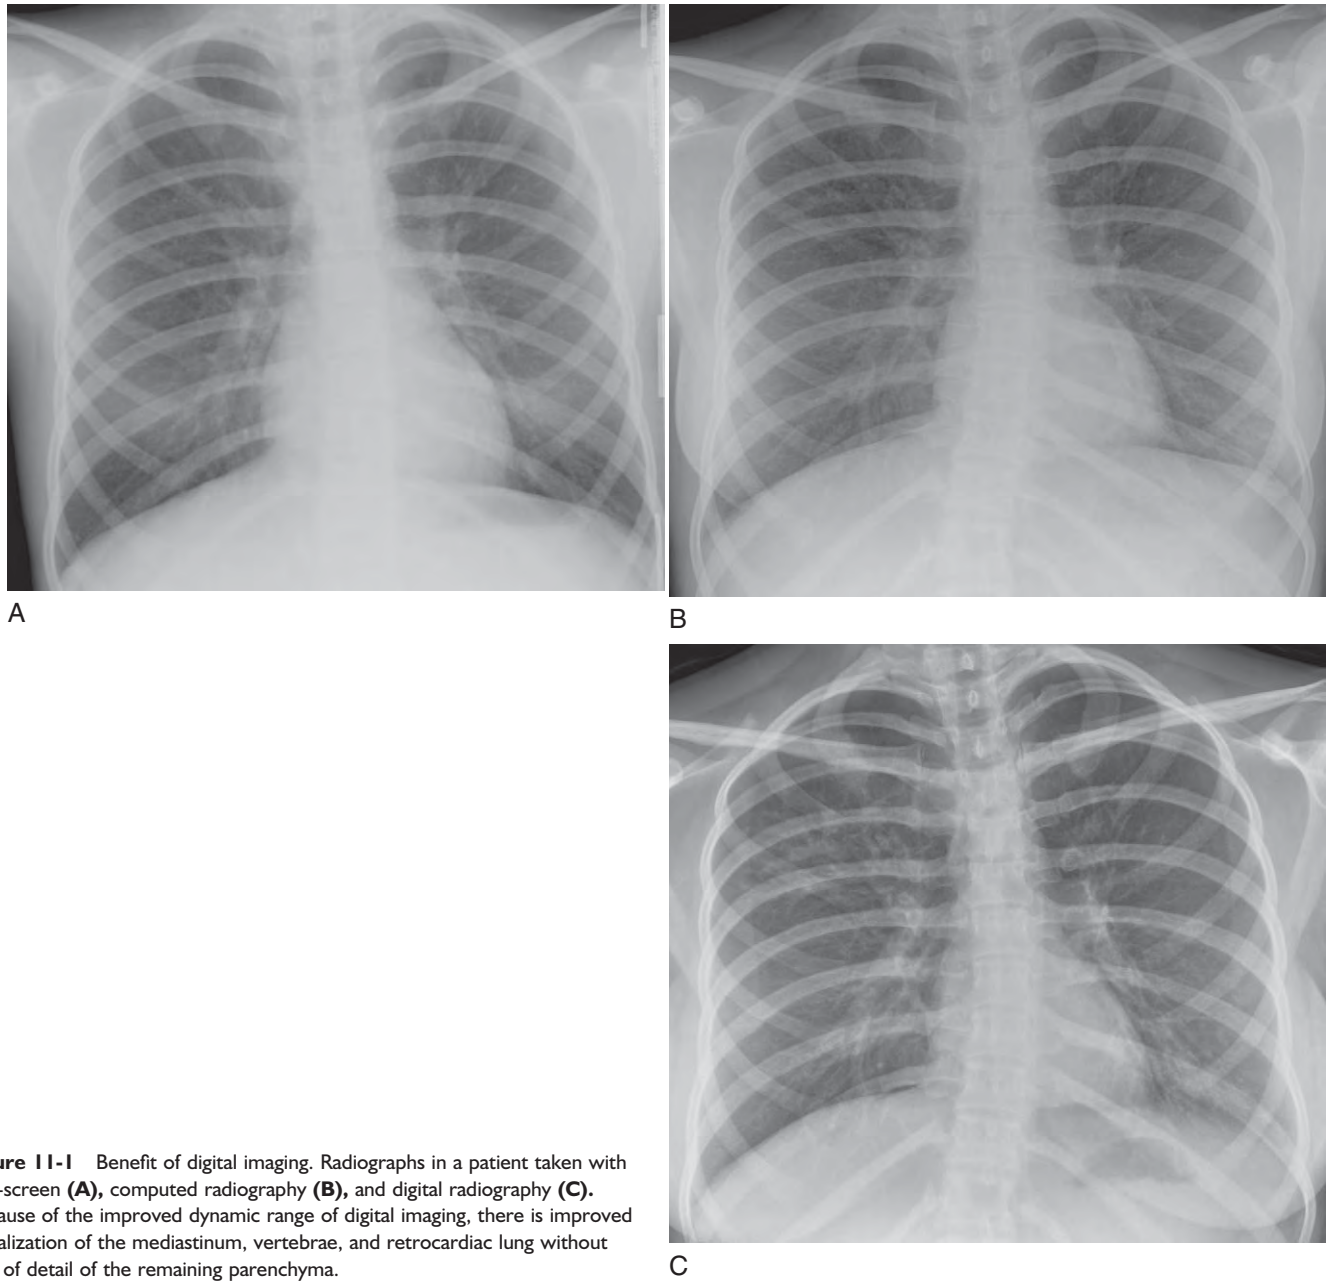
The most commonly used imaging modality is radiography, which utilizes x-rays, a form of electromagnetic radiation. A spectrum of x-rays of varying energies is produced when an electron beam emitted from a cathode strikes a target anode. The characteristics of this x-ray beam can be varied by altering the maximum voltage across the x-ray tube (kvP), the tube current in milliamperes (mA), and filtration. The characteristics of the beam are altered so that a sufficient number of x-ray photons traverse the body and interact with the film or detector such that an image is produced after processing. The photons in the beam that do not pass through the patient are generally deposited in the patient as absorbed radiation.

Current concern regarding the long-term effects of low-dose radiation exposure comes from extrapolation of data obtained from patients with a history of high-dose radiation exposure such as in atomic bomb survivors.[1] These effects include an increased risk of leukemia and other malignancies, and consequently every effort should be made to limit radiation exposure. This can be achieved if the ALARA (As Low As Reasonably Achievable) principle is implemented. The most effective method of achieving this reduction is to limit radiation exposure to those children who truly need the study and, if possible, performing imaging with modalities that do not use radiation. In addition, using low-dose techniques such as coning of the primary radiation beam, shielding of gonads, and using high-speed rare earth radiography systems will help in dose reduction in patients that do need to be exposed to radiation for diagnosis.[2,3] The introduction of digital (DR) and computed radiography (CR) has decreased the need for radiographs to be repeated, thus saving the patient from further exposure. CR and DR allow the image to be manipulated so that an adequate image is obtained rather than an image that is underexposed or overexposed (Fig. 11-1).

Both a frontal and a lateral radiograph are obtained in most patients, as additional information may be gleaned from a lateral radiograph that is not evident on the frontal radiograph alone[4] (Fig. 11-2). A frontal radiograph only is usually obtained in patients who are immobile, such as in intensive care. Occasionally, decubitus views are also obtained, usually to assess for air trapping (abnormal side down) (Fig. 11-3) or to evaluate for an effusion (abnormal side down) (Fig. 11-4).

Fluoroscopy

Fluoroscopy, which also uses x-rays, enables dynamic visualization by the radiologist of air- or contrast-filled structures and can be used to detect dynamic airway caliber changes, evidence of external compression on the trachea, and signs of air trapping from a foreign body. It is also used in esophagrams, video swallowing studies, and other positive contrast studies. This technique uses an image intensifier to convert the x-rays exiting from the patient into an image that can be viewed live and then can be recorded for review and storage. As with radiography, the use of digital fluoroscopy allows for postprocessing of the image without increasing the patient's exposure to radiation.



A

B

C

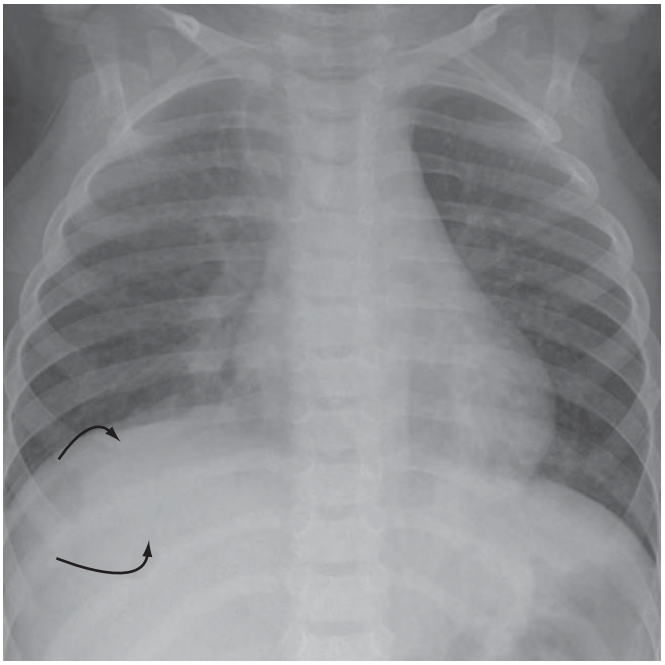
Figure 11-1 Benefit of digital imaging. Radiographs in a patient taken with film-screen **(A),** computed radiography **(B),** and digital radiography **(C).** Because of the improved dynamic range of digital imaging, there is improved visualization of the mediastinum, vertebrae, and retrocardiac lung without loss of detail of the remaining parenchyma.

Nuclear Medicine

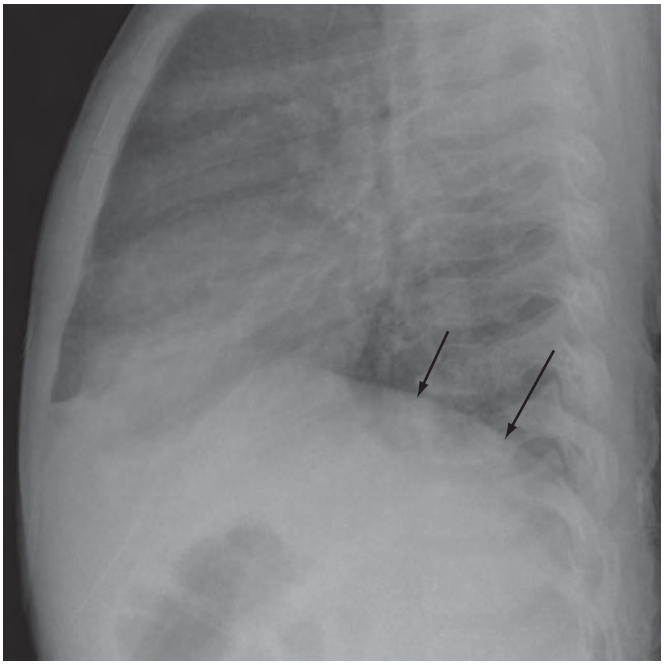
In radiography, fluoroscopy, and other forms of imaging that use x-rays, the radiation used to make the image originates from a source external to the patient. In nuclear medicine imaging, the radiation source is the patient who has been administered the radiation-emitting substance at the start of the examination. This material can be given via various routes such as intravenously, orally, or by inhalation and is administered in such a way that its uptake is primarily in the organ of interest. The emitted energy is detected by a scintillation camera, and an image is produced.

Technetium-99m attached to macroaggregates of albumin, which are large enough to lodge in the capillary network of the lungs, are injected intravenously for lung perfusion scans, while ventilation scans are performed during the inhalation of technetium-99m–labeled diethylenetriaminepentaacetic acid (DTPA) or other radiolabeled material that is distributed in the lungs during inhalation (Fig. 11-5). Nuclear imaging is also used to demonstrate gastroesophageal reflux by mixing technetium-99m sulfur colloid with liquid or semisolid material. Patients at risk for aspiration of saliva can be investigated by performing a nuclear salivagram using sulfur colloid.[5]

Positron emission tomography (PET) is increasing in use and importance in the investigation of tumors, especially lymphoma. The degree of uptake of the most commonly used radioisotope, fluorodeoxyglucose (FDG), is related to the degree of glucose utilization. Malignant tumors are generally more metabolically active than benign tumors, with metastases being as metabolically active as the primary tumor. Infections can also accumulate FDG.

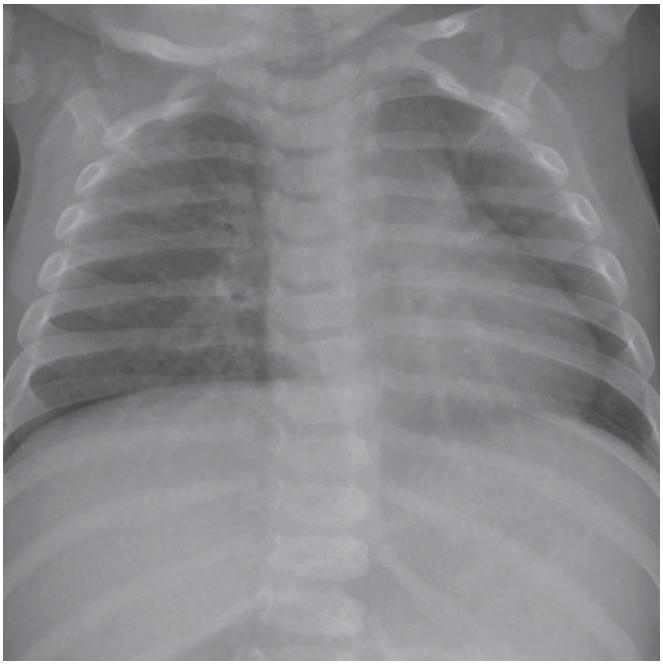


A



B

Figure 11-2 Usefulness of a lateral image: a 2-year-old boy with a cough and fever. The frontal radiograph **(A)** demonstrates a subtle increased density in the right lower lobe *(curved black arrows)*. However, on the lateral radiograph **(B),** the left hemidiaphragm is easily visible *(arrows)*, while the right hemidiaphragm is obscured by consolidated lung.



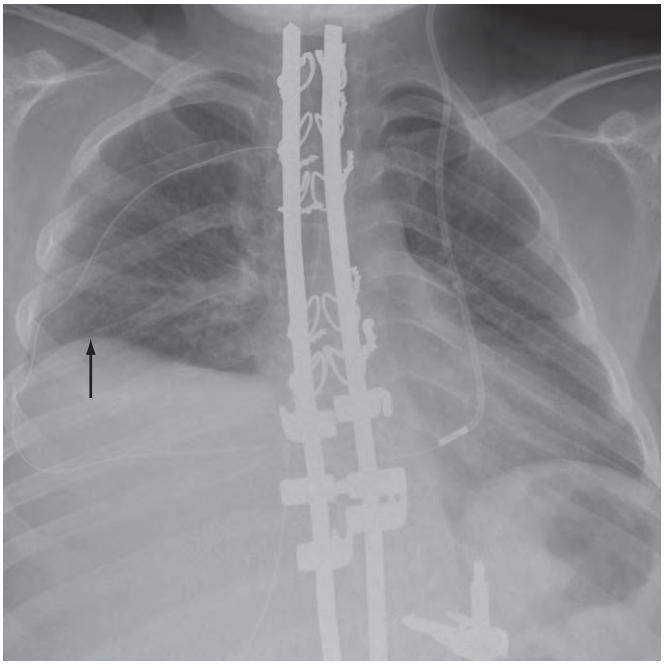
A

B

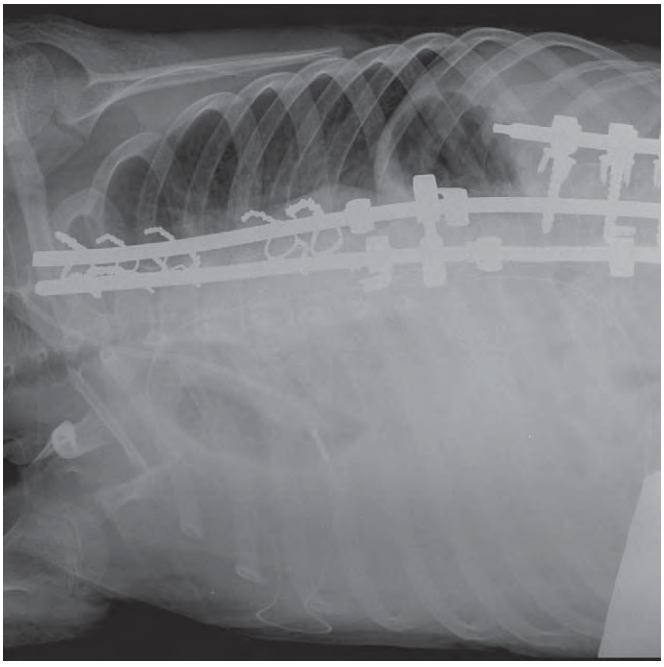
Figure 11-3 Usefulness of decubitus imaging: a 7-month-old girl with a cough. The frontal radiograph **(A)** demonstrates subtle increased lucency in the left lung. In the left lateral decubitus position **(B),** the left lung does not decrease in volume as expected. At bronchoscopy, a leaf was extracted from the left main bronchus.

Ultrasound

In ultrasound, high-energy sound waves are transmitted by a transducer into the area of interest. Tissues transmit and reflect these waves differently depending on their composition, and the reflected sound waves are recorded by the transducer, allowing for characterization of these tissues. As ultrasound does not use ionizing radiation, it is an imaging modality greatly favored for investigating pediatric patients. However, because air is a poor conductor of sound waves, ultrasound has limited use in the investigation of pulmonary disease as aerated lung generates an uninterpretable image. Hence, the use of ultrasound in imaging the chest is limited to the evaluation of nonaerated structures such as pleural fluid, the thymus, the diaphragm including diaphragmatic motion,[6] and soft tissue lesions of the chest wall (Fig. 11-6).



A



B

Figure 11-4 Usefulness of decubitus images: a 13-year-old boy status post spinal surgery. The frontal radiograph **(A)** demonstrates elevation and lateral displacement of the apex of the right hemidiaphragm *(arrow)*. Right lateral decubitus image **(B)** demonstrates layering of pleural fluid along the right chest wall, confirming the suspicion that the elevated diaphragm was due to a subpulmonic effusion.

Although the presence of a pleural effusion is usually already known from radiographs, the complexity of a parapneumonic pleural fluid collection (Fig. 11-7) and the need for intervention can be accurately assessed by ultrasound. Children with septations identified on ultrasound have been shown to benefit from intervention, whereas children with no septations do not.[7]

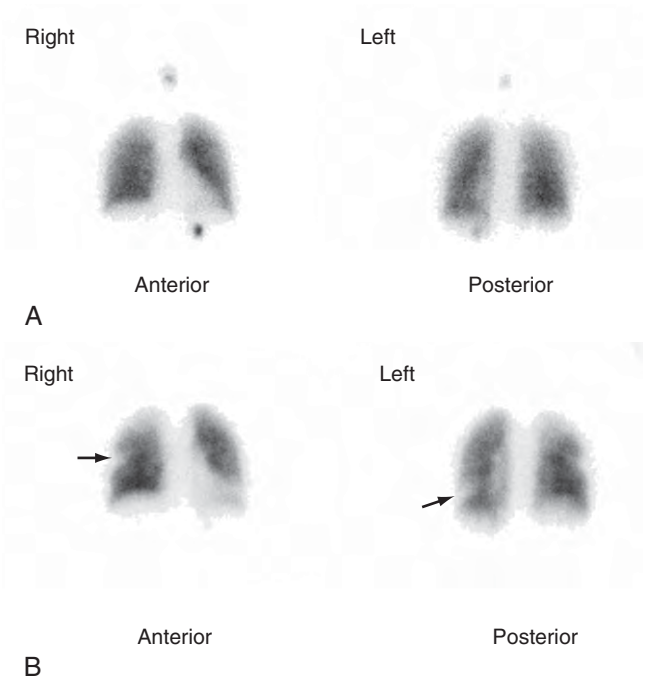


Figure 11-5 Nuclear medicine imaging: teenager with a history of a glioblastoma multiforme who presents with shortness of breath. Ventilation imaging **(A)** demonstrates even distribution of isotope throughout the lungs bilaterally. Perfusion imaging **(B)** demonstrates multiple perfusion defects *(arrows)* consistent with a high probability of pulmonary emboli.

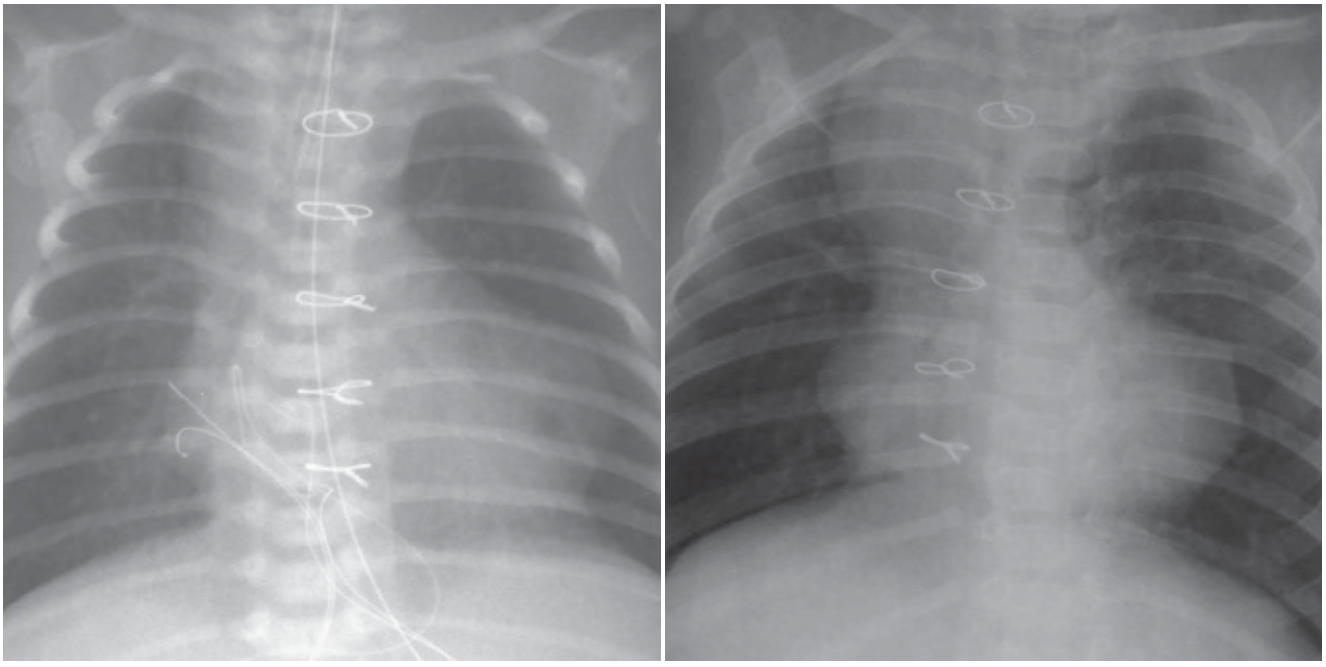
Ultrasound imaging of the fetus allows for the diagnosis of congenital lung lesions such as congenital diaphragmatic hernia, congenital cystic adenomatoid malformation, and pulmonary agenesis, allowing for anticipation of perinatal problems.

Many congenital lesions decrease in size during the third trimester, but the lesions do not completely resolve. Postnatal CT scans will demonstrate these lesions, while chest radiographs frequently will not.[8]

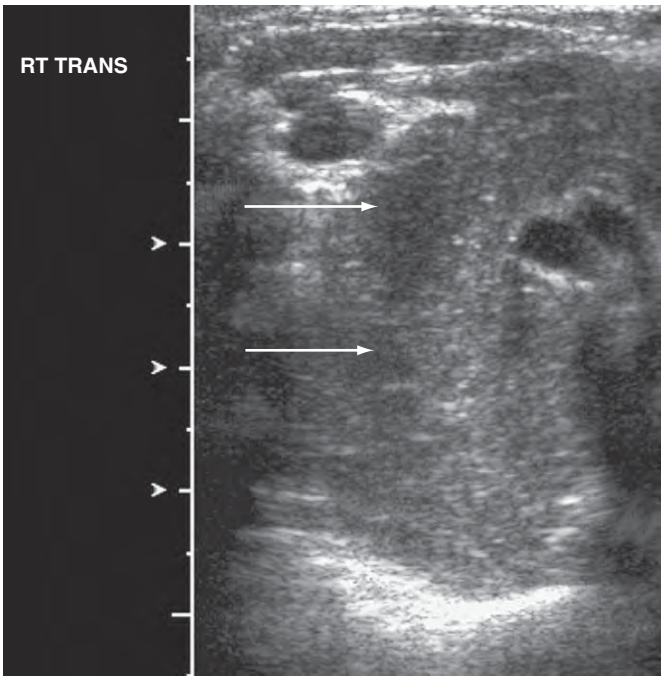
Color flow Doppler ultrasound imaging demonstrates the direction and relative velocity of flowing blood. This allows vascular structures to be accurately identified as arteries or veins and permits analysis of the vascularity of a mass. Again, because of the poor transmission of sound waves through aerated lung, color flow Doppler is useful only in evaluating chest wall or mediastinal lesions.

Computed Tomography

With CT, a group of detectors record x-rays that have been transmitted through a patient, having originated from an anode as it rotates around the body within the CT gantry. The images performed at each position during the rotation of the anode around the patient are combined during processing to form a cross-sectional image of the patient at that slice position, before the next slice position is imaged. Like radiography, the quantity of x-rays reaching the detector determines the various densities recorded; however, the range of densities that can be recorded is far greater, allowing far more accurate characterization of abnormal areas. Various algorithms are used to reconstruct the image depending on the structure that is of interest (lung, mediastinum, bone). The



A B



C

Figure 11-6 Utility of ultrasound imaging: infant status post surgery for congenital heart disease. Radiograph **(A)** prior to discharge demonstrates a normal mediastinum. Subsequent radiograph **(B)** 6 months later demonstrates a widened mediastinum. Ultrasound **(C)** demonstrates this to be due to rebound of normal thymic tissue *(arrows)*.

quality of CT imaging and the speed at which the imaging can be performed are continually being improved. CT scanners now use what is called spiral or helical technique, in which the patient is moved continuously through the CT scanner without stopping for each slice. In addition, a broad band of x-rays is received by a series of detectors in the longitudinal plane, producing multiple slices for each rotation of the gantry. The time taken to perform spiral CT of the chest is on the order of 2 to 5 seconds using a multidetector scanner, depending on the size of the patient. This speed allows the radiologist to obtain diagnostic quality images in uncooperative patients.

CT provides the best imaging of the anatomy of the lungs and tracheobronchial tree. Parenchymal detail, such as the secondary pulmonary lobule, can be visualized on high-resolution computed tomography (HRCT), which is used to sample the parenchyma in diffuse lung disease (Fig. 11-8).

In the spiral CT, imaging is performed contiguously from the apices of the lungs through the bases during inspiration. In traditional HRCT, there are a few important differences from spiral CT. First, imaging is performed not only during inspiration but also during expiration to assess for air trapping (Fig. 11-9). Second, very thin slices (approximately 1 mm) are taken with a gap between each slice. In inspiration, the

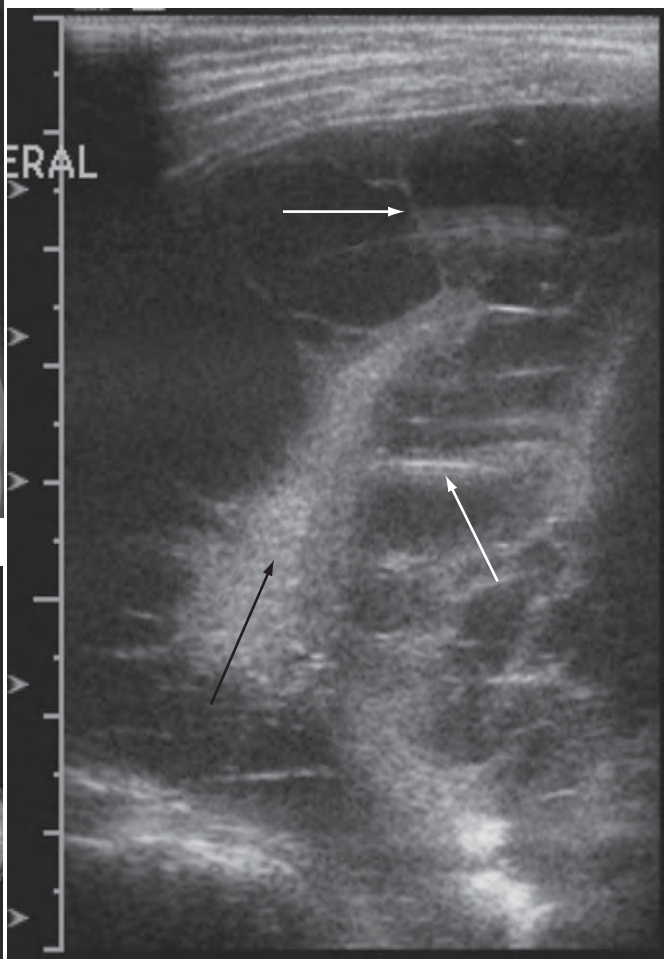
B



C

Figure 11-7 Utility of ultrasound: a 2-year-old boy with hypoxia and fever. Radiograph **(A)** demonstrates homogeneous opacification of the lower right chest. A CT scan **(B)** demonstrated a simple-appearing pleural effusion *(white arrows)* in the right hemithorax. Ultrasound examination **(C)** demonstrated the consolidated lung *(black arrow)* surrounded by fluid that contains many septations *(white arrows)*, indicating that this was a complex effusion.

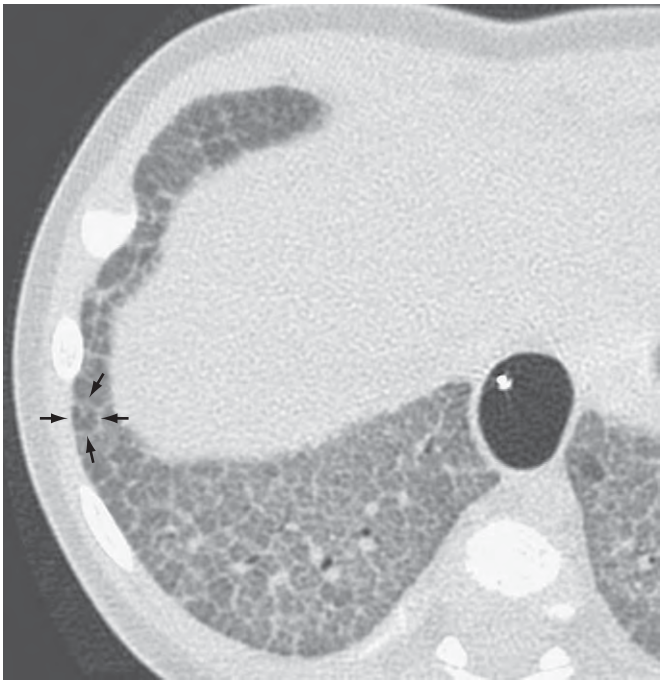


Figure 11-8 Detail seen with high-resolution computed tomography (HRCT): 3-month-old boy with chronic respiratory distress. HRCT image demonstrates interlobular septal thickening with diffuse ground-glass opacification. Note the visualization of secondary pulmonary lobules *(arrows)* in this patient with alveolar proteinosis.

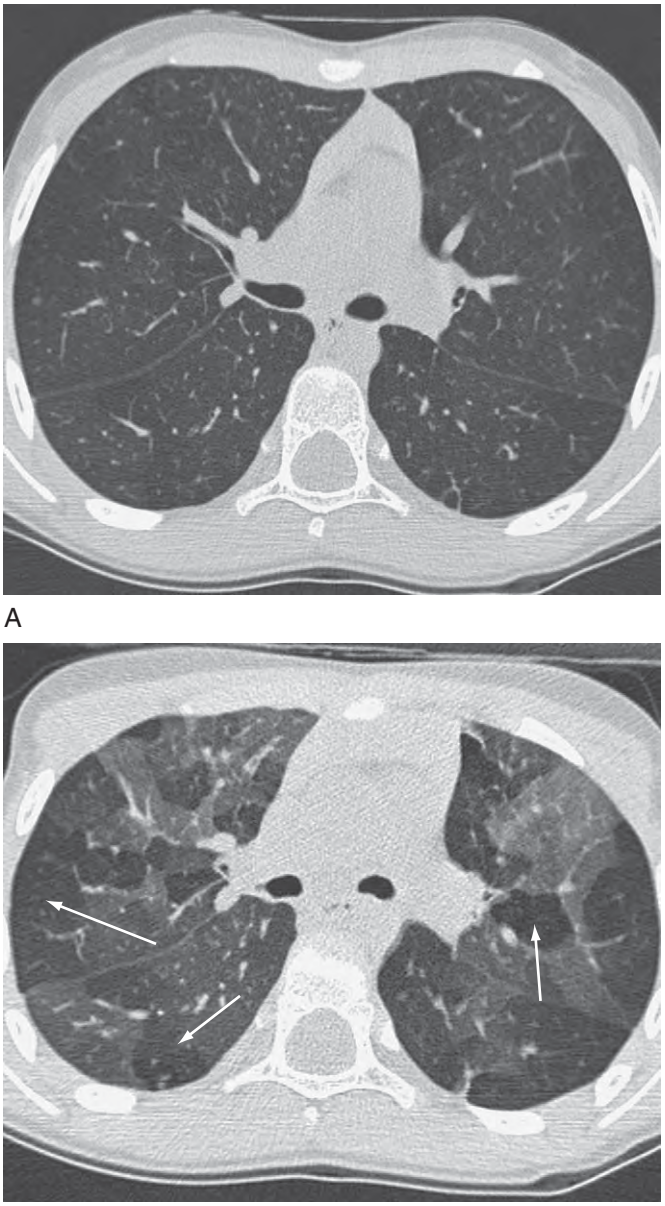

Figure 11-9 Utility of expiratory images in HRCT: 6-year-old girl with known cystic fibrosis. Image **A** was obtained during inspiration and is normal. Image **B** was obtained in expiration at the same level and demonstrates multiple regions of air trapping *(arrows)*.

gap is of the order of 10 mm, while the gap is larger, usually 20 mm, in expiration. These thin slices allow the clinician to look at fine detail, but as there is a gap between slices, some lung parenchyma is not imaged. Hence, although HRCT may help to further characterize a known diffuse parenchymal disease such as interstitial lung disease or to look for a diffuse disorder such as bronchiectasis, it is not recommended to search for small focal lesions such as metastases or small foci of atypical infection. Third, contrast is not administered in standard HRCT.

It is important that the patient does not move while CT images are being obtained in order to prevent degradation by motion artifact, and young or uncooperative children may need to be sedated. In general, children over 5 years of age can cooperate for a spiral CT scan. Children 6 to 8 years old can perform the necessary respiratory maneuvers for an inspiratory and expiratory HRCT scan.

If sedation is used to keep the patient motionless, respiratory motion alone may degrade images sufficiently to interfere with correct interpretation, especially during HRCT, when the aim of the study is to view fine structures. In addition, inspiratory and expiratory images cannot be obtained. In sedated children, respiratory artifact may be decreased and lung volume controlled using several methods. Decubitus imaging, performed by placing the patient on his or her side, provides an inspiratory image of the nondependent lung and an expiratory image of the dependent lung.[9] Motion can be eliminated and lung volume precisely controlled using a controlled ventilation technique that induces respiratory pauses with mask ventilation.[10] Finally, general anesthesia can be used.

The radiation risk from CT scanning has received a great deal of attention since 2001. Publications have suggested a risk of up to one fatal cancer for every 1000 CT scans.[11] While this level of risk can be disputed, the Biological Effects of Ionizing Radiation report in 2005 supported this level of risk and accepted the linear no-threshold model as most appropriate.[12] This model states that any radiation exposure carries some risk of causing cancer and that this risk is proportional to the amount of radiation. Authors have also pointed out that children are at greater risk than adults from the same amount of radiation.[11]

This concern must be balanced by the clear benefit provided by an indicated CT scan. There is wide agreement that this benefit is essentially always greater than the radiation risk. Several recommendations can be made to optimize this risk/benefit situation.

CT scanning should only be performed when necessary. When appropriate, other modalities that use less or no ionizing radiation should be performed rather than CT. The CT technique that affects the radiation dose should follow the ALARA principle. In children, this requires techniques that vary depending on the size of the patient.

Magnetic Resonance Imaging

Like ultrasound, magnetic resonance (MR) imaging does not use ionizing radiation to create an image. Instead, pulsed radiofrequency waves are sent into the patient, who is lying in a strong magnetic field. This causes hydrogen protons within the patient to realign parallel to each other, and as they relax and return to their resting state, they emit radiofrequencies that are collected and processed to form an image. MR imaging has the ability to image in any plane with excellent tissue contrast. Because of the relative paucity of protons in the lungs and the interference caused by the inhomogeneity of air and soft tissue in aerated lung, MR image quality is limited within the lung parenchyma. Another disadvantage of MR imaging relative to CT is the need for patients to remain motionless for a long time, increasing the need for sedation (Table 11-1). However, because of the excellent ability of MR imaging to characterize various tissues, the multiplanar imaging capability, and the lack of ionizing radiation, MR imaging is the method of choice for investigating mediastinal and chest wall masses and congenital aortic anomalies[13] (Fig. 11-10).

Table 11-1
Computed Tomography versus Magnetic Resonance Imaging

	Pros	Cons
Computed tomography	Rapid Decreased need for sedation versus magnetic resonance imaging Readily available Evaluates lung parenchyma Sensitive to focal calcifications	Sedation often necessary Relatively high radiation dose Iodinated contrast load worsens renal insufficiency Hypersensitivity reactions to contrast not uncommon
Magnetic resonance imaging	No radiation No need for iodinated contrast Excellent for detection of mediastinum and chest wall abnormalities	Longer imaging times Increased need for sedation versus computed tomography More difficult to perform Less readily available Relatively expensive Does not evaluate lung parenchyma Not sensitive to focal calcifications

Radiograph **(A)** demonstrates a large left chest wall mass *(curved black arrow)* deviating the heart to the right side *(black arrow)*. On an axial T2-weighted sequence **(B),** the excellent spatial resolution of MR imaging allows differentiation of the mass *(black arrows)* from the thymus *(curved black arrow)*, the trachea *(curved white arrow)*, and the aortic arch *(white arrow)*.

Angiography and Interventional Radiology

Angiography is an invasive technique traditionally used to investigate vascular lesions of the chest, such as pulmonary arteriovenous malformations or fistulas, pulmonary sequestration, pulmonary embolism, and hemoptysis secondary to cystic fibrosis or bronchiectasis (Fig. 11-11). In an angiographic procedure, fluoroscopy with the ability to capture multiple frames per second is used. These cine runs are performed in multiple projections in order that a three-dimensional appreciation of the lesion is obtained. Because this exposes the patient to a relatively large dose of radiation, and because of the invasive nature of the procedure, current imagers favor investigating vascular lesions using the excellent anatomical imaging and reformation capabilities of CT or MR imaging. Increasingly, however, treatment of these vascular lesions can be safely carried out by intravascular interventional techniques, such as embolization under fluoroscopic guidance, which are less invasive and have less morbidity than traditional surgical techniques.[14]

Interventional radiology, using ultrasound and fluoroscopic guidance, can help in the drainage of complex or loculated pleural effusions that otherwise may need surgical intervention.[15] Interventional radiology can also be of assistance in performing percutaneous biopsy or drainage of chest wall, lung parenchymal, and mediastinal masses or abscesses.[16]

ANATOMIC EVALUATION OF THE UPPER RESPIRATORY TRACT

Nasal Airway

Due to the complex anatomy of the nasal airway, plain film imaging is limited in its ability to detect abnormalities, and CT and MR imaging are both better choices. The most common congenital abnormality of the nasal cavity is choanal atresia. If clinically suspected, CT is the procedure of choice due to its ability to identify whether the abnormality is due to a bony, membranous, or mixed atresia, and it will also identify the thickness of a bony plate and whether the abnormality is unilateral, bilateral, complete, or incomplete[17] (Fig. 11-12). Other congenital nasal masses, such as dermoids, nasal gliomas, and nasal meningoceles or encephaloceles, are best investigated with MR imaging because it will better

Figure 11-11 Angiography: 19-year-old woman with a history of cystic fibrosis and complicated by a history of recurrent hemoptysis. identify the extent of a soft-tissue mass and the nature of a cranial bony defect before surgical treatment. Care needs to be exercised when performing sedation for imaging neonates with nasal obstruction, as they are obligatory nasal breathers.

Box 11-1 Causes of Nasal and Paranasal Sinus Opacification

- Sinonasal polyp
- Mucocele
- Mucus retention cyst
- Antrochoanal polyp
- Sinusitis
- Juvenile nasopharyngeal angiofibroma
- Rhabdomyosarcoma

Paranasal Sinuses

Plain film imaging of the paranasal sinuses includes occipitofrontal (Caldwell), occipitomental (Water), and lateral views, each optimum for examining different sinuses. The maxillary sinuses or antra and the ethmoid air cells are present at birth. The maxillary antra are visible on radiographs from approximately 2 to 3 months of age, with the ethmoid air cell being visible between 3 and 6 months of age. The sphenoid sinuses become aerated between 7 months and 2 years of age with the frontal sinuses beginning to aerate between 6 and 12 years. The paranasal sinuses enlarge and undergo progressive pneumatization as the child ages, and generally reach adult sizes at 10 to 14 years. The maxillary antra, ethmoid air cells, and frontal sinuses are frequently involved by inflammatory disease with the sphenoid sinuses less frequently involved.

Inflammatory Sinus Disease

Mucosal thickening and opacification of the paranasal sinuses on plain films are very common in asymptomatic children (Box 11-1). Hence, commencement of therapy based solely on the presence of sinus opacification is unwarranted. The only sensitive plain film sign of acute infection is an air-fluid level (Fig. 11-13). The presence of diffuse opacification or mucosal thickening alone does not correlate with infection and may be seen with many conditions including allergic rhinitis, cystic fibrosis and asthma (Fig. 11-14). Artifactual opacification caused by rotation and normal variant underpneumatization are also commonly seen.

The role of advanced cross-sectional imaging like CT and MR imaging is to demonstrate the anatomy of the sinuses including the osteomeatal unit when surgery is being contemplated, and also to examine for suspected complications such as subperiosteal orbital abscess (Fig. 11-15) and periorbital cellulitis, as well as intracranial complications such as abscess formation, meningitis, and venous sinus thrombosis.[18]

Trauma

The bones of the nasosinus complex are among the thinnest in the body, and this makes them liable to fracture, but it also makes it difficult to detect fractures of these bones on plain film. Hence, CT has replaced plain film as the imaging method of choice for detection of fractures but should only be used when detection of a fracture will lead to alteration of

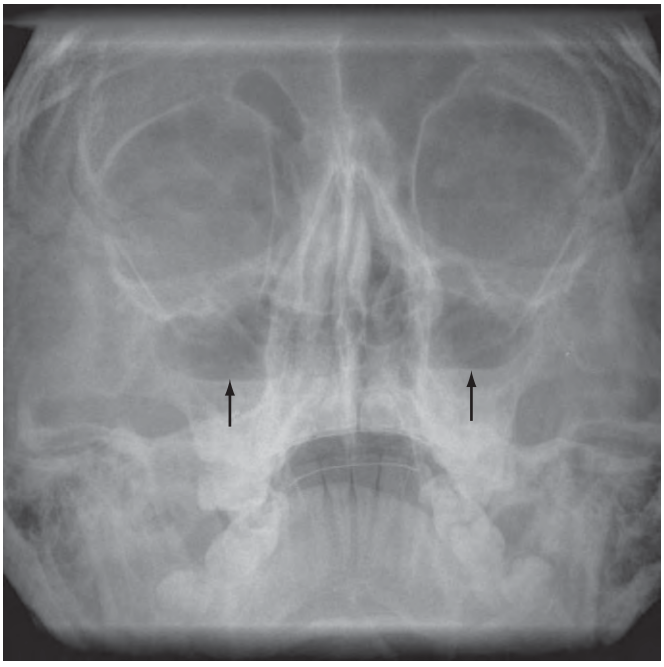

Figure 11-13 Acute sinusitis: 12-year-old boy with facial pain and congestion. Water view of the paranasal sinuses demonstrates an air-fluid level in the bilateral maxillary antra *(arrows)*, consistent with acute sinusitis.

management, such as a depressed fracture of the orbital floor with entrapment of the inferior rectus muscle and resultant diplopia[19] (Fig. 11-16).

Masses

Because tumors of the nose and paranasal sinuses are uncommon in children, they often go undetected early on as they can present with common complaints such as nasal congestion. One such tumor is a rhabdomyosarcoma, which is the most common soft tissue tumor of the head and neck region in children. Juvenile nasopharyngeal angiofibroma (JNA) is the most common benign nasopharyngeal tumor of childhood, occurring primarily in male adolescents. As well as presenting with nasal congestion, a JNA should be suspected in someone presenting with catastrophic or recurrent nosebleeds. In cases of both rhabdomyosarcoma and JNA, plain film imaging is usually nonspecific with evidence of sinus opacification (see Box 11-1). Imaging of these tumors with CT and MR imaging is needed to demonstrate the extent of the mass. In cases of rhabdomyosarcoma, imaging may also identify lymph node metastases, whereas in JNA, cross-sectional imaging will demonstrate the characteristic vascularity of this tumor and may identify large feeding arteries (Fig. 11-17). Embolization of these feeding vessels is often carried out by interventional radiology in order to decrease the size of the mass before definitive surgery or to stop an ongoing bleed.[20]

IMAGING OF THE EXTRAPULMONARY AIRWAY: PHARYNX TO THE CARINA

Upper airway symptoms of cough, stridor, wheezing, and hoarseness are common in the pediatric population. Concern for a foreign body aspiration is also a common presenting complaint. Correspondingly, imaging of the upper airway is frequently performed in pediatric radiology departments.

If radiographic investigation is needed, frontal and lateral radiographs usually suffice. These are obtained with a high-kilovoltage technique, are magnified, and have added filtration. The lateral film is taken with the neck extended during maximum inspiration so that the redundant retropharyngeal soft tissues are not falsely thickened. Failure to use this

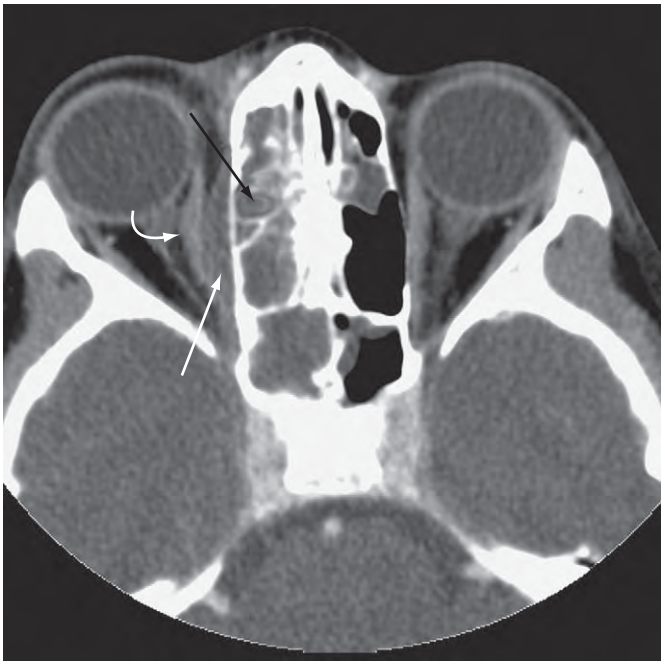

Figure 11-15 Complication of infective sinusitis: 9-year-old girl with sinusitis and periorbital swelling. Axial CT image demonstrates opacification of the ethmoid air cells *(black arrow)* with spread of infection into the adjacent right orbit *(white arrow)*, displacing the medial rectus muscle medially *(curved white arrow)*.

Figure 11-16 Sinus trauma: 14-year-old boy who was kicked in the face and was complaining of diplopia. Coronal reformatted CT image demonstrates fat *(white arrow)* and inferior rectus muscle *(black arrow)* trapped in the left orbit below a fracture of the orbital floor. This will prevent the inferior rectus muscle from contracting normally, resulting in diplopia. Note the normally positioned right inferior rectus muscle *(curved white arrow)*.

Figure 11-17 Juvenile nasopharyngeal angiofibroma: 13-year-old boy with a history of persistent nasal congestion. Axial T1-weighed precontrast **(A)** and coronal T1-weighed postcontrast **(B)** MR images following contrast administration demonstrate a lobulated mass in the left infratemporal fossa and nasal cavity *(white arrows)*. The intense enhancement on the postcontrast images is due to the vascular nature of the tumor. Note the fluid-filled obstructed left maxillary antrum *(curved white arrow)*.

Box 11-2 Causes of an Enlarged Retropharyngeal Space

- Cellulitis
- Phlegmon or abscess
- Lymphadenopathy
- Tumor (e.g., neuroblastoma, hemangioma)
- Localized trauma such as with foreign body aspiration
- Artifactual from poor radiographic technique

technique can result in thickening of the retropharyngeal/prevertebral soft tissues (Box 11-2).

If adequate radiographic imaging cannot be obtained, then fluoroscopy can be used to determine whether the thickening of the retropharyngeal soft tissues is real. With the patient in the lateral position, the pharyngeal tissues will be seen to thin during inspiration if the thickening is a pseudo-mass but will remain thickened if there is pathology in this region (Fig. 11-18). If the retropharyngeal thickening is real and the symptoms are acute, then CT may be performed to evaluate for a drainable abscess[21] (Fig. 11-19).

Epiglottitis is rarely seen in the United States due to the widespread use of the *Haemophilus influenzae* type b vaccine, but it still is encountered in children who did not receive a vaccine, in people who were vaccinated but have a deficient immune system, and in patients with epiglottitis from other infections such as *Streptococcus pneumoniae* and *Staphylococcus aureus* or inflammatory conditions such as thermal burns (Fig. 11-20). When epiglottitis is clinically suspected but a radiograph is needed, care should be taken to have someone trained in airway management and intubation with the patient while the study is being performed. Imaging should be obtained with the patient upright, as positioning the patient supine may cause respiratory distress and apnea. Findings include thickening of the epiglottis, aryepiglottic folds, or both.

The subglottic airway is a common site of pathology in younger children. On an anteroposterior radiograph, the normal subglottic airway has a symmetrical squared-off appearance often referred to as "shouldering" (Fig. 11-21). Signs of pathology of the subglottic airway include loss of normal shouldering and symmetrical narrowing or an asymmetrical indentation on the subglottic air column. Inflammatory or diffuse abnormalities such as laryngotracheal bronchitis (viral croup) result in loss of the normal shouldering and the airway assumes the appearance of a steeple (Fig. 11-22). Focal lesions such as a subglottic hemangioma will result in a focal asymmetrical indentation (Box 11-3).

As a result of the introduction of the *H. influenzae* type b vaccine and a reduction in the incidence of epiglottitis, the most common cause of life-threatening upper airway disease in children in the United States is bacterial tracheitis.[22] In this condition, lateral radiograph findings may resemoble these of croup or may have associated mucosal irregularity and thin projections of material into the tracheal lumen (Fig. 11-23).

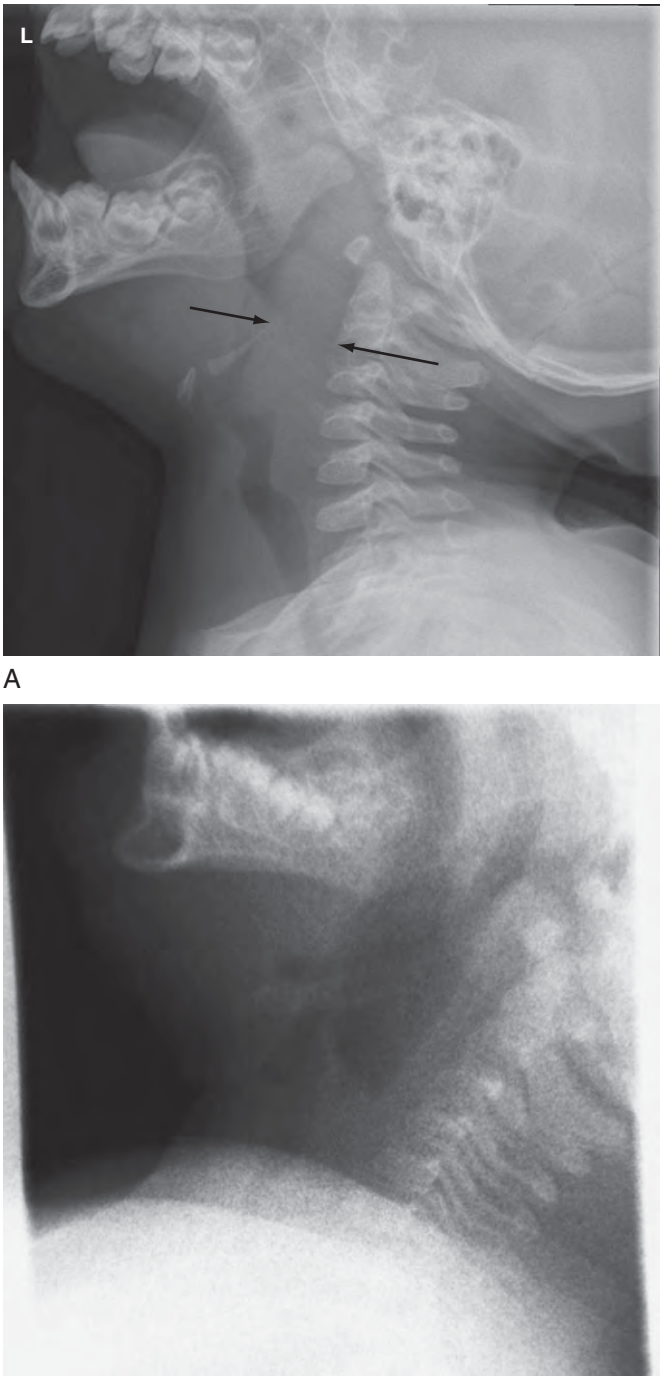

Figure 11-18 Evaluation of prevertebral soft tissues using fluoroscopy: 11-month-old boy presenting with stridor. Lateral radiograph of the airway **(A)** demonstrates apparent thickening of the prevertebral soft tissues *(arrows)*. On the lateral image obtained in inspiration during fluoroscopic evaluation **(B),** the prevertebral soft tissues are seen to be normal in thickness.

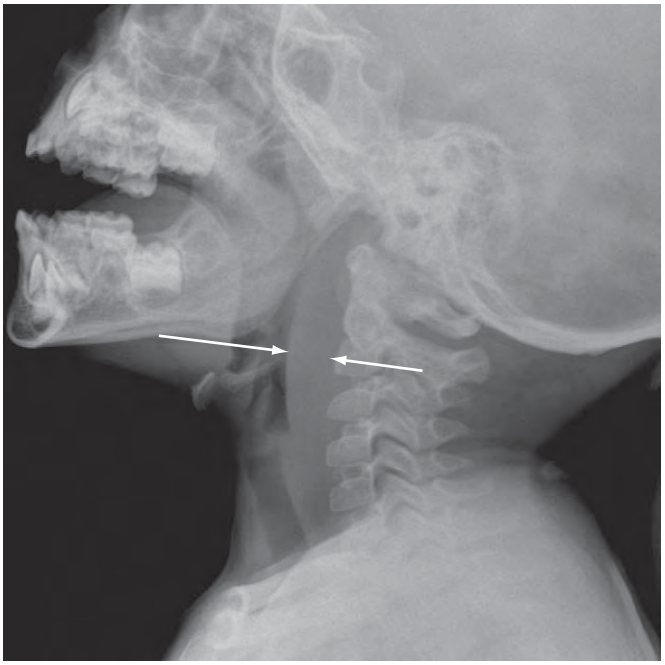
The trachea below the subglottic region has parallel walls as it descends to the carina. As it approaches the carina, it normally veers slightly to the right as it passes the aortic arch. In young infants, it is normal to have buckling of the cervical portion of the trachea to the right. If the intrathoracic trachea remains midline or deviates to the left, then a congenital vascular lesion such as a right-sided aortic arch or a double



A

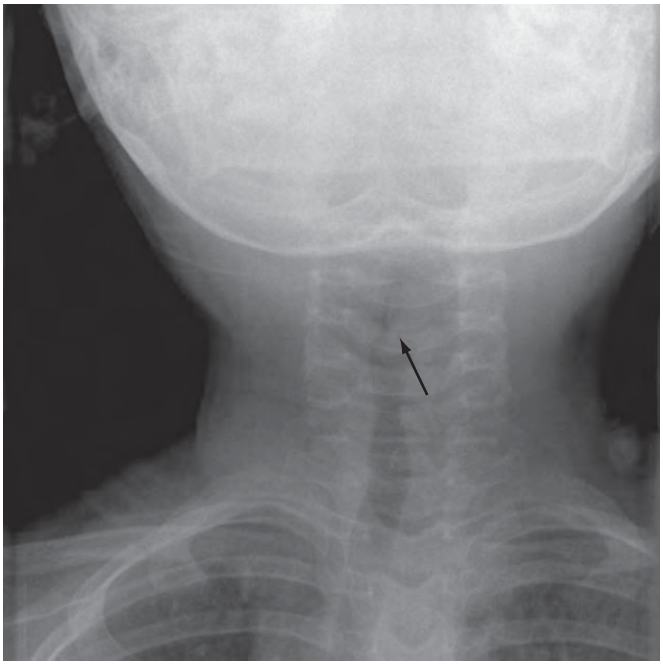
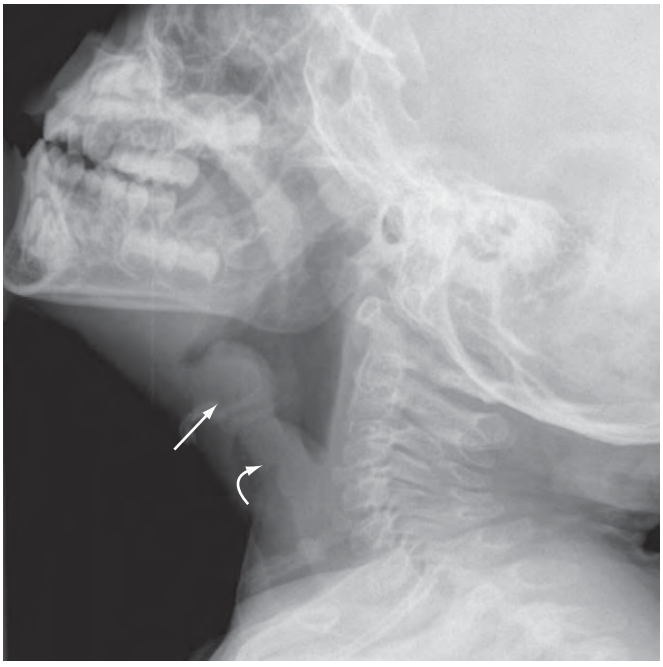
Figure 11-19 Retropharyngeal abscess: 3-year-old boy with fever and a stiff neck. Lateral radiograph **(A)** demonstrates thickening of the prevertebral soft tissues *(white arrows)*. On a contrast-enhanced CT image **(B),** there is a rim-enhancing well-circumscribed low-attenuation lesion in the left retropharyngeal space *(black arrows)* consistent with an abscess.



A

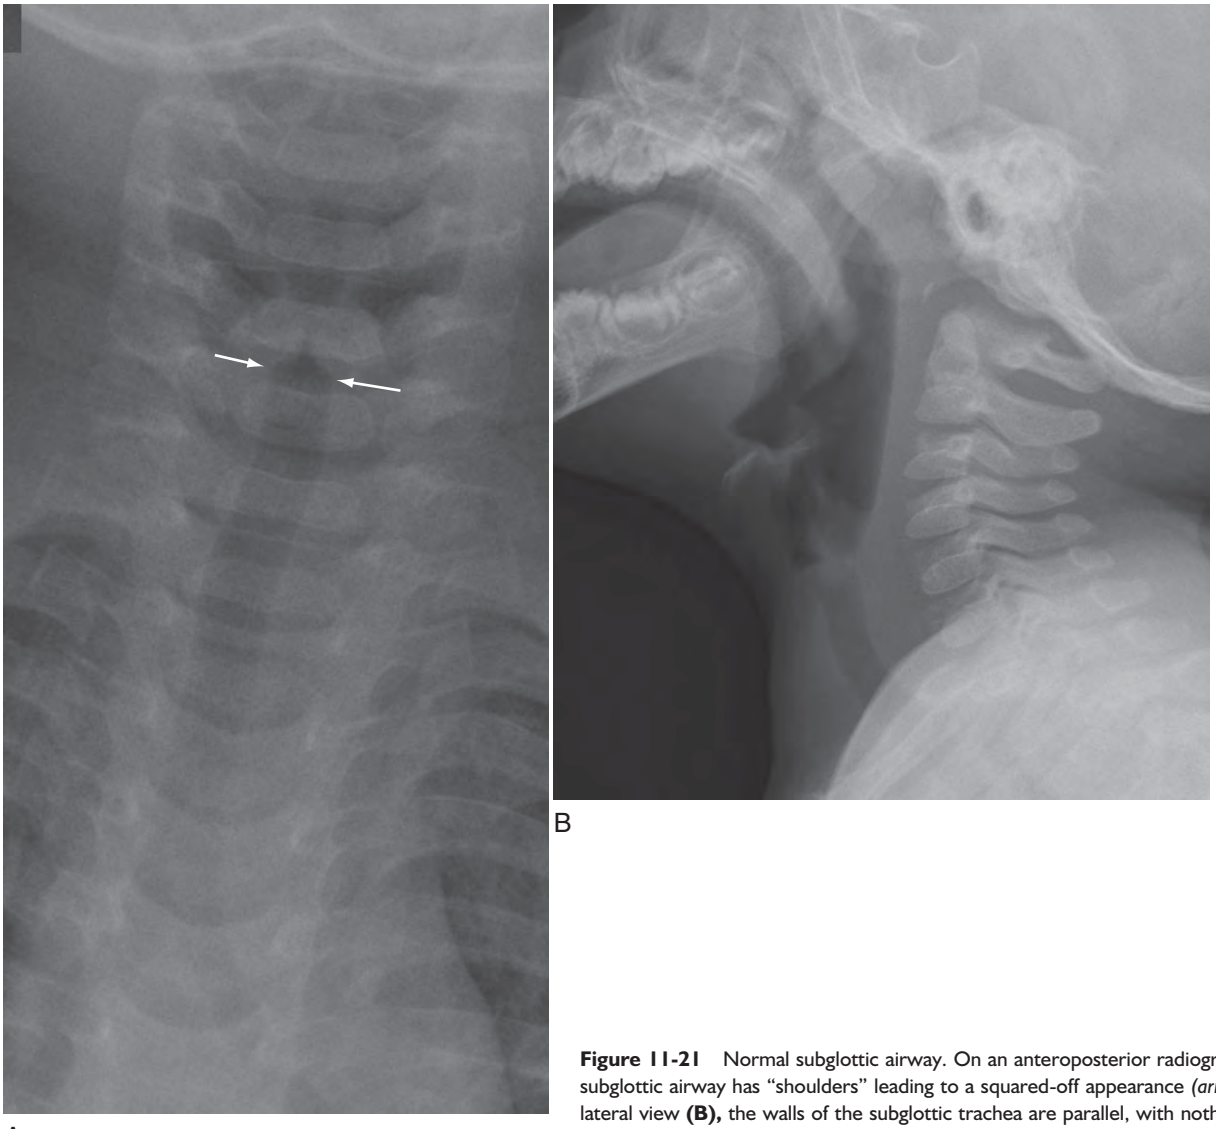


B

Figure 11-20 Epiglottitis: 2-year-old girl with respiratory distress and stridor. Anteroposterior radiograph **(A)** demonstrates an indentation on the left side of the subglottic airway *(black arrow)* with resultant asymmetrical narrowing of the subglottic airway. On the lateral radiograph **(B),** there is thickening of the aryepiglottic folds *(curved white arrow)* and epiglottis *(white arrow)*, resulting in a thumb-like configuration.

aortic arch is suspected, especially if the lateral view shows an indentation on the posterior trachea.

Cross-sectional imaging of the airway with CT and MR imaging is helpful when there is a concern for extrinsic compression of the airway.[23] Both modalities will identify the abnormal vessel, but CT is better at demonstrating the effect of the vessel on the trachea. Virtual endoscopy using CT has found favor in some centers because it nicely demonstrates the endotracheal and endobronchial lumens. However, as these patients will also receive a bronchoscopy, we believe that the extra radiation the patient receives from the CT is rarely justified in the pediatric population.



A B

Figure 11-21 Normal subglottic airway. On an anteroposterior radiograph **(A),** the subglottic airway has "shoulders" leading to a squared-off appearance *(arrows)*. On a lateral view **(B),** the walls of the subglottic trachea are parallel, with nothing projecting from the mucosa into the lumen.

- Tracheitis (symmetrical or asymmetrical)
- Hemangioma (symmetrical or asymmetrical)

CHEST

Plain Film

The chest radiograph is one of the most common radiographic studies performed in the pediatric population and can be one of the more difficult studies to interpret. Because it is a cornerstone in the investigation of pulmonary diseases, it is important that pulmunologists become comfortable with interpreting chest radiographs. Not only should they be comfortable with recognizing abnormalities, but they also need to appreciate when a study is technically suboptimum, as this can make correct interpretation more difficult. In addition, they need to be able to recognize the different appearances of the normal chest radiograph as a child ages. In this section, we initially describe ways to evaluate a radiograph for adequate technique and describe some of the common normal variants before describing a system for evaluating a chest radiograph.

Technique

Due to the challenge of keeping an uncooperative child still, one of the most common technical abnormalities on a chest radiographs is rotation, which may mask an abnormality or produce the appearance of a lesion that is not present. On a correctly centered chest radiograph, the anterior ends of corresponding ribs are equidistant to the ipsilateral pedicle of the vertebra at that level. In addition, the medial ends of the clavicles should be equidistant to the spinous process of the vertebra at that level. Movement of an uncooperative child will also result in blurring of the radiograph.

A radiograph obtained with inadequate inspiration will result in symmetrical increased density in the lungs, and will spuriously enlarge the cardiomediastinal silhouette (Fig. 11-24). With adequate inspiration, the anterior ends of 6 ribs should be seen above the dome of the diaphragm.

As children come in all shapes and sizes, obtaining an optimally exposed radiograph can be a challenge. On appropriately exposed radiograph, the pedicles of the vertebral bodies should be visible through the cardiac silhouette and the pulmonary vessels in the middle third of the lungs should be visible.

Normal Variants

As the child grows, there are changes in the normal appearance of the chest radiograph. It is important to be able to recognize these normal variations in appearance, as this will help prevent anxiety and reduce the number of resultant unnecessary and potentially harmful investigations.

The neonatal chest is relatively box shaped, and as the child grows, it becomes more elongated in the craniocaudal plane. Not only does the shape of the thoracic cavity change, but the appearance of the intrathoracic structures also

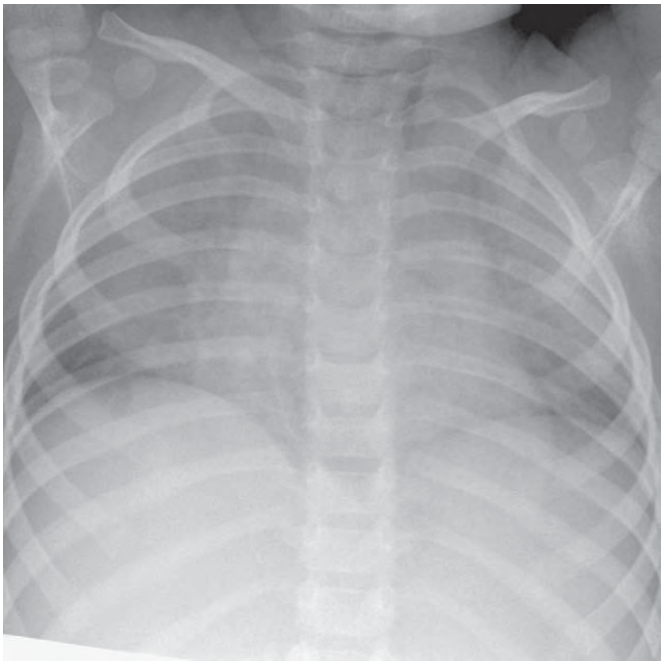
Figure 11-23 Bacterial tracheitis: 7-year-old boy with stridor. Anteroposterior view **(A)** demonstrates symmetrical narrowing of the subglottic airway. Lateral view **(B)** shows a more focal area of narrowing in the subglottic airway with projections *(arrows)* from the mucosa into the tracheal lumen. These projections or webs are not always visible in bacterial tracheitis and can also be seen with adhered mucus.



A

B

Figure 11-24 Effect of poor inspiration. Anteroposterior radiograph **(A)** looks abnormal with diffuse increased haziness throughout both lungs and borderline cardiomegaly. The anterior ends of three ribs can be seen above the diaphragm. A repeat radiograph **(B)** performed immediately following **(A)** during inspiration demonstrates a normal heart size and clear lungs. Five ribs can be seen above the diaphragm.

changes. The most striking changes occur in the normal thymus, and this can be a source of confusion. In the infant, the thymus is at its largest relative to the chest cavity. As the child grows, so does the thymus, albeit at a slower rate, and reaches its maximal size at puberty and then begins to involute through adolescence. In infancy, the thymus has a quadrilateral shape that is often asymmetrical and may make it appear like a mediastinal mass or upper lobe pneumonia on radiographs. Often, it is difficult to separate the thymus from the heart contour, giving the appearance of an enlarged heart. However, close inspection often reveals a small notch between the left lobe of the thymus and the left heart border. In addition, the soft constituency of the thymus allows the right lobe to extend into the horizontal fissure, leading to a characteristic sail-like configuration. Because of the pliability of the gland, it may become molded by the ribcage and adopt a wave-like contour that may be exaggerated on obliqued radiographs (Fig. 11-25). As childhood progresses, the thymic contour becomes narrower as it assumes a triangular configuration and generally is no longer visible on radiographs at age 5 years, although rarely it remains visible until puberty. The thymus may decrease in size during times of stress or chemotherapy for malignancy and may increase in size when the stress has been removed or after chemotherapy has been completed.

A not uncommon mimic of a pneumothorax is normal skinfolds. Unfortunately, this is especially true in supine radiographs such as those obtained in intensive care units, where pneumothoraces secondary to positive pressure ventilation are more common. Usually, they can be differentiated because skinfolds often can be followed beyond the chest wall and do not run parallel to the rib cage. Also, lung vascular markings may be seen beyond a skinfold (Fig. 11-26). If in doubt, a repeat radiograph or a decubitus radiograph may be performed for confirmation.

On supine anteroposterior radiographs, the heart often appears enlarged, especially if the image is not obtained during deep inspiration. In infants, this is confounded by the presence of the relatively large thymus, as discussed earlier. A lateral radiograph is usually sufficient to confirm the normal heart size.

Analyzing a Radiograph

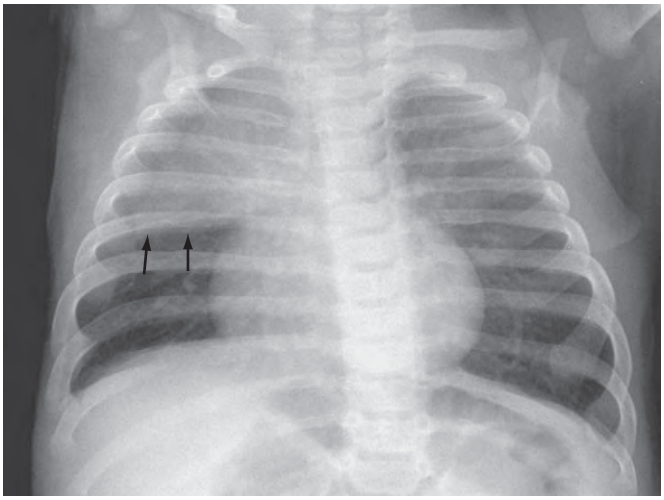
Using a systematic approach for analyzing a chest radiograph is very important as it helps prevent missing a subtle but important abnormality once a trivial but more obvious abnormality has been identified. The order in which you evaluate a radiograph is not as important as having a system that ensures that you examine each region. The ABCs approach is one method that is easy to remember, as follows.

ABDOMEN

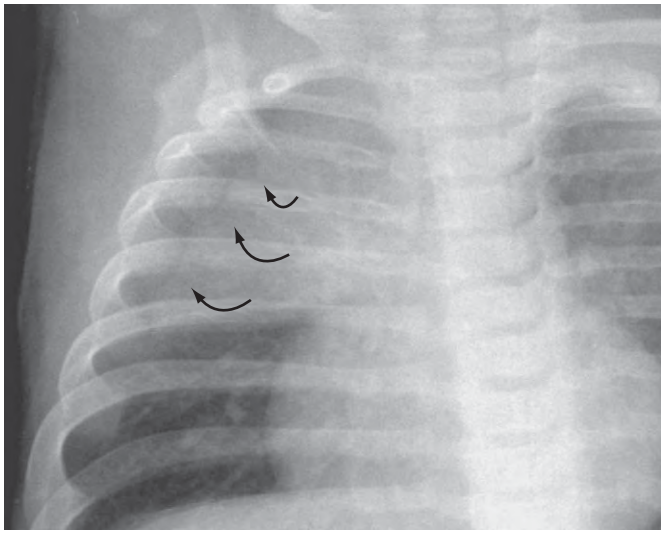
Disease processes in the abdomen may present with respiratory symptoms and vice versa. Although the area of the abdomen that is visible is limited, the chest radiograph may contain evidence of dilated bowel loops, free intraperitoneal air, abdominal situs inversus, organomegaly, gallstones, and renal calculi.

AIRWAY

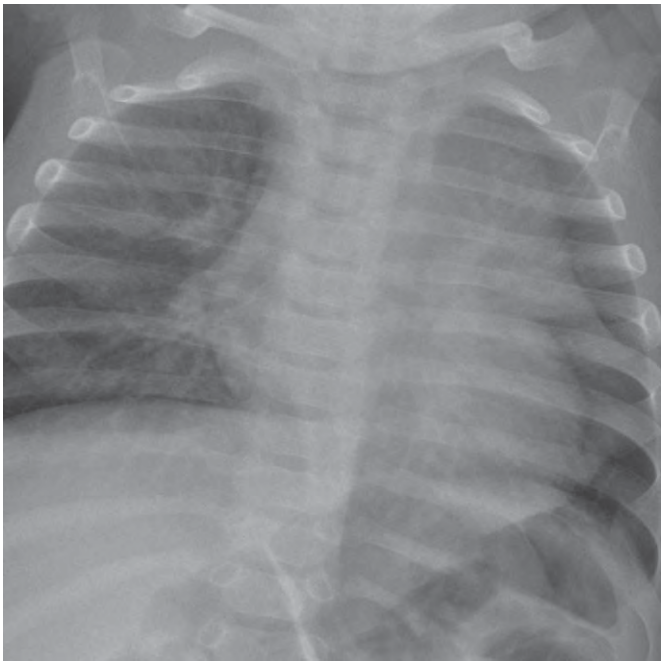
Although the airway is best assessed on dedicated airway radiographs, much information can be obtained from a chest radiograph. On the frontal radiograph, the normal airway deviates to the right, especially at the level of a normal left-sided aortic arch. If the trachea remains in the midline or deviates to the left, this is suspicious for an extrinsic mass or a congenital vascular anomaly such as a right-sided arch or a double aortic arch (Fig. 11-27). Similarly, posterior



A



B



C

Figure 11-25 Varying appearances of the thymus. Anteroposterior radiograph **(A)** demonstrates a prominent right lobe of the thymus. Note the straight inferior border *(arrows)* and oblique lateral border giving the appearance of a sail. Close inspection of the lateral border **(B)** demonstrates an undulating wave-like edge *(curved black arrows)*. Sometimes, the left lobe of the thymus may be prominent **(C),** and in such cases may be separated from the left heart border by a notch.

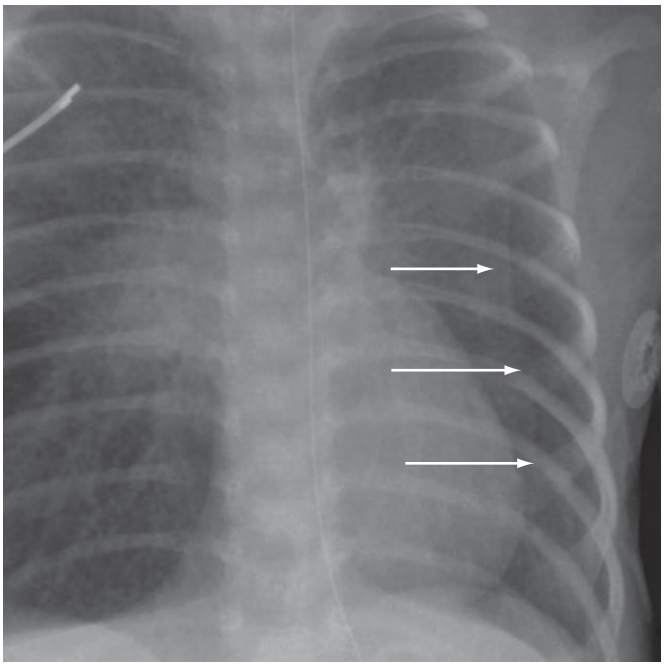


Figure 11-26 Skinfold mimicking a pneumothorax. Radiograph in a 26-day-old girl demonstrates an interface *(arrows)* in the left hemithorax. Lung markings are seen peripheral to the interface, and a subsequent radiograph did not show signs of a pneumothorax.

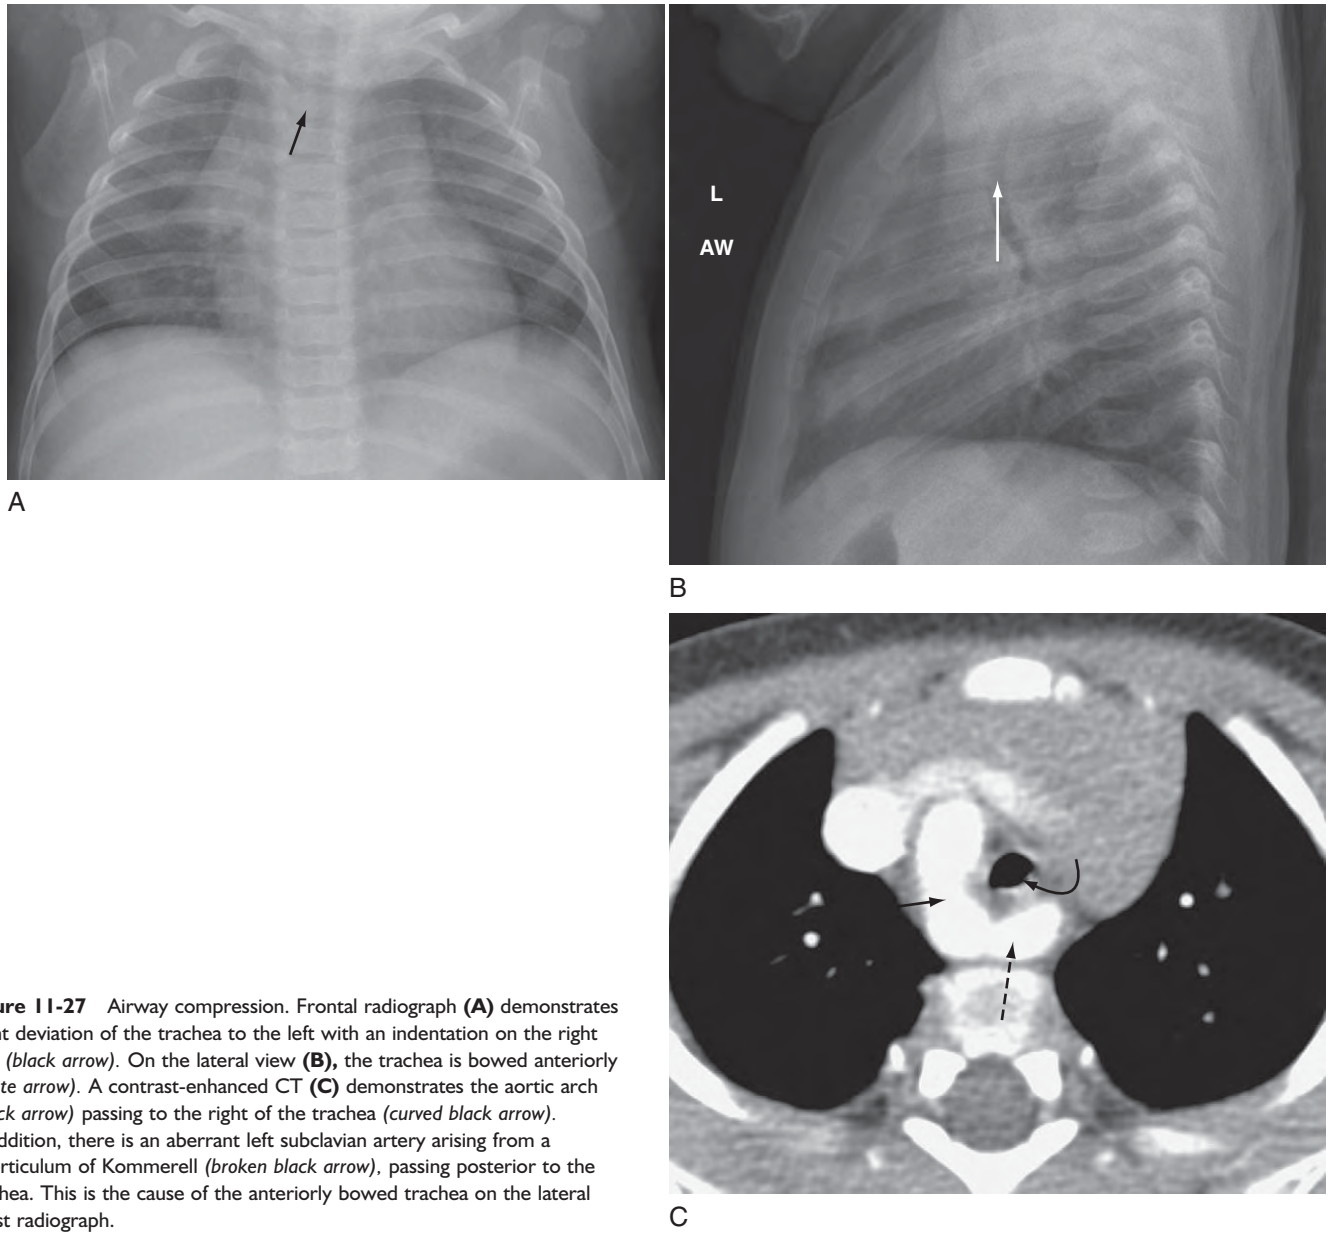

A

B

C

Figure 11-27 Airway compression. Frontal radiograph **(A)** demonstrates slight deviation of the trachea to the left with an indentation on the right wall *(black arrow)*. On the lateral view **(B),** the trachea is bowed anteriorly *(white arrow)*. A contrast-enhanced CT **(C)** demonstrates the aortic arch *(black arrow)* passing to the right of the trachea *(curved black arrow)*. In addition, there is an aberrant left subclavian artery arising from a diverticulum of Kommerell *(broken black arrow)*, passing posterior to the trachea. This is the cause of the anteriorly bowed trachea on the lateral chest radiograph.

indentation on the trachea on the lateral chest radiograph can be seen with an aberrant subclavian artery.

The trachea should be visible from the glottis to the carina on both the frontal and lateral radiographs as a lucent tube with parallel well-defined walls. Ill definition or obliteration of a portion of the airway should be further investigated.

BONES AND SOFT TISSUES

Lesions of the chest wall may present with respiratory symptoms. Bony lesions may also lead to deformity or chest pain, and in younger children with nonspecific symptoms such as fussiness, a chest radiograph should be carefully examined for signs of child abuse, such as rib fractures (Fig. 11-28).

CATHETERS AND TUBES

It is important to pay careful attention to any catheters, tubes, sutures, monitoring leads, pacing devices, or nerve stimulators, as they are not an uncommon source of morbidity. It is recommended to follow each individual device all the way to the tip (Fig. 11-29).

CHEST

As described previously, the age of the patient influences the size of the normal thymus, which is reflected in the varying appearance of the upper mediastinum in infancy and childhood. After early childhood, any widening of the upper mediastinum should raise a concern for a mass or lymphadenopathy.

The heart size is best evaluated using a combination of the frontal and lateral chest radiographs. On the frontal radiograph, enlargement is considered if the ratio of the transverse diameter of the heart is greater than half the maximum transverse diameter of the chest. It is not unusual for the cardiac silhouette to look enlarged on a supine anteroposterior chest radiograph obtained during inadequate inspiration. On the lateral view, enlargement is confirmed if the posterior

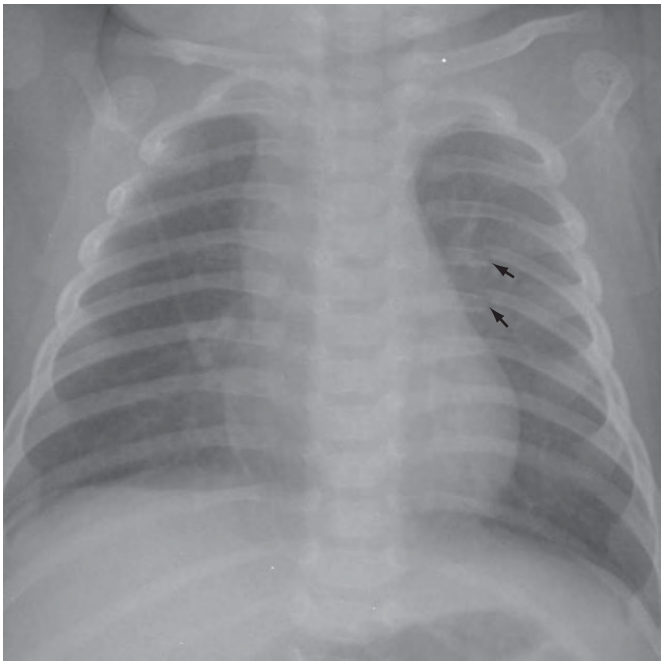

Figure 11-28 Evaluating for rib fractures: 9-month-old girl who was brought to the emergency department with lethargy and fever. A chest radiograph demonstrates left posterior rib fractures *(arrows)*. This appearance and clinical history are of concern for nonaccidental trauma.

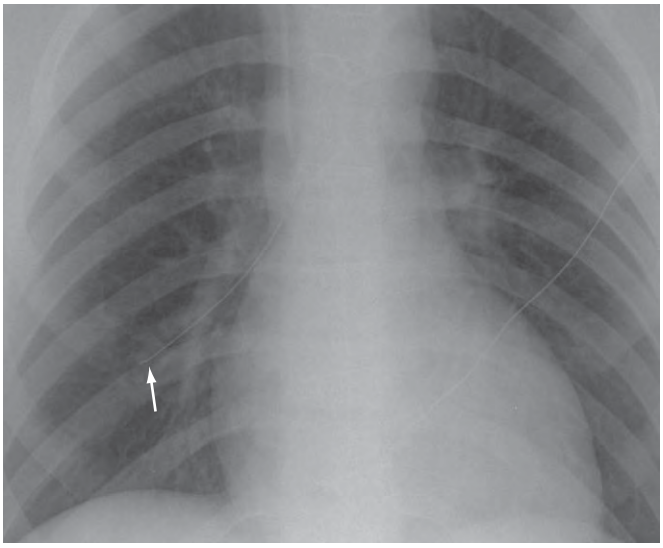

Figure 11-29 Follow tubes and lines to their tip: 17-year-old boy who is recently postsurgery. Chest radiograph demonstrates a nasogastric tube in a right lower lobe bronchus.

border of the heart extends beyond the tracheal air column (Fig. 11-30).

When evaluating the lungs, it is helpful to start by comparing the density of the two lungs at the same level, as these should be symmetrical. There should also be no significant difference in the density of the apex of the lungs compared with the base. The density of the lungs depends on a number of factors but essentially reflects the relative aeration of the lung. An opacity reflects replacement of aerated lung by soft tissue or fluid density material and may be due to atelectasis, consolidation, a mass, etc. The reason the heart, mediastinum, and diaphragm are normally visible is because these structures are bordered by aerated lung, which has a much lower density. When normal low-density air is replaced by fluid or solid material, there is no longer an appreciable difference in density compared with surrounding soft tissue structures such as the heart or diaphragm, and this leads to loss of the visualization of these structures. This is called the silhouette sign (Fig. 11-31). If a bronchus is visible within an opacity, this is referred to as an air bronchogram, formed by fluid-filled alveoli surrounding an air-filled bronchus (Fig. 11-32).

Decreased density reflects a relatively increased ratio of air to fluid/interstitium. This may be due to air trapping (e.g., an inhaled foreign body), an aerated cyst (e.g., a pneumatocele), or a decrease in blood flow to that area (e.g., congenital lobar emphysema) (Fig. 11-33).

In pediatric patients, a pleural effusion is the most common manifestation of pleural disease. In upright patients, a small effusion is usually seen as blunting of the costophrenic angles, while larger effusions will lead to a band of increased density between the lung and the ribs. On the lateral view, a meniscus of fluid is seen in the posterior costophrenic angle ascending along the posterior chest wall for a variable distance. If the patient is supine, then effusions may manifest as general increased density throughout the affected hemithorax due to the fluid layering posteriorly. Occasionally, fluid primarily collects in a subpulmonic location between the lung and the diaphragm and can be recognized by lateral displacement of the apex of the diaphragm from the midclavicular line. A large pleural effusion is one cause of complete opacification of a hemithorax (Box 11-4). A pneumothorax is manifested as a lucent area lateral to the lung that does not contain normal lung markings. In a supine patient, the pneumothorax may only be appreciated as generalized increased lucency of the affected hemithorax. Additional signs of a pneumothorax in a supine patient include deepening of the costophrenic angle or a sharp outline of the heart border or hemidiaphragm (Fig. 11-34).

Box 11-4 Causes of a Unilateral Opaque Hemithorax

- Lung aplasia/agenesis
- Collapse of ipsilateral lung

IMAGING FOR COMMON PEDIATRIC RESPIRATORY PROBLEMS

Certain clinical scenarios are more commonly encountered than others, and, as such, general algorithms can be applied. Other less common but clinically important questions may benefit from general recommendations.

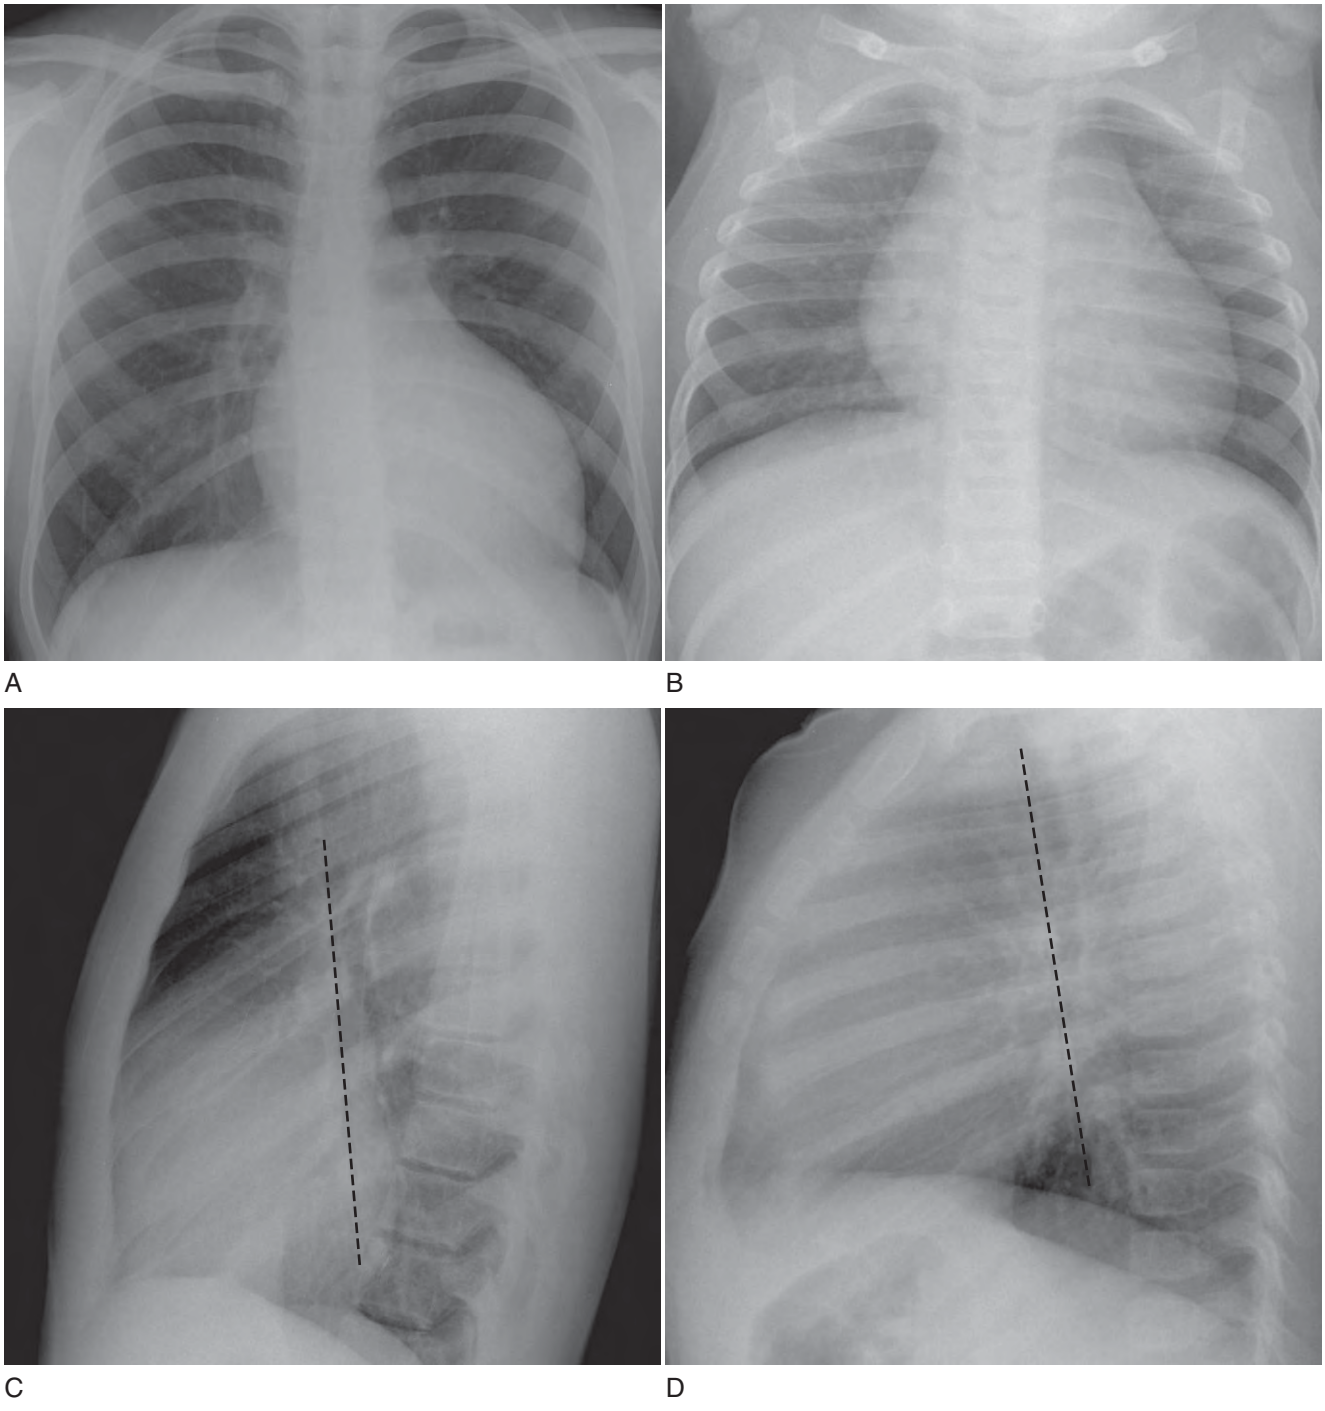

Figure 11-30 Assessment of cardiomegaly. Frontal chest radiographs (**A** and **B**) are both of concern for cardiomegaly. Lateral radiograph **C** demonstrates enlargement of the heart because the ventricular margin passes posterior to a line extended as an inferior continuation of the trachea. In fact, the heart crosses the thoracic vertebrae. Lateral radiograph **D** demonstrates normal heart size as a similar line passes posterior to the ventricular margin. The apparent enlargement was due to a prominent thymus.

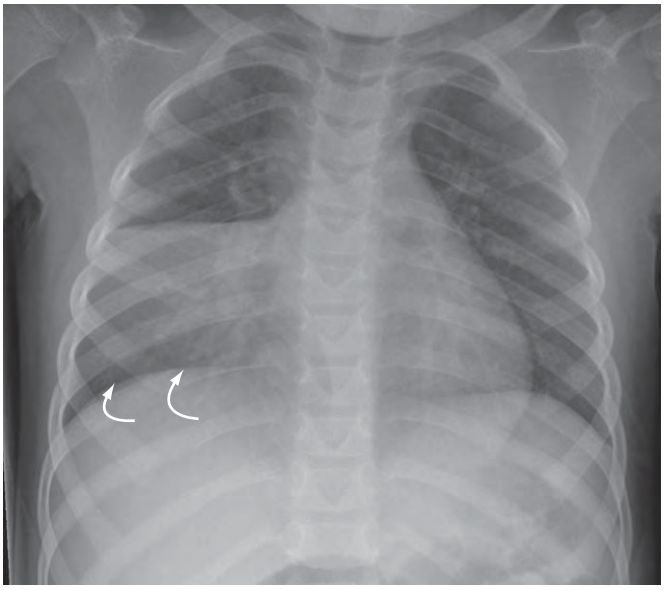
Neonate

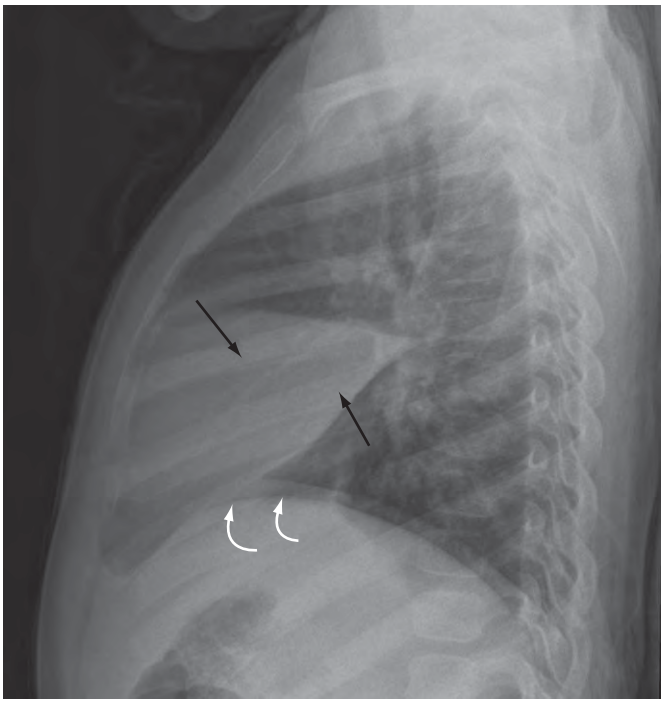
In general, a single frontal view of the chest suffices to answer most clinical questions. Occasionally, a lateral or other additional view may be helpful. A chest CT scan may be indicated for better definition of a congenital lesion such as a congenital cystic adenomatoid malformation for presurgical planning. Evaluation of a suspected congenital vascular anomaly such as a vascular ring can be evaluated with MR imaging, which will spare unnecessary radiation exposure. However, if a lung parenchymal abnormality is also a concern, then CT is preferable. An esophagogram with barium or low-osmolar contrast material can also be used to define a vascular ring or sling, or a congenital esophageal abnormality such as a tracheoesophageal fistula.

Child with Suspected Pulmonary Infection

Chest radiographs are often performed in young children with an unexplained fever. The yield is generally low, however,



A



B

Figure 11-31 Silhouette sign. On the frontal radiograph **(A),** the right heart border is not visible because aerated lung has been replaced by fluid-filled lung in the middle lobe. On the lateral view **(B),** this is confirmed as the consolidated middle lobe is seen as a triangular-shaped density overlying the heart *(black arrows)*. Note that the right hemidiaphragm remains visible on both the frontal and lateral radiographs as it is outlined by aerated lung *(curved white arrows)*.

unless there are accompanying respiratory symptoms. A chest radiograph in an older child (older than 3 years) with an unexplained fever is not indicated because the diagnostic yield is so low.

In patients with signs of an acute respiratory infection, a chest radiograph may be performed, although it is not always necessary. More appropriately, a chest radiograph should be performed in those patients who are not responding as expected to standard therapy. If complications such as a

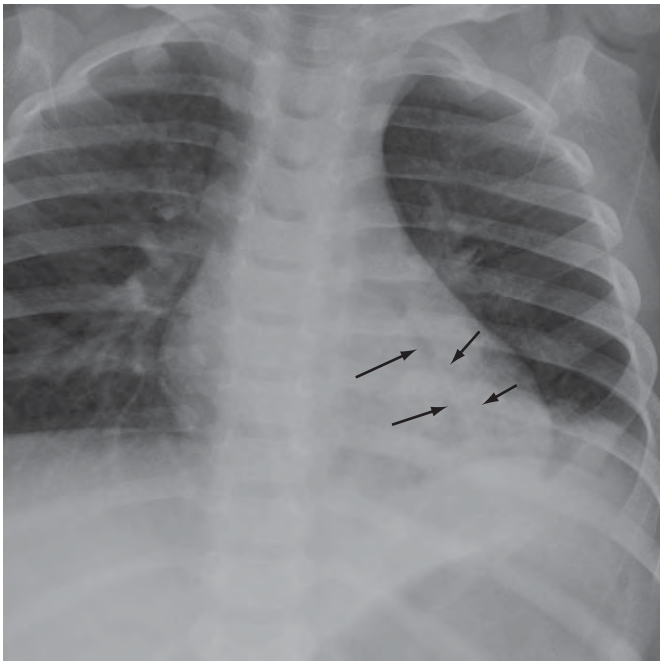


Figure 11-32 Bronchogram sign. Frontal radiograph in a 21-month-old boy with cough and fever demonstrates an irregular increased density in the left lower lobe. Air-filled bronchi are seen *(arrows)* because they are surrounded by nonaerated lung.

cavitary pneumonia or an abscess or other complications such as a loculated parapneumonic effusion or an empyema are suspected, then a contrast-enhanced CT scan may be helpful in evaluating the extent of the disease. If drainage of a parapneumonic effusion is being contemplated, then an ultrasound will help determine if the effusion is simple enough to be drained by placing a chest tube or if it is a complex effusion that needs surgical drainage.

In a patient with a history of recurrent pneumonias, an esophagram or a video swallowing study may demonstrate predisposing causes such as a tracheoesophageal fistula or aspiration. Similarly, a nuclear medicine sulfur colloid study can be used to detect gastroesophageal reflux that may predispose to aspiration. An HRCT scan can demonstrate signs of residual damage from recurrent pneumonia such as scarring and bronchiectasis and may suggest previously unsuspected disorders such as cystic fibrosis (Fig. 11-35).

Wheezing Child

Wheezing is a common presenting complaint in childhood, and although most commonly it is caused by small airway diseases such as a viral infection or asthma, it may also be caused by any obstructing central airway lesion such as a foreign body (Fig. 11-36), a compressing aberrant vessel, or a mediastinal mass. Not every child who presents with asthma or signs of a viral infection needs a chest radiograph, which should be reserved for those who do not respond as expected to standard therapy or demonstrate signs or symptoms of complications such as lobar collapse, pneumothorax, or superimposed infection. A chest radiograph in a wheezing child often shows hyperinglation, which is seen in conditions that cause air trapping but may be seen in multiple other conditions also, in both neonates and older children (Box 11-5).

C

Figure 11-35 Aspiration: 17-year-old with a history of cerebral palsy and aspiration. A chest radiograph **(A)** demonstrated some subtle ill-defined opacities in the perihilar regions with bilateral lower lobe atelectasis. A CT scan **(B)** performed at the same time demonstrated bronchiectasis in the right lung base *(curved white arrows)*, presumed secondary to recurrent aspiration. A further CT scan **(C)** performed 8 months later demonstrated a cavitary pneumonia in the same location, consistent with aspiration pneumonia.

Complications of Malignancy

In a patient with a known malignancy, pulmonary metastases may be obvious on a chest radiograph. However, spiral CT is needed to evaluate the true extent of metastatic disease. In a patient with a known malignant tumor and a normal chest radiograph, CT should also be performed to assess for metastases. Patients who are immunocompromised due to therapy and have an unexplained fever should be investigated with chest CT even if the chest radiograph is normal, as infections in this population may be subtle (Fig. 11-37). Both metastases and opportunistic infections in oncology patients may appear as multiple pulmonary nodules, which may also be seen in a variety of other conditions (Box 11-6).

Mediastinal and Parenchymal Masses

In the pediatric population, mediastinal masses are usually visible on a chest radiograph, which are often obtained for an unrelated reason. As implied previously, the most common mediastinal mass is the normal thymus, which usually can be diagnosed on a chest radiograph. Confirmation, if needed, may be achieved with MR imaging or CT, but an ultrasound scan can also identify normal thymic tissue.

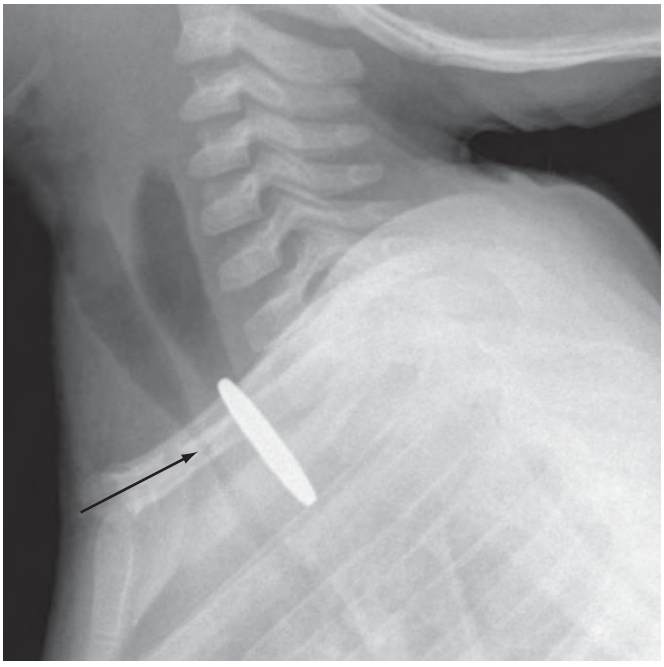

Figure 11-36 Esophageal foreign body: 9-month-old girl with a history of recurrent wheezing, not responding to medical therapy. Lateral radiograph demonstrates the coin in the proximal esophagus, resulting in inflammation and thickening of the esophageal wall. Over time, this has involved the tracheal wall with resultant narrowing of the tracheal lumen *(arrow)*.

Investigation of other causes of a mediastinal mass should also be performed with CT or MR for a number of reasons: (1) to try to identify the location of the mass and the organ of origin, (2) to look for signs of involvement of surrounding structures, and (3) to evaluate whether the mass is cystic or solid and, if possible, to identify component tissues in complex masses such as a teratoma.

The mediastinum can be divided into anterior, middle, and posterior compartments, and identifying which compartment a mass arises in helps to narrow the differential diagnosis (Fig. 11-38). Anterior mediastinal masses are most commonly due to lymphoma and germ cell tumors. Usually, these can be differentiated by the presence of some calcification and/or fat in a teratoma (Fig. 11-39). Middle mediastinal masses most commonly are due to lymphoma and foregut duplication cysts (Fig. 11-40), while posterior mediastinal masses are usually neurogenic in origin (Box 11-7).

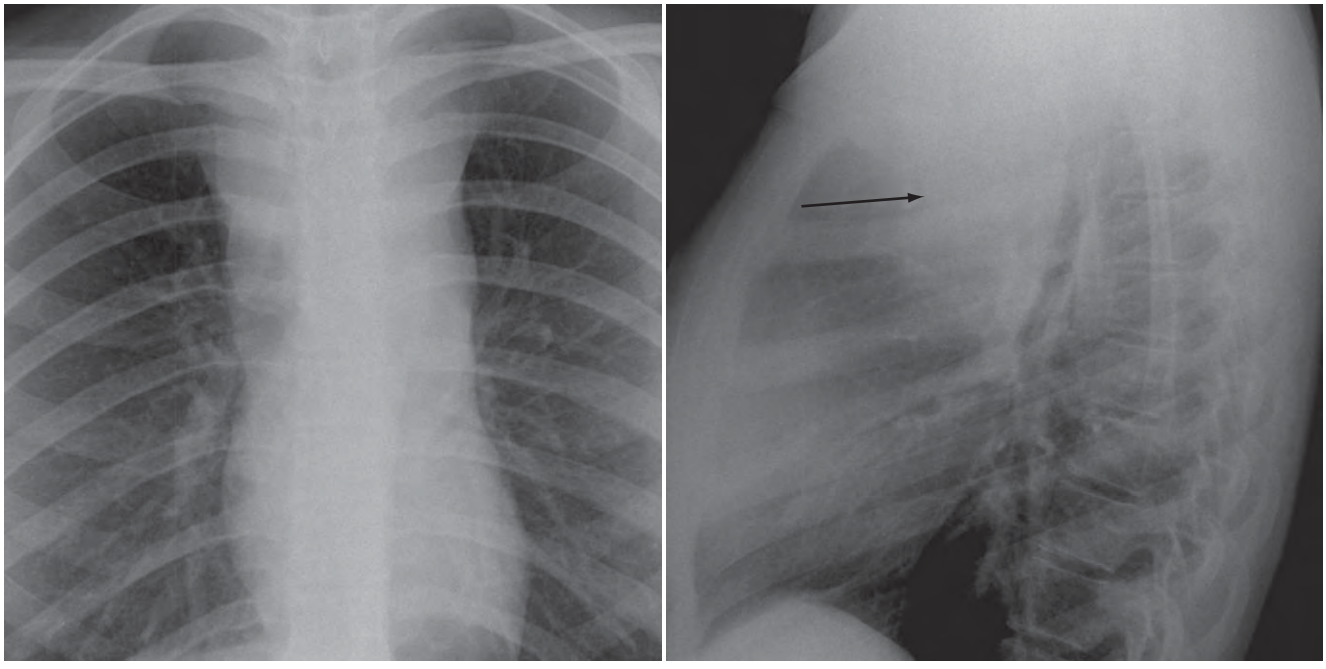
Parenchymal masses other than congenital lesions such as sequestration and congenital cystic adenomatoid malformation and those related to bacterial infection (i.e., round pneumonia) are uncommon in infants and children. Granulomatous infections are common in some geographical areas, but primary lung tumors such as pleuropulmonary blastoma are rare.

CONCLUSION

Plain film radiography continues to be the mainstay of pediatric imaging, and pediatric pulmonologists should be comfortable with evaluating a chest radiograph. Cross-sectional imaging techniques, especially HRCT, are becoming increasingly important as a means of investigating the respiratory tract but should be used only when the clinical information to be gained outweighs the potential risk of radiation and also the risk of any required sedation. Special techniques such as controlled ventilation or decubitus imaging can be used to optimize the quality of the images obtained in sedated children.

Imaging of the airway for intrinsic abnormalities is primarily performed with radiography. Extrinsic airway compression and mediastinal abnormalities can be imaged with CT or MR imaging. The choice of which modality to use should be decided on a case-by-case basis.

Nasal and paranasal structures are optimally imaged with CT and MR imaging.



A B

C

Figure 11-39 Anterior mediastinal mass: 15-year-old girl with a cough and chest pain. Frontal radiograph **(A)** demonstrates widening of the mediastinum. Lateral radiograph **(B)** localizes this to the anterior mediastinum *(arrow)*. Contrast CT **(C)** demonstrates a homogeneous attenuation mass anterior to the aortic arch *(arrow)* in the anterior mediastinum. This is too large to be a normal thymus in a teenager. Homogeneous anterior mediastinal masses are lymphoma until proven otherwise.

CHAPTER 12 Respiratory Function Testing in Infants and Preschool-Aged Children

Peter D. Sly and Wayne J. Morgan

TEACHING POINTS

- Lung function testing is feasible in infants and preschool-aged children.
- Attention to detail in optimizing the measurement conditions is critical to producing reliable results.
- International efforts at producing standardized measurement techniques and reference values are continuing.
- Before introducing these techniques locally, labs should study healthy children to ensure that the available reference data are applicable to their population.

Measurement of lung function in adults and older children has become a routine part of the management of respiratory diseases. Pulmonary function tests provide objective evidence regarding the nature and control of respiratory diseases and the effect of therapy and provide opportunities to study the mechanisms by which diseases alter lung function. These objective assessments have been unavailable to those managing respiratory diseases in infants and younger children until relatively recently. Many advances have been made in the past decades, and now the techniques and equipment necessary to measure lung function in infants and young children are readily available. Measurements of lung function in preschool-aged children are being used clinically in many parts of the world.

This chapter is not intended to be sufficiently detailed that the reader can learn to measure lung function in infants and young children from these pages. A joint task force from the American Thoracic Society and European Respiratory Society has produced numerous publications about how these tests should be performed.[1-9] The interested reader is referred to these publications for practical details of the various tests.

LUNG FUNCTION TESTING IN INFANTS

Influence of Measurement Conditions on Lung Function

A major requirement for most methods of measuring lung function in infants is to have the infant sleeping. This is necessary to effect reproducible results. However, infants cannot be relied on to sleep naturally on demand or to remain asleep long enough to allow pulmonary function to be measured. Thus, the majority of infant lung function tests are performed with the infant sedated, most commonly with chloral hydrate or a similar sedative. Sedating infants for pulmonary function testing is considered safe, with no reported adverse effects despite many thousands of tests having been performed throughout the world.[10] However, a fall in arterial oxygen saturation has been reported in wheezy infants sedated for pulmonary function testing,[11] so continuous monitoring of oxygen saturation is considered mandatory in such infants.

Standardization of measurement conditions must address both laboratory conditions and the infant's state with respect to factors that influence the results of respiratory function tests, such as feeding, posture, and sleep state.[6]

Measurement Techniques

The techniques used to measure pulmonary function in infants can be conveniently grouped into four groups: measures of lung volume, measurements of ventilation inhomogeneity, measures of forced expiratory flow, and measures of compliance and resistance.

Measures of Lung Volume

Knowledge of lung volume can play an important role in the respiratory care of infants and young children and can assist in the interpretation of measurements of resistance, compliance, and forced expiratory flow. Two main techniques are used for measuring lung volumes in infants: body plethysmography and gas-dilution techniques.

BODY PLETHYSMOGRAPHY

In body plethysmography, the infant is placed inside a rigid, closed container (a plethysmograph) and makes respiratory efforts against an occlusion at the airway opening; the respiratory efforts rarefy and compress the thoracic gas (Fig. 12-1). Calculation of the amount of gas in the thorax during occluded breathing efforts is made by applying Boyle's law. The assumptions underlying this technique are discussed more fully in Chapter 13. There are, however, a number of particular difficulties in applying these assumptions to measurements in infants. The success of the plethysmographic measurement of lung volume relies on the plethysmograph having an adequate frequency response over the range of frequencies used. In an adult plethysmograph, with a volume typically 50 to 100 times that of the adult's intrathoracic volume, the fre-

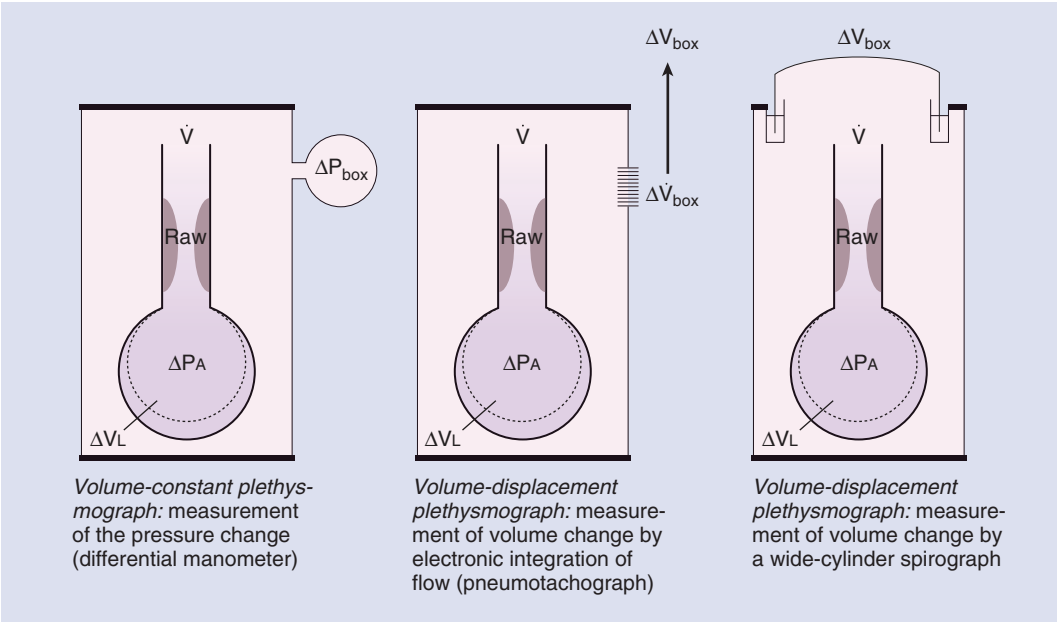

Figure 12-1 Types of plethysmographs. Dotted lines indicate volume change by compression; solid lines indicate volume change by expansion of thoracic gas (ΔV_L). ΔV_{box}, Change in volume in plethysmograph; ΔP_{box}, change in pressure in plethysmograph; $\dot{V}$, gas flow; Raw, airway resistance; ΔP_A, change in alveolar pressure; ΔV_L, change in lung volume. (Redrawn from Tammeling GJ, Quanjer PH: Contours of Breathing. Burlington, Ontario, Canada, Boehringer Ingelheim Pharmaceuticals, 1985.)

quency response is poor (<0.2 Hz) because of the thermal time constant of the box and the necessary presence of a slow leak to allow for gas expansion resulting from the heat generated by the subject. Adults and older children are asked to make occluded breathing efforts at a frequency of approximately 1 Hz. This is primarily to keep the glottic aperture open, aiding the transmission of alveolar pressure to the airway opening and minimizing the difference in airway resistance (Raw) between inspiration and expiration.[12] However, this technique ensures that the box is being operated at a frequency at which the frequency response is adequate and that gas compression within the box is essentially isothermal.

The infant plethysmograph is considerably smaller than the adult, giving it a greater surface area–to-volume ratio. Thus, the mean distance over which heat diffusion must occur between any point inside the plethysmograph and its walls is greatly reduced. This in turn leads to a much reduced thermal time constant,[13] which adversely influences the frequency response of the plethysmograph in the frequency range usually encountered in infants. The thermal time constant of a 60-L plethysmograph, with metal walls, was reported to be 0.16 second.[13] Gas compression within this box was found to be polytropic (i.e., between isothermal and adiabatic) over a frequency range of 0.1 to 3 Hz. Infants, obviously, cannot be requested to breathe at a particular frequency, and the respiratory rate is likely to change during measurements, particularly those that involve giving the infant a bronchodilator or bronchial challenge agent.[13] Changes in the frequency of the occluded breathing efforts result in changes in the value of thoracic gas volume calculated simply because of the polytropic gas compression.

An alternative to the "constant-volume" plethysmograph is the "flow plethysmograph" in which a pneumotachograph measures gas flow between the plethysmograph and the exterior (see Fig. 12-1, center). The flow signal can be integrated to produce the volume change occurring in the box resulting from respiration (i.e., tidal volume). During occluded breathing efforts, this volume should equal the change in volume recorded in a constant-volume plethysmograph (see Chapter 13). In a flow plethysmograph, the gas displacement minimizes polytropic gas compression and eliminates thermal effects. If the resistance and inertance of the pneumotach are too high, the flow signal may be damped, introducing errors into the calculations of lung function. These errors can be improved by using a screen pneumotachograph fitted flush with the plethysmograph wall without any connecting tubing or by correcting for the resistance and inertance of the pneumotachograph.[14]

Transmission of the changes in alveolar pressure to the airway opening during occluded breathing efforts occurs with a time constant dependent on the Raw and upper airway compliance. Infants have higher Raw and more compliant upper airways, both of which increase the time required to transmit alveolar pressure changes to the upper airway. This problem is magnified in conditions with increased Raw, such as wheezing illnesses. Under these conditions, the airway opening pressure may markedly underestimate alveolar pressure, resulting in overestimations of thoracic gas volume and thus limiting the accuracy and usefulness of this technique in infants with airway disease. Recent advances in technology and attention to detail in calculation of results have brought marked improvements in the accuracy of plethysmography in infants.[15]

GAS-DILUTION TECHNIQUES

The most common application of the gas-dilution technique is the helium-dilution technique. This technique is based on

the principle of gas equilibration between an unknown lung volume and a known volume containing helium as an indicator gas. Gas is mixed by ventilatory movements, and the lung volume is calculated from the change in helium concentration. Lung volume can also be measured using the nitrogen-washout technique. With this technique, the infant breathes from a reservoir of nitrogen-free gas, and the washout of nitrogen in the alveolar gas is measured with a rapidly responding nitrogen analyzer.

The major problems with these techniques include the following:

1. Any leak in the circuit results in the final concentration of gas (especially helium) being artificially low, with the consequent overestimation of lung volume. For these tests, the infant breathes through a facemask, increasing the possibility of leaks, which may be difficult to detect.
2. Adequate time must be allowed for the helium to be distributed throughout the lung and for the final helium concentration to become stable. In the presence of small airways and in conditions with increased Raw, the time required for equilibration may be considerable. Long equilibration times may be impractical when testing infants.
3. Gas-dilution techniques measure the lung volume readily communicating with the airway opening, which may be substantially less than the total lung volume. The response to treatments, such as bronchodilators, can be difficult to interpret because a beneficial treatment effect may be measured as a decrease in lung volume if most airways are patent or as an increase in lung volume if the bronchodilator opens previously closed airways, resulting in an increased volume of lung in communication with the airway opening.

Measurements of Ventilation Homogeneity

The realizations that lung disease in infants with cystic fibrosis begins in the lung periphery and that measurements of forced expiration may not be sensitive enough to detect signs of early disease have led to an increase in interest in tests that measure ventilation distribution in infants. The multiple breath nitrogen washout technique has been used for decades in adults and has been investigated in infants.[16] Techniques using the inert gases SF6 and/or helium as a tracer gas are becoming increasingly popular.[17,18] The most common indices of lung function calculated from these multiple breath inert gas techniques are the functional residual capacity (FRC) and the lung clearance index (LCI). The measurements are performed as follows:

- Tidal breathing is monitored and when a stable pattern with a stable end-expiratory level has been achieved the breathing circuit is switched to one containing the tracer gas (e.g., 4% SF6).
- The gas concentration is measured during tidal breathing until a stable plateau has been achieved. This phase is known as the wash-in phase.
- The breathing circuit is then switched to one without the tracer gas and gas concentration monitored until the concentration has dropped to 1/40 of the plateau concentration (the washout phase).
- FRC is calculated from the cumulative expired tracer gas volume divided by the difference in end-tidal tracer gas concentration at the start of the washout and the end-tidal tracer gas concentration at the end of the washout.
- LCI is calculated as the number of lung volume turnovers (cumulative exhaled volume/FRC) required to lower tracer gas concentration to 1/40 of the starting concentration.

LCI is a useful measure of volume homogeneity and is essentially constant at 6 to 7 throughout childhood.[17] LCI also appears to be abnormal in children with cystic fibrosis and is more sensitive to the presence of early lung disease than standard spirometry.[17]

Measures of Forced Expiratory Flow

The primary method used to measure forced expiratory flows in infants has been the rapid thoracic compression (RTC) technique. The RTC technique produces forced expiratory flows by suddenly applying a pressure to the thorax and abdomen at the end of a tidal inspiration, using an inflatable thoracoabdominal jacket connected to a positive-pressure reservoir. Flow is measured at the mouth with an appropriately sized pneumotachograph attached to a mask sealed around the infant's nose and mouth.[19] Flow is integrated to obtain volume, and a flow-volume curve is constructed. Before the RTC maneuver, a reproducible end-expiratory volume (FRC) is established from at least three tidal breaths. An RTC initiated at the end of inspiration then produces a partial expiratory flow-volume curve, with exhalation continuing to a volume below the previous FRC. RTC maneuvers are repeated at increasing jacket pressures until the pressure that produces the highest expiratory flows is determined. The maximum flow occurring at the previously established tidal FRC ($\dot{V}$max FRC) is reported.

Use of the RTC has led to major advances in understanding the normal growth and development of the respiratory system and of the development of respiratory diseases. For example, $\dot{V}$max FRC shows an essentially linear increase with somatic growth and with lung volume throughout the first year of life.[20,21] Seidenberg and coworkers[22] demonstrated that lung function abnormalities persist for up to 3 months in the absence of clinical symptoms after an episode of acute viral bronchiolitis. However, the RTC technique has not proved to be the "panacea" it initially promised to be and has largely been replaced by the raised volume RTC (RVRTC), in which the infant's lungs are inflated to a volume approaching total lung capacity before the forced expiration is initiated[9] (see later).

The utility of measurements of forced expiration relies on expiratory flow limitation being achieved. Although this may be the case with the RTC technique in infants with airway obstruction, flow limitation is unlikely to be achieved in healthy infants. Furthermore, FRC is notoriously variable in infants, even over short periods, which leads to substantial variability in the values of $\dot{V}$max FRC (Fig. 12-2). Many studies have consistently failed to demonstrate a bronchodilator response after therapy with inhaled β-sympathomimetics; yet many clinical studies have shown that infants can benefit from the administration of inhaled bronchodilators. One possible reason for this discrepancy is that bronchodilators alter

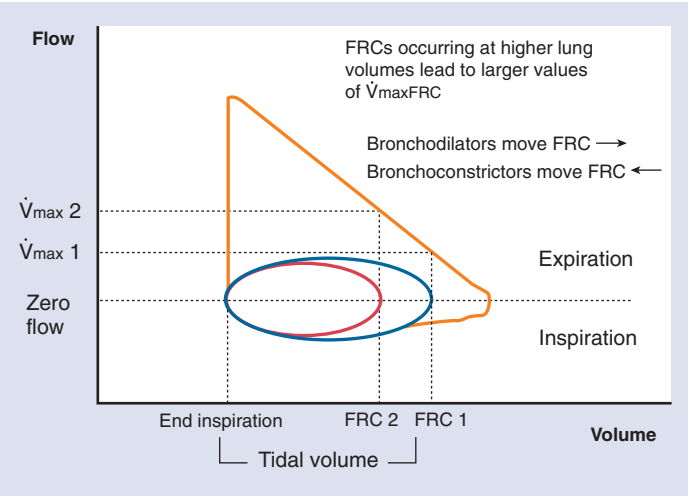

Figure 12-2 Effect of variation of FRC on V̇max FRC as calculated from a partial expiratory flow-volume curve.

FRC, possibly reducing hyperinflation. This would reduce the V̇max FRC, masking the expected increase after bronchodilator treatment (see Fig. 12-2).

In an attempt to overcome many of the problems with the RTC technique, Turner and colleagues[23,24] developed a technique in which the lungs were inflated to a preset pressure using a pump before the RTC. They reason that the use of a standard inflation pressure reduces the variability of the measurements produced. They then measure the volume forcibly exhaled in a given time, usually 0.75 second (Fig. 12-3). This technique is analogous to the 1-second forced expiratory volume (FEV_1) that is routinely measured in older children and adults. In addition, because the forced expiration is induced from a higher lung volume, full forced expiratory flow-volume curves appear to be possible (Fig. 12-4). Other groups have used various methods to inflate the lungs and various inflation pressures have been used. The American Thoracic Society (ATS)–European Respiratory Society (ERS) Task Force has published standardized guidelines for the RVRTC,[9] and the interested reader is referred to that publication for further information.

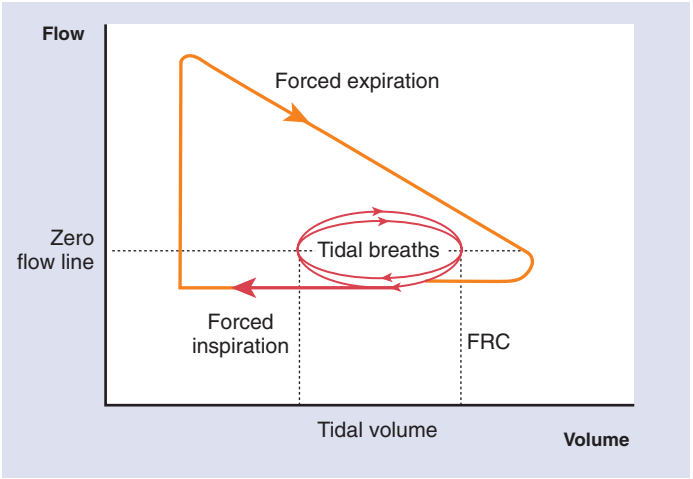

Figure 12-4 Flow-volume plot of the raised-volume RTC maneuver.

Measures of Resistance and Compliance

A number of techniques are available for measuring resistance and compliance in spontaneously breathing infants. The most commonly used tests are occlusion tests, which invoke the Hering-Breuer reflex, and body plethysmography. Other possibilities include the use of forced oscillation techniques. Older techniques involving the measurement of esophageal pressure as an index of pleural pressure have largely fallen out of favor for use in spontaneously breathing infants and are not discussed here further.

TECHNIQUES THAT INVOKE THE HERING-BREUER REFLEX

Techniques invoking the Hering-Breuer reflex rely on the assumptions that this reflex, producing complete relaxation of both inspiratory and expiratory respiratory muscles, can be elicited during airway occlusion and that airway opening pressure comes into equilibrium with alveolar pressure during the occlusion. Occlusion techniques may involve multiple occlusions at different lung volumes or single occlusions at end-inspiration.

Multiple-Breath Occlusion Technique

In the multiple-breath occlusion technique, pressure is measured at the mouth during brief airway occlusions performed on multiple breaths. Occlusions are performed at different volumes above FRC, and the individual measurements are plotted as volume versus pressure. The slope of the line of "best fit" is the compliance of the respiratory system (Fig. 12-5). In the single-breath occlusion technique, the airway is occluded at the end of inspiration, with the subsequent expiration occurring passively. A passive expiratory flow-volume curve is then constructed and a line fitted to the linear portion (Fig. 12-6). Compliance is calculated by dividing the total exhaled volume by the pressure at the airway opening recorded during the occlusion. The slope of the linear part of the passive flow-volume curve is equal to the reciprocal of the expiratory time constant (τrs). Resistance can be calculated by dividing the time constant by the compliance.

The problem with these techniques is ensuring relaxation of the respiratory muscles after airway occlusion and equilibration of airway opening and alveolar pressures. Generally,

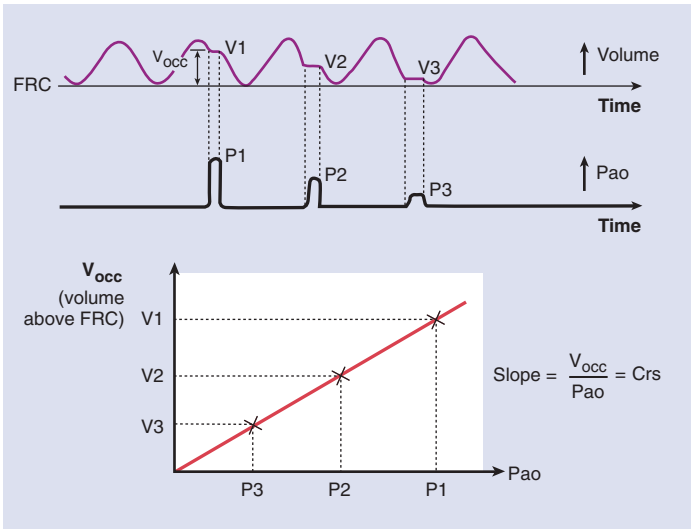

Figure 12-5 Calculation of compliance of the respiratory system using the multiple-breath occlusion technique. V_{occ}, volume at which occlusion is made; V, volume; P, pressure; Pao, pressure at the airway opening; Crs, compliance of the respiratory system.

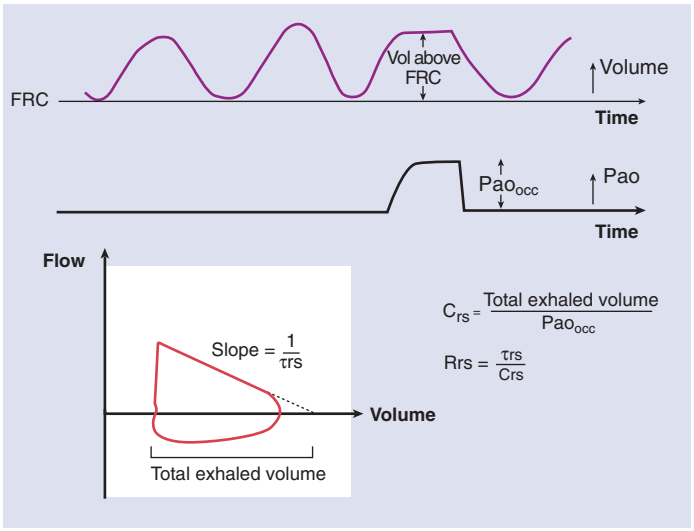

Figure 12-6 Calculation of respiratory compliance (Crs) and resistance (Rrs) using the single-breath occlusion technique. Pao_{occ}, airway opening pressure following occlusion; Pao, pressure at the airway opening; τrs, expiratory time constant.

the presence of a plateau in airway opening pressure indicates that both of these assumptions have been satisfied. The ERS/ATS Task Force has recommended that occlusions should be held for a minimum of 400 milliseconds.[25] The length of the airway occlusion can influence the values of compliance calculated from the subsequent expiration, with compliance decreasing by 0.15 ml/cm H_2O for each 0.1 second of occlusion time.[26] These data strongly argue for standardizing the length of occlusion and discarding data in which a plateau is not achieved. The ERS/ATS Task Force recommends that a plateau should be maintained for at least 100 miiliseconds.[25]

Low-frequency Forced Oscillation Technique

Forced oscillation techniques are described in detail in Chapter 13. These techniques have been used in infants, and impedance spectra have been measured above 4 Hz.[27,28] In infants, the forcing function is generally applied through a facemask and includes the impedance of the nose. When making measurements in infants, the clinician must take extreme care to prevent leaks around the facemask. An adaptation of the forced oscillation technique, using lower frequencies, has been developed for infants.[29] By applying the forcing function during a pause in breathing produced by invoking the Hering-Breuer reflex, reliable impedance data can be obtained from 0.5 to 20 Hz. The impedance spectra showed the same marked frequency dependence (Fig. 12-7) reported in paralyzed animals[30,31] and in adults studied either during voluntary muscle relaxation[32,33] or during mechanical ventilation with paralysis.[34] Fitting the constant phase model[31] to the respiratory system impedance (Zrs) allows partitioning into components representing the airway resistance (together with any Newtonian resistance in the chest wall) and the lung parenchyma, i.e.:

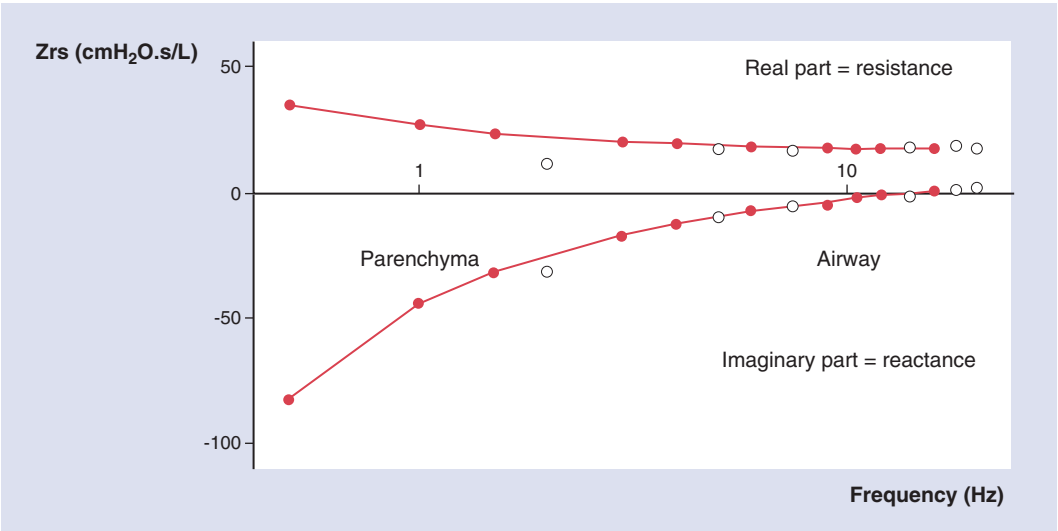

Figure 12-7 Respiratory system impedance (Zrs) measured in an infant. The upper panel shows the resistive component and the lower panel the reactance plotted as a function of frequency.

$$Zrs = Raw + j\omega Iaw + (G - jH)/\omega^{\alpha}$$

where Raw and Iaw are the frequency-independent resistance and inertance of the airways (see earlier); G and H are the coefficients for tissue damping and elastance, respectively; j is the imaginary unit, and ω is the angular frequency. The frequency dependence of the respiratory tissues is governed by the coefficient α, which can be expressed as $\alpha = (2/p)\arctan(H/G)$. As shown schematically in Figure 12-7, Zrs in the lower frequency range (<4 to 6 Hz in infants) is dominated by the mechanical properties of the pulmonary parenchyma, whereas those at higher frequencies are dominated by the mechanical properties of the conducting airways.

Interrupter Technqiue

Respiratory system resistance can also be measured in infants using the interrupter technique. The use of this technique is far more common in preschool-aged children, and the reader is directed to that section for a description of the technique. The major difference in infants is that the measurement is made through a facemask, which adds a compliant compartment (the gas in the facemask) in front of the respiratory system. This can decrease the accuracy of the measurements, especially in the presence of airway obstruction.

Body Plethysmography

Body plethysmography is commonly used to measure Raw in adults and older children but has been modified for infants by the inclusion of a rebreathing bag containing heated, humidified, oxygen-enriched gas at body temperature, pressure, and saturation. This sophisticated technique requires a large amount of expertise and training but can produce simultaneous measurements of lung volume and Raw. The ATS-ERS Task Force expended a great deal of time developing standardized techniques and has worked with industry to ensure that reliable equipment is commercially available. The interested reader is directed to the task force publications[6,15] for further information.

Measures of Tidal Breathing Parameters

Inductance plethysmography is a noninvasive technique that can be used for measuring tidal breathing in infants. The inductance plethysmograph consists of a pair of wire bands that are usually embedded into an elastic material encircling the chest wall and abdomen. The wires are arranged in a sinusoidal fashion and are excited by an oscillator to produce impedance proportional to the area enclosed within the band. By calibrating the impedance signal with known volume changes, it is possible to calculate changes in the cross-sectional areas of the thoracic and abdominal cavities in terms of changes in lung volume. However, the calibration is notoriously unstable and extremely sensitive to changes in body posture. A new generation of respiratory inductance plethysmographs was introduced in the mid-1980s. These devices produce an automatic qualitative calibration during the initial period of operation. Subsequent measurements of tidal breathing excursion are related to that measured during this initial period.[35]

The shape of the tidal breathing flow-volume curve can be influenced by airway function. Martinez and coworkers[36] reported that the time to peak tidal expiratory flow (Tptef) expressed as a percentage of total expiratory time (TE) (Fig. 12-8) (referred to by them as Tme/Te) was low in infants who subsequently developed wheezing lower respiratory illnesses. Martinez and coworkers[36] used a pneumotachograph and facemask in sedated infants to measure Tptef/TE. Stick and associates[37] demonstrated that Tptef/TE could be successfully measured using an uncalibrated respiratory inductance plethysmograph during quiet sleep in infants. The precise physiologic interpretation of Tptef/TE is unclear. In adults, Tptef/TE is correlated with airway conductance, lower values occurring with subjects with airway obstruction and low airway conductance.[38] This can be conceptualized by comparing the normally rounded shape of the expiratory limb of the flow-volume loop seen during tidal breathing (see Fig. 12-8, left), at which Tptef/TE approximates 0.5 with the peaked shape of the expiratory limb of a forced expiratory flow-volume curve (see Fig. 12-8, right), at which Tptef/TE approaches 0.15 to 0.2. For a given level of respiratory drive, as airways become more obstructed the tidal flow-volume curve becomes more like that normally seen during forced expiration, and Tptef/TE decreases. Martinez and coworkers[36] interpreted a low premorbid value of Tptef/TE as being indicative of smaller than usual airways, making the infants more likely to develop wheezing illnesses with the usual respiratory tract viral infections. However, the flow-volume

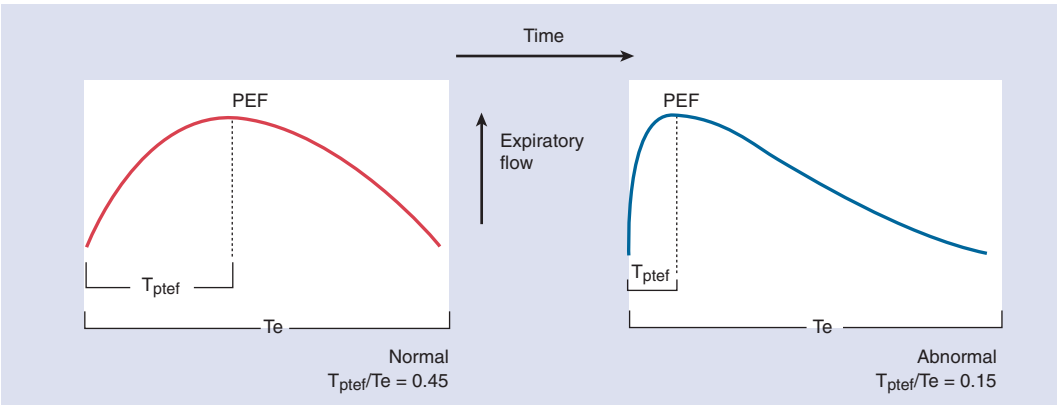

Figure 12-8 Calculation of the ratio of time to T_{ptef}/T_E from tidal expiratory flow and time recordings. PEF, peak expiratory flow.

curve represents an "integrated" output from the respiratory system, and factors other than airway conductance are likely to influence the expiratory flow pattern. Tptef/TE is also influenced by respiratory rate, becoming lower as respiratory rate increases and becoming lower in the prone than the lateral or supine sleeping positions.[39,40] Thus, it is not possible to assign precise physiologic meaning to Tptef/TE.

LUNG FUNCTION TESTING IN PRESCHOOL-AGED CHILDREN

Children under the age of 7 to 8 years are frequently unable to perform the standard lung function tests used in older children and adults. Evaluating lung function in young children is important not only for clinical reasons but also due to the considerable growth and development of the respiratory system that occur, with associated changes in lung mechanics.[41] Children commonly present with recurrent cough and wheeze during this period. Many of these children will lose their symptoms as they grow, yet others will continue to have asthma that persists into adult life.[42] The treatment implications of these two clinical patterns are different, and we are currently hampered by a lack of objective assessments to help distinguish between these two patterns. In addition, children recovering from chronic neonatal lung disease and children afflicted with cystic fibrosis are prone to recurrent or persistent respiratory symptoms. Objective assessments of pulmonary function in these children would be expected to improve clinical management.

The preschool-aged group presents a number of special challenges. Children in this age group are not able to voluntarily perform many of the physiological maneuvers required for the pulmonary function tests used in older children and adults. They have a short attention span and are easily distracted. Due to these issues, the children need to be engaged and encouraged by the operator to participate in the test. A child-friendly laboratory is essential for success, and staff must be prepared to adjust to the child's schedule.

A number of pulmonary function tests have been attempted in conscious children within the preschool-aged group. These include standard spirometry,[43-50] $\dot{V}$maxFRC,[51-53] forced oscillation,[54-60] interrupter resistance,[55,58,59,61-67] specific airway resistance measured in a plethysmograph,[58,59,68] FRC using gas dilution techniques,[53,66,69] and measurements of gas mixing indices.[17,18] Commercial equipment is available for most of these tests, although not specifically designed for preschool-aged children. Equipment dead space, resistance, and software programs designed for adults, not young children, may introduce unpredictable errors into the measurements, and no systematic research on these factors has been conducted.

The emotional developmental stage of the preschool-aged child will be an important determinant of the child's success at performing pulmonary function tests. This influence will be greatest in tests requiring more active cooperation from the child. For example, young children frequently have difficulties in performing the forced expiratory maneuvers required for spirometry. They can either blow "hard" or "long," but frequently cannot blow both "hard and long."[44] Measurements that can be made during tidal breathing, such as with forced oscillation, the interrupter technique, and gas washout techniques, may be more suitable for the child unable to accurately perform spirometry.

The physiological developmental stage of the respiratory system must also be considered in determining which outcome variables are applicable to this age group. For example, recent studies have demonstrated that the ratio of FEV_1 to forced vital capacity in healthy 5- to 6-year-old children is approximately 90% to 95%,[43,46,49,50] implying that young children essentially empty their lungs within 1 second. The physiological and clinical utility of FEV_1 comes from its location on the effort-independent (flow-limited) part of the maximal forced expiratory flow-volume (MEFV) curve (see Chapters 7 and 13). The flow-limited portion of the MEFV curve extends down to lung volumes as low as 85% to 90% of exhaled vital capacity in adults. The ability to maintain flow-limitation at low lung volumes depends largely on the ability of the chest wall muscles to maintain sufficient driving pressure to exceed that needed to ensure flow-limitation. It is highly unlikely that children in the preschool-aged group will have the chest wall muscle strength to maintain flow-limitation to lung volumes as low as 90% exhaled vital capacity. While this concept is not new,[70] the use of variables such as $FEV_{0.75}$ or $FEV_{0.5}$ has not yet been adopted into clinical practice and most commercial equipment does not report such variables.

The most appropriate lung function test for use in the preschool-aged group will depend on the purpose for measuring lung function. The interrupter technique is easily implemented and is suitable for use in epidemiological studies, particularly those involving measurements in the field. However, it may be more suited for studies reporting group mean data than for studies reporting individual data. Measurements capable of reflecting changes in the lung parenchyma, such as gas washout techniques and potentially forced oscillation, are likely to be more suitable for detecting early lung disease in a condition such as cystic fibrosis, which is known to start in the peripheral airways. The clinical and research roles for measuring bronchodilator responses and for provocation testing still need to be evaluated.

CHAPTER 13 Lung Function in Cooperative Subjects

Peter D. Sly, Rachel A. Collins, and Wayne J. Morgan

TEACHING POINTS

- Descriptive terms have been used to subdivide lung volumes into a number of fractions related to normal physiologic function where each subdivision is called a *volume*, and any combination of two or more volumes is called a *capacity*.
- The lung becomes stiff near total lung capacity with a marked decrease in compliance.
- The energy used to move the lungs during quiet breathing is proportional to volume multiplied by elastance plus flow multiplied by resistance. During tidal breathing, 90% of the energy expended is to overcome elastic forces.
- Lung function can be evaluated in children unable to perform forced expiratory maneuvers by using forced oscillation systems.
- Expiratory flow is proportional to lung elastance and inversely proportional to airway resistance, but is independent of the force driving flow over most of the expired vital capacity as long as reasonable effort is made.
- The forced vital capacity and forced expiratory volume in 1 second (FEV_1) are the most informative measures obtained with spirometry. In young children, timed volumes of shorter duration ($FEV_{0.5}$, $FEV_{0.75}$) provide information comparable to FEV_1 in older children and adults.

The measurement of pulmonary function provides an objective assessment of the state of the respiratory system and useful information for the diagnosis and management of respiratory tract illnesses in adults and children. A basic knowledge of the physiologic principles behind the tests and techniques used for making the measurements is necessary to understand the appropriate use of lung function testing and to intelligently interpret the data produced. The American Thoracic Society (ATS) and European Respiratory Society (ERS) have revised their interpretive strategies.[1]

Many measurements of respiratory function are based on forced expiratory maneuvers. Spirometry has been shown to be feasible in preschool-aged children as young as 3 years[2-5] and can be performed successfully in 70% to 80% of children by the age of 5 to 6[6] with the use of visual incentives and extensive coaching by staff experienced in measuring pulmonary function in children. A well-trained technician experienced in handling children and a laboratory setting that children do not find threatening are essential for gaining the child's confidence and producing reliable measurements of pulmonary function.[7] An ATS/ERS statement[8] outlines general standards for lung function testing and includes guidelines for selection and training of personnel.

This chapter deals with the basic physiologic principles of lung function testing. For applications of these tests in particular conditions, the reader is referred to the chapters dealing with those conditions.

PRINCIPLE 1: LUNG VOLUMES

The measurement of static lung volume (i.e., the amount of gas within the lungs at any given point during inflation or deflation) can provide important information about the state of the respiratory system. Also, because the value of many parameters of lung function, including resistance, compliance, and forced expiratory flows, depends on the lung volume at which they are measured, knowledge of lung volume aids interpretation of other measures of lung function.

Subdivisions of Lung Volume

Traditionally, descriptive terms have been used to subdivide lung volume into a number of fractions related to normal physiologic function (Fig. 13-1). By convention, each subdivision is called a *volume*, whereas any combination of two or more volumes is called a *capacity*. The more commonly used subdivisions follow:

1. *Tidal volume* (V_T) is the volume of gas breathed in and out with each breath.
2. *Vital capacity* (VC) is the maximum volume that can be exhaled after a maximal inspiration (i.e., VC = V_T + inspiratory reserve volume + expiratory reserve volume).
3. *Functional residual capacity* (FRC) is the amount of gas remaining in the lungs at the end of expiration (whether that expiration is during tidal breathing or during periods of increased ventilatory requirements such as exercise).
4. *Total lung capacity* (TLC) is the total amount of gas within the lungs after a maximal inspiration (TLC = FRC + inspiratory capacity).
5. *Residual volume* (RV) is the amount of gas left in the lungs after a maximal expiration (RV = TLC − VC).

The commonly used terms to subdivide lung volume are illustrated in Figure 13-1.

With normal tidal breathing in adults and older children, the normal end-expiratory lung volume (i.e., FRC) coincides with the elastic equilibrium volume (EEV) of the respiratory system. This EEV occurs where the outward elastic recoil of

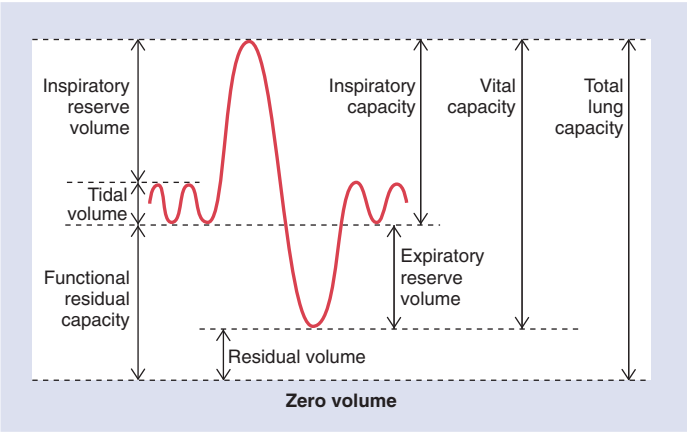

Figure 13-1 The subdivisions of lung volume.

the chest wall is balanced by the inward elastic recoil of the lungs (Fig. 13-2). The EEV is the volume the respiratory system assumes if all muscle forces are relaxed (e.g., during passive expiration) and normally occurs at approximately 40% of VC. However, under various normal and abnormal clinical situations, FRC may be above or below EEV. At times of increased ventilatory requirements, such as during exercise or with lung disease, active expiration can push FRC below EEV. Similarly, if the recoil of the chest wall is decreased (e.g., in normal neonates) or if the lung recoil is increased, such as that seen in diseases characterized by "stiff lungs" (e.g., respiratory distress syndrome), EEV may occur at a lower lung volume, at which there is risk of closure of the small airways. Breathing from low lung volumes is inefficient because extra force is required to open the closed airways. Under these circumstances, FRC is usually actively elevated above EEV by various means, including an increased respiratory rate, thus beginning the next inspiration before EEV has been reached, and a slowed expiration caused by contracting the inspiratory muscles or adductor muscles of the glottis.

PRINCIPLE 2: RESISTANCE AND COMPLIANCE

Elastic Properties of the Respiratory System

The respiratory system is composed of a collection of elastic structures. When a force is applied to an elastic structure, the structure resists deformation by producing an opposing force to return the structure to its relaxed state. This opposing force is known as the *elastic recoil pressure*. The force required to stretch a purely elastic structure depends on how far it is stretched, not how rapidly it is being stretched. Similarly, the pressure required to overcome the elastic recoil of the lung and chest wall depends on the lung volume above or below EEV. The *elastic recoil pressure* (Pel) divided by the lung volume gives a measure of the elastic properties of the respiratory system (*elastance* [E]): E = Pel/V. The reciprocal of elastance is known as *compliance* (C) and describes how much the respiratory system is inflated for a given change in applied pressure: C = V/Pel. When lung volume is plotted on the ordinate and elastic recoil pressure is plotted on the abscissa, the slope of the pressure-volume curve is equivalent to the compliance of the respiratory system (Fig. 13-3).

Dynamics of Respiration

Ventilation of the lungs involves motion of the respiratory system, which is produced by forces required to overcome the elastic, flow-resistive, and inertial properties of the lungs and chest wall. Under normal circumstances, these forces are produced by the respiratory muscles.

The force required to move a block of wood over a surface is determined by the friction between the block of wood and the surface and by how fast the wood is moving. It is not, however, determined by the block's position. Similarly, the pressure required to produce a flow of gas between the atmosphere and the alveoli must overcome the frictional resistance of the airways. This pressure is proportional to the flow ($\dot{V}$) (i.e., the rate at which volume is changing), as follows:

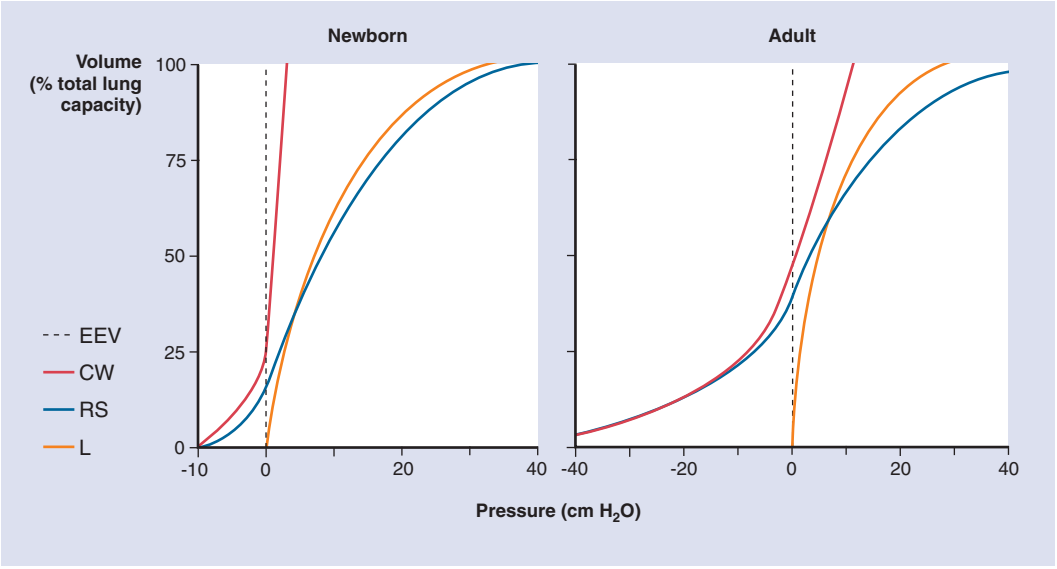

Figure 13-2 Pressure-volume curves of the newborn and adult lung, demonstrating the effect of lung (L) and chest wall (CW) compliance on elastic equilibrium volume (EEV). RS, respiratory system. (Redrawn from Agostini E: J Appl Physiol 14:909, 1959.)

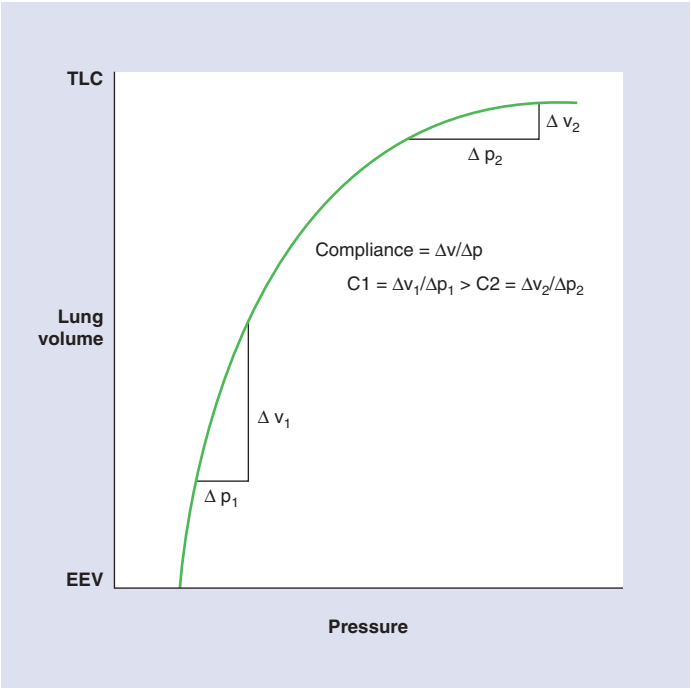

Figure 13-3 Static pressure-volume curve of the lung allows calculation of compliance (C), which decreases at high lung volumes. EEV, elastic equilibrium volume; TLC, total lung capacity.

$$\overline{Pao - P_A = Pfr \propto \dot{V}}$$

where Pao is pressure at the airway opening (usually atmospheric pressure), P_A is alveolar pressure, and Pfr is the pressure required to overcome frictional resistance. The pressure required to produce a unit of flow is known as the *flow resistance* (R), as follows:

$$\overline{R = Pfr/V'}$$

Most commonly used tests of pulmonary function model the respiratory system as a single compartment with a single resistance and a single elastance (Fig. 13-4). The equation of motion describing the balance of forces acting on the system during ventilation follows:

$$\overline{P = EV + R\dot{V} + I\ddot{V}}$$

where P is the applied pressure, I is the coefficient of inertance, E is elastance, $\dot{V}$ is gas flow, and $\ddot{V}$ is gas acceleration. Under most circumstances, the inertance is negligible and therefore ignored. During spontaneous breathing, the applied pressure is produced by the respiratory muscles and can be measured as the transpulmonary pressure. During tidal respiration, approximately 90% of the applied pressure is required to overcome elastic forces, and approximately 10% is required to overcome flow-resistive forces.

Traditionally, the majority of the force developed during breathing has been thought to be required to move gas through the airways, with little energy dissipated by the tissues of the respiratory system. In recent years, the contribution of tissue viscoelasticity to the behavior of the respiratory system has become increasingly apparent. The energy

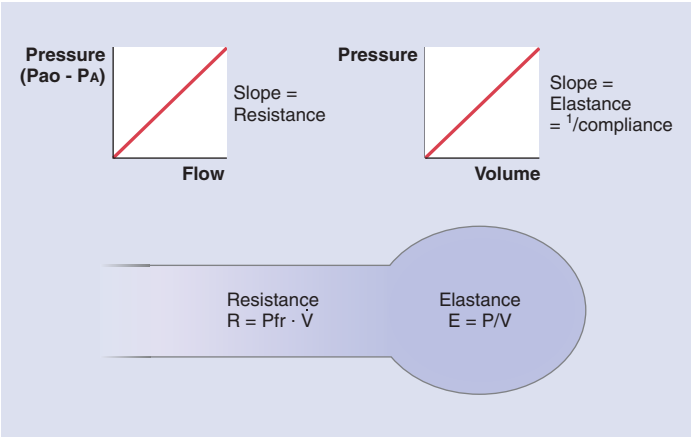

Figure 13-4 Diagram of the single-compartment model of the lung, consisting of a resistance and compliance in series. Pao, pressure at the airway opening.

expended moving the tissues has been called *tissue viscance* or *resistance*, although it is a non-Newtonian resistance. When measured during inspiration, tissue resistance increases with increasing lung volume,[9,10] whereas airway resistance falls. Tissue resistance contributes approximately 65% of respiratory system resistance at FRC in mechanically ventilated animals and increases to as much as 95% at higher lung volumes.[10,11] The contribution of tissue resistance to respiratory system resistance in humans under the same circumstances is not known.

Physiology: Measurement Techniques

MEASUREMENT OF LUNG VOLUMES

Plethysmography

Thoracic gas volume (Vtg) at FRC is usually measured directly in a plethysmograph using techniques based on Boyle's law.[12] In other words, for a given amount of gas at a constant temperature, the product of pressure (P) and volume (V) is constant, as follows:

$$\overline{P \times V = (P + \Delta P) \times (V + \Delta V)}$$

Assuming the product $\Delta P \bullet \Delta V$ is negligible, this equation can be written as follows:

$$\overline{V = -\Delta V/\Delta P \times P}$$

Vtg is measured by having the subject make breathing efforts against an occluded airway while sitting in a plethysmograph. During occluded breathing efforts, the changes in intrathoracic gas volume are assumed to occur by gas compression-decompression alone. From Boyle's law, as previously expressed, the Vtg at which the occluded breathing efforts were made can be calculated, as follows:

$$\overline{Vtg = -\Delta V/\Delta P_A \times P_B}$$

where ΔV is the change in gas volume during the occluded breathing efforts, which is measured with the plethysmograph; ΔP_A is the change in alveolar pressure, which is measured from changes in airway opening pressure during the

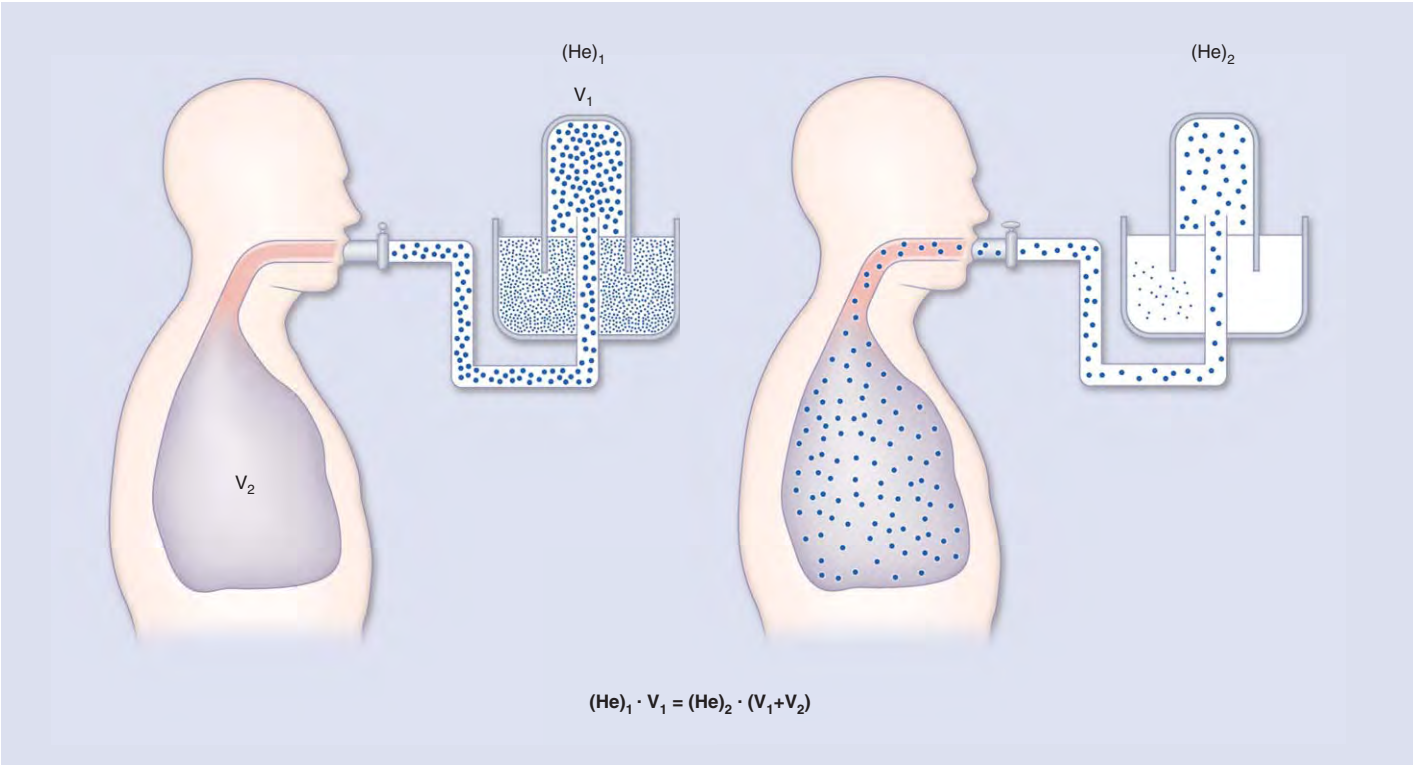

Figure 13-5 The calculation of lung volumes using the helium-dilution technique. He, helium; V, volume.

occluded breathing efforts; and P_B is the barometric pressure in the room minus water vapor pressure at body temperature.

The application of Boyle's law to plethysmography is based on the following assumptions:

1. During occluded breathing efforts, there is no flow along the airways, and the changes in alveolar pressure can be represented by changes in airway opening pressure.
2. Gas compression and decompression, both within the lungs and within the plethysmograph, occur under isothermal conditions.
3. Compression of abdominal gas is negligible.

In healthy subjects seated in an adult-sized plethysmograph, these assumptions are reasonably valid. The major potential source of error comes from the compliance of the upper airways, especially the cheeks.[12] The respiratory system can be represented as two compliant compartments (i.e., the upper airways and the alveolar gas compartment) separated by a resistive element (the airways). Changes in pressure in the alveolar compartment are transmitted to the airway opening with a time constant determined by the airway resistance and the compliance of the upper airway. If either the airway resistance or the compliance of the upper airway increases, the time constant of transmission may become long enough that the changes in airway opening pressure underestimate changes in alveolar pressure, resulting in an overestimation of the true lung volume. For subjects with normal lungs, supporting the cheeks with hands is usually sufficient to ensure accurate measurements of lung volume.

The original plethysmographs were largely constant-volume, "pressure" plethysmographs. However, this type has now been largely replaced by variable-volume "flow" plethysmographs. These plethysmographs include a pneumotachograph in the wall and measure the flow into and out of the box produced by chest wall movement during the occluded breathing efforts. This flow is then integrated to give the volume change resulting from compression of the Vtg during occluded breathing efforts. These flow plethysmographs have the advantage of an improved frequency response at low frequencies without sacrificing performance at higher frequencies. They are suitable for measuring volume variations over a wide range of amplitudes and frequencies and also allow the measurement of forced expiration within the plethysmograph.

Once Vtg has been measured, TLC and RV are calculated from Vtg and measurements of inspiratory capacity and VC. The RV may be falsely elevated if the child does not exhale fully. RV is one of the most variable of all lung function tests in children,[13] and the results must be interpreted with caution. Caution also must be exercised in the measurement and interpretation of lung volumes by plethysmography in the presence of marked airway obstruction.

Gas Dilution

Alternatively, lung volumes can be measured by gas dilution. In theory, these techniques are simple, involving the measurement of the dilution of a known concentration of gas by an unknown volume (the Vtg) (Fig. 13-5). With measurement of the final gas concentration, it is possible to calculate Vtg. Although the helium-dilution method is simple to perform and is relatively inexpensive,[14] it is time consuming, has potentially limiting cooperation, and is likely to significantly underestimate the Vtg in the presence of airway obstruction.

The apparatus required for measuring lung volume by gas dilution is relatively simple; it consists of a spirometer, gas reservoir, gas analyzer, and system for supplying oxygen and removing carbon dioxide during the test. The system functions as a closed circuit, which must be free of leaks. The subject is instructed to breathe to and from the spirometer, and when a regular respiratory pattern has been established, the circuit is switched so that the subject breathes to and from the gas reservoir, which contains a known concentration of the indicator gas. By convention, the indicator gas is introduced at the end of expiration. When the gas concentration in the circuit (including the lungs) reaches a new equilibrium, the final concentration is used to calculate the new volume of the system (i.e., circuit plus lungs). Any leak in the circuit results in a falsely low final concentration and an overestimation of the end-expiratory lung volume. Gas-dilution techniques measure the part of the lung volume that is readily available for gas exchange and does not measure "trapped" gas. Therefore in subjects with significant airway obstruction, the Vtg measured by gas dilution is likely to be significantly lower than that measured by plethysmography.

MEASUREMENT OF RESISTANCE AND COMPLIANCE

Plethysmography

Airway resistance is most commonly measured in children by plethysmography. When a subject breathes within a plethysmograph, volume changes are recorded in proportion to variations in alveolar pressure and in alveolar gas volume (i.e., Vtg), provided volume changes due to other influences, such as changes in gas conditions from body temperature, pressure, and saturation within the lungs to ambient temperature and pressure (saturated) within the box, can be eliminated. Under these circumstances, the change in volume can be expressed as follows:

$$\Delta V = \Delta P_A \times Vtg/P_B$$

Alveolar pressure is the product of resistance to gas flow by flow at the airway opening (Raw), as follows:

$$\Delta V = (Raw + Req) \times \dot{V} \times Vtg/P_B$$

where Req is the resistance of the equipment connected to the airway. Calculation of airway resistance follows:

$$Raw = (\Delta V/\dot{V} \times P_B/Vtg) - Req$$

This technique has been standardized for use in adults and children and includes measuring Vtg, as previously described; opening the shutter; connecting the subject to the box or a gas-conditioning circuit through a flowmeter; and asking the patient to pant while supporting the cheeks with the hands. Panting is usually made at a frequency of 1 to 3 Hz with a V_T of 50 to 150 mL, giving an airway opening flow of 0.3 to 3.0 L/s peak to peak. Precise details are published elsewhere.[12]

Occlusion Techniques and Esophageal Manometry

Measurement of compliance in spontaneously breathing subjects requires either that the subject relax the respiratory muscles against an occluded airway at various points during inspiration and expiration or the insertion of an esophageal balloon. These techniques measure compliance of the respiratory system and lung and are not commonly used in children and are not discussed here. Measurement of airway resistance using occlusion techniques is feasible in preschool-aged children[15] and is discussed in Chapter 12.

Forced Oscillation

Because the forced oscillation technique requires little active cooperation from the subject, it is attractive for use in children, particularly those unable to perform forced expiration adequately. It was introduced in the 1950s as a method for determining the impedance of the total respiratory system (Zrs) by applying sinusoidal variations in pressure to the respiratory system (Prs) and measuring the resulting flow ($\dot{V}$).[16] In essence, Zrs is calculated from Prs/$\dot{V}$ and can be expressed as an amplitude ratio and a phase shift between the signals. This technique can also measure Zrs at different frequencies and thus represents the frequency-dependent behavior of the respiratory system (Fig. 13-6). It assumes that both the measuring system and the mechanical properties of the respiratory system are linear during the time of measurement and for the amplitude of the pressures applied.[17] The ERS guidelines for measurement and reporting of forced oscillation data have been described by Oostveen and associates.[18]

The signal applied to the respiratory system is known as a *forcing function*. Over the years, a number of different forcing functions have been used to measure Zrs. The simplest consists of a single sinusoid, which measures Zrs at that (single) frequency. Measurements can be repeated at different frequencies, and a picture of the frequency-dependent behavior of the respiratory system can be built. Alternatively, multiple sinusoids can be applied at the same time. If this approach is adopted, the clinician must carefully limit the amplitude of the resulting signal because too great an amplitude may be uncomfortable for the subject and result in nonlinear behavior of the respiratory system. Forcing functions can be opti-

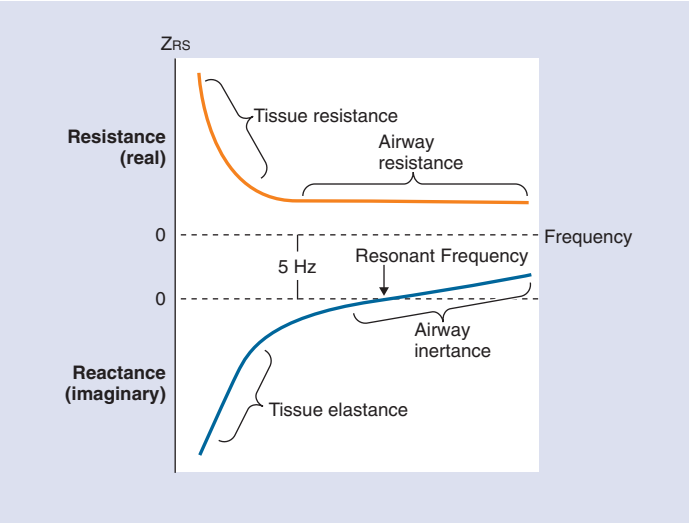

Figure 13-6 Zrs data from the forced oscillation technique. Low-frequency data represent tissue elastance and resistance, and high-frequency data represent airway resistance and inertance. *Real* and *imaginary* are terms defining the phase relationship of the signals.

mized in a number of ways, such as ensuring that the components are not integer multiples of one another[19] or that no component is either the sum or the difference of other components.[20] Both of these optimization procedures are designed to reduce the effects of nonlinearities and to reduce harmonic distortion. For more detailed descriptions, the reader is referred to the specialized literature.

Whatever forcing function is used, some estimate of the reliability of the Zrs data is required. Reliability is generally assessed by determining the "coherence function." This is in essence the correlation between the input signal (the forcing function) and the output signal (the flow, $\dot{V}$). Perfect correlation results in a coherence value of 1.0. By convention, Zrs is considered to be reliable if the coherence is at or above 0.95 at a particular frequency. Measurement noise reduces the reliability of Zrs, which is reflected in a decreased coherence. In this context, the breathing frequency and heart rate can decrease the reliability of Zrs at those frequencies (and at their harmonics) and usually limit the lower end of the frequency spectrum that can be measured in children.[21-23]

Calculation of Zrs from data obtained using forcing functions that contain multiple frequencies is usually performed in the frequency domain. This is done using fast Fourier transformations or similar mathematical techniques. A description of the mathematics involved is beyond the scope of this chapter, but the resultant Zrs spectrum is conventionally expressed as *real* and *imaginary parts*. The real part is related to the component in phase with the pressure signal and reflects the resistive behavior of the respiratory system. The imaginary part is related to the component of flow out of phase with pressure and reflects the elastic and inertive behaviors of the respiratory system (see Fig. 13-6).

Many studies have used parameter-estimating techniques to produce values of resistance, elastance, and inertance from Zrs spectra.[23-31] These studies have demonstrated that the real part of Zrs reflects airway resistance at higher frequencies (above 5 to 10 Hz in adults and older children), whereas the low frequencies (<2 Hz) reflect the resistive properties of the lung tissues and chest wall (see Fig. 13-6). At low frequencies, the imaginary part is dominated by elastic behavior, whereas at high frequencies, inertive behavior dominates. The elastic and inertive behavior of the respiratory system are 180 degrees out of phase with each other (i.e., they have the opposite sign). The frequency at which these properties are equal and opposite and therefore cancel each other out is known as the *resonant frequency* of the respiratory system (see Fig. 13-6). This can be recognized as the frequency at which the imaginary part of Zrs crosses the zero axis. The resonant frequency has been reported to change with age and with lung disease.[21,23,32]

The use of forced oscillation in children has been limited by some of the practical problems encountered when applying this technique and by the lack of user-friendly, commercially available equipment. The following major technical problems need to be overcome:

1. Interference from the breathing frequency
2. Leak around the mouthpiece
3. Upper airway compliance

The breathing frequency causes a loss of coherence from the forcing function for up to five harmonics of the fundamental frequency. In practice, this means that no useful Zrs data are obtained at frequencies below 4 Hz in spontaneously breathing children. Adults are frequently able to hold their breath with their glottis open for long enough to measure Zrs at lower frequencies. This does not appear to be the case in most children.

Leak around the mouthpiece acts as a resistance pathway in parallel with the respiratory system. This resistance mainly affects the lower frequencies and results in overestimation of resistance and underestimation of elastance. The effect of a leak is compounded in situations in which the airway resistance is increased, such as with airway disease or during bronchoprovocation tests.

The compliance of the upper airways acts as a shunt compliance in parallel with the respiratory system. This results in shunting of the forcing function away from the respiratory system, especially at higher frequencies. This in turn results in overestimation of airway resistance and underestimation of inertance (with a shift of the resonant frequency to a higher frequency). The effect of a shunt compliance is increased in situations in which airway resistance is increased (see previous section).

Measurements of Forced Expiration

Measurements of forced expiration have become the major method used to detect the presence of obstructive lung disease. The ATS/ERS guidelines for spirometry have been updated.[33] The use of such measurements is derived from the observation that expiratory flow is independent of the force driving flow over most of the expired VC as long as reasonable effort is made[34] (Fig. 13-7). This observation led directly to the description of the maximum expiratory flow volume (MEFV) curve, which emphasized that at most lung volumes, there was a limit to maximum expiratory flow ($\dot{V}$max). The peak expiratory flow (PEF) is discussed later, and flows near RV may be effort dependent because expiratory muscle contraction may not be able to provide sufficient force to maintain flow limitation at this low lung volume.

FLOW LIMITATION

The mechanism for expiratory flow limitation is complex. Elegant descriptions can be read in the *Handbook of Physiol-*

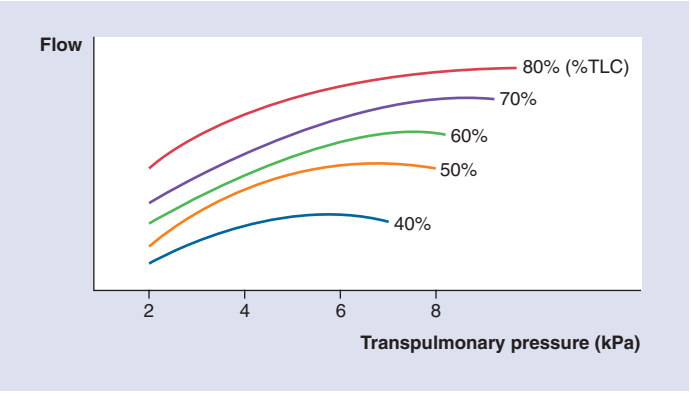

Figure 13-7 Isovolume pressure-flow curves in a normal adult at different proportions of total lung capacity. (Redrawn from Tammeling GJ, Quanjer PH: Contours of Breathing, Burlington, Ontario, Canada, 1985, Boehringer Ingelheim Pharmaceuticals.)

ogy published by the American Physiological Society.[35] In fluid dynamic terms, a system cannot carry a greater flow than the flow for which fluid velocity equals wave speed at some point in the system. The wave speed is the speed at which a small disturbance travels in a compliant tube filled with fluid. In the arteries, this is the speed at which the pulse propagates. In the airway the speed is higher than this, mainly because the fluid density is lower. The wave speed (c) in a compliant tube with an area (A) that depends on a lateral pressure (P) filled with a fluid of density (ρ), is given by:

$$c = (AdP/\rho dP)^{1/2}$$

where dP/dA is the slope of the pressure-area curve for the airway (i.e., an expression of airway wall compliance). $\dot{V}max$ is the product of the airway area and fluid velocity at wave speed, as follows:

$$\dot{V}max = cA$$

At high lung volumes, the flow-limiting site in the human airways is typically in the second and third airway generations. As lung volume decreases, airway caliber decreases, the flow-limiting site moves peripherally, and $\dot{V}max$ decreases. At low lung volumes, the density dependence of $\dot{V}max$ is small, and the viscosity dependence is large and becomes the predominant mechanism limiting expiratory flow.

Flow limitation in a compliant tube is accompanied by "flutter" of the walls at the site of flow limitation.[36] This flutter conserves the energy in the system because the driving pressure in excess of that required to produce $\dot{V}max$ is dissipated in causing the wall flutter. In the presence of airway obstruction, this flutter may become large enough to generate sound, which is heard as wheezing. Thus, expiratory wheezing is a sign of expiratory flow limitation.

MEFV CURVES

Most children can accomplish forced expiratory maneuvers by the age of 7 years. To produce reliable MEFV curves, children need to be able to give a maximal effort without hesitation for at least 3 seconds. In young children, a learning effect may be operative, so more than the standard three tests may be required to obtain consistent, representative data. The VC and the forced expiratory volume in 1 second (FEV_1) are the most informative measures. Indices derived from expiratory times of less than 1 second may be useful in young children who are unable to produce prolonged expirations,[6] however, the discriminative ability of these indices is yet to be determined (see Chapter 12 for further discussion). Forced expiratory flows at lower lung volumes are more sensitive, but their variability is greater. The forced expiratory flow occurring between 25% and 75% of expired VC is frequently used as an indication of "small airway" disease. This practice is based on the assumption that the site of flow limitation is likely to exist in the small airways over this volume range. There is no direct evidence to support this assumption, especially in children. Figure 13-8 shows the relationship between the spirogram (a volume-time plot of forced expiration) and an MEFV curve.

PEAK EXPIRATORY FLOW

Peak expiratory flow (PEF) is the maximum flow achieved during a forced expiration starting from the level of maximal lung inflation.[37] Primarily a measure of large airway caliber, PEF can be used to identify and assess airflow limitation in clinical practice and epidemiologic studies and can aid

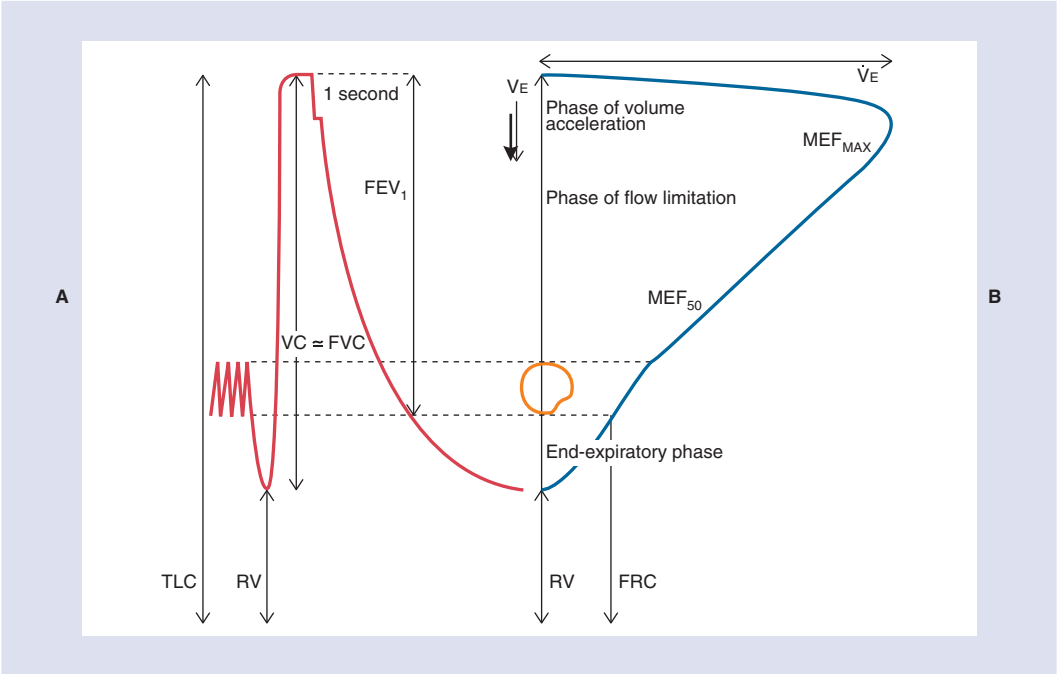

Figure 13-8 **A,** Spirogram. **B,** Maximum expiratory flow volume curve. FEV_1, forced expiratory volume in 1 second. (Redrawn from Tammeling GJ, Quanjer PH: Contours of Breathing, Burlington, Ontario, Canada, 1985, Boehringer Ingelheim Pharmaceuticals.)

in the monitoring of disease progress and the effects of treatment.

In healthy subjects, PEF is determined by lung volume, airway caliber, lung elastic recoil, expiratory muscle strength, and the duration of pause at TLC before forced expiration. Traditionally, PEF was not thought to be flow limited because a plateau is not seen on isovolume pressure-flow curves, presumably because of the inability of the respiratory muscles to generate sufficient force. More recently, it has been demonstrated that PEF is determined by a wave-speed ($\dot{V}ws$) flow-limiting mechanism in the central airways, occurring when the velocity of the accelerating flow reaches $\dot{V}ws$ at some point in the airway.[38] The three main contributing factors to PEF in this model are Pel, the resistance upstream of the flow-limiting segment (Pfr), and the relationship between distending pressure and airway cross-sectional area (A) at the most upstream position at which $\dot{V}$ equals $\dot{V}ws$. According to this model, PEF will be large when Pel is large, Pfr is small, A is large, and airway wall compliance is small. Breath-hold at TLC before performance of the expiratory maneuver results in stress-relaxation of the viscoelastic elements of the lung and decreased airway wall compliance, reducing the maximum achievable wave speed and thus PEF.[39]

Flow limitation at PEF does not mean that it is independent of effort. The magnitude of PEF depends on how this maximum flow is reached. If expired volume from the TLC at which PEF is reached is small, PEF will be higher because at higher lung volume, the higher elastic recoil pressure and lower upstream resistance result in a greater wave speed and a higher PEF. In any interpretation of changes in PEF, the magnitude of effort and the volume at which PEF is reached are critical.

Miniature PEF meters are cheap and portable and can be used in the home, but there is little evidence to suggest that home PEF monitoring improves clinical outcomes. Issues with equipment accuracy, compliance, and lack of technical expertise all contribute to the unreliability of home PEF monitoring, and evidence suggests that patient education and symptom monitoring may be more useful in disease management.[40]

PEF increases with height during childhood; however, there is a wide range of normal values at any given height, making expression of a measured PEF as a percentage of predicted normal based on population studies unlikely to be useful. PEF may be more usefully expressed relative to each child's "personal best" determined by monitoring it for 1 to 2 weeks at a time when the child is well. This value can then be used as a basis for comparison during exacerbations of asthma.

CHAPTER 14

Gas Exchange and Acid-Base Physiology

Gas Exchange, Oxygen Delivery, and Ventilation

Marc D. Berg and Robyn J. Meyer

TEACHING POINTS

- Major contributors to oxygen delivery are hemoglobin level, oxygen saturation, and cardiac output.
- Interference with any step in oxygenation, including pulmonary gas exchange, loading, transport, unloading, and tissue gas exchange, may cause hypercapnia and hypoxic cellular damage.
- Arterial hypoxemia may be caused by diffusion defects, shunting, or hypoventilation.
- Arterial carbon dioxide is determined mainly by the degree of alveolar ventilation in relation to the patient's carbon dioxide production.

BASIC PHYSIOLOGY OF GAS EXCHANGE

Normal Gas Exchange

In the body, gas exchange occurs via simple diffusion at the lung (pulmonary gas exchange) and at the tissue (intracellular gas exchange). Once a gas has diffused into the blood at one of these sites, it is dissolved into plasma and bound to hemoglobin (loading). The gas then circulates with blood (transport) until it reaches the other site of gas exchange. The gas is then released from the blood (unloading), thus completing the process of gas exchange. Eventually, oxygen is consumed in the tissue, and carbon dioxide is eliminated through the lungs.

Oxygenation, the process by which oxygen is added to the pulmonary blood, occurs at the alveolus. The term *ventilation* generally refers to the removal of carbon dioxide from the alveoli. The rate of gas diffusion through the alveolar-capillary membrane is determined by several factors, including (1) the pressure difference of each gas between both sides of the membrane, (2) the solubility of the gas, (3) the surface area of the membrane, (4) the distance through which the gas must diffuse, and (5) the molecular weight of the gas.[1]

Different gases at the same pressure diffuse at different rates proportional to their diffusion coefficients. Solubility and molecular weight are two important factors that determine the diffusion coefficient of a gas. If the diffusion coefficient for oxygen is 1, the relative diffusion coefficients for different gases in the body fluid are as follows: carbon dioxide, 20.3; carbon monoxide, 0.81; nitrogen, 0.53; and helium, 0.95. Therefore, carbon dioxide diffuses more rapidly than oxygen across membranes. The rate of equilibration of these gases at the alveolar level, however, is roughly equal because the driving pressure of oxygen is much higher than that of carbon dioxide. The driving pressure is determined by the difference in partial pressure in the alveolus versus the end-capillary.

In normal spontaneous respiration, oxygenation and ventilation occur simultaneously. Any change in ventilation also has an impact on oxygenation. Room air at sea level contains oxygen at a partial pressure of 160 mm Hg. The conducting airways then completely saturate the inspired gas with water vapor, dropping the inspired partial pressure of oxygen (PIO_2) to 150 mm Hg. Assuming a normal ventilation/perfusion ratio in the lung, this results in an alveolar partial pressure of oxygen (PAO_2) of 100, compared with deoxygenated pulmonary arterial blood with a partial pressure of oxygen (PO_2) of about 40 mm Hg; that is, there is a driving pressure for diffusion across the pulmonary alveolar-capillary membrane of 60 mm Hg. This driving pressure coupled with the thin (0.5 μm) alveolar capillary membrane allows complete equilibration of oxygen partial pressure between the alveolus and pulmonary capillary approximately one third of the distance across the alveolus. Room air contains essentially no carbon dioxide and allows the removal of carbon dioxide from pulmonary arterial blood with an equilibration at about 40 mm Hg in the pulmonary blood leaving the alveolus.

Oxygenation improves as PAO_2 increases due to increases in the concentration of inspired oxygen (FIO_2), barometric pressure, or the alveolar ventilation/perfusion ratio. The amount of surface area available for gas exchange increases with increases in mean airway pressure as additional alveoli are recruited. Moreover, the thickness of the interstitial space, the area between the alveolar and capillary basement membranes, is also affected by alveolar pressure. Higher alveolar pressures decrease the thickness of the interstitial space, allowing more effective gas exchange. Although alveolar pressure generally improves oxygenation, it is important to note that excessive distention of the alveolus with very high alveolar pressure may actually worsen oxygenation. This occurs through a tamponade of pulmonary capillary blood

flow secondary to the high alveolar pressure that is transmitted to the pulmonary capillary bed. This leads to the development of ventilation-perfusion ($\bar{V}/\dot{Q}$) mismatch and, as perfusion approaches zero, alveolar dead space. Alveolar dead space is the ventilation of nonperfused alveoli.

Ventilation improves with increased minute ventilation, which is the product of tidal volume and respiratory rate. Any increase in alveolar dead space (V_D) without a concomitant increase in tidal volume (V_T) leads to an increased dead space–to–tidal volume ratio (V_D/V_T) and reduced alveolar ventilation ($\bar{V}_A$). Alveolar ventilation decreases the partial pressure of carbon dioxide (P_{CO_2}) in the alveoli, thereby maintaining a lower alveolar P_{CO_2} (P_{ACO_2}) (40 mm Hg) relative to the pulmonary artery P_{CO_2} (45 to 47 mm Hg). Because the diffusion coefficient of carbon dioxide is 20 times greater than that of oxygen, this small gradient of P_{CO_2} (5 to 7 mm Hg) is all that is needed to support diffusion across the alveolar membrane and remove the carbon dioxide produced during cellular metabolism. At rest, this efficient diffusive process is completed in approximately one-third of the distance through the alveolar capillary bed, thus there is substantive reserve for complete diffusion with increased venous P_{CO_2} or blood flow such as during exercise.

Oxygen Delivery

Loading

P_{AO_2} can be calculated using a simplified version of the alveolar gas equation[2]:

$$\begin{aligned} P_{AO_2} &= F_{IO_2} \cdot (P_B - P_{H_2O}) - PaCO_2/R \\ &= 0.21 \cdot (760 - 47) - 40/0.8 \\ &= 150 - 50 \\ &= 100 \text{ mm Hg} \end{aligned}$$

where F_{IO_2} is fractional concentration of oxygen in room air (~0.21), P_B is barometric pressure at sea level (~760 mm Hg), $PaCO_2$ is partial pressure of arterial carbon dioxide (~40 mm Hg), and R is respiratory quotient (~0.8).

The approximate P_{AO_2} in room air is 100 mm Hg at sea level, and the P_{O_2} of the venous blood entering the pulmonary end-capillary bed averages 40 mm Hg at sea level. Oxygen diffuses into the blood from alveoli with the pressure difference of approximately 60 mm Hg. The P_{O_2} in pulmonary end-capillary blood rises quickly to the level of P_{AO_2}. Bronchial circulation, which accounts for 2% of the total pulmonary blood flow, bypasses the pulmonary circulation. This is known as an intrapulmonary shunt as deoxygenated blood passes through the lungs without receiving oxygen, mixes with newly oxygenated blood and returns to the left atrium to be pumped to the body. Because of this pulmonary shunt effect, the P_{O_2} in arterial blood decreases by approximately 5 mm Hg to 95 mm Hg.

Normally, about 97% of the oxygen in the blood is transported in chemical combination with hemoglobin in the red blood cells, and the remaining 3% is carried in the dissolved state in the water of plasma and cells. Therefore, under normal conditions, oxygen is transported to the tissues almost entirely by hemoglobin. Each hemoglobin molecule can loosely bind to four oxygen molecules. The percentage of the hemoglobin bound with oxygen increases as blood P_{O_2} increases. The affinity of hemoglobin for oxygen increases after the hemoglobin has previously bound with other oxygen molecules.[3] The relationship between oxygen affinity and hemoglobin is described by the oxygen-hemoglobin dissociation curve. This curve is an S-shaped curve that increases maximally between a P_{O_2} of 10 and 50 mm Hg. In a healthy individual, arterial blood has a P_{O_2} of 95 mm Hg, and the oxygen saturation is about 97%. A normal systemic venous P_{O_2} is about 40 mm Hg, with an oxygen saturation of about 75%. The ability of hemoglobin to bind oxygen changes in various conditions, and the oxygen saturation will vary at the same P_{O_2} (Fig. 14-1). The following factors affect oxyhemoglobin affinity: the hemoglobin amino acid sequence (hemoglobinopathy, carboxyhemoglobin, methemoglobin), temperature, P_{CO_2}, pH, and concentration of 2,3-diphosphoglycerate. For example, when blood carbon dioxide is removed by the lung and the blood pH increases, the oxygen-hemoglobin dissociation curve shifts to the left, and more oxygen binds to hemoglobin for transport (Bohr effect), thus improving oxygen loading in the lung.[4] Conversely, oxygen affinity to hemoglobin decreases with decreased pH and increased P_{CO_2} in the tissues, causing the oxygen-hemoglobin dissociation curve to shift to the right, thus facilitating the unloading of oxygen to the tissue (Fig. 14-2).

Transport

Once hemoglobin binds oxygen to become oxyhemoglobin, blood flow transports the oxyhemoglobin to the tissue, where oxygen is needed for efficient energy production.

The total amount of oxygen transported to the tissue is calculated as follows:

$$\begin{aligned} \dot{D}_{O_2} &= CO \cdot Ca_{O_2} \\ &= CO \cdot (Hgb \cdot Sa_{O_2} \cdot 1.34) + (Pa_{O_2} \cdot 0.003) \\ &\sim CO \cdot Hgb \cdot Sa_{O_2} \end{aligned}$$

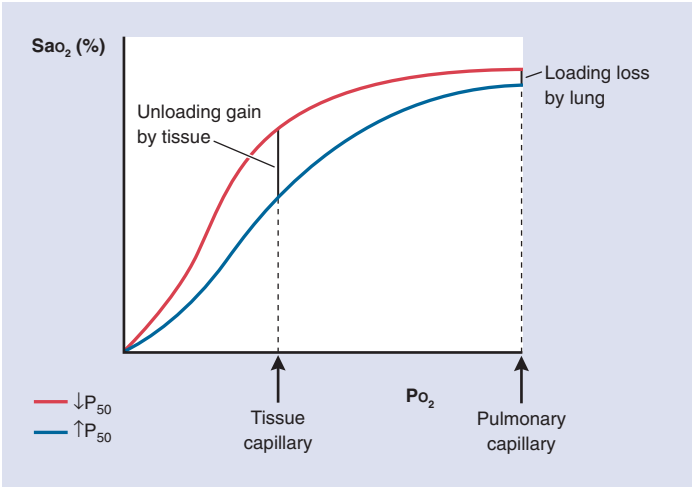

Figure 14-1 The effect on oxygen loading and unloading caused by an increase in oxygen affinity (decrease in P_{O_2} required to saturate 50% of functional hemoglobin [P_{50}]) and a decrease in oxygen affinity (increase in P_{50}). The loading loss and unloading loss and gain are indicated by the heights of the heavy vertical bars between the two curves. Sa_{O_2}, arterial oxygen saturation. (Data from Klocke RA. In Bryan-Brown CW, Ayres SM [eds]: New Horizons: Oxygen Transport and Utilization. Fullerton, CA, Society of Critical Care Medicine, 1987, p. 243.)

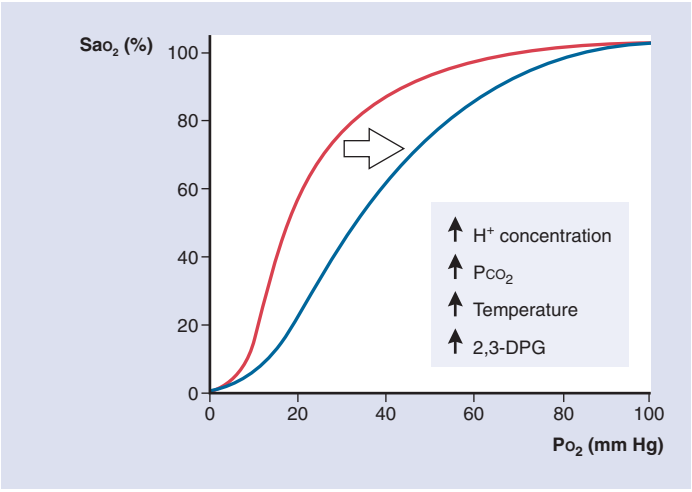

Figure 14-2 Shift of the oxygen-hemoglobin dissociation curve to the right by an increase in the number of hydrogen ions (H^+), the number of carbon dioxide molecules, the temperature, or the concentration of 2,3-diphosphoglycerate (2,3-DPG). (Data from Klocke RA. In Bryan-Brown CW, Ayres SM [eds]: New Horizons: Oxygen Transport and Utilization. Fullerton, CA, Society of Critical Care Medicine, 1987, p. 243.)

where $\dot{D}O_2$ is the total amount of oxygen delivered per minute (in liters per minute), CO is cardiac output (in liters per minute), CaO_2 is arterial oxygen content (in milliliters per liter), Hgb is hemoglobin (grams per deciliter of blood), SaO_2 is arterial oxygen saturation, and PaO_2 is the partial pressure of arterial oxygen (in mm Hg). The dissolved oxygen per PO_2 per deciliter of blood is 0.003 mL/mm Hg/dL of blood.

Example: What is the amount of oxygen delivered when the cardiac output is 5.0 L/min with a hemoglobin level of 15 g/dL, an arterial oxygen saturation of 98%, and an arterial PaO_2 of 100 mm Hg?

$$
\begin{aligned}
DO_2 &= CO \cdot CaO_2 \\
&= CO \cdot (Hgb \cdot SaO_2 \cdot 1.34) + (PaO_2 \cdot 0.003) \\
&= 5\ \text{L/min} \cdot [(15\ \text{g/dL} \cdot 0.98 \cdot 1.34\ \text{mL/g}) + \\
&\quad (100\ \text{mm Hg} \cdot 0.003\ \text{mL/mm Hg/dL})] \\
&= 5\ \text{L/min} \cdot (19.7\ \text{mL/dL} + 0.3\ \text{mL/dL}) \\
&= 5\ \text{L/min} \cdot 20\ \text{mL/dL} \\
&= 1000\ \text{mL of oxygen/min}
\end{aligned}
$$

It is worth noting that the major factors affecting oxygen delivery include cardiac output, hemoglobin level, and oxygen saturation, whereas the effect of dissolved oxygen from arterial PaO_2 is minuscule, 19.7 versus 0.3 mL/dL.

Unloading

When oxyhemoglobin reaches the low PO_2 environment in the tissue, the hemoglobin quickly unloads oxygen. The amount of oxygen unloaded depends on the PO_2 gradient between blood and tissue. When the tissue consumes more oxygen, the tissue PO_2 decreases. Thus, the PO_2 gradient between the blood and tissue increases and allows the hemoglobin to unload more oxygen. If the blood PO_2 is higher than the level necessary to fully saturate hemoglobin with oxygen, however, the amount of oxygen that the hemoglobin unloads changes little (see Fig. 14-2). As noted above, the Bohr effect facilitates unloading of oxygen in the tissue, where carbon dioxide and hydrogen ion levels increase, thus reducing hemoglobin's affinity for oxygen.

Carbon Dioxide

Loading

Unlike oxygen, which primarily binds with hemoglobin, carbon dioxide is carried in four different forms. First, a significant portion of carbon dioxide is transported in the dissolved state, although a small portion of the dissolved carbon dioxide is removed with a small arteriovenous difference. The amount of dissolved carbon dioxide in venous blood is 2.7 mL/dL (PCO_2 of 45 mm Hg) and 2.4 mL/dL at the level of the alveoli (PCO_2 of 40 mm Hg). Because the rate of carbon dioxide diffusion into alveoli depends on the difference between alveolar and venous blood levels of carbon dioxide, the small difference between the levels of dissolved and alveolar carbon dioxide (only 0.3 mL/dL) does not lead to clinically significant carbon dioxide removal.

Second, the dissolved carbon dioxide in the blood reacts with water to form carbonic acid. This mechanism accounts for a very small amount of carbon dioxide transport. There is a direct relationship between carbonic acid and dissolved carbon dioxide. At 37° C, each carbonic acid molecule is in equilibrium with 340 molecules of carbon dioxide. As the level of carbon dioxide increases, the level of carbonic acid also increases. Because PCO_2 and carbonic acid values are higher in venous blood than in arterial blood, venous blood is slightly more acidic (pH, 7.38) than arterial blood (pH, 7.40).

Third, a majority of carbon dioxide travels to the lung in the form of bicarbonate. This is a reversible reaction and accounts for about 70% of the carbon dioxide transported from the tissue to the lung. Although some of the carbon dioxide that enters the blood forms bicarbonate, the amount formed tends to be very small because of the slow reaction rate in plasma. Carbon dioxide diffuses into erythrocytes, where carbonic acid formation rapidly occurs because of carbonic anhydrase in the red blood cells (Fig. 14-3). The carbonic acid dissociates into hydrogen ions and bicarbonate. The hydrogen ion is rapidly buffered by binding to hemoglobin. Bicarbonate diffuses into the plasma via a bicarbonate chloride carrier protein while the chloride moves into the red blood cell to maintain electrochemical neutrality.

Fourth, carbon dioxide reacts directly with amine radicals of hemoglobin molecules to form the compound carbaminohemoglobin. The reaction is slow and accounts only for 20% of carbon dioxide to be removed. The loading process of carbon dioxide in the tissue is facilitated by the Haldane effect; the carbon dioxide–carrying capacity of hemoglobin increases when the oxygen molecule is unloaded at the tissue level.

Transport

Carbon dioxide, which is produced in the tissue, diffuses into the blood, and blood flow carries the three different forms of carbon dioxide to the lung for elimination. Blood flow is a major determining factor in gas transport when the amount of gas loaded remains constant. Besides cardiac output, vascular supply, blood viscosity (e.g., polycythemia), and red cell deformability (e.g., sickle cell disease, microcyte) affect

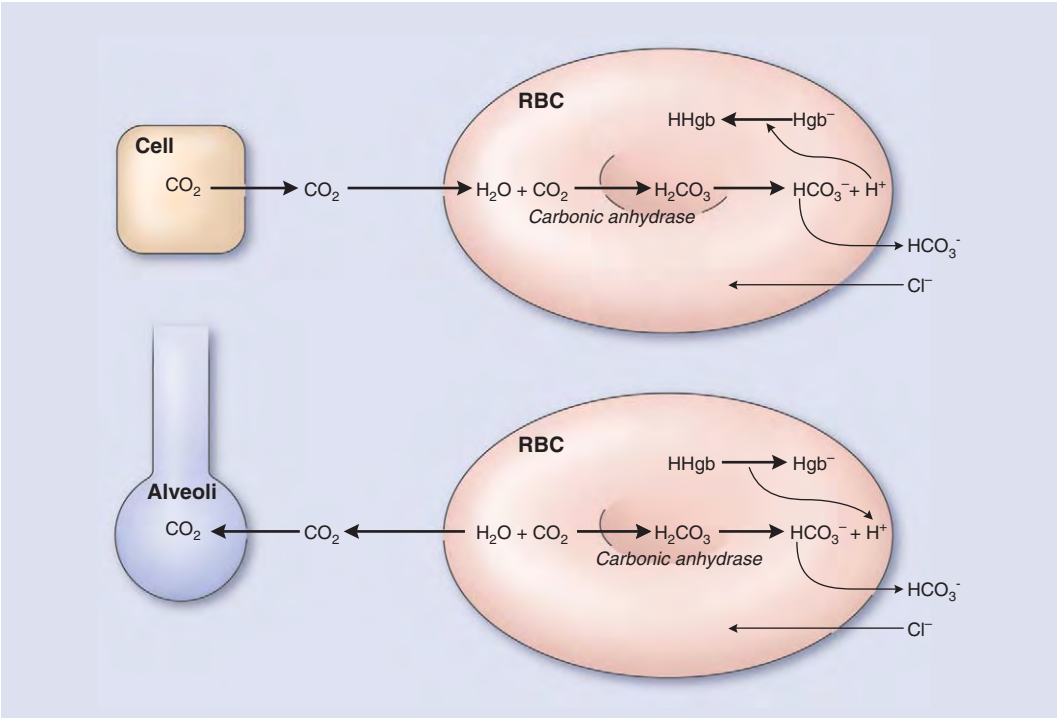

Figure 14-3 Carbon dioxide transport is facilitated by red blood cells (RBCs). A major portion of the carbon dioxide produced by tissues is transported to the lungs as bicarbonate (HCO_3^-). As carbon dioxide enters the red blood cell, carbonic acid (H_2CO_3) is formed and subsequently dissociates to form bicarbonate and a hydrogen ion (H^+). As the hydrogen ion binds with hemoglobin (Hgb), bicarbonate leaves the cell in exchange for chloride (Cl^-) (chloride shift). At the alveolar level, the red blood cell undergoes the same process in reverse. HHgb, hydrogen ion bound to Hgb. (Modified from Malley WJ: Clinical Blood Gases. Philadelphia, WB Saunders, 1990, p 113.)

microcirculation and play important roles in gas exchange at the tissue level.[5]

Unloading

Carbon dioxide arrives in the lung as dissolved carbon dioxide, carbonic acid, carbaminohemoglobin, and bicarbonate ions for elimination by pulmonary gas exchange. In a normal adult, normal ventilation disposes of an average of 10,000 to 15,000 mmol of carbon dioxide per day. As the dissolved carbon dioxide diffuses across the alveolar membrane and plasma carbon dioxide levels decrease, carbonic acid in the red blood cells is converted into carbon dioxide and water by carbonic anhydrase (see Fig. 14-3). Carbonic anhydrase inhibitors may increase carbon dioxide tension in the tissues and decrease carbon dioxide tension in the alveoli, although the mechanism of action for these drugs is more complex.[6] A transient decrease in the rate of carbon dioxide elimination results but is rapidly overcome by compensatory mechanisms. When carbon dioxide moves out of the erythrocyte, bicarbonate moves back in exchange for chloride. The bicarbonate is necessary to replenish the bicarbonate consumed in the hydrolysis reaction. Carbaminohemoglobin unloads the carbon dioxide in the lung, where the P_{CO_2} is lower. The process of carbon dioxide loading and unloading is facilitated by the Haldane effect; the binding of oxygen with hemoglobin displaces carbon dioxide and hydrogen ions from the hemoglobin. The concept of the Haldane effect, like that of the Bohr effect in oxygen carriage, is that the affinity of hemoglobin for carbon dioxide varies with chemical conditions such as P_{O_2}. When hemoglobin is oxygenated in the lung to release hydrogen ions, carbonic acid and ultimately carbon dioxide are produced, with the effect being a reduced affinity to carbon dioxide in the lung resulting from oxygenation. The opposite occurs in the tissue, where hemoglobin releases oxygen and takes up or buffers hydrogen, leading to increased affinity for carbon dioxide.

Abnormal Gas Exchange

When any step in the process of gas exchange between the lung and the tissue is inhibited, less oxygen reaches the tissue. The lack of oxygen causes hypoxic cellular damage. Moreover, the level of intracellular carbon dioxide increases and ultimately creates a hypercapnic or respiratory acidosis. Hypoxic injury and hypercapnic acidosis can be caused by defective pulmonary gas exchange, loading, transporting, unloading or defective tissue gas exchange. If not corrected in time, these conditions can cause irreversible tissue injury. Therefore, it is important to understand the pathophysiology of the hypoxia and hypercapnia to elucidate their causes and give specific therapy before any permanent tissue damage occurs.

HYPOXIA

Pathophysiology

Cells require a continuous supply of energy to perform their functions within an organ and to maintain adequate control

over membrane permeability.[7] A failure of cellular energy metabolism results in organ dysfunction and cell death as control is lost over solute and metabolite exchange across the cell membrane.[8]

Generation of energy occurs in both the presence and absence of oxygen, although aerobic metabolism using oxygen is greatly more efficient. Approximately 20 times more energy is produced in mitochondria by oxidative phosphorylation when substrate consumption is coupled to the consumption of oxygen than when it is without oxygen (i.e., anaerobic).[9] Adenosine triphosphate (ATP) in mitochondria diffuses to the sites of energy use in the cytosol, where a large amount of chemical energy is released from the hydrolysis of one of ATP's high-energy phosphate bonds. The adenosine triphosphatases (ATPases) are the enzymes that control the hydrolysis of ATP, resulting in the formation of adenosine diphosphate (ADP), inorganic phosphate (Pi), and a hydrogen ion (H^+), as follows:

$$ATP \rightarrow ADP + Pi + H^+$$

ADP, Pi, and the H^+ return to the mitochondria, where they serve as substrates for the formation of other ATP molecules.

Measuring the metabolic by-products of the anaerobic reactions, such as the arterial lactate level, may be useful in monitoring the adequacy of global tissue oxygenation. These metabolic by-products, however, do not reflect the hypoxic status of individual organs because of the variable regional blood flow to each organ, changes in tissue lactate accumulation, and washout.[10] Lactate is metabolized by various organs and produced in the liver in response to circulating catecholamines. Lactate metabolism in the body is complicated and lactate values must be interpreted in the context of other clinical and laboratory measures of tissue oxygenation. Lactate levels have been found to be predictive of mortality in some studies[11] but not in others.[12] Sublingual capnometry is a newer technique that shows potential to provide a better noninvasive measure of tissue hypoxia.[12] Phosphorus-31 magnetic resonance spectroscopy can monitor ATP formation, which is indicative of the adequacy of tissue oxygenation.[13] This method has some advantages over other techniques because it measures the level of high-energy phosphate regionally, such as in skeletal muscle, the brain, and the heart. The major drawback is that the patient needs to be in a magnetic cylinder, making it impractical to use in many critically ill patients.

CAUSES OF TISSUE HYPOXIA

Normally, the amount of oxygen delivered to the tissue is 3 to 4 times the amount of oxygen the tissue consumes. There is a significant reserve before the oxygen level reaches the critical point where tissue hypoxia occurs (Box 14-1). Therefore, arterial hypoxemia, which is the state of low blood oxygen content resulting from low P_{O_2}, does not necessarily create tissue hypoxia. As long as capillary P_{O_2} at the tissue level remains higher than the minimum tissue P_{O_2} of 20 mm Hg, there will be oxygen to diffuse from the capillary blood into the tissue for consumption (consumable oxygen).[14] Assuming that Pa_{O_2}, hemoglobin, tissue oxygen consumption, and oxygen diffusion rates remain constant, the blood flow through the tissue determines capillary and venous P_{O_2} (Fick principle). Hypoxic lactic acidosis does not develop in hypoxemia when there is enough tissue perfusion to maintain capillary P_{O_2} above the tissue requirements for oxygen.

In acute hypoxemia, the P_{O_2} chemoreceptors of the carotid arteries and aortic arch quickly recognize low blood P_{O_2}. The respiratory center and the heart are stimulated to increase minute ventilation and cardiac output, respectively, thereby preventing tissue hypoxia. In chronic hypoxemia with chronic lung diseases or cyanotic heart diseases, hemoglobin levels increase to maintain the amount of oxygen for transport. Mitochondria can become more efficient to produce energy with a limited oxygen supply to prevent tissue hypoxia.[15]

Tissue ischemia is low oxygen delivery to the tissue due to decreased blood flow. In contrast to hypoxia, tissue ischemia can cause hypoxic injury even with a normal Pa_{O_2}.[16] When cardiac output decreases, there is not enough tissue perfusion to maintain the P_{O_2} gradient for diffusion between the blood and the tissue. Thus, ischemia is much worse than hypoxemia in the development of hypoxic cellular injury leading to the aphorism "blue blood is better than no blood."[17]

BOX 14-1 Causes of Hypoxia

Pulmonary Gas Exchange

- Inadequate oxygenation of the airway
- Decreased ventilation and perfusion (e.g., intrapulmonary shunt)
- Disruption of alveolar-capillary diffusion (e.g., pulmonary edema, pneumonia)

Loading

- Dysfunctional hemoglobin (e.g., carboxyhemoglobin, methemoglobin)
- Changes in the factors shifting the oxygen-hemoglobin dissociation curve (e.g., pH, P_{CO_2}, 2,3-diphosphoglycerate level, body temperature)
- Venous-to-arterial shunts ("right-to-left" cardiac shunt)

Transport

- Hemoglobin and hematocrit
- Red blood cell deformability
- Low cardiac output: generalized or local ischemia
- Tissue edema

Unloading

- Changes in the factors shifting the oxygen-hemoglobin dissociation curve (e.g., pH, P_{CO_2}, 2,3-diphosphoglycerate level, body temperature)

Tissue Gas Exchange

- Capillary "shunt" resulting from peripheral vasodilation (e.g., septic shock)
- Poisoning of cellular enzymes (e.g., cyanide poisoning)
- Diminished cellular metabolic capacity (e.g., beriberi)

HYPERCAPNIA

Pathophysiology

Carbon dioxide is produced in the tissues as the result of aerobic metabolism and removed from the body through tissue gas exchange, loading, transport, and unloading and, finally, pulmonary gas exchange. The disruption of any of these processes causes carbon dioxide to accumulate in the body fluid and thus produces hypercapnia.

Because of the free diffusibility of carbon dioxide across cell membranes, a sudden increase in extracellular P_{CO_2} decreases the intracellular pH.[18] Because of the abundance of carbonic anhydrase in the cytosol, carbonic acid is formed, thus rapidly causing intracellular acidosis.[19] Most effects of hypercapnia occur at the cellular level. The reduced intracellular pH decreases oxidative metabolism and inhibits the activity of contractile elements by interfering with both excitation–contraction coupling and actin–myosin interaction.[20] Myocardial and skeletal muscle contractility decreases, although most of this impairment is reversible.[21]

In the intact animal, the depressant effect of hypercapnia is offset by the stimulating action of carbon dioxide on the central and autonomic systems. Carbon dioxide is a potent vasodilator. Hypercapnia dilates the coronary arteries and cerebral arteries and may improve blood flow through the normal myocardium and normal brain tissue. Conversely, hypercapnia may reduce perfusion through the injured ischemic areas; this is the "steal phenomenon."[22,23] Increased P_{CO_2} diminishes cerebral vascular tone. Cerebral blood volume increases, potentially raising intracranial pressure.[24,25]

Hypercapnic acidosis constricts pulmonary arteries and renal arteries, leading to pulmonary artery hypertension and decreased renal blood flow.[26-28] Additional cardiovascular effects of hypercapnia include increased cardiac output, tachycardia and systemic hypertension, in part due to catecholamine release. In high-risk patients, extreme levels of hypercapnia can lead to myocardial depression and arrhythmias.[29] Increased P_{CO_2} and low pH shift the oxygen-hemoglobin dissociation curve to the right, which decreases oxygen affinity for the hemoglobin molecule. When the Pa_{O_2} is in the normal range, the rightward shift of the oxygen-hemoglobin dissociation curve is advantageous because there is easier unloading of oxygen to the tissue. However, when the Pa_{O_2} is low, it is more difficult to load oxygen at the pulmonary alveolar-capillary level because of decreased oxygen affinity (see Fig. 14-2).

The concomitant tissue hypoxia potentiates the adverse effects of acute hypercapnic acidosis[30]; if tissue oxygenation is maintained, however, hypercapnia and intracellular acidosis are better tolerated. With time, the acidosis resolves through the excretion of hydrogen ions from the kidneys and the increased resorption of bicarbonate ions.[31,32] Clinically, permissive hypercapnia, which allows a P_{CO_2} rise with alveolar hypoventilation, is an accepted mode of ventilation to prevent further lung injury when oxygenation is well maintained and severe systemic acidosis is avoided.[33-36]

Causes of Hypercapnia

Arterial P_{CO_2} (Pa_{CO_2}) is proportional to carbon dioxide production ($\dot{V}_{CO_2}$) and inversely proportional to alveolar ventilation ($\dot{V}_A$):

$$Pa_{CO_2} = K \cdot \dot{V}_{CO_2} / \dot{V}_A$$

The constant K has the value of 0.863 mm Hg when carbon dioxide is expressed in milliliters per minute under standard conditions (dry gas at standard temperature and pressure) and alveolar ventilation is expressed in liters per minute under body conditions (saturated gas at body temperature and pressure).

The disruption of any of these processes causes the accumulation of carbon dioxide in the body fluid to produce hypercapnia (Box 14-2). In hypoxia resulting from poor perfusion through the pulmonary membrane or through the tissues, serious hypercapnia usually does not occur because carbon dioxide diffuses 20 times as rapidly as oxygen. However, in hypoxia caused by hypoventilation, carbon dioxide transfer between the alveoli and the atmosphere is affected as much as oxygen transfer.

Diminished blood flow in circulatory deficiency removes less carbon dioxide from the tissues, resulting in tissue hypercapnia. However, the transport capacity of the blood for carbon dioxide is about 3 times that for oxygen, so tissue hypercapnia is much less severe than tissue hypoxia.

BOX 14-2 Causes of Hypercapnia

Carbon Dioxide Production

- Increased body temperature: approximately 10% per degree of temperature
- Excessive muscular activity: shivering, rigor, seizure
- Physiologic stress
- Sepsis
- Parenteral nutrition with glucose

Decreased Carbon Dioxide Clearance

- Increased tissue carbon dioxide levels
- Tissue-gas exchange
- Poor tissue perfusion (e.g., ischemia)
- Disrupted diffusion (e.g., tissue edema)
- Loading
- Capillary shunt resulting from peripheral vasodilation (e.g., septic shock)
- Transport
- Low hemoglobin level or hematocrit
- Decreased red blood cell deformability
- Low cardiac output
- Increased blood carbon dioxide levels
- Unloading
- Venous-to-arterial shunts ("right-to-left" cardiac shunt)
- Pulmonary gas exchange
- Decreased ventilation (e.g., respiratory depression, neuromuscular disorder, chest deformity)
- Increased dead space (e.g., upper airway obstruction, lower airway obstruction: reactive airway disease)
- Disruption of alveolar-capillary diffusion (e.g., pulmonary edema, pneumonia)

DISORDERS OF OXYGENATION AND VENTILATION

Oxygen

Each arterial blood gas value should first be evaluated in the context of normal values. Arterial oxygen values, which are affected by age and altitude, can also be altered by the F_{IO_2}, the condition of the alveolar air-blood barrier, and pulmonary blood flow. At sea level, a Pa_{O_2} of 97 mm Hg (range = 80 to 103 torr) is considered normal. A patient with normal lungs receiving supplemental oxygen should have a Pa_{O_2} approximately 5 times the F_{IO_2} (Table 14-1). The Pa_{O_2} decreases in the elderly and varies depending on whether an individual is sitting or supine.[37]

If arterial hypoxemia is present, it may be caused by hypoventilation, absolute (right to left) shunting, diffusion defects, or relative shunting (low $\dot{V}/\dot{Q}$ ratio). Hypoventilation can be rapidly diagnosed by the presence of elevated arterial P_{CO_2} values. Calculation of the alveolar-arterial ($A_{-}a$) oxygen tension gradient while the patient is breathing room air can be helpful in discriminating hypoventilation from shunting. An $A_{-}a$ gradient greater than 20 mm Hg suggests causes other than hypoventilation (i.e., $\dot{V}/\dot{Q}$ reduction, diffusion block, and right-to-left shunt all increase $A_{-}a$ gradient).

Table 14-1
Predicted Effect of F_{IO_2} on Blood Oxygen Content

F_{IO_2}	Predicted Arterial P_{O_2}
30%	150 mm Hg
40%	200 mm Hg
50%	250 mm Hg
80%	400 mm Hg
100%	500 mm Hg

From Shapiro BA, et al: Clinical application of blood gases, 5th ed. St Louis, Mosby, 1994, p. 65.

An *absolute shunt* is defined as blood passing from the right to the left side of the heart without being oxygenated. Absolute shunting does not respond to increases in the inspired oxygen level because the shunted blood never comes in contact with oxygen. Shunting may also occur at the level of the alveoli. Blood cannot be oxygenated when the alveolus is blocked, collapsed, or filled with fluid. There is also anatomic shunting resulting from persistent pulmonary hypertension and congenital heart defects.

When there is no extrapulmonary right-to-left shunt, the P_{O_2} represents pulmonary gas exchange, whereas a venous blood gas value represents the balance between oxygen delivery and oxygen uptake; i.e., tissue gas exchange. Pulmonary gas exchange relies on pulmonary function, and tissue gas exchange is particularly affected by tissue perfusion. Therefore, the interpretation of blood gas values will be different based on where the blood sample was taken.

When there is a right-to-left shunt, total cardiac output ($\dot{Q}t$) is composed of shunted blood ($\dot{Q}s$) and pulmonary end-capillary blood flow ($\dot{Q}c$) (Fig. 14-4), as follows:

$$\dot{Q}t = \dot{Q}s + \dot{Q}c$$

The total amount of oxygen ejected from the left side of the heart is equal to the amount of oxygen carried in pulmonary end-capillary blood plus the amount of oxygen carried in shunted blood, as follows:

$$\dot{Q}t \cdot Ca_{O_2} = \dot{Q}s \cdot C\bar{v}_{O_2} + \dot{Q}c \cdot Cc'_{O_2}$$

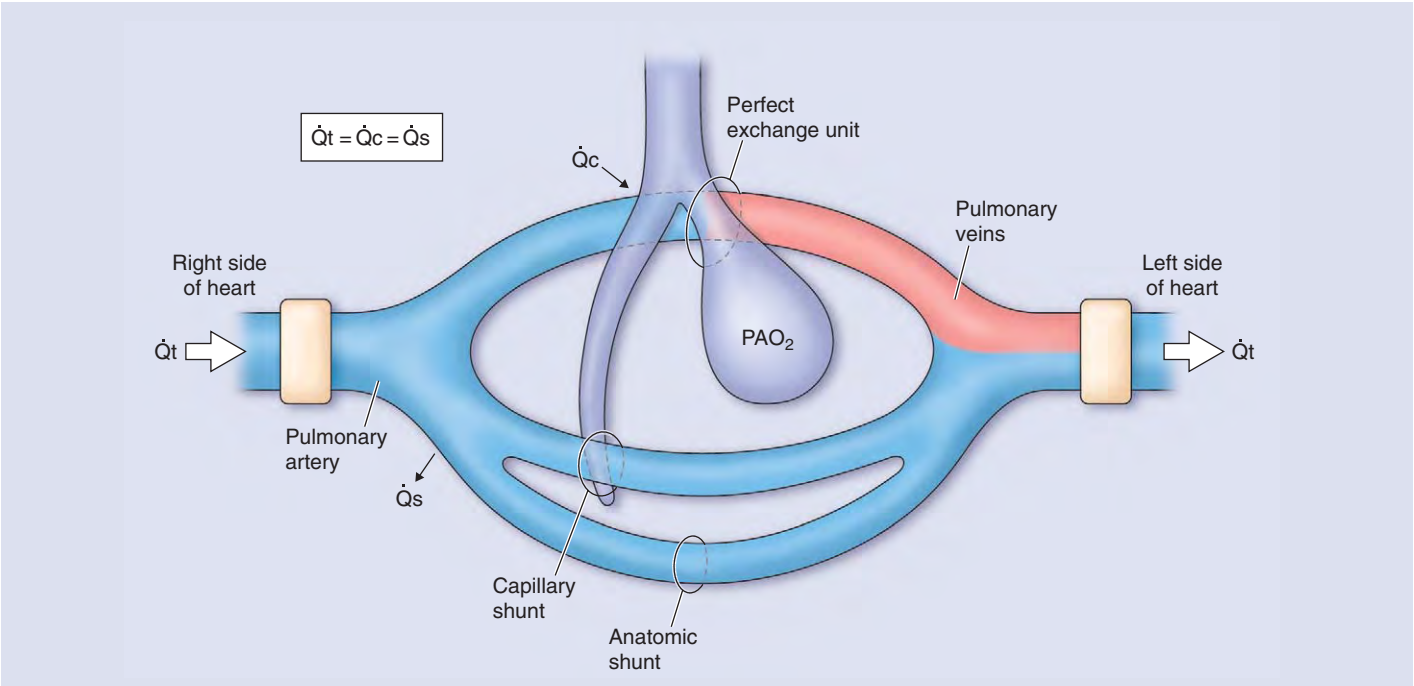

Figure 14-4 A visual concept of physiologic shunting. Pa_{O_2}, partial pressure of alveolar oxygen. (Data from Shapiro BA, et al. In Shapiro BA, et al [eds]: Clinical Application of Blood Gases, 5th ed. St Louis, Mosby, 1994, p 88.)

where Ca_{O_2}, Cc'_{O_2}, and $C\bar{v}_{O_2}$ are the arterial, pulmonary end-capillary, and mixed venous oxygen contents, respectively.

The shunt equation is used to solve for $\dot{Q}s/\dot{Q}t$, as follows:

$$\dot{Q}s/\dot{Q}t = Cc'_{O_2} - Ca_{O_2}/Cc'_{O_2} - C\bar{v}_{O_2}$$

As before, oxygen content is measured directly or calculated according to the following formula:

$$O_2 \text{ content} = (Sa_{O_2} \cdot Hgb \cdot 1.34) + (0.003 \cdot Pa_{O_2})$$

The pulmonary end-capillary oxygen content is not measured clinically; instead, it may be calculated by assuming that it is equivalent to the P_{AO_2}.

The classic shunt ($\dot{Q}s/\dot{Q}t$) (i.e., anatomic shunt plus capillary shunt) is not exposed to P_{AO_2} and therefore is not affected by F_{IO_2}.[38] This shunt is commonly calculated while the patient breathes 100% inspired oxygen and represents only complete $\bar{V}/\dot{Q}$ mismatch (i.e., $\bar{V}/\dot{Q}=0$; a complete absence of gas exchange between the pulmonary capillary and the alveolus) and not the venous admixture seen in states of impaired ventilation and perfusion matching (i.e., $\bar{V}/\dot{Q}<1$, but not 0). When the patient is breathing less than 100% inspired oxygen, the calculated intrapulmonary shunt represents the venous admixture with low $\bar{V}/\dot{Q}$. This is called *physiologic shunt* ($\dot{Q}sp/\dot{Q}t$). When $\dot{Q}sp/\dot{Q}t$ is applied to patients with diseased lungs, it represents the degree of impairment of the lung as an oxygenator. When mixed venous blood is not available to be used in the calculation (i.e., the patient does not have a pulmonary artery catheter), a modified version of the shunt equation can be used. Several formulas have been proposed, one such employs the algebraic combination of the Fick equation and the shunt equation to arrive at a formula for the calculation of $\dot{Q}sp/\dot{Q}t$ without a direct measurement of mixed venous blood (Cv_{O_2}).[39] The resulting equation is:

$$\dot{Q}s/\dot{Q}t = \dot{Q}c \cdot [Cc'_{O_2} - Ca_{O_2}/\bar{V}_{O_2}]$$

Many studies have been published assessing the reliability of the newer oxygen tension–based indexes in reflecting $\dot{Q}sp/\dot{Q}t$.[40-45] These include the alveolar-arterial P_{O_2} gradient ($P_{AO_2} - Pa_{O_2}$), the arterial-alveolar oxygen tension ratio (Pa_{O_2}/P_{AO_2}), the ratio of arterial oxygen tension to inspired oxygen concentration (Pa_{O_2}/F_{IO_2}), the oxygenation index ($[F_{IO_2} \cdot Paw \cdot 100]/Pa_{O_2}$) where Paw is the mean airway pressure, and the respiratory index ($P_{AO_2} - Pa_{O_2}/Pa_{O_2}$).[40-44,46] The clinical application of $P_{AO_2} - Pa_{O_2}$ is limited in patients who have a Pa_{O_2} much less than 150 mm Hg and in whom the F_{IO_2} is varied. With a Pa_{O_2} less than 100 mm Hg, changes in the oxygen content increasingly become a function of changes in hemoglobin saturation rather than in dissolved oxygen. In contrast to the $P_{AO_2} - Pa_{O_2}$, the Pa_{O_2}/P_{AO_2} is relatively unaffected by changes in the F_{IO_2}. So that calculation of the P_{AO_2} could be avoided, the Pa_{O_2}/F_{IO_2} index was introduced. This index is affected by changes in arterial Pc'_{O_2} values, and values less than 2 have been reported to correlate well with $\dot{Q}sp/\dot{Q}t$ values of more than 20%. While applicable only to mechanically ventilated patients, the oxygenation index accounts for the significant effect of mean airway pressure on oxygenation. Last, $P_{AO_2} - Pa_{O_2}/Pa_{O_2}$ was introduced to minimize the inherent problems of $P_{AO_2} - Pa_{O_2}$, and it is a better indicator than $P_{AO_2} - Pa_{O_2}$ in estimating $\dot{Q}sp/\dot{Q}t$.

Carbon Dioxide

The arterial concentration of carbon dioxide (Pa_{CO_2}) is determined mainly by the degree of alveolar ventilation ($\dot{V}A$) in relation to the patient's carbon dioxide production ($\dot{V}_{CO_2}$) as follows:

$$P_{ACO_2} - \dot{V}_{CO_2}/\dot{V}A$$

Alveolar ventilation is lowered by increased alveolar dead space, which occurs when alveoli are ventilated but not perfused. This circumstance is reflected in a measured gradient between P_{ETCO_2} and mixed alveolar P_{CO_2}. P_{ETCO_2} is lower than alveolar P_{CO_2} because of the addition of alveolar dead space gas, which does not contain carbon dioxide.[47]

P_{ACO_2} is difficult to measure directly, and the assumption is made that it is equal to Pa_{CO_2}. This assumption is valid because carbon dioxide is highly diffusible across the alveolar-capillary membrane, which quickly equilibrates P_{ACO_2} and pulmonary end-capillary Pc'_{CO_2}. The difference between mixed venous P_{CO_2} (46 mm Hg) and pulmonary end-capillary P'_{CO_2} (40 mm Hg) is small. Consequently, even a large admixture of venous blood to the pulmonary end-capillary from a large shunt produces only a small increase in arterial P_{CO_2}. Further, eupneic respiratory drive responds to Pa_{CO_2}, and this leads to an increase in ventilation with a reduction in Pa_{CO_2} to normal. Thus, children with right to left shunts rarely have increased Pa_{CO_2} in the absence of pulmonary disease and ventilatory compromise.

Under normal conditions the balance between carbon dioxide production and alveolar ventilation is set so that arterial P_{CO_2} is maintained at 40 mm Hg (37 to 45 mm Hg).[48] An arterial blood gas P_{CO_2} of less than 37 mm Hg with a pH of more than 7.45 is consistent with hyperventilation. A patient with a P_{CO_2} greater than 45 mm Hg with a pH less than 7.35 probably has significant ventilatory failure. Many patients with lung disease breathe more rapidly (tachypnea) or more deeply (hyperpnea) or a combination of both in order to maintain a normal P_{CO_2}. Small changes in P_{CO_2} evoke a rapid increase in ventilation to restore the P_{CO_2} toward normal. Stimuli such as hypoxemia, fever, anxiety, central nervous system disease, septicemia, and medications can increase ventilation,[49] whereas central nervous system depression and pulmonary disease may cause an increase in the P_{CO_2}. The P_{CO_2} rises or decreases until it achieves a new equilibrium; at equilibrium, carbon dioxide production equals excretion. Because respiration is so efficient, modest changes in carbon dioxide production usually do not alter the P_{CO_2}.

Carbon dioxide production increases in response to several conditions, including exercise, burns, and sepsis. Carbon dioxide production can transiently rise as a result of a sodium bicarbonate infusion. After accepting a hydrogen ion, bicarbonate can be converted into carbon dioxide and water via the reaction catalyzed by carbonic anhydrase as presented

later in the chapter. Therefore, infusion of sodium bicarbonate can increase the P_{CO_2} level in an individual whose minute ventilation cannot be increased. In an intensive care unit setting, carbon dioxide production may rise as the respiratory quotient (RQ) rises when patents are metabolizing a larger percentage of carbohydrates (i.e., more carbon dioxide is produced when metabolizing carbohydrates than protein or fat). In an individual with normal lung function, minute ventilation can be increased to compensate for the increased carbon dioxide production.

Acid-Base Physiology

Peter D. Yorgin

TEACHING POINTS

- Homeostasis of the extracellular fluid hydrogen ion concentration is achieved by carbon dioxide–bicarbonate, phosphate, and protein buffering systems.
- Interpretation of blood gas pH requires the assessment of the primary disturbance, P_{CO_2} and HCO_3^- values, and determination of the appropriate compensatory response to the primary disturbance.
- Use of the modified Henderson-Hasselbalch equation can help to assess the accuracy of blood gas data and is useful in determining the appropriate compensatory response.
- Serum anion gap, urine anion gap, and delta anion gap are useful tools in assessing the cause of a metabolic acidosis.
- Chemical diuretics cause significant hypokalemic metabolic alkalosis through the urinary loss of chloride.

The human body has respiratory, renal, blood, and cellular buffering systems that intricately maintain acid-base homeostasis of the extracellular fluids. The redundancy of these systems allows for the robust protection of acid-base homeostasis during health and illness. Nevertheless, genetic defects, acquired disease, and even iatrogenic factors can cause acid-base disorders. This chapter reviews the systems responsible for acid-base homeostasis, provides clinical examples to illustrate common acid-base disorders, and emphasizes the concepts necessary to assess acid-base status. This chapter is not meant to be an exhaustive review of acid-base physiology but instead has been written to be useful to clinicians seeking a practical approach to acid-base problems. Excellent comprehensive reviews of acid-base physiology can be found elsewhere.[1,2]

GENERAL ACID-BASE CONCEPTS

pH

pH is a convenient means of easily expressing the concentration of hydrogen ion (H^+) in a solvent. The pH system was developed because expressing H^+ concentrations using molality can be difficult. For example, a pH of 7 could be written as 0.0000001 mol/L. pH utilizes a logarithmic scale to express H^+ molality in a solution. pH can be expressed in the form of an equation:

$$pH = -\log[H^+]$$

A solution with a pH of 6 has 10 times the amount of H^+ than does a solution with a pH of 7. If water is the solvent, the pH of an acidic solution is less than 7 (H^+ concentra-

tion = 10^{-7} mmol/L), and a pH greater than 7 is alkaline. An acid is a compound that donates a H^+, or proton, to a base, which is a proton acceptor. An acid is considered to be dissociated after the proton has been donated. Solutions of weak acids and salts of their conjugate bases form buffer solutions. An alkali is a base that donates hydroxide ions (OH^-).

In a healthy individual, the extracellular fluid pH is maintained within a narrow range, pH 7.38 tp 7.42 (H^+ concentration = $10^{-7.38\text{-}7.42}$ mol/L). The evaluation of blood pH is helpful in the evaluation of numerous disorders but particularly so in patients with pulmonary and renal diseases.

pH CAN BE DETERMINED IF P_{CO_2} AND HCO_3^- VALUES ARE KNOWN: THE HENDERSON-HASSELBALCH EQUATION

The pH of blood can be directly measured, using a pH probe (and the Nernst equation), by photochemical sensors (optodes),[3] or it can be calculated using the Henderson-Hasselbalch equation,[4] which describes the relationship between carbonic acid and bicarbonate (HCO_3^-):

$$H_2CO_3 \rightarrow H^+ + HCO_3^-$$

The equation is modified so that the concentration of H^+ can be determined by knowing both the HCO_3^- and H_2CO_3 concentrations. Because a positive value expressed in pH is desirable, the log of both sides of the equation must be obtained.

$$-\log[H^+] = pH = pK + \log[HCO_3^-]/[H_2CO_3])$$

$$pH = pK + \log([HCO_3^-]/H_2CO_3])$$

The pK, in this situation, represents the pH value at which HCO_3^- and H_2CO_3 are found in equal concentrations. The pK practically represents the pH at which there is the greatest amount of buffering capacity. The pK of the CO_2-HCO_3^- buffering system is 6.1. At a pH of 7.40, carbonic acid concentrations are very low and cannot be measured easily. Conversely, P_{CO_2} values are higher and can be easily measured. In most equations, the carbonic acid value is replaced by a solubility coefficient multiplied times the partial pressure of carbon dioxide (CO_2). Using the solubility coefficient, which is 0.0308 for results in mmol/L at 37° C, pH can be defined:

$$pH = pKa + \log([HCO_3^-]/[(0.0308)(CO_2)])$$

THE CO_2-HCO_3^- BUFFERING SYSTEM IS THE FIRST LINE OF DEFENSE AGAINST ACID-BASE PERTURBATIONS

Slight changes in the blood and interstitial fluid H^+ concentration have profound effects on the rate of chemical reactions within the cell. Buffers, found within cells and in blood, quickly limit the change in H^+ concentrations, unlike the renal and respiratory systems, which take time to respond. Buffers have the capacity to combine with an acid or a base and limit the change in H^+ concentrations to less than what would occur without the buffer. An acid-base buffer is usually composed of two or more chemical compounds.

The CO_2-HCO_3^- extracellular buffering system protects against dramatic changes in blood H^+ concentration. The CO_2-HCO_3^- extracellular buffering system has two buffering molecules: carbonic acid (H_2CO_3) and HCO_3^-. Under appropriate conditions, H^+ and HCO_3^- can combine to form carbonic acid. Carbonic acid, in a reversible process, dissociates to yield H_2O and CO_2.

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3 \leftrightarrow H_2O + CO_2$$

If an acid is added to the CO_2-HCO_3^- buffering system, more carbonic acid is generated, as shown in the following reaction:

$$H^+ + HCO_3^- \leftrightarrow H_2CO_3$$

If a base is added to the CO_2-HCO_3^- buffering system, more HCO_3^- is generated, as shown in the following reaction:

$$H_2CO_3 + OH^- \leftrightarrow H_2O + HCO_3^-$$

A MODIFIED VERSION OF THE HENDERSON-HASSELBALCH EQUATION HAS UTILITY FOR THE CLINICIAN

Because the Henderson-Hasselbalch equation can be difficult to use in clinical situations, other, more clinician-friendly formulas have been developed.[5] The Henderson formula makes use of the fact that H^+ concentrations change in a linear fashion in pH around 7.40 (Fig. 14-5). Therefore, the equation can be restated:

$$H^+ \text{ concentration} \cong (K) \text{ lungs/kidneys}$$

where (K) equals 24. Or

$$H^+ \text{ concentration} \cong 24\ (P_{CO_2}/HCO_3^-)$$

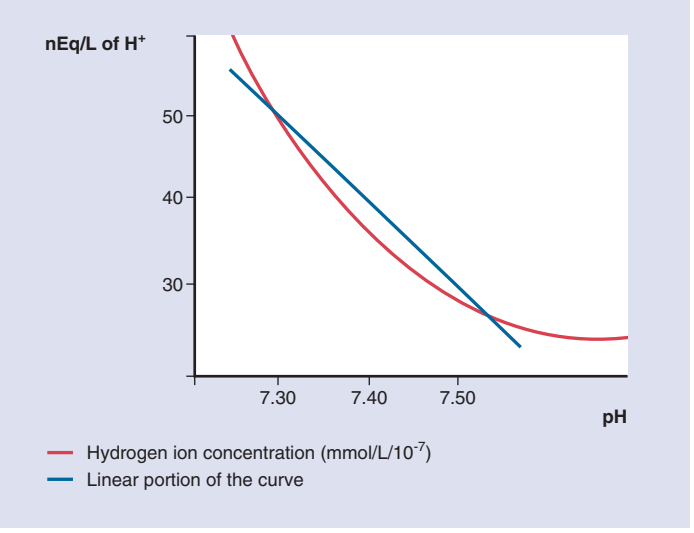

Figure 14-5 Relative to pH, the hydrogen ion concentration (mmol/L/10^{-7}) of blood changes in a linear fashion in a limited area surrounding a pH of 7.40. The Henderson formula can be of great clinical use because of this relationship.

The H^+ concentration at a normal pH (7.40) is 40 nmol/L, which is 0.000000040 mol/L (see Fig. 14-1). An individual with a P_{CO_2} of 40 and an HCO_3^- of 24 mmol/L would have a calculated H^+ concentration of 40 nmol/L (normal) = pH 7.40. For any increase in the H^+ concentration by 1 nmol/L, the pH will decrease by 0.01; for any decrease in the H^+ concentration by 1 nmol/L, the pH will increase by 0.01. If the H^+ concentration was 50 (an increase of 10), then the pH would be 7.30 (a decrease of 0.1 pH unit).

Example: A 2-month-old boy presents with respiratory distress and a large left lower lobe infiltrate on chest radiograph. The blood gas pH is 7.16 with a P_{CO_2} of 63 mm Hg. The reported HCO_3^- (24 mmol/L) may be incorrect or may indicate the presence of mixed acid-base disorder. Is the blood gas correct?

Solution: To determine the H^+ concentration, the equation would be arranged as follows:

$$H^+ \text{ concentration} = [24(63 \text{ mm Hg } (P_{CO_2})]/ 24 \text{ mmol/L } (HCO_3^-)$$

H^+ concentration = 63 = pH of ~7.17. The blood gas reported is internally consistent.

The serum HCO_3^- value is lower than one would expect in a child with a respiratory acidosis. There should be a compensatory metabolic alkalosis. What should the HCO_3^- value be if the pH was 7.40 with a P_{CO_2} of 63 mm Hg?

Solution: The equation can be altered in the following fashion to determine the HCO_3^- if the infant had a normal metabolic response:

$$HCO_3^- = (K)\ P_{CO_2}/H^+ \text{ concentration}$$

The normal H^+ concentration is 40 (equivalent to a pH of 7.40). Therefore, the appropriate serum HCO_3^- value should be 37.8 mmol/L. In this case, the infant has a mixed acid-base disorder consisting of respiratory acidosis and metabolic acidosis. An attempt should be made to identify the source of the metabolic acidosis.

Phosphate and Protein Buffering Systems

The results of actual blood gas analyses are often slightly different than when the results are calculated using the Henderson-Hasselbalch equation because phosphate and protein provide buffering capacity. The phosphate buffering system functions like the CO_2-HCO_3^- buffering system. Two compounds, $H_2PO_4^-$ and HPO_4^-, act as buffers. When a strong acid is added, the following reaction occurs:

$$HCl + Na_2HPO_4 \rightarrow NaH_2PO_4 + NaCl$$

In this reaction, a strong acid, hydrochloric acid, is converted into a weak acid, NaH_2PO_4, thereby causing only a minor change in the pH. If a strong base is added to the buffer system, the following reaction occurs:

$$NaOH + NaH_2PO_4 \rightarrow Na_2HPO_4 + H_2O$$

With this reaction, a strong base is exchanged for a weak base, causing only a minor shift toward an alkaline pH.

The phosphate buffer system has a pKa of 6.8, which means that there are similar concentrations of $H_2PO_4^-$ and HPO_4^- at the pH of 7.40. Therefore, the phosphate buffering system has its best buffering capacity in the normal blood pH range. Yet, the concentrations of $H_2PO_4^-$ and HPO_4^- are much less than those of the HCO_3^- system and therefore contribute less buffering capacity.

The Role of Intracellular Buffering

Cells and the calcium salts in bone make contributions to the buffering of extracellular fluid. Intracellular proteins act as potent buffers and perhaps account for as much as three quarters of all chemical buffering in the body. Some amino acids, such as histadine-related compounds, form free radicals that can disassociate to form base and H^+. Hydrogen ions can bind to imidazole groups of histidine residues in proteins that are found in muscle.[6] Intracellular H^+ concentrations are primarily affected by CO_2 concentrations, which rapidly diffuse through the cell membrane to affect intracellular pH.[7] Bicarbonate, which can move into the cell via an electrogenic Na-HCO_3^- cotransport mechanism, also influences intracellular pH.[8] The calcium salts in bone tend to contribute little to acid-buffering capacity unless calciuria ensues.[8] The calciuria due to long-term acidosis can lead to bone demineralization.

The plasma HCO_3^- increases immediately in response to an increase in P_{CO_2} (Table 14-2). The immediate HCO_3^- changes are modest (4 to 5 mmol/L) and incomplete compared with those in response to a chronic respiratory abnormality. The small changes in serum HCO_3^- are due to intracellular nonbicarbonate buffers.[9,10] During an acute decrease in P_{CO_2}, the production of lactic and citric acid increases slightly, thereby decreasing serum HCO_3^-.[11,12]

Pulmonary Regulation of Acid-Base

The pulmonary compensatory response to acute metabolic acidosis or alkalosis is swift (see Table 14-2). If a strong acid is added to blood, the pH begins to drop as HCO_3^- is consumed and P_{CO_2} begins to rise. Blood pH cannot directly influence the central respiratory center due to the blood-brain barrier. Instead, as P_{CO_2} increases, CO_2 carbonic acid

Table 14-2
Rules of Acute Respiratory Compensation

Change	Rule	Example
↑P_{CO_2}	For every 1–mm Hg increase in P_{CO_2}, the pH will decrease by 0.008 pH unit.	P_{CO_2} 40 → 60 pH 7.40 → 7.24
Compensation to ↑P_{CO_2} ↓P_{CO_2}	The HCO_3^- will increase by 0.1 mmol/L for every 1–mm Hg increase in P_{CO_2}. For every 1–mm Hg decrease in P_{CO_2}, the pH will increase by 0.007 pH unit.	HCO_3^- 24 → 26 P_{CO_2} 40 → 20 pH 7.40 → 7.54
Compensation to ↓P_{CO_2}	The HCO_3^- will decrease by 0.25 mmol/L for every 1–mm Hg decrease in P_{CO_2}.	HCO_3^- 24 → 19

and H^+ levels increase in the cerebrospinal fluid. Hydrogen ions directly stimulate the central respiratory center, causing ventilation to increase. Additional ventilatory stimuli are supplied by peripheral chemoreceptors that respond to the rising H^+ concentrations. Because the lungs represent an open system by which CO_2 can be rapidly disposed, the blood pH can be rapidly corrected to 7.40 by decreasing the P_{CO_2} value to less than 40 mm Hg.

When a strong base is added to blood, the pH rises rapidly and carbonic acid and P_{CO_2} levels decrease. Ventilatory drive decreases in response to decreased serum and cerebrospinal fluid H^+ levels, causing an increase in P_{CO_2}. The compensatory respiratory acidosis response is characterized by an increase in the P_{CO_2} until the pH is normalized at approximately 7.40. The compensatory response is limited by coincident hypoxia; as ventilation decreases, so does the P_{O_2}.

Renal Regulation of Acid-Base

The kidneys maintain acid-base balance via three major mechanisms: HCO_3^- reabsorption, H^+ excretion, and HCO_3^- excretion. Renal acid-base homeostasis starts with the process of glomerular filtration. The concentration of low-molecular-weight constituents of glomerular filtrate, including HCO_3^-, is very similar to that of plasma. Large negatively charged molecules, such as albumin, are not filtered due to the negatively charged proteins, including nephrin and podcin, found in the slit diaphragms between podocytes. After emerging from Bowman's capsule, the filtrate first comes in contact with the convoluted proximal tubule (Fig. 14-6). The proximal tubule reabsorbs approximately 75% of the filtered HCO_3^-, causing the filtrate pH to drop from 7.25 to 6.7 in the proximal tubule. The proximal renal tubular cell cytoplasm is negatively charged (–70 mV) due to the presence of a Na^+,K^+-ATPase pump in the basal membrane,[13] which pumps out three sodium (Na^+) molecules in exchange for two potassium (K^+) molecules[13,14] (Fig. 14-7). The intracellular negative charge inhibits the direct diffusion of HCO_3^-, which is negatively charged, through the luminal membrane of the cell. Conversely, the movement of H^+ from the urine into the renal tubular cells by diffusion is aided by a low tubular pH and intracellular negative charge.

Bicarbonate is reclaimed in the proximal tubule by an elegant mechanism (see Fig. 14-7). On the luminal surface, H^+ is secreted in exchange for Na^+ via an Na^+/H^+ antiporter.[14,15] There also is Na^+-independent H^+ secretion into the tubule lumen via an electrogenic ATP-dependent pump.[16,17] The Na^+-H^+ antiporter appears to have the greatest role in mediating HCO_3^- absorption in the proximal tubule.

In the lumen, H^+ combines with HCO_3^- to form H_2CO_3 (carbonic acid). Luminal carbonic anhydrase[18] facilitates the dehydration of carbonic acid into H_2O and CO_2.[19,20] Although HCO_3^- is unable to pass into the proximal tubular cell, CO_2 easily diffuses into the cell, where it combines with H_2O in the presence of intracellular carbonic anhydrase to form H_2CO_3. The carbonic acid is converted into HCO_3^- and H^+. The HCO_3^- leaves the cell across the basolateral membrane in exchange for Cl^-[21] or leaves with Na^+ via electrogenic Na^+-$3HCO_3^-$ cotransport.[22] The H^+ can be secreted into the tubule lumen again, where it once again can facilitate the reabsorption of HCO_3^-. Bicarbonate reabsorption in the proximal tubule is regulated in part by luminal HCO_3^- concentration, glomerular filtration rate (GFR), peritubular fluid pH, extracellular fluid volume, and K^+ depletion[23] (Table 14-3).

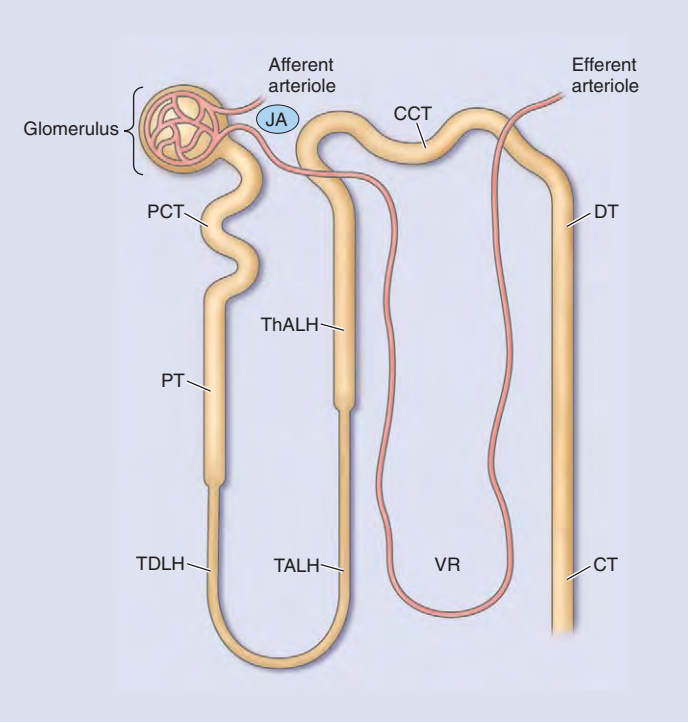

Figure 14-6 Nephron diagram. Blood is brought to the glomerulus by the afferent arteriole and leaves via the efferent arteriole. In some nephrons the efferent arteriole changes course, becoming the vasa recta (VR), which courses through the interstitial area between the ascending loop of Henle and the distal/collecting tubule. Other portions of the nephron are designated by the following abbreviations: CCT, cortical convoluted tubule; CT, collecting tubule; DT, distal tubule; JA, juxtaglomerular apparatus; PCT, proximal convoluted tubule; PT, proximal tubule; TALH, thin ascending loop of Henle; TDLH, thin descending loop of Henle; ThALH, thick ascending loop of Henle.

The distal tubule reabsorbs the remaining HCO_3^- and acidifies the urine. The collecting duct has two types of cells: principal cells and intercalated cells.[18] The principal cells primarily absorb Na^+ in exchange for K^+. There are two types of intercalated cells, one that excretes HCO_3^- and another that excretes H^+.[24] The urine is acidified by luminal vacuolar H^+-ATPase[25] and H^+,K^+-ATPase (Fig. 14-8). The H^+,K^+-ATPase is expressed only in response to K^+ depletion. This pump plays a role in the metabolic alkalosis that is caused by protracted severe hypokalemia, which is seen in patients with diuretic-induced hypokalemia. Alkalemia acts as a stimulus

Table 14-3
Factors That Affect Renal Bicarbonate Reabsorption

Factor	Effect
Increased GFR	↑ Bicarbonate absorption
Increased luminal pH	↑ Distal tubule acidification
Increased peritubular pH	↓ Bicarbonate absorption
Extracellular volume	↓ Bicarbonate absorption (slight)
Potassium depletion	↑ Bicarbonate absorption

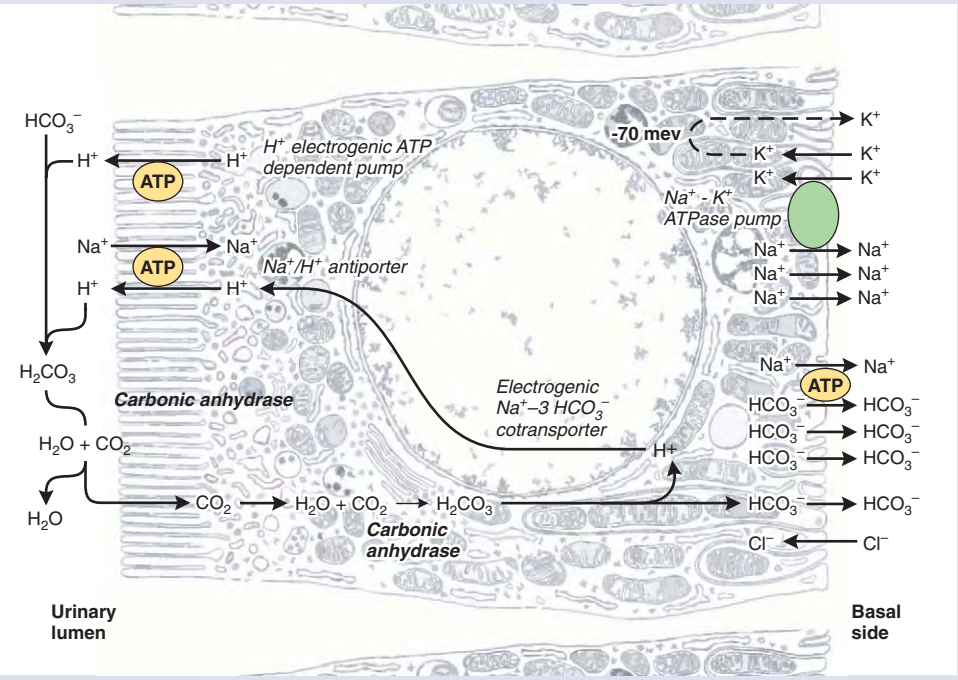

Figure 14-7 One of the major functions for the proximal renal tubule cells is to reabsorb bicarbonate. Hydrogen ion into the tubule lumen combines to form carbonic acid. Carbonic acid, in the presence of carbonic anhydrase, is split into water and CO_2. The CO_2 freely diffuses into the cell, where it combines with water, in the presence of carbonic anhydrase, to form carbonic acid. The carbonic acid splits to form H^+ and HCO_3^-. The HCO_3^- is transported across the basolateral membrane in exchange for chloride or with sodium. ATP, adenosine triphosphate; CO_2, carbon dioxide; HCO_3^-, bicarbonate; H_2CO_3, carbonic acid; H_2O, water; K^+, potassium; mEv, millivolts; Na^+, sodium.

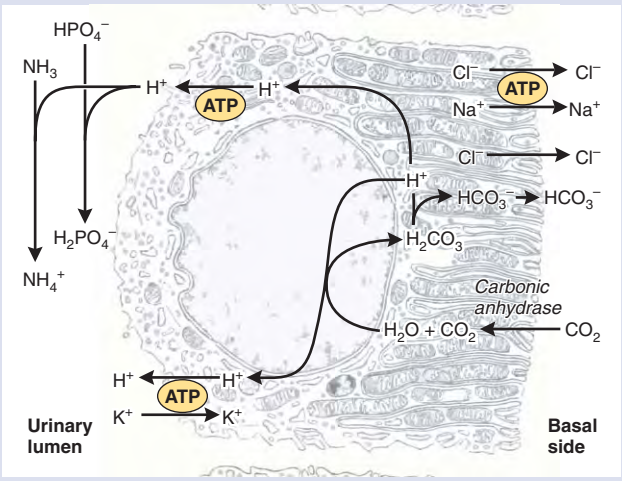

Figure 14-8 One of the major functions of the distal tubule is to acidify the urine. Hydrogen ions are secreted into the tubule lumen, where binding with ammonia and phosphoric acid allows for the reclamation of bicarbonate. ATP, adenosine triphosphate; CO_2, carbon dioxide; HCO_3^-, bicarbonate; H_2CO_3, carbonic acid; H_2O, water; K^+, potassium; Na^+, sodium.

to increase HCO_3^- secretion in the distal tubule. Most distal renal tubular cells, however, secrete H^+. The secretion and loss of H^+ indirectly increase the amount of serum HCO_3^- reabsorbed. Bicarbonate is transferred across the basement membrane in exchange for Cl^-.

Despite the large amount of H^+ in the urine, little of it is excreted as HCl (hydrochloric acid) due to the presence of ammonium and phosphate buffers. If urinary HCl concentrations were high, the conditions needed to form stones, including uric acid stones, would be enhanced, and the low urinary pH could be injurious to the renal tubule and uroepithelium. The H^+ combines with either ammonia or phosphate to buffer the pH.

Ammonia is produced by the conversion of glutamine to ammonia in most renal tubule cells except those in the thin segment of the loop of Henle. The secreted H^+ combines with ammonia, to form ammonium (NH_4^+). Renal tubular ammonia release increases concomitantly with increases in H^+ secretion. This observation is of particular importance when discriminating between renal tubular acidosis and other, mostly gastrointestinal, causes of nonanion gap metabolic acidosis. When a patient has a chronic metabolic acidosis, the ammonium concentration in the urine increases.[26]

Approximately 20% of all filtered phosphate is not reabsorbed before the distal tubule. Phosphate can combine with either one or two H^+ and is typically excreted with Na^+.[27]

Table 14-4
Rules of Chronic Acid-Base Compensation

Chronic Change	Rule	Example
↑P_{CO_2}	For every 1–mm Hg increase in P_{CO_2}, the pH decreases by 0.0025 pH unit.	P_{CO_2} 40 → 60 pH 7.40 → 7.35
Compensation for ↑P_{CO_2} ↓P_{CO_2}	The HCO_3^- will increase by 0.4 mmol/L for every 1–mm Hg increase in P_{CO_2}.	HCO_3^- 24 → 28
	For every 1–mm Hg decrease in P_{CO_2}, the pH increases by 0.003 pH unit.	P_{CO_2} 40 → 20 pH 7.40 → 7.46
Compensation for ↓P_{CO_2} ↑HCO_3^-	The HCO_3^- will decrease by 0.5 mmol/L for every 1–mm Hg decrease in P_{CO_2}.	HCO_3^- 24 → 14
	For every 1–mm Hg increase in HCO_3^-, the pH increases by 0.003-0.008 pH unit.	HCO_3^- 24 → 34 pH 7.40 → 7.43-48
Compensation for ↑HCO_3^- ↓HCO_3^-	The P_{CO_2} will increase by 0.2-0.9 mm Hg for every 1–mm Hg increase in HCO_3^-.	P_{CO_2} 40 → 48
	For every 1–mm Hg decrease in HCO_3^-, the pH decreases by 0.012 pH unit.	HCO_3^- 24 → 14 pH 7.40 → 7.28
Compensation for ↓HCO_3^-	The P_{CO_2} will decrease by 1.25 mm Hg for every 1–mm Hg decrease in HCO_3^-.	P_{CO_2} 40 → 28

Each time H^+ is buffered by the ammonia or phosphate buffering system, a new HCO_3^- molecule is produced by the renal tubule cell and released into the blood.

Chronic Buffering Processes

With any level of chronically elevated or decreased P_{CO_2}, serum HCO_3^- changes cause the pH to return toward normal (Table 14-4) but not completely back to normal. Several hours to days are needed for the full renal response, a compensatory metabolic acidosis, to hypocapnea to begin.[28] A decrease in P_{CO_2} causes a decrease in renal tubular HCO_3^- reabsorption.[29-33] Hydrogen ion secretion by the proximal and distal renal tubules is also diminished.[34,35] The increase in serum chloride (Cl^-) occurs through a shift of Cl^- out of the red blood cells, extracellular volume contraction, and enhanced renal Cl^- reabsorption.

When P_{CO_2} rises, the kidney compensates by secreting more H^+[36,37] and by increasing the amount of HCO_3^- reabsorbed.[29,31,32,38-40]

INTERPRETATION OF ACID-BASE STATUS FROM BLOOD GAS RESULTS

General Approach to Evaluating Acid-Base Status

To effectively assess acid-base status, the clinician is greatly assisted by reviewing simultaneous blood chemistry and blood gas results. The following steps are most helpful in yielding a diagnosis:

1. Assess the serum pH, because it indicates whether a patient is acidemic or alkalemic.
2. Assess the P_{CO_2} and serum total CO_2-HCO_3^- values relative to the pH to determine the primary cause of the pH disturbance.
3. Calculate the expected respiratory or renal compensation. If memorization of the compensation rules seems overwhelming, the modified version of the Henderson-Hasselbalch equation can be used to determine the appropriate respiratory or renal response when one assumes a normal pH.
4. Calculate the anion gap and delta anion gap to distinguish the cause for metabolic acidosis and to determine if there is an additional acid-base disorder.

pH

The first step in analyzing a blood gas is to determine whether the patient is acidemic or alkalemic. The normal pH of extracellular fluids is 7.38 to 7.42. Any increase in P_{CO_2} or decrease in HCO_3^- such that the pH is lower than 7.38 is referred to as an *acidemia*. Any uncompensated decrease in P_{CO_2} or increase in HCO_3^- such that the pH is higher than 7.42 is characterized as an *alkalemia*. When there is a perturbation in the blood pH, the etiology is either respiratory or metabolic. For example, if the patient is acidemic, then there will be an excess of P_{CO_2} or a decrease in HCO_3^-.

Any change in the H^+ concentration in blood causes a defense of the pH by compensatory mechanisms. For example, if there is a perturbation in P_{CO_2}, then the serum HCO_3^- will increase or decrease to compensate, thereby normalizing the pH. When a primary respiratory or metabolic process overwhelms the compensatory mechanism, the blood pH changes.

Example: A neonate with respiratory distress has the following blood gas: pH: 7.33, P_{CO_2}: 52 mm Hg, HCO_3^-: 26 mmol/L. What is the primary disturbance?

Diagnosis: In this particular case, the patient is acidemic due to a primary *respiratory acidosis* with an incomplete *compensatory metabolic alkalosis*.

pH has a significant effect on serum K^+ values. As extracellular H^+ increases, H^+ moves into cells in exchange for K^+. Therefore, in response to acidemia, the serum K^+ rises by 0.6 mEq/L for every decrease in blood pH of 0.1. Conversely, every pH increase of 0.1 leads to a decrease in serum K^+ of 0.2 to 0.4 mEq/L.

P_{CO_2}

The partial pressure of carbon dioxide (P_{CO_2}) in the blood and its relationship to gas exchange is discussed in detail earlier in Gas Exchange, Oxygen Delivery, and Ventilation. However, the P_{CO_2} has profound effects on blood pH and is measured directly with a CO_2 electrode, which is a core element of a multianalyte blood gas machine (normal range: 35 to 40 mm Hg). The actual HCO_3^-, standard HCO_3^-, and base excess are then computed from the pH and P_{CO_2} using the Siggaard-Andersen nomogram (see Fig. 14-8). The arterial P_{CO_2} will vary inversely with alveolar ventilation in a linear manner:

$$Paco_2 \sim K \times \dot{V}CO_2/\dot{V}A$$

where $\dot{V}CO_2$ is the volume of CO_2 produced by the body's metabolism per minute (L/min), and $\dot{V}A$ is the alveolar ventilation (L/min).

Thus, assuming a constant metabolic production of CO_2, a reduction in alveolar ventilation by half will lead to a doubling of P_{CO_2} from 40 mm Hg to 80 mm Hg, causing a respiratory acidosis. Conversely, a doubling of alveolar ventilation will lead to a reduction of P_{CO_2} from 40 mm Hg to 20 mm Hg, causing a respiratory alkalosis.

Blood measurement technique can invalidate the obtained P_{CO_2} result. Air bubbles in the specimen should be avoided because they will cause a spurious fall in P_{CO_2} and an increase in P_{O_2}. The anticoagulant heparin is acidic and in excess can lead to false reduction in the P_{CO_2} and HCO_3^- results. Conversely, when there is delayed measurement, continued metabolism by the erythrocytes reduces pH and P_{O_2} and increases P_{CO_2}. For this reason, specimens are kept on ice prior to measurement.

BICARBONATE

Serum HCO_3^- or total CO_2 values are routinely measured using analytical clinical laboratory or blood gas equipment. Some laboratories will report serum total CO_2 values instead of HCO_3^-. The total CO_2 value includes HCO_3^-, H_2CO_3, dissolved CO_2, carbonate, and CO_2 bound to amino acids. Total CO_2 can be determined by adding a strong acid to blood. Because 95% of the total CO_2 value is HCO_3^-, the total CO_2 value is usually 2 mmol/L higher than the calculated HCO_3^- value. Serum HCO_3^- levels can be estimated from total CO_2 values. Serum HCO_3^- and total CO_2 can be determined from known pH and P_{CO_2} values using the Henderson-Hasselbalch equation.

Serum total CO_2 and HCO_3^- values change in response to blood CO_2 levels due, in part, to the H^+ accepting capacity of hemoglobin and other proteins. When CO_2 is bubbled through a HCO_3^- solution without hemoglobin, the HCO_3^- concentration does not change. Therefore, hemoglobin plays a role in mediating HCO_3^- response to P_{CO_2}. If sodium bicarbonate is infused into blood, P_{CO_2} values increase.

Example: A 17-year-old girl with diabetic ketoacidosis has a serum HCO_3^- of 5 mmol/L, pH of 7.11, and P_{CO_2} of 16.5 mm Hg. After fluids and 100 mEq of sodium bicarbonate were infused, a repeat blood gas shows a HCO_3^- value of 13 mmol/L, P_{CO_2} of 30, and pH of 7.25. Why is the P_{CO_2} rising when the pH is still less than 7.38?

Diagnosis: As sodium bicarbonate is infused, the P_{CO_2} rises because of a decrease in respiratory drive from the rising pH and due to the conversion of H^+ and HCO_3^- to H_2O and CO_2.

In children and adults, the normal serum HCO_3^- value is 24 mmol/L (range, 22 to 29 mmol/L). In newborns, the values are significantly lower due to an expanded extracellular volume, decreased renal tubule ammonia production, a lower HCO_3^- reabsorption threshold, and a limited ability to excrete H^+.[41] A modest metabolic acidosis tends to facilitate an increase in the respiratory drive in the postnatal period. Mean serum HCO_3^- values are lower in preterm infants (18 to 20 mmol/L) than those born at term (20 to 22 mmol/L).

There has been a significant amount of controversy as to whether to correct metabolic acidosis with a sodium bicarbonate or other buffers in critical care situations.[42] Most investigators have concluded that HCO_3^- therapy is not indicated for the treatment of physiologic metabolic acidosis, even lactic acidosis, because it resolves without buffer treatment. There is value, however, in giving buffer therapy to patients with renal tubular acidosis and diarrheal HCO_3^- losses.

BASE EXCESS

Base excess or base deficit is characterized by the amount of base that is required to normalize the pH of the blood. Normal values range from −2 to +2 mEq/L. Base excess can be determined by plotting the values on the Sigaard-Andersen nomogram (Fig. 14-9) or by calculating the formula where the base excess is based on P_{CO_2} and pH or P_{CO_2} and HCO_3^-.

$$\text{Base excess} = 0.9287\ [HCO_3 - 24.4 + 14.83\ (pH - 7.4)]$$

$$\text{Base excess} = 0.02786 \times P_{CO_2} \times 10^{(pH\ -6.1)} + 13.77 \times pH - 124.58$$

Positive base excess numbers indicate the presence of a metabolic alkalosis, whereas negative numbers indicate the presence of a metabolic acidosis. The base deficit can be used to calculate the amount of HCO_3^- (or other base) needed to normalize the pH. Because the volume of distribution of HCO_3^- is 0.4,[43,44] the formula to calculate the amount of base that is required to normalize the pH of the blood is as follows:

$$\text{Base required} = (\text{Base excess} \times -1) \times (\text{Weight in kg}) \times 0.4$$

Example: A 12-year-old boy with chronic renal failure (estimated GFR = 25.3 mL/min/1.73 m^2) aspirates after having a hypertension-induced seizure and is now intubated and on a ventilator. His blood gas shows a pH of 7.19, P_{CO_2} of 46 mm Hg, and HCO_3^- of 18 mmol/L. His hemoglobin is 10.1 g/dL. The base excess is −10.8 mEq/L. How much sodium bicarbonate per kilogram would be needed to normalize the HCO_3^-?

Solution: The amount of HCO_3^- per kilogram needed to correct the metabolic acidosis is determined by multiplying the negative base excess by the volume of distribution (0.4). The patient would need 4.3 mEq per kilogram of HCO_3^-.

As with the serum anion gap, serum albumin concentrations impact base excess calculations.[45] If the serum albumin is low, as often occurs in critical care settings, the base excess will be more positive than the reported value, as demonstrated in this equation:

$$\text{Base excess correction} = 0.25\ (4.2 - \text{Serum albumin in g/dL})$$

DELTA ANION GAP

This measurement assesses the change in the anion gap relative to HCO_3^- and is of use in patients who have an anion gap metabolic acidosis. The delta anion gap can be calculated using the following equation:

$$\text{Delta anion gap} = (\text{Anion gap} - 10) \div (24 - HCO_3^-)$$

The normal delta anion gap is 1 to 1.6. If the delta anion gap is less than 1, then the HCO_3^- has decreased more than the

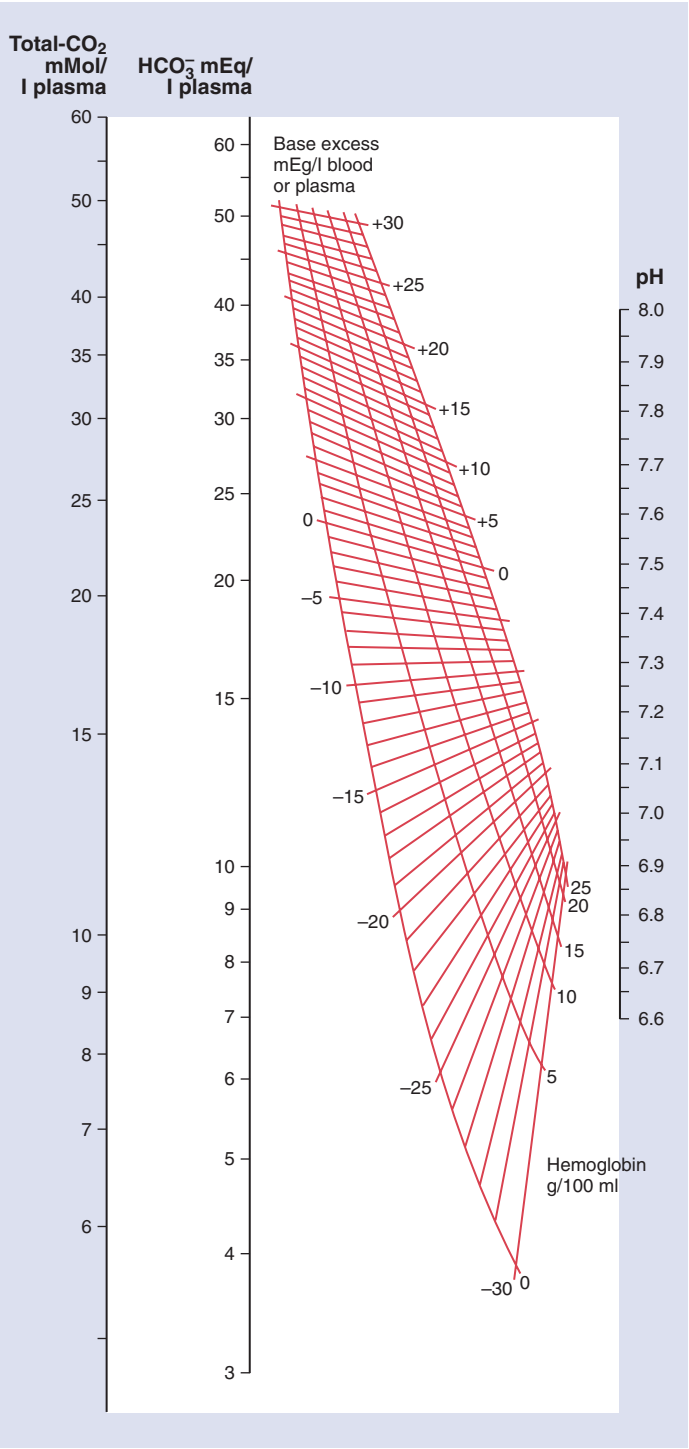

Figure 14-9 Siggaard-Andersen alignment nomogram. Scales for pH, P_{CO_2}, base excess of whole blood of different hemoglobin concentrations, plasma bicarbonate, and plasma CO_2. (Redrawn from Siggaard-Andersen O: The acid-base status of blood. Scand J Clin Lab Invest 15:211-217, 1963, by permission of Scandinavian University Press.)

amount that could be explained by the anion gap and therefore there is an additional metabolic acidosis. Conversely, if the delta anion gap is greater than 1.6, then the HCO_3^- is higher than one would expect given the anion gap, thus indicating that the patient has an undetected metabolic alkalosis.

Example: A 3-year-old boy was brought to the emergency department after ingesting an unknown quantity of aspirin. His blood gas shows a pH of 7.20, P_{CO_2} of 46 mm Hg, and HCO_3^- of 18 mmol/L. Other values are serum Na^+ of 132 mEq/L, Cl^- of 102 mEq/L, and serum total CO_2 of 8 mmol/L. Calculate the delta anion gap.

Solution: The anion gap is 22 mmol/L, 12 mmol/L higher than the 10 mmol/L given in the equation. The serum total CO_2 is 8 mmol/L, 16 mmol/L less than the normal 24 mmol/L. The delta anion gap is 0.75, indicating the patient has at least two causes for his metabolic acidosis. The respiratory compensation is appropriate given the severity of metabolic acidosis.

METABOLIC AND RESPIRATORY DERANGEMENTS

Metabolic Acidosis

There are three basic mechanisms that can cause serum HCO_3^- levels to fall, yielding a metabolic acidosis: (1) an acid is added to the body fluids, HCO_3^- buffers the acid, leaving less HCO_3^-, (2) HCO_3^- is lost through the gastrointestinal tract[46] or by the kidneys, or (3) serum HCO_3^- levels are decreased by dilution with a non–HCO_3^--containing solution.[47] The compensatory response to both acute and chronic metabolic acidosis is a respiratory alkalosis, where hyperventilation decreases P_{CO_2} values.

Any evaluation of any metabolic acidosis should include a determination of the serum anion gap. The limits of electrochemical neutrality (e.g., the sum of all the positively charged ions equals the sum of the negatively charged ions [anions]) ensure that there are equal numbers of positive and negative ions in body fluids. The anion gap can be determined by the use of the following equations:

$$\frac{Na^+ + \text{Unmeasured cations} = (Cl^- + HCO_3^-) + \text{Unmeasured anions}}{}$$

$$\frac{\text{Anion gap} = Na^+ - (Cl^- + HCO_3^-) = \text{Unmeasured anions} - \text{Unmeasured cations}}{}$$

Unmeasured cations include K^+, Ca^{2+}, and Mg^{2+}. Unmeasured anions include albumin and phosphate. Note that serum K^+ in this formula is considered as an unmeasured cation and should not be added to the Na^+ in the calculation of the anion gap. The normal anion gap is 12±4 mmol/L.[48] Under normal conditions, the anion gap is predominantly composed of negative charges on serum proteins including albumin[48,49] (Fig. 14-10). The anion gap falls by 2.5 mmol/L for every 1-g/L reduction in serum albumin.[50] The anion gap is clinically useful because it can be used to determine the cause of the metabolic acidosis.[51]

Most patients with a metabolic acidosis have either an increased or a normal anion gap. If, hypothetically, hydrochloric acid is infused into the blood, then there is a milliequivalent per milliequivalent replacement of HCO_3^- for Cl^-, yielding a normal anion gap acidosis. The same is true for intestinal or renal loss of HCO_3^-. The determination of a urine anion gap can be particularly helpful in diagnosing renal tubular acidosis.[52] However, if HCO_3^- is replaced by an unmeasured anion, the anion gap will increase. Changes in the anion gap are linked to P_{CO_2}. For every 1-mmol/L rise in

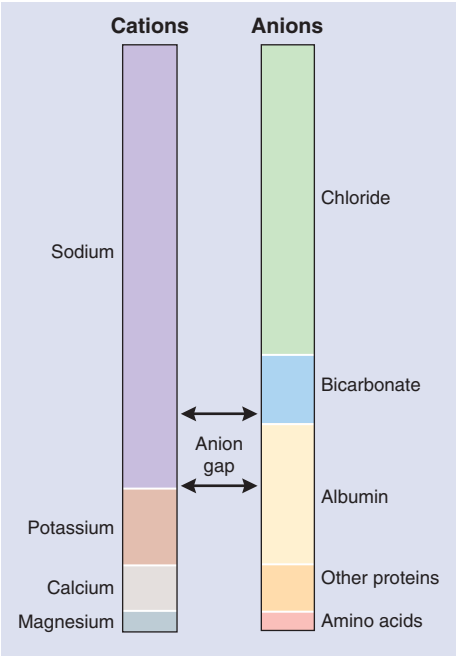

Figure 14-10 Serum anion gap. Due to the demands of electrochemical neutrality, the concentration of positive and negative ions in serum must be equal. The serum sodium value is greater than that of chloride and bicarbonate combined. The normal ion gap, 12 ± 4 mmol/L, is composed of albumin, phosphates, and amino acids. If the anion gap is elevated, bicarbonate has been replaced by other anions, making the anion gap greater than normal.

Table 14-5
Causes of an Anion Gap Acidosis

Cause	Unmeasured Anion
Toxins and drugs	
Ethanol	Lactic acid
Ethylene glycol	Oxalic acid
Isoniazid toxicity	Lactic acid
Methanol	Formic acid
Paraldehyde	Acetic acid
Salicylates	Lactic acid
Isopropyl alcohol	Oxalic acid
Lactic acidosis	Lactic acid
Uremia	Uric, oxalic, succinic, pimelic, and adipic acids
Amino acidopathies	
Maple syrup urine disease	α-Keto-isocaproic, α-keto-β-methylvaleric, α-ketoisovaleric, Indolacetic, acetoacetic, and β-hydroxybutyric acids
Isovaleric acidemia	Isovaleric acid
Glutaric acidemia	Glutaric, lactic, Isobutyric, isovaleric, and α-methylbutyric acids
Propionyl coenzyme A carboxylase deficiency	Propionic, methylcitric Propionylglycine, acetoacetic, β-hydroxypropionate, and β-hydroxybutyric acids
Methylmalonic acidurua	Methylmalonic acid
Defects in carbohydrate metabolism	
Diabetic ketoacidosis	Acetoacetic and β-hydroxybutyric acids
Fructose-1,6-diphosphatase deficiency	Lactic and pyruvic acids
Glucose-6-phosphatase deficiency	Lactic acid
Pyruvate carboxylase deficiency	Lactic and pyruvic acids
Succinyl-coenzyme A–transferase deficiency	Acetoacetic and β-hydroxybutyric acids

serum anion gap, the P_{CO_2} should decrease by 1 mm Hg. An increased anion gap can be caused by an increase in unmeasured anions and/or a decrease in unmeasured cations[48] (Table 14-5). A decreased anion gap is often due to hypoalbuminemia, hypercalcemia, hyperkalemia, hypermagnesemia, or lithium.

Most of the acute change in serum HCO_3^- is repaired by intracellular buffering processes.[53] Hemoglobin, phosphorus, protein, and bone[31,54] all contribute to buffering H^+. Serum Cl^- levels rise in response to the decrease in HCO_3^- levels.

There is increasing evidence that intravenous sodium bicarbonate infusions should not be used to treat critically ill patients with an anion gap metabolic acidosis.[7,55,56] There are also insufficient data to recommend sodium bicarbonate infusion in newborn resuscitation.[57-59] Thus, sodium bicarbonate treatment is typically reserved for the treatment of a hyperchloremic metabolic acidosis, including renal tubular acidosis, diarrhea, a ureterosigmoidostomy, and amino acid or cholestyramine infusions. In addition to sodium bicarbonate, sodium acetate (in intravenous solutions), oral sodium citrate, and potassium citrate may be used to correct a persistent hyperchloremic acidosis.

Because the injectable solution of sodium bicarbonate has a Na^+ content of 1000 mEq/L, large doses can cause significant hypernatremia.[56] Intravenous use of diluted sodium bicarbonate solution in concentrations of 140 mEq/L in patients with normal renal function rarely causes hypernatremia. In situations where a patient remains acidemic but is significantly hypernatremic, *tris*-hydroxymethyl aminomethane (THAM) can be used.[55] THAM can be used in patients with renal acidosis, salicylate or barbiturate intoxication, and increased intracranial pressure associated with cerebral trauma.[60] THAM dosing is based on the following formula:

$$\text{THAM (mL of 0.3 mol/L solution)} = \text{Lean body weight (kg)} \times \text{Base deficit (mmol/L)}$$

Serum K^+ values inversely correlate with serum HCO_3^- values. Serum K^+ concentrations fall with an infusion of HCO_3^- due to the movement of K^+ back into cells in exchange for H^+. A pH increase of 0.1 leads to a decrease in serum K^+ of 0.2 to 0.4 mEq/L. Conversely, for every decrease in blood pH of 0.1, the serum K^+ rises by 0.6 mEq/L.

Respiratory Acidosis

Any process that interferes with ventilation can cause a respiratory acidosis. The causes of ventilatory failure include chronic obstructive pulmonary disease, drugs, extreme ventilation-perfusion mismatch, extensive infiltrative process, exhaustion, neuromuscular disorders, and excessive CO_2 production.

The compensatory response to respiratory acidosis is a metabolic alkalosis. Hypercapnia stimulates the secretion of H^+ by the distal tubule (see Fig. 14-8), which lowers urine pH.[17,61,62] Serum HCO_3^- values also increase because HCO_3^- secretion in the distal tubule is inhibited.[63] The higher

HCO_3^- concentration is maintained by enhanced renal HCO_3^- reabsorption in both proximal and distal tubules. As serum HCO_3^- levels increase, the serum Cl^- levels must decrease. Hypercapnia leads to a decrease in proximal sodium chloride reabsorption and causes chloriuresis. The compensatory response of metabolic alkalosis, to chronic hypercarbia, usually takes 1 to 2 days.

Example: A 16-year-old boy with a pulmonary hemorrhage due to Wegener granulomatosis has a pH of 7.32, $PaCO_2$ of 52 mm Hg, and HCO_3^- of 26 mmol/L.

Diagnosis: The elevated HCO_3^- could not have caused the acidemia, so the principal cause of the acidemia is a respiratory acidosis. Yet, the renal compensatory process either is incomplete or has not had time to correct the pH to normal.

Occasionally, an overshoot in HCO_3^- generation occurs so that the blood is alkaline due to nighttime hypercapnia or a renal response geared to blood PCO_2 rather than pH. Therefore, the patient with a chronic respiratory acidosis may present with a modest alkalosis.

If there were no compensatory process, the recognition of the inciting problem would be quite easy. Formulas have been derived that describe the relationship between CO_2 and HCO_3^- in acute and chronic acid-base disorders (see Tables 14-2 and 14-4). These formulas can assist in the determination of the primary event and the subsequent compensatory process. In most cases, the direction of the pH deviation suggests the primary process.

Discriminating between Acute and Chronic Respiratory Acidosis

Acute respiratory acidosis is usually caused by an abrupt decline in ventilation that causes the PCO_2 to rise and pH to fall. A child with acute respiratory acidosis frequently is hypoxic and presents with tachypnea, dyspnea, and hyperpnea.

Example: An arterial blood gas sample obtained from a child with known severe asthma, now presenting to the emergency department with status asthmaticus, reveals a low pH (7.26) with a high PCO_2 (62 mm Hg) and a slightly elevated serum HCO_3^- (27 mmol/L).

Diagnosis: These results are consistent with a child who has impending respiratory failure. Most asthmatics have a mild respiratory alkalosis at the time of presentation. The elevated HCO_3^- is attributable to buffering by intracellular buffering mechanisms. The increase in serum HCO_3^- by 1 mmol/L for every 10–mm Hg increase in PCO_2[64] is immediate.

Renal buffering does not noticeably impact the pH until 12 to 24 hours after the respiratory acidosis begins.[65] Treatment of the patient with acute respiratory acidosis involves rapid recognition and correction of the inciting cause coupled with oxygen administration. Sodium bicarbonate, which can cause a rise in PCO_2, should be used only to preclude the serious cardiovascular affects of acidosis.

The basis for chronic respiratory acidosis is typically a decrease in alveolar ventilation. Plasma CO_2 values are elevated; however, unlike in the patient with acute respiratory acidosis, effective renal compensation has occurred. Therefore, serum pH values are only slightly below normal. For each increase in the PCO_2 of 1 mm Hg, the HCO_3^- value increases by 0.41 mmol/L.[66] Serum Cl^- values are decreased to reciprocate the increase in serum HCO_3^-.

Example: A 3-month-old infant with bronchopulmonary dysplasia on diuretic therapy has the following venous blood gas and laboratory results: pH 7.38, PCO_2 66 mm Hg, PO_2 43 mm Hg, HCO_3^- 37 mmol/L, serum Na^+ 136 mEq/L, serum K^+ 2.9 mEq/L, serum total CO_2 39 mmol/L, serum Cl^- 86 mEq/L.

Solution: This blood gas obtained from a child with stable bronchopulmonary dysplasia is remarkable for the normal to slightly low pH, a markedly elevated PCO_2, and the appropriately elevated HCO_3^- (i.e., an effective renal compensation for the chronic respiratory acidosis).

Loop and thiazide diuretics are helpful in the management of chronic pulmonary disease because excessive fluid causes pulmonary congestion. Yet, loop and thiazide diuretics can cause worsening of the metabolic alkalosis by causing a contraction alkalosis, as shown in the example above.

Metabolic Alkalosis

Metabolic alkalosis, an acid-base disorder characterized by an increased concentration of serum HCO_3^-, can be caused by three major mechanisms: (1) intravascular volume contraction where Cl^- is lost disproportionately to HCO_3^-, (2) loss of H^+, or (3) net addition of HCO_3^- to the extracellular space.

Chloride loss, without concurrent H^+ loss, most commonly occurs with gastrointestinal disease, chemical diuretic use,[67] cystic fibrosis,[68,69] Bartter syndrome,[70] or Gitelman syndrome.[71,72] With intractable Cl^- depletion, the kidney increases the reabsorption of HCO_3^- by increasing distal tubule H^+ secretion. A metabolic alkalosis can develop when Cl^- is lost in excess of Na^+ from the gastrointestinal tract of patients with acute diarrhea.[73] Chloride losses due to diarrhea may range from 10 to 110 mEq per liter of stool. There is a rare congenital form of chloride diarrhea in which there is a defect in bowel transport of Cl^-.[74,75] Chemical diuretics, including loop (furosemide, bumetanide, ethacrynic acid) and thiazide (including chlorothiazide, hydrochlorothiazide, and metolazone) diuretics, can cause a profound loss of Cl^- by the kidney. Loop diuretics such as furosemide, bumetanide, and ethacrynic acid block the symporter within the thick ascending limb of the loop of Henle[76] (Fig. 14-11). Owing to the large amount of Na^+ and Cl^- reabsorption attributable to the symporter, the diuresis seen with a loop diuretic is much greater than that seen with any other class of diuretic. The normally functioning symporter cotransports two Cl^- molecules, one K^+ molecule, and one Na^+ molecule from the tubule lumen into the cell.[77] Loop diuretics also increase the excretion of calcium and magnesium, thereby increasing the risk of urolithiasis.[78] Thiazide diuretics, including hydrochlorothiazide, metolazone, and chlorothiazide, inhibit the function of a sodium chloride pump found within the distal convoluted tubule and decrease calciuria.

Bicarbonate values rise acutely with the use of loop and thiazide diuretics due to at least four mechanisms. First, contraction of the intravascular volume, without net loss of HCO_3^- causes an increase in serum HCO_3^- levels.

Second, increased salt delivery to the distal tubule stimulates K^+ and H^+ secretion independent of an aldosterone effect,[79] thus contributing to higher serum HCO_3^- values.

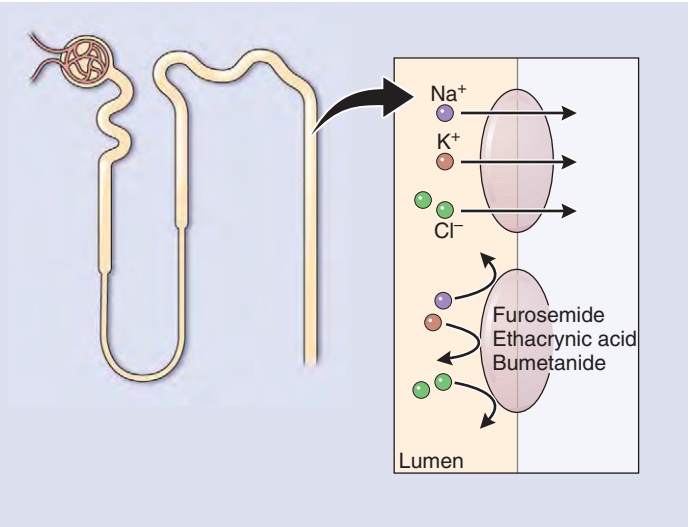

Figure 14-11 The thick ascending limb symporter reabsorbs two chloride molecules with one potassium and one sodium molecule. Dysfunction of the symporter causes Bartter syndrome. Loop diuretics inhibit symporter function, causing the loss of sodium, chloride, potassium, and water in the urine, and decrease the effectiveness of the countercurrent exchange.

Third, extravascular volume contraction causes the GFR to decrease. As a result, more Na^+ and water are reabsorbed in the proximal tubule. Because Na^+ delivery is decreased to the collecting duct, the juxtaglomerular apparatus secretes renin into the afferent arteriole. A renin-mediated increase in angiotensin II leads to an increase in aldosterone levels. Aldosterone binds to a cytoplasmic receptor found in distal renal tubular cells. The aldosterone–cytoplasmic receptor complex is translocated to the nucleus where the gene for the Na^+ pump is upregulated, transcribed, and translated. The Na^+ pump protein is transferred to the luminal surface, where it reabsorbs Na^+ in exchange for K^+. As K^+ depletion develops, luminal H^+,K^+,ATPase increases. Renal proton secretion decreases the H^+ concentration in serum, thereby increasing pH and HCO_3^-. As plasma K^+ levels begin to decrease due to diuretic-mediated K^+ depletion, aldosterone levels decrease. In the distal tubule, aldosterone promotes H^+ excretion in exchange for Na^+. As aldosterone levels decline, the amount of H^+ secreted by the tubule also declines. This represents an important feedback mechanism to prevent severe hypokalemia and metabolic alkalosis.

Finally, profound hypokalemia due to K^+ depletion causes K^+ to egress from somatic cells. Because all cells have a K^+-Na^+ pump that keeps intracellular levels of Na^+ low, Na^+ cannot move into the cell in exchange for the K^+ leaving the cell. Hydrogen ions; however, can move into the cell, thereby decreasing serum H^+ concentrations. Serum HCO_3^- levels rise in response.

Treatment of the hypokalemic, hypochloremic metabolic alkalosis caused by diuretics typically consists of KCl- or K^+-sparing diuretics. Potassium chloride therapy is advantageous in that both K^+ depletion and Cl^- deficiency are corrected.

Example: A 4-month-old girl with bronchopulmonary dysplasia has chronic CO_2 retention and is receiving furosemide and metolazone therapy. ABG results show pH 7.41, P_{CO_2} 58 mm Hg, P_{O_2} 53 mm Hg, and HCO_3^- 36 mmol/L. Her serum Na^+ is 137 mEq/L, serum K^+ 2.4 mEq/L, serum Cl^- 86 mEq/L, and serum total CO_2 36 mmol/L. How would one describe this acid-base problem?

Diagnosis: In this particular case, the child is slightly alkalemic due to (1) respiratory acidosis and (2) excessive metabolic alkalosis compensatory response because of the contraction alkalosis.

Patients with Bartter syndrome, which is caused by a malfunction or absence of the $2Cl^-$-Na^+-K^+ symporter in the thick ascending limb of the loop of Henle, also experience profound chloriduria and metabolic alkalosis.[71] The Cl^- depletion causes extracellular volume contraction and increases the serum HCO_3^-. Patients with cystic fibrosis can present with significant metabolic alkalosis due to the loss of Cl^- through sweating.[68,80]

Hydrogen ions can be lost through gastrointestinal or renal mechanisms. The secretion of HCl in the stomach leaves behind a cation and HCO_3^- in the serum. If the H^+ is lost from the body (e.g., vomiting), there will be a net increase in HCO_3^-. Renal H^+ losses can be accelerated by the presence of aldosterone,[81,82] angiotensin II,[82] and diuretics.

Hydrogen ion concentrations can decrease in response to changes in intracellular and extra cellular K^+ distribution. With significant K^+ depletion, K^+ moves out of the cell in order to maintain the ratio of intracellular and extracellular K^+ and a hydrogen ion moves in to maintain electrochemical neutrality. Sodium cannot be exchanged for K^+ because all cells have a Na^+-K^+ pump that pumps Na^+ out of the cell. Hydrogen ions move from the extracellular space into the intracellular space, thus causing a metabolic alkalosis.

The administration of HCO_3^- or substances that generate HCO_3^- such as citrate, acetate, or lactate will cause a rise in serum HCO_3^- levels. Because the kidney has the capacity to excrete HCO_3^- and decrease urinary acidification in response to an alkali load,[83] the alkalosis that develops in response to exogenous alkali is typically mild.

There are three mechanisms that act to return the pH toward 7.40 when a metabolic alkalosis develops. There are intracellular buffering mechanisms by which H^+, derived from intracellular proteins and phosphate, is released into the extracellular space. Lactic acid levels also increase and provide additional H^+ for buffering.[43] The kidney has the capacity to excrete HCO_3^- via beta intercalated cells in the distal tubule.[18] Compensatory respiratory acidosis is the third process by which the pH is returned toward normal. The degree of compensation via respiratory acidosis is somewhat limited because Pa_{O_2} also drops with hypoventilation and the body will not develop a compensatory respiratory acidosis to the point of hypoxemia. Nevertheless, ventilatory drive is decreased and Pa_{CO_2} values can increase to approximately 55 mm Hg. With respiratory compensation, the Pa_{CO_2} should increase by 0.25 to 1 times the HCO_3^- change.

There are factors such as volume depletion, aldosterone, and K^+ depletion that interfere with renal HCO_3^- wasting, thus maintaining the alkalosis.[84] Volume depletion decreases the amount of glomerular filtrate delivered to the proximal tubule; therefore, Na^+ and HCO_3^- reabsorption are increased. Aldosterone increases distal tubule H^+ secretion via the H^+,K^+-ATPase luminal pump.[81,82] Potassium depletion increases the rate of HCO_3^- reabsorption,[85] thus causing a metabolic alkalosis.

Occasionally, metabolic alkalosis can occur in patients who experience a rapid resolution of their chronic hypercapnia but cannot excrete HCO_3^- rapidly enough. Conversion of large amounts of lactic acid due to shock can also cause a metabolic acidosis.[86]

The effective treatment of a metabolic alkalosis depends on the recognition of Cl^-- responsive and -resistant processes. Sodium or potassium chloride replacement will lead to rapid resolution of the Cl^- depletion–induced metabolic alkalosis.[87] Blocking the reabsorption of HCO_3^- in the urine with acetazolamide can correct a metabolic alkalosis. The reabsorption of HCO_3^- is dependent on the presence of carbonic anhydrase, which is found in large amounts only in the convoluted proximal tubule.[88] Inhibition of carbonic anhydrase yields an inability of the tubule to reabsorb HCO_3^-. The use of even a single dose of acetazolamide, a carbonic anhydrase inhibitor, can lead to a rapid improvement of a metabolic alkalosis.[89,90]

Acetazolamide has also been effectively used to prevent altitude sickness.[91-93] Acetazolamide causes a metabolic acidosis by decreasing the reabsorption of HCO_3^- in the proximal tubule. In response to a metabolic acidosis, the respiratory drive increases, thereby increasing O_2 levels.

Individuals who have sodium chloride–resistant metabolic alkalosis typically have increased mineralocorticoid activity or pseudohyperaldosteronism (Liddle syndrome) or may be K^+ depleted.[94] Patients with apparent mineralocorticoid activity experience growth failure, hypertension, and a chronic hyokalemic metabolic alkalosis.[95] Mineralocorticoid activity can be blocked with spironolactone,[72,96,97] triamterene,[98] or amiloride.[97]

Although not commonly used, the intravenous infusion of hydrochloric acid has also been used to correct a severe metabolic alkalosis.[99-101]

Respiratory Alkalosis

Respiratory alkalosis is caused by a process whereby the pH rises in response to a decreasing P_{CO_2}. The P_{CO_2} falls when ventilatory losses of CO_2 exceed CO_2 production. Generally, ventilation can be increased due to central or peripheral neural stimulation, mechanical ventilation, or voluntary effort.

The renal compensatory mechanism is a metabolic acidosis. Buffering by H^+ release from intracellular sources constitutes the first defense against respiratory alkalosis.[10] Amazingly, buffering is complete in minutes and persists for at least 2 hours.[102] In response to acute respiratory alkalosis, the HCO_3^- decreases by 1 to 3 mmol/L for every 10–mm Hg decrease in Pa_{CO_2}.

The kidney compensates in response to respiratory alkalosis by reducing the amount of new HCO_3^- generated and by excreting HCO_3^-.[30] The process of renal compensation occurs within 24 to 48 hours.[28] The stimulus for the renal compensatory mechanism is not pH, but rather P_{CO_2}.[103,104] In chronic respiratory alkalosis, the plasma HCO_3^- is decreased 2 to 5 mmol/L for every 10–mm Hg decrease in P_{CO_2}. The only means to treat a respiratory alkalosis is to correct the underlying disorder responsible for causing the disorder.

Table 14-6
Simple Acid-Base Disorders

Type of Disorder	pH	$Paco_2$	HCO_3^-
Metabolic acidosis	↓	↓	↓
Metabolic alkalosis	↑	↑	↑
Acute respiratory acidosis	↓	↑	↑
Chronic respiratory acidosis	↓	↑	↑
Acute respiratory alkalosis	↑	↓	↓
Chronic respiratory alkalosis	↑	↓	↓

From Schrier RW: Renal and Electrolyte Disorders, 3rd ed. Boston, Little Brown and Company, 1986, p. 146.

Simple Acid-Base Disorders

Acid-base problems generally fall into two broad categories: those with a single primary disorder coupled with a compensatory response, a simple acid base disorder, or those in which two or more primary disorders occur together, a mixed acid-base disorder. The type of acid-base disorder can be determined by evaluating the pH, P_{CO_2}, and the HCO_3^-. In a simple acid-base problem, the P_{CO_2} and the HCO_3^- always move in the same direction (Table 14-6). Expected arterial CO_2 values in patients with metabolic acidosis can be calculated based on the serum HCO_3^- concentration according to the following simplified equation[105]:

$$Pa_{CO_2} = 1.5(HCO_3^-) + 8$$

Movement of the P_{CO_2} and HCO_3^- in opposite directions indicates a mixed acid-base disorder. Assessment of the appropriateness of the compensation using Tables 14-2 and 14-4 and Figure 14-12 can also be helpful in uncovering a mixed acid-base problem.

Example: A 2-year-old boy with hypochloremic metabolic alkalosis is diagnosed as having Bartter syndrome. His initial blood gas result was pH 7.42, P_{CO_2} 50 mm Hg, and HCO_3^- 32 mmol/L.

Diagnosis: This is an example of simple acid-base disorder with a metabolic alkalosis and a compensatory respiratory acidosis.

Mixed Acid-Base Disorders

A mixed acid-base disorder is a combination of two primary disorders.[49] Recognition of a mixed acid-base disorder is dependent on determining whether the compensatory process was adequate and appropriate. Frequently, the blood gas result will fall outside of the predictive bands found in an acid-base nomogram (see Fig. 14-12). Patients with mixed acid-base disorders may have a serious deviation of the pH, while others may have a normal pH. When there is a significant deviation of the pH, one of the two primary disorders blocked the compensation for the other.

Example 1: A 9-month-old boy with renal tubular acidosis is unable to take his medication due to the respiratory distress associated with respiratory syncytial virus. His admission arterial blood gas results are pH 7.19, Pa_{CO_2} 56 mm Hg, Pa_{O_2} 67 mm Hg, and HCO_3^- 17 mmol/L.

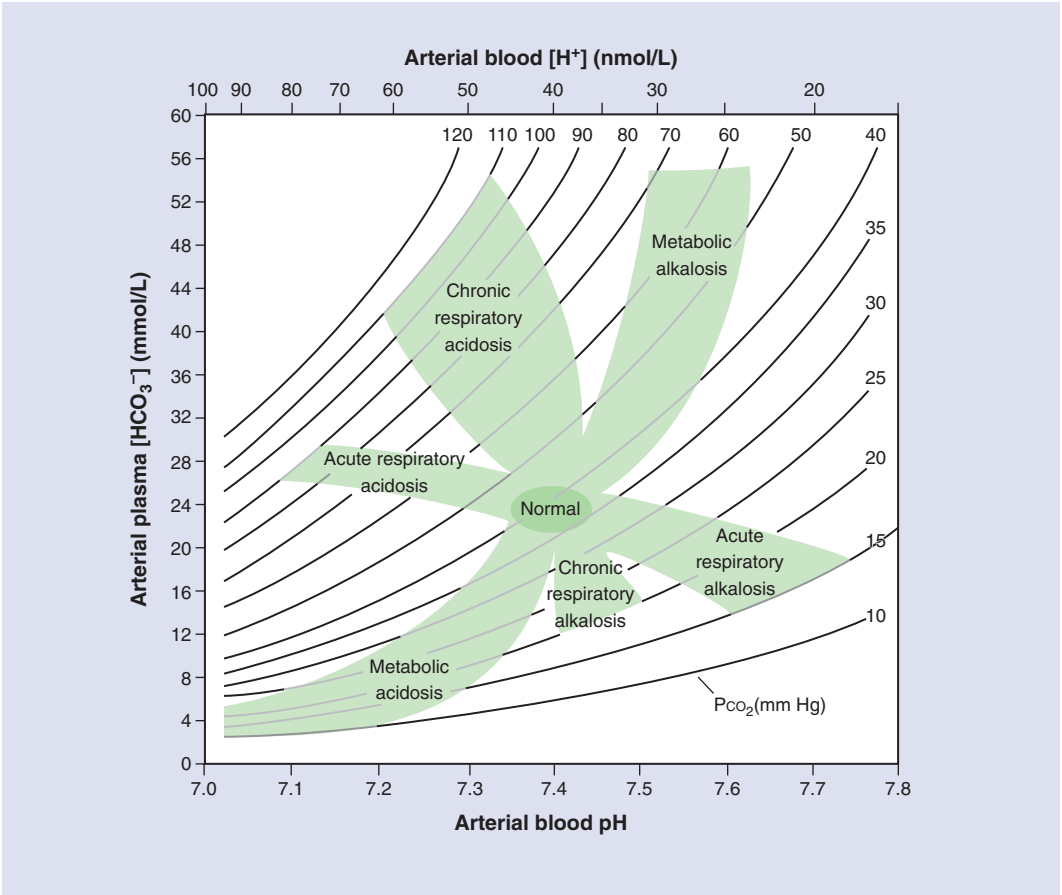

Figure 14-12 Acid-base nomogram. The nomogram bands represent 95% confidence limits for an acid-base disorder. (Redrawn from Brenner B, Rector FC: Acid-base disorders. In Brenner B, Rector FC [eds]: The Kidney, 7th ed. Philadelphia, WB Saunders, 2004, p. 938, with permission.)

Solution: This is an example of a mixed acid-base disorder with a metabolic acidosis and acute respiratory acidosis. Note that the P_{CO_2} and HCO_3^- do not move in the same direction.

Example 2: A 13-month-old girl presents with a 2-day history of nonbilious vomiting and diarrhea. The child has vomited 10 times over the past 36 to 48 hours. Initial laboratory tests show a serum HCO_3^- of 14 mmol/L.

Diagnosis: This is an example of a mixed acid-base disorder because the patient has a metabolic acidosis but also has metabolic alkalosis due to vomiting with loss of HCl. The metabolic alkalosis is not obvious due to the severity of the metabolic acidosis. Without the vomiting, the metabolic acidosis would have been worse.

Occasionally, the amount of compensation is excessive given the clinical situation. For example, children presenting with aspirin intoxication will typically have Pa_{CO_2} values lower than expected based on the acidosis caused by the aspirin alone.[106] The excessive respiratory alkalosis is attributable to the stimulatory effect that aspirin has on ventilation.

Patients with chronic lung disease typically have high P_{CO_2} values and an appropriate compensatory metabolic alkalosis. The addition of diuretics, which are frequently used to decrease alveolar interstitial edema, causes serum HCO_3^- values to increase to levels greater than expected on the basis of the respiratory acidosis alone. The blood gas results are frequently consistent with a simple metabolic alkalosis.[107] A patient's history may be the only means by which the mixed acid-base disorder may be suspected.

Example: A 15-month-old girl with bronchopulmonary dysplasia receives furosemide at a dosage of 1 mg/kg/day. Her typical blood gases on 0.5 L of nasal O_2 are as follows: pH 7.49, Pa_{CO_2} 55 mm Hg, Pa_{O_2} 87 mm Hg, and HCO_3^- 42 mmol/L.

Diagnosis: This patient has mixed acid-base disorder; chronic respiratory acidosis, compensatory metabolic alkalosis, and metabolic alkalosis due to a severe contraction alkalosis. The child develops a viral pneumonia. The arterial blood gas results are pH 7.33, Pa_{CO_2} 74 mm Hg, Pa_{O_2} 67 mm Hg, and HCO_3^- 39 mmol/L. If one were not familiar with the case, this would appear to be an acute respiratory acidosis with an incomplete compensatory metabolic alkalosis; however, with an increase of the $Paco_2$ value by 34 mm Hg (above 40 mm Hg), one would anticipate an acute HCO_3^- compensation of only 3 to 4 mmol/L. Moreover, the blood gas value falls into the chronic respiratory acidosis prediction band.

CHAPTER 15 Diagnostic and Therapeutic Procedures

Robert E. Wood

TEACHING POINTS

- The most serious complication of a diagnostic procedure, other than death of the patient, is to do the procedure and obtain the wrong answer.
- Patients (and their families) should be as comfortable and safe as possible during procedures. Sedation/anesthesia can be critical elements in achieving this goal, but so are more subtle factors such as body language and the words one uses.
- A diagnostic procedure is indicated when there is a critical lack of information necessary for the care of the patient, which is best obtained by that procedure.
- Every human activity has risk, even the lack of activity. We must balance risk and benefit in planning and performing diagnostic procedures. Not doing a diagnostic procedure may increase the patient's risk, by forcing the physician to treat by Levi's method (the seat of one's pants), rather than on the basis of firm knowledge.
- Cognitive errors (wrong procedure, wrong analysis, etc.) can be as serious as technical errors.
- A, B, C: Tend to airway, breathing, then anything else.

GENERAL PRINCIPLES

Invasive procedures should be performed only when less invasive or noninvasive or less expensive procedures cannot yield the same or equivalent information. They should be performed only with the proper equipment and with sufficient numbers of trained and skilled personnel (both operator and assistants). The procedure should be performed in an appropriate setting, such as a well-equipped and staffed procedure (or operating) room or an intensive care unit, rather than at the patient's bedside.

Careful attention should be given to the timing of procedures. In general, earlier diagnosis results in earlier selection of the most effective therapy and avoids the confounding influence of empirical therapy. This should in turn result in savings of more than just money. Elective procedures should, in general, not be performed at hours that will result in significant delays in the processing of diagnostic specimens. Finally, scheduling of elective procedures to avoid meal times and to possibly coincide with normal nap times may reduce stress and strain on patients as well as parents.

Careful and appropriate monitoring of the patient's vital signs (pulse, respiratory rate, and blood pressure) and physiologic status (mental status, oxygen saturation) before, during, and after the procedure is essential. In general, one person (not the operator) should be responsible for monitoring the patient and responding to changes in status.[1]

Patients should be comfortable during and after procedures and within the limits of safety, reasonable convenience, and cost. In many, if not all, cases, this means sedation, which must be carried out with skill and with appropriate agents. If adequate provision cannot be made for safe and effective sedation and monitoring of the patient, then general anesthesia should be used.

SEDATION AND ANESTHESIA FOR PROCEDURES

Optimal sedation or anesthesia of a patient in preparation for a procedure provides for relief of anxiety and pain and also ensures that the patient remains relatively still during the procedure. Although general anesthesia can achieve all these goals, sedation can be used safely and effectively in most children for most diagnostic procedures. On the other hand, physicians should not hesitate to use general anesthesia whenever it is in the patient's best interests, whether for safety or for comfort. Examples of situations in which general anesthesia may be appropriate for procedures normally done with sedation include patients with an unstable airway, patients who have been traumatized by numerous prior procedures, patients who are known to respond poorly to conventional sedation, and patients for whom a prolonged or difficult procedure is anticipated. Current anesthetic techniques have greatly reduced the risk traditionally associated with general anesthesia,[2,3] and patients should not be deprived of the benefits of general anesthesia when it is appropriate, even though it is more expensive.[4] With either general anesthesia or sedation, monitoring of the patient must not stop when the procedure is over, because respiratory depression may last longer than sedation, especially when the stimulation associated with the procedure is no longer a factor.

Sedation is a state of depressed awareness between the fully conscious state and surgical anesthesia. Responsiveness to pain and other stimuli is decreased, as are reflexes. As the depth of sedation increases, respiratory drive is depressed. Careful and continuous monitoring is necessary to ensure

patient safety. Current guidelines for sedation[1,5] require that vital signs, oxygenation, and the patency and adequacy of the airway be monitored continuously during sedation. C*onscious sedation* is a buzzword and refers to the level of sedation at which the patient maintains protective reflexes and response to verbal commands. Conscious sedation may be most appropriate for nonpainful procedures, such as radiographic imaging studies. In practice, many (especially younger) pediatric patients require a deeper level of sedation to safely and effectively tolerate potentially painful procedures. Therefore, extra care must be taken to provide effective monitoring, and sedative agents should be chosen with regard to duration of action.

The choice of medications for pediatric sedation is an important determinant of success. Children (and their parents) are anxious about impending medical procedures. Children who must undergo repeated procedures are particularly vulnerable to psychologic trauma and should be handled with extra care.[6] Agents that partially or totally block short-term recall (e.g., benzodiazepines) can be extremely valuable. However, these agents are not in themselves usually sufficient for effective sedation for invasive procedures except perhaps at high doses. In general, both an analgesic agent and an anxiolytic agent should be used for any procedure involving pain; analgesia and sedation are not necessarily the same. Both types of agents depress the respiratory drive, and their effects may be additive.

Because children often become upset before a procedure, some form of presedation is useful if there is no contraindication such as unstable upper airway obstruction. Chloral hydrate has traditionally been used for this purpose; some concerns have been raised about this agent (potential mutagenicity in bacterial studies), but it has been approved for use in children by the American Academy of Pediatrics.[7] Other medications can be used, including oral[8] or nasal midazolam or ketamine.[9] A child who is comfortably sleepy separates more easily from a parent and can then be given additional medications to achieve the degree of sedation needed for the procedure itself. If the child is upset and crying at the time that medications are being given for sedation, larger doses will be required. Some children become excited and disinhibited when given sedative agents; this is usually only a stage through which they pass on the way to sedation, but it is more likely to be a problem if inadequate initial doses are used.

Chemical sedation is more readily controlled if the agents are given by the intravenous (IV) route because there is less uncertainty regarding absorption and the time course of the medication's effect. It may be helpful to place a lidocaine and prilocaine cream (EMLA Cream)[10] on potential IV sites before presedation to facilitate IV placement after the child has become somewhat sedated. In general, fractional dosing should be used and the patient's response assessed before additional medications are given. The response to medications such as midazolam and narcotics should be maximal within 2 to 3 minutes. Rapid infusion leads to a high concentration in the brain, with hypotension and respiratory depression or even apnea; infusion over 60 to 90 seconds is equally efficacious and safer than bolus infusion.

There are many safe and effective techniques for chemical sedation (Table 15-1),[11] and the operator should choose one or two and develop expertise with these, including a thorough knowledge of the pharmacology of the drugs, their side effects, and interactions. When there is doubt about a technique, consultation should be obtained from a pediatric anesthesiologist.

Table 15-1
Drugs Commonly Used for Pediatric Sedation

Agent	Dose/Route	Comment
Diphenhydramine	1 mg/kg PO	This is a very mild sedative.
Chloral hydrate	75-100 mg/kg PO	Maximum dose is 2 g; this medication may cause gastric irritation.
Midazolam	0.75 mg/kg PO	Onset occurs in 10-20 min.
	0.4 mg/kg nasal	—
	0.05-0.2 mg/kg IV	Maximal effect occurs in 2-3 min.
Meperidine	1-4 mg/kg IV	—
Morphine sulfate	0.05-0.1 mg/kg IV	—
Fentanyl	1-3 µg/kg IV	This medication may cause rigid chest syndrome.
Ketamine*	2-10 mg/kg IM	This medication should be used with midazolam and atropine.
	1-3 mg/kg IV	—
Methohexital*	1-2 mg/kg IV	This medication provides 1-5 min of general anesthesia.
Pentobarbital	1-3 mg/kg IV	This medication is used primarily for imaging studies.
	2-6 mg/kg IM	—
	2-6 mg/kg PO	—
Reversal Agents†		
Naloxone	Neonates: 0.01-0.1 mg/kg IV	—
	Infants <20 kg: 0.1 mg/kg IV	—
	Children >20 kg: 2 mg IV	—
Flumazenil	Children <20 kg: 0.01 mg/kg IV	—
	Children >20 kg: 0.2 mg IV	—

PO, oral; IM, intramuscular.
*Agents that may require special (anesthesia) qualifications for use.
†The effect of such agents (especially reversal of respiratory depression) may not last as long as that of the primary agent; repeated doses may be required, and careful monitoring is always necessary.

Patients (and their parents) who are under stress are more open to suggestion than they ordinarily would be; that is, they behave as though they are in a light hypnotic trance. Physicians must be aware of this phenomenon and use it for the patient's benefit. Inadvertent negative suggestions can have a dramatic impact on the patient's (or parents') behavior. One should be careful to use positive suggestion, avoiding negatives, and to prepare the patient for an experience that will be as relaxed and comfortable as possible. Children in particular are quite suggestible, and operators skilled in the techniques of hypnosis or simple distraction can often perform minor procedures with no sedation at all.[12] Because many pediatric practitioners are not necessarily skilled in these techniques, it seems most practical to combine simple relaxation and positive suggestion with chemical sedation.

Sedation diminishes protective reflexes; one of the major risks of sedation is aspiration of gastric contents. Patients should have nothing by mouth for several hours before sedation. Clear fluids may be given up to 2 hours before sedation.[13,14] Young infants may become dehydrated or hypoglycemic if they have nothing by mouth for too long, so IV fluid may be necessary before a procedure.

After completion of the procedure, the patient must be carefully monitored to ensure safe emergence from sedation. Some practitioners reverse the effect of the sedation (e.g., using naloxone, flumazenil, or both agents).[15] However, this practice may have serious shortcomings. The effect of the reversing agent may not last as long as that of the primary agent; therefore, patients treated with reversing agents must be monitored longer and more carefully. Furthermore, extremely rapid reversal of sedation can be frightening and disorienting; it is kinder and gentler to allow the patient to awaken naturally as long as vital signs are stable. On the other hand, reversal agents should be available for use in an emergency when IV sedation is performed.

There are only semantic differences between deep sedation and light general anesthesia. In many cases, it is extremely advantageous to utilize the services of a pediatric anesthesiologist for children undergoing invasive procedures. The agents used by anesthesiologists have more rapid onset, and recovery is usually much faster, than with the agents traditionally used by pediatricians for sedation. An anesthesiologist can take full responsibility for monitoring the child, as well as for recovery afterwards. The result can be a safer and more comfortable experience for the child.

BRONCHOSCOPY

Indications

Bronchoscopy affords direct visual inspection of the upper and lower airways and allows collection of diagnostic specimens such as washings, brushings, or biopsies. The most common indications for diagnostic bronchoscopy in pediatric patients include stridor, atelectasis, recurrent or persistent pneumonia, suspected foreign body aspiration, persistent wheezing unresponsive to medical therapy, hemoptysis, persistent cough, suspected congenital anomalies, upper airway obstruction, and suspected vocal cord paralysis. Because upper airway lesions are frequently associated with lower airway lesions,[16,17] it is usually appropriate to examine both the upper and lower airways even when the primary indication for the procedure involves the upper airway (e.g., stridor, suspected vocal cord paralysis).

Bronchoscopy can be used for therapeutic purposes as well. Extraction of foreign bodies from the airways, removal of tissue masses or other forms of airway obstructions such as mucus plugs, and therapeutic bronchopulmonary lavage are primary examples of therapeutic bronchoscopy.

Contraindications

Bronchoscopy is contraindicated when other, less invasive or less risky procedures can yield the same diagnostic information or therapeutic benefit. Relative contraindications (some of which may in themselves be indications) include massive hemoptysis, severe airway obstruction, severe hypoxemia, severe bronchospasm, and bleeding diatheses such as thrombocytopenia. All these conditions require additional care with sedation and anesthesia, instrumentation, airway management, preparation of the patient, and monitoring before, during, and after the procedure. None, however, is an absolute contraindication to bronchoscopy if the potential benefit of the procedure exceeds the potential risk. In some circumstances in which the potential benefit to the patient is marginal and the risk to medical personnel is significant (such as patients with cavitary tuberculosis), bronchoscopy may be contraindicated.

Instrumentation

Bronchoscopy may be performed with either rigid or flexible (fiberoptic) instruments. In general, depending on the training and preference of the operator and the availability of suitable instruments, either type of bronchoscope can be used for most purposes. However, there are some specific situations in which a flexible instrument has special advantages. These include examination of the lower airways in a patient who is intubated with an endotracheal or tracheostomy tube (the flexible bronchoscope can be passed through the tube without having to extubate the patient) and a patient in whom there is an unstable cervical fracture, cervical ankylosis, or mandibular hypoplasia (these conditions all make it difficult or impossible to pass a rigid bronchoscope into the trachea through the mouth). A flexible bronchoscope has a much smaller diameter than a rigid instrument and thus can be passed farther into the distal airways. Because it is flexible, it can also reach the upper lobes more easily than a rigid instrument.

There are situations in which the use of a rigid bronchoscope is necessary or more advantageous. These include the extraction of tracheal or bronchial foreign bodies and the evaluation of patients with suspected H-type tracheoesophageal fistula, laryngoesophageal cleft, and bilateral abductor paralysis of the vocal cords. Because the rigid bronchoscope is passed through the mouth, it yields a better view of the posterior aspect of the larynx and trachea than a flexible bronchoscope, which is usually passed through the nose and thus approaches the larynx from the posterior aspect, giving a better view of the anterior part of the larynx and upper trachea.

FLEXIBLE BRONCHOSCOPES

Flexible bronchoscopes are constructed of thousands of glass fibers that carry the image (some instruments have a video chip at the tip to generate the image) and illumination, and their distal tips can be angulated to direct the instrument into the desired anatomic location. Most of these instruments have a small but functional suction channel, which allows the instillation and retrieval of liquids such as saline (for diagnostic lavage or clearing secretions from the lens) and medications such as topical anesthetics or antibiotics. The most important aspect of a flexible bronchoscope is that it must be small enough to allow the patient to ventilate around it; the standard "pediatric" instruments have a diameter of 2.8 or 3.7 mm. An ultrathin instrument with a diameter of 2.2 mm (but no suction channel) is also available. The standard pediatric flexible bronchoscope can be used in patients of virtually any age, but may result in total airway obstruction in children who weigh less than 2.5 kg. The smallest "adult" flexible bronchoscope is 4.9 mm in diameter and can be used (if necessary) in children as young as about 4 years. Although the potential for airway obstruction is higher with this larger instrument, it has a larger suction channel, and the image quality is higher.

The image seen through a flexible bronchoscope is composed of several thousand points of light and color, each representing the light transmitted by a single glass fiber. Although the resolution of the flexible instrument is necessarily lower than that of a rigid bronchoscopic telescope, it is nevertheless quite adequate for diagnostic purposes. The glass fibers are fragile. Flexible bronchoscopes should be handled only by responsible, well-trained persons. A flexible bronchoscope should never be passed through a patient's mouth (even under general anesthesia and even through an endotracheal tube) without a suitable bite block in place; the cost in dollars per millisecond can be astronomical.

RIGID BRONCHOSCOPES

Rigid bronchoscopes are essentially metal tubes; it is difficult to see well through a rigid bronchoscope unless a telescope is used. The glass rod (Hopkins) telescope[20] gives infinite resolution and good illumination. Telescopes are available with distal prisms to facilitate views of the upper lobes. The greatest advantage of a rigid bronchoscope is its relatively large inner diameter, through which one can ventilate the patient's lungs and pass a wide variety of instruments.

Techniques for Bronchoscopy

Bronchoscopy is usually performed with the patient supine and the bronchoscopist standing (or sitting) behind the patient's head. A flexible bronchoscope allows other positions for both the patient and bronchoscopist.

Care should be taken to achieve effective topical anesthesia of the larynx before the tip of the bronchoscope is passed through the glottis. Although some bronchoscopists use transtracheal injection of lidocaine in adults, this is a dangerous practice in children and is unnecessary. For flexible bronchoscopy, simple instillation of lidocaine into one nostril (0.5 to 1 mL of 2% lidocaine) usually results in effective anesthesia of the nose and larynx. Additional lidocaine (0.5 to 1 mL of 2% lidocaine) is sprayed onto the larynx through the suction channel of the bronchoscope. For rigid bronchoscopy, the larynx can be directly sprayed with lidocaine after exposure with a laryngoscope. A 1% solution is used below the glottis to reduce the amount of lidocaine absorbed by the patient. The total dose should not exceed approximately 7 mg/kg.[21]

FLEXIBLE BRONCHOSCOPY

After adequate sedation or anesthesia, the upper airway is anesthetized with topical lidocaine. The flexible bronchoscope is passed through one nostril. In some circumstances, the bronchoscope may be passed through the mouth, but this is more difficult than transnasal passage, is less informative, and risks damage to the instrument if an effective bite block is not used. Other approaches include passage through an endotracheal tube (oral or nasal), a nasopharyngeal tube, or a tracheostomy tube or stoma.

As the bronchoscope is passed into the trachea, the patient must be assessed for adequacy of ventilation and topical anesthetic effect. If necessary, supplemental oxygen can be given through the suction channel of the flexible bronchoscope, but care must be taken not to wedge the tip of the instrument into a bronchus while oxygen is being passed through the channel; this will prevent the development of a pneumothorax. The tip of the bronchoscope is then directed to systematically inspect all the airways.

RIGID BRONCHOSCOPY

Rigid bronchoscopy is almost always performed with general anesthesia. Ventilation must be interrupted while a laryngoscope is inserted to allow the bronchoscope to reach the larynx. The tip of the bronchoscope is gently passed through the glottis and into the trachea under direct vision. When the shaft of the bronchoscope has been advanced far enough that the ventilating side holes are below the glottis, the anesthesia circuit is attached to the bronchoscope, and ventilation can be resumed. When forceps or other instruments are passed through the bronchoscope, ventilation must be interrupted unless a Venturi jet ventilation system is being used or flexible instruments are being passed through a side port. Some operators use the glass rod telescope alone, with the patient breathing spontaneously. This technique requires careful attention to anesthetic technique.

The patient's neck must be somewhat extended and the mandible brought forward to pass a rigid bronchoscope into the trachea. This allows good visualization of the laryngeal anatomy, but distorts the airway dynamics. For evaluation of airway dynamics, flexible instruments are superior.

In many patients, a combination of both rigid and flexible instrumentation provides optimal diagnostic and therapeutic results.

BRONCHIAL BRUSHING

Small-diameter brushes can be passed through the suction channel of flexible bronchoscopes (or through a rigid bronchoscope) to obtain specimens containing large numbers of epithelial cells. In adults, this is often done in the evaluation of suspected malignancy (which is rare in pediatric patients). A more common use for bronchial brushing is to obtain microbiologic specimens that are (supposedly) uncontaminated by secretions from the upper airways. Microbiology

specimen brushes are protected by plastic sheaths, which in turn are protected by outer sheaths plugged with wax.[22,23] As the catheter/brush assembly traverses the bronchoscope, the wax plug and outer catheter prevent contamination of the brush with material inside the suction channel of the bronchoscope. The assembly is passed under direct vision to near the desired location, and the inner catheter is advanced out the end of the outer catheter, dislodging the wax plug (which melts or is coughed out later). The brush is then advanced into position, and the specimen is obtained by repeatedly moving the brush against the bronchial wall; it is then withdrawn into the inner catheter. The inner catheter is withdrawn into the outer catheter, and the entire assembly is then removed from the bronchoscope. The outer catheter may then be wiped with alcohol; the inner catheter and then the brush are extended, and with sterile wire cutters, the brush is cut off into a suitable specimen container.

This technique can be used to obtain a lower airway specimen uncontaminated by secretions previously suctioned through the bronchoscope. Unfortunately, many patients aspirate oral secretions during topical anesthesia and passage of the bronchoscope, so a specimen obtained with a microbiology specimen brush is clearly not guaranteed to be uncontaminated by upper airway flora.

However, the smallest specimen brush is too large to pass through the suction channel of the pediatric flexible bronchoscope, so in most pediatric patients, the clinician must be content with direct aspirates or specimens from bronchoalveolar lavage (BAL) for microbiologic studies (see later section). If the child is large enough for a small adult bronchoscope (4.9-mm diameter; 2.0-mm suction channel), then a microbiology brush may be used.

Complications of Bronchoscopy

The complications of bronchoscopy[24-30] depend on the technique and instruments used, the underlying risk factors of the patient, the skill, experience, and diligence of the bronchoscopy team, and, of course, luck. The bronchoscopist should identify risk factors in advance, reduce the risk when possible, and carefully balance risk against benefit when choosing instruments and techniques.

In general, complications may be classified as mechanical, physiologic, infectious, and cognitive. Mechanical complications include trauma to the airway and airway obstruction and are best prevented by the careful selection and use of instruments. If a bronchoscope is passed through an area of compressed or stenosed airway, mucosal edema or accumulation of mucus may occlude that airway after the procedure. Judicious use of systemic steroids may be indicated when the risk of edema after the procedure is high. Epistaxis or bronchial hemorrhage can result from trauma from the bronchoscope itself or from instruments passed through the bronchoscope. Perforation of the tracheobronchial mucosa may lead to air leaks (which may require the insertion of a chest tube) or hemorrhage; perforation is most common when transbronchial biopsy is performed. Hemorrhage usually is transient, and no intervention is needed except suctioning or perhaps local lavage with ice-cold saline or 1:10,000 epinephrine. Severe hemorrhage may require selective intubation of the contralateral mainstem bronchus, packing of the bronchus, or the use of a bronchial-blocking balloon catheter. Clots remaining in the airways after hemorrhage may require removal by extensive suctioning or even rigid bronchoscopy.

Physiologic complications result from alterations in gas exchange or vagal tone. Hypoxemia may develop when the airway is obstructed by the bronchoscope, when ventilation is interrupted (as during the extraction of a foreign body), or as a result of respiratory depression induced by sedation. Flooding of the airways with saline (or blood) also may lead to hypoxemia. Hypercarbia is usually the result of excessive sedation or anesthesia but may also occur in the setting of high-grade airway obstruction. Brief hypercarbia is usually of little consequence, however, and the administration of supplemental oxygen during the procedure can usually prevent or reduce the magnitude of hypoxemia.

Changes in vagal tone (usually because of insufficient topical anesthesia) can lead to bradycardia. Other cardiac dysrhythmias may occur, especially in patients with hypoxemia or preexisting cardiac problems. Laryngospasm and bronchospasm may also occur; both can be prevented or minimized by effective topical anesthesia. Similarly, ineffective topical anesthesia in the distal airways can result in severe coughing, which may then lead to mechanical trauma. On the other hand, excessive use of topical agents (usually lidocaine) can result in hypotension, seizures, and other effects. Bronchoscopy can also result in increased intracranial pressure.[31]

Infectious complications of bronchoscopy may affect either the patient or the bronchoscopy personnel; care must be taken to ensure that instruments are not contaminated from the previous patient and that proper technique is used to protect patient and personnel alike.[32-35] Although children are less likely than adults to aerosolize *Mycobacterium tuberculosis* during coughing, bronchoscopists have been infected in this way by pediatric patients; of course, other infectious agents can also be spread in this fashion. Patients may aspirate oropharyngeal secretions, thus contaminating their lower airways, and infection can be spread from one area of the lungs to another during bronchoscopy. Finally, pseudoinfections can occur when the specimens, but not the patient, are contaminated; this can result in considerable diagnostic and therapeutic confusion.[36,37]

Cognitive complications include the failure to recognize pathology, the failure to perform a procedure when it is indicated, the performance of procedures when they are not indicated, and the use of inappropriate instruments or technique. The most serious complication of a diagnostic procedure, other than death of the patient, is to fail to gain the desired information (or to reach the wrong diagnostic conclusion) while placing the patient at all the risk, cost, and discomfort of the procedure.

BRONCHOALVEOLAR LAVAGE

One of the more important aspects of diagnostic bronchoscopy is the retrieval of specimens from the distal airways. Although direct aspiration of secretions from the proximal airways can be useful, a more representative and informative specimen can be obtained by washing a relatively large area of the distal airways and alveolar spaces with sterile saline. Strictly speaking, in bronchoalveocan lavage (BAL),[38,39] a

sufficient volume of saline is used to ensure that the fluid subsequently aspirated contains some of the fluid lining of the alveolar surface. When relatively small volumes of saline are used, the term *bronchial lavage* is often used. In practice, especially in pediatric patients, it may be difficult to ascertain the minimum volume necessary to achieve BAL.[40] On the other hand, for the most common clinical indications in pediatric patients, it may make very little difference to the interpretation of the data whether a bronchial lavage or BAL is performed. This is especially true in the diagnosis of pulmonary infections.

Indications

BAL is performed in pediatric patients primarily to obtain a representative sample from the distal airways for microbiologic studies.[40] For example, patients with pulmonary infiltrates and presumed pulmonary infection who do not produce sputum are candidates for diagnostic BAL. On the other hand, most pediatric patients with pneumonia have a viral infection and do not require bronchoscopy or BAL; immunosuppressed patients, those who have recurrent or persistent pneumonia (including those in whom therapy has failed), or those with unusual clinical circumstances may benefit from the procedure, however. Young patients with cystic fibrosis, in whom it may be difficult to ascertain the flora of the lower respiratory tract, may also benefit.[41,42]

BAL is indicated in the investigation of interstitial pulmonary disease. Although such use in adults has been relatively disappointing in terms of the ability to make specific diagnoses of noninfectious entities, it is nevertheless reasonable to use BAL to exclude infection before the decision to perform an open lung biopsy is made.[43,44]

In addition to microbiologic studies, the content of proteins, cells, and other constituents of the airway surface fluid may be determined.[45] The cellular component may be of particular interest.[46-48]

Contraindications

There are no absolute contraindications to BAL if it is skillfully performed with suitable technique. Only about half the saline used for BAL is recovered, leaving the rest in the alveolar spaces and distal airways. Although this is absorbed over several hours, significant impairment of gas exchange may result from flooding of the alveolar spaces with saline or from the airway occlusion required during the procedure.[49] Patients who are profoundly hypoxic may suffer further respiratory embarrassment as a result of BAL; the relative effect can be minimized by the use of a smaller instrument (which would wedge into a more distal airway, thus washing a smaller volume of lung). Patients with severe pulmonary hypertension may be at high risk for complications.[28]

Instrumentation

Successful and safe BAL requires that the saline be delivered to a discrete portion of the lungs. Therefore the delivery system, a flexible bronchoscope or a catheter, should be gently wedged into a bronchus. Merely instilling saline into a endotracheal tube, for example, may be unsafe or ineffective because large volumes produce respiratory distress and small volumes do not reliably reach the alveoli. In either case, the amount of saline recovered by suction is relatively small.

Techniques

BAL is most readily performed with a flexible bronchoscope,[39] which can be directed to the area of primary interest. The bronchoscope is advanced into the selected bronchus until its tip is gently wedged in place. Sterile saline is instilled through the suction channel; this may be done with a syringe, or if large volumes will be used, tubing from a reservoir may be connected to the suction adapter. When the desired volume has been instilled, the fluid is withdrawn using gentle suction.

When a rigid bronchoscope is used, a catheter must be passed through the bronchoscope and wedged into position. Such catheters are small relative to a flexible bronchoscope and therefore sample a more limited region of the lung than BAL performed with a flexible bronchoscope. It may also be more difficult to direct the catheter into a specific bronchus.

Nonbronchoscopic BAL may be performed by passing a catheter through an endotracheal or tracheostomy tube.[50,51] In special circumstances, this might be done with fluoroscopic guidance, but nonbronchoscopic BAL is usually done in the setting of diffuse lung disease, when there is relatively little need to direct the catheter to a specific site. As with rigid bronchoscopes, nonbronchoscopic BAL samples a smaller site than flexible bronchoscopic BAL. Nevertheless, significant diagnostic information can often be obtained with relatively little cost and risk.

For achieving some measure of reproducibility and standardization of BAL technique in adults, the same volumes and aliquot numbers are used for each procedure. Typically, these may be three 100-mL aliquots or five 50-mL aliquots.[38] Cells migrate more slowly than soluble constituents, and the total yield of cells approaches a limit as the number of aliquots increases.[52] Various markers have been used to determine the dilution of the epithelial lining fluid (ELF); urea is used most commonly. It is assumed that urea exists in the ELF at the same concentration as in plasma; therefore the ratio of urea in BAL fluid to urea in plasma gives a measure of the dilution of ELF in the BAL fluid.[53] However, BAL does not sample a static space or volume of airway surface liquid. There is a constant exchange of fluid, electrolytes, and other soluble constituents across the airway and alveolar epithelium.[54-56] Thus the concentration of any material or cell type in the BAL specimen depends on the volume of fluid used for the lavage, the efficiency of mixing and recovery, the initial concentration in the ELF, the time during which the fluid resides in the alveolar space, and the rate of flux of the material or fluid into the BAL fluid during the procedure.

In pediatric subjects, there is no agreement regarding standard technique. Wedging the same size bronchoscope into an airway in children of various ages and sizes (or using a different size bronchoscope) results in washing a greatly varying proportion of total lung volume. For example, in a newborn, a 3.5-mm flexible bronchoscope may wedge into a lobar bronchus, whereas in a 4-year-old child, it may wedge into a subsubsegmental bronchus. It is unclear whether using the

same volume of saline in these two situations results in washing similar surface areas. Reported techniques include volumes of 0.5 to 3 mL/kg or the use of a fixed volume (usually two aliquots of 10 mL each) for each patient almost regardless of age.

In general, it is useful to perform BAL with more than one aliquot of saline. Some authorities discard the return from the first aliquot, suggesting that it represents "bronchial" rather than "alveolar" washings.[57] The composition of the first aliquot is indeed somewhat different from subsequent aliquots, but there is no practical way to obtain a pure bronchial or alveolar fraction. In pediatric practice, there is little rationale or justification for discarding the first aliquot or processing it differently because material from the proximal airways is washed distally and therefore contaminates the subsequent aliquots.

If BAL is being performed to evaluate a specific radiologic lesion, then the bronchoscope should be positioned in the appropriate bronchus. On the other hand, if there is no localized area of disease, it is advantageous to choose the lingula or right middle lobe for lavage. These bronchi are relatively long and relatively horizontal, and the tip of the bronchoscope is more likely to remain comfortably wedged in the bronchus (even with coughing) than if it is wedged into a basal segment of one of the lower lobes.

The amount of fluid returned is usually between 40% and 60% of that instilled. In patients whose bronchi collapse around the tip of the bronchoscope, there may be more difficulty achieving return of the saline. Patients under general anesthesia or on mechanical ventilation also have low returned volumes.

Complications

A significant percentage of patients who undergo BAL experience transient fever and even chills, usually beginning 4 to 6 hours after the procedure. This phenomenon is almost always self-limiting, should be anticipated, and is readily treated with antipyretics. It most likely results from absorption of toxins or inflammatory mediators from the alveolar surface and is more common in patients whose airways are inflamed.[58,59]

BAL can result in hypoxemia because residual saline in the lavaged area interferes with gas exchange until the saline has been absorbed. It may also stimulate mucus production and cough. Wedging of the bronchoscope into an airway may result in localized bleeding. If the bronchoscope is not wedged snugly, saline spills into adjacent bronchi and stimulates cough and respiratory distress.

Specimen Handling

The purpose of BAL is to obtain a specimen for analysis; the care with which the specimen is handled is as important to the success of the procedure as the techniques used to obtain the specimen. Prompt processing reduces the loss of labile substances (or organisms) or the overgrowth of microbial species. Cells adhere to glass surfaces, and specimens collected or transported in glass containers may be depleted of their cellular content in relatively nonpredictable ways.

The analyses performed on BAL specimens should be determined by the indications for the procedure, although it makes sense to perform bacterial cultures (preferably, a quantitative culture) in almost all cases. At least a simple cytologic preparation should also be made. Other cultures and diagnostic tests (e.g., antigen detection, polymerase chain reaction) can be performed according to the clinical indications. BAL can be used for research applications,[60] and a wide variety of substances have been measured in BAL specimens from pediatric patients.

INTERPRETATION OF FINDINGS

There are many difficulties inherent in the interpretation of findings from BAL fluid; these relate to the area of lung sampled, the (variable and usually unknown) dilution of the fluid, and the expected normal values.[38,61,62] In some cases, interpretation is simple. For example, identification of material or organisms that should not be present in normal lungs, such as the cysts of *Pneumocystis jiroveci*, should give a relatively unequivocal diagnosis. In the case of substances that may be found in the lungs under normal conditions, interpretation is more challenging and may depend on relative quantitation. An example is the presence of lipid in alveolar macrophages. A large amount of lipid (large intracytoplasmic droplets in a substantial percentage of cells) strongly suggests aspiration.[63] However, chronic and sometimes acute inflammation can result in the accumulation of lipid in macrophages, presumably as a result of the phagocytosis of dead neutrophils and debris. There is some suggestion that such "endogenous" lipid may be discriminated by the size of the intracytoplasmic lipid droplets and by the number of cells containing such droplets, but there is no gold standard by which such identification can be proved. If aspiration is suspected, lipid stains should be performed, but the unequivocal identification of exogenous substances (perhaps by chemical means) would be more definitive proof of aspiration.

Microbiologic diagnosis is complicated,[64] especially by the relative difficulty of ensuring that the specimen is not contaminated with oral secretions. Bacteria may contaminate the bronchoscope during passage through the nose or mouth, or they may be aspirated into the trachea as a result of topical anesthesia. Although the risk of orotracheal aspiration can be reduced by placement of the patient into a head-down position before the application of the topical anesthetic and by being careful not to suction through the instrument channel until the tip of the bronchoscope is at least at the level of the carina, the clinician can never be certain that there is no contamination (this is also true when a microbiology specimen brush is used, as discussed previously). Quantitative culture can be helpful in this regard. Clearly, there is a difference between 2000 and 2,000,000 colonies in each milliliter of BAL fluid, the latter being more consistent with pulmonary infection and the former with oral contamination. Furthermore, except in patients who have neutropenia, pulmonary infection should be accompanied by significant numbers of neutrophils in the BAL fluid. Therefore BAL specimens should be examined microscopically to ascertain the relative distribution and number of cell types. (Gram's stains are not optimal for this purpose.) The absence of inflammatory cells should make the clinician very suspicious that the bacteria in the BAL specimen are from the mouth

and not the lungs. The presence of intracytoplasmic bacteria is also strong evidence of infection.[48] Care must be taken to avoid overinterpretation.[61]

The total number of cells in the BAL fluid depends on the technique used for BAL as well as the concentration of cells in the ELF. The significance of cell counts is subject to considerable uncertainty, although if the same technique is always used, the clinician may have more confidence in relative numbers. In the author's experience, the fluid from BAL performed using two 10-ml aliquots of saline in pediatric patients in whom no infection or inflammation is suspected (and in whom cultures are sterile) contains 100,000 to 300,000 cells/milliliter, 95% of which are alveolar macrophages and 1% to 2% are neutrophils. In patients with infection, the cell numbers and the percentage of neutrophils are much higher (ranging up to 99% neutrophils). Other authors have reported similar findings.[45,47,65]

Eosinophils are rarely seen in BAL fluid from subjects free of lung disease but are seen in the BAL fluid of patients with allergic states, foreign body reactions, and parasitic diseases. Increased percentages of lymphocytes may be seen in the BAL fluid of patients with sarcoidosis and other interstitial diseases.[66,67]

INTUBATION

Indications

An artificial airway is established to bypass airway obstruction, to facilitate mechanical ventilation, or to achieve repeated access to the lower airways for suctioning. The choice of tube type depends on the indications for and the anticipated length of intubation.

Contraindications

There are no absolute contraindications to the establishment of an artificial airway. Certain factors make the procedure more difficult or risky and may mandate one or another alternative technique (including tracheostomy). Risk factors include bleeding diatheses, severe hypoxemia, cardiovascular instability, and severe airway obstruction. However, some of these are also indications for intubation. Unstable cervical fractures mandate endoscopic rather than conventional intubation because the neck must be kept immobilized. Great care must be taken if a patient requires intubation with a full stomach because the risk of aspiration is great.

Instrumentation

The essential requirements for intubation include a suitable artificial airway and a method for visualizing the larynx (i.e., a laryngoscope). In some situations, an endotracheal tube may be passed via the nose and into the trachea without exposing the larynx for direct visualization; in others, a flexible bronchoscope may be used to direct the endotracheal tube.

Intubation must be performed in an appropriate setting, with appropriate measures for monitoring the patient and for altering the approach if warranted. Rarely must a patient be intubated immediately; in most circumstances, bag and mask ventilation is sufficient until suitable preparations can be completed. Alternative methods for ventilating the patient's lung must always be available before elective intubation is attempted; these include (at least) a mask, a self-inflating resuscitation bag or an anesthesia bag with a source of compressed oxygen, and an oral airway of appropriate size.

Table 15-2
Suggested Endotracheal Tube Sizes*

Age	Internal Diameter	Length	
		Oral	Nasal
Premature	2.5-3.0 mm	8 cm	11 cm
Newborn	3.0-3.5 mm	9 cm	12 cm
6 mo	3.0-3.5 mm	10 cm	14 cm
1 yr	4.0-4.5 mm	12 cm	16 cm
2 yr	5.0-5.5 mm	14 cm	17 cm
2-4 yr	5.5-6.0 mm	15 cm	18 cm
4-7 yr	6.0-6.5 mm	16 cm	19 cm
7-10 yr	6.5-7.0 mm	17 cm	21 cm
10-12 yr	7.0-7.5 mm	20 cm	23 cm
12-16 yr	7.5-8.0 mm	21 cm	24 cm

From Chatburn RL, Lough MD: Pediatric respiratory therapy, 3rd ed. St Louis, Mosby, 1985, pp 148-191.
*Note: Tube size should allow an air leak at a pressure not exceeding 25 cm H_2O.

The endotracheal tube must be the appropriate diameter for the patient's airway. Table 15-2 lists the customary tube sizes.[68] Useful approximations for the appropriate endotracheal tube size include the diameter of the fifth digit of the patient's hand or the following formula:

$$\text{Diameter in millimeters} = (\text{Age}/4) + 4$$

Tubes of this size and at least one size larger and smaller should be available before the clinician attempts intubation. In general, there should be a leak of air around the endotracheal tube at no greater than 25 cm H_2O pressure to reduce the potential for trauma to the subglottic space and development of subglottic stenosis.[69] Depending on the indication for intubation, an endotracheal tube may have a cuff near its distal end to seal the trachea, a monitoring lumen through which gas may be sampled, both, or neither. Although cuffed tubes are less often used in pediatric patients because the cricoid diameter is relatively small and thus there is relatively little leak around the endotracheal tube, they may be warranted if relatively high airway pressures are required to maintain ventilation. In adolescents or adults, the diameter of the endotracheal tube is relatively smaller in relation to the tracheal or cricoid diameter, and a cuff may be necessary for conventional ventilation.

Techniques for Intubation

PREPARATION OF THE PATIENT

For elective intubation, the patient should have an empty stomach[14,70] and should be given appropriate medications to reduce anxiety and relieve pain. Topical anesthesia of the larynx improves patient comfort and reduces the risk of adverse reactions such as laryngospasm and severe vagal reactions. In an emergency, it is probably even more important to have effective laryngeal anesthesia to reduce the probability of gagging and emesis, which could lead to aspiration. This

may be accomplished by instilling 1 to 2 mL of 2% lidocaine through the mouth or nose; effective topical anesthesia is achieved within 30 to 60 seconds. It is not necessary to apply the lidocaine directly to the glottis; the superior laryngeal nerve crosses the floor of the pyriform sinuses and is very superficial; pooling of lidocaine in the pyriform sinuses results in effective laryngeal anesthesia. Atropine may be administered to reduce salivary secretions and to reduce the potential for vagal stimulation. Patients may have severe vagal reactions when the larynx is manipulated without effective laryngeal anesthesia, even under what appears to be a surgical level of general anesthesia.

ORAL INTUBATION

With oral intubation the patient's neck is slightly extended, and a laryngoscope is gently inserted into the mouth. The laryngoscope should be held in the left hand and passed along the right side of the tongue. The tongue is then moved toward the left, exposing a path for visualization and passage of the endotracheal tube along the right side of the mouth. The laryngoscope blade is used to elevate the tongue; the tip of the blade is placed into the vallecula. In some circumstances, it may be necessary to elevate the epiglottis with the tip of the laryngoscope blade, but this may traumatize the epiglottis or vocal cords and is usually not necessary. The laryngoscope is lifted straight up to expose the larynx. Under direct vision, the endotracheal tube is inserted into the mouth and is guided through the glottis. It may help to stiffen the endotracheal tube with a soft-metal stylet, but the tip of the stylet should never extend beyond the end of the endotracheal tube; the use of stylets increases the risk of laryngeal trauma during intubation. Alternatively, the endotracheal tube can be stiffened by cooling it in ice for a few minutes. The tube is passed into the trachea to the desired distance, and the laryngoscope is withdrawn from the mouth.

The position of the endotracheal tube is then verified. Definitive proof that the tube is in the trachea involves demonstration of carbon dioxide in the exhaled gases. In the operating room, a capnometer is often used for this purpose; disposable indicators are also available that demonstrate a color change when exposed to carbon dioxide.[71] The more traditional and common method is to observe for chest rise and to listen for breath sounds while the patient is ventilated with an anesthesia bag; the breath sounds should be symmetric bilaterally (assuming that the patient had symmetric breath sounds before intubation). Observation of condensation of moisture in the tube during exhalation is not definitive because it can be seen with esophageal intubation as well. Success is clinically verified when the patient's condition stabilizes or improves. The tube is secured in position, and its location is definitively verified via a chest radiograph (or a flexible bronchoscope [see later section]).

In newborns, an endotracheal tube can be guided into the larynx with the index finger without using a laryngoscope. Although this method is useful in an emergency, its disadvantage is that the larynx is not visualized.

NASAL INTUBATION

Passage of the endotracheal tube through the nose has some advantages over oral intubation. A nasal tube leaves the mouth free so that infants can carry on nonnutritive sucking. A nasal tube is more easily secured in position and moves less than an oral tube. Because it passes behind the tongue, a nasal tube may be more comfortable than an oral tube. On the other hand, nasal intubation may be more difficult, and sometimes there may be nasal trauma. There is a small but significant incidence of sinusitis complicating nasal intubation. Some (especially inexperienced) operators may find nasal intubation more difficult; it may be useful to initially intubate orally and then to switch to a nasal tube when the patient is more stable.

Passage of a nasotracheal tube is performed in much the same fashion as oral intubation, except that the tube is first passed through one nostril to a depth such that its tip can be expected to be just above the larynx. The tube should be lubricated with a sterile, water-soluble jelly, and the nose anesthetized with topical lidocaine before insertion of the tube. When the larynx is exposed with a laryngoscope, the tip of the tube is grasped with McGill forceps and advanced into the glottis. Alternatively, the tube can be advanced while the neck is flexed or extended to guide the tip of the tube into the glottis. An assistant advances the tube or controls the patient's head and neck. Some operators prefer to perform blind nasal intubation without laryngoscopy; in this technique the tube is inserted through the nose and advanced to a position estimated to be near the larynx. By listening to the breath sounds through the tube and observing for condensation of moisture in the tube, the clinician can estimate the location of the tip of the tube. The tube is advanced while the patient's neck is flexed or extended to, it is hoped, advance the tube into the trachea. Although this technique sounds awkward, it can be surprisingly successful when performed by experienced operators, and it may be necessary in a patient whose mouth cannot be opened. (However, see the section on endoscopic intubation for a more effective technique.)

ENDOSCOPIC INTUBATION

Although the standard methods for oral and nasal intubation are successful in most cases, there are clearly circumstances in which these techniques are difficult or inappropriate. These situations include patients with mandibular hypoplasia, cervical or mandibular ankylosis, masses in the mouth or neck, and severe contractures of the neck. A flexible bronchoscope provides a nearly foolproof method for accomplishing the intubation and a diagnostic evaluation of the airway.[72,73]

A flexible bronchoscope of appropriate size is passed through the endotracheal tube. The flexible bronchoscope is then passed through the nose or mouth and into the trachea. When the tip of the bronchoscope reaches the carina, the endotracheal tube is advanced over the bronchoscope until the tip of the tube is seen just above the carina. The bronchoscope is then withdrawn. Experienced operators should be able to accomplish this maneuver in 1 minute or less. Not only is the airway anatomy visualized, but the location of the tip of the endotracheal tube is also immediately verified. When the tube has been positioned and the patient's lung has been ventilated for at least 1 minute, the lower airways should be examined to ensure that there is no anatomic abnormality and that the lobar and segmental airways are patent.

Virtually any patient can undergo endoscopic intubation; intubation can be performed on a premature infant when a 2.5- or 3.0-mm endotracheal tube is used with a 2.2-mm ultrathin flexible bronchoscope. The standard 2.8-mm pediatric flexible bronchoscope can be used with endotracheal tubes ranging in size from 3.0 to 4.5 mm; with larger tubes, a larger flexible bronchoscope should be used.

Although bronchoscopic intubation is simple in principle and is almost always successful, it requires a skilled and experienced operator. The procedure may be difficult in patients in whom there is a mass lesion or pharyngeal collapse. Insufflation with oxygen through the suction port of the bronchoscope (or through a nasopharyngeal tube) can be very helpful; occasionally the clinician may need to use a rigid laryngoscope to lift the mandible and tongue so that the glottis can be visualized.

During bronchoscopic intubation, there is a risk of damage to the flexible bronchoscope; it is likely that more bronchoscopes are damaged in the process of intubation than with any other procedure. This is especially true of the ultrathin instruments.

CARE OF THE INTUBATED CHILD

The endotracheal tube must be secured in place, with reasonable provision for comfort, so that it cannot easily be dislodged. Tubing attached to the endotracheal tube should be supported in a way that reduces tension on the tube. Inspired gases must be adequately humidified to prevent inspissation of secretions, and secretions should be removed from the tube by suctioning at regular intervals. Suction catheters should not routinely be passed beyond the tip of the endotracheal tube.

In a patient whose respiratory tract has been intubated for more than a few hours, additional factors must be taken into account. Phonation is impossible, and if the patient is awake and alert, some provision for effective communication may be necessary. Sedation may be appropriate for the duration of intubation because many children are frightened and uncomfortable. Chest physiotherapy should be routinely performed to help mobilize secretions to the tip of the tube. Nutritional needs must be met by routes other than the oral route.

When the patient requires intubation over a period of several days to weeks, secretions may accumulate in the tube despite regular suctioning and saline irrigation. This may require that the tube be changed. In general, however, the number of tube changes should be kept to a minimum because each change introduces the potential for trauma to the subglottic space. When prolonged intubation is contemplated, serious consideration should be given to tracheostomy.

LARYNGEAL MASK AIRWAY

An alternative to endotracheal intubation that may be useful in selected circumstances is the laryngeal mask airway.[74,75] This device consists of a triangular mask (with an inflatable cuff around the perimeter) attached to a large-bore airway. The mask is inserted into the posterior pharynx; the apex of the triangle enters the proximal esophagus. The cuff is inflated to seal the mask around the larynx and the base of the tongue. The laryngeal mask airway may be used for short-term anesthesia or for endoscopic procedures performed under general anesthesia when the supraglottic airway does not need to be examined.

TRACHEOSTOMY

A tracheostomy is an artificial airway inserted surgically into the cervical trachea. The terms tracheostomy and tracheotomy (the latter referring to the surgical placement of the tracheostomy tube) are used interchangeably in practice. Tracheostomy tubes may be maintained indefinitely and are generally comfortable (once the postoperative period is over). They may be removed and replaced with relative ease and allow the patient to swallow and to phonate.

Indications

The primary indication for tracheostomy is the maintenance of a long-term artificial airway. Although endotracheal tubes may be maintained in infants and young children for weeks to several months, placement of a tracheostomy tube reduces the risk of laryngeal damage. In patients with large pharyngeal tumors or severe subglottic obstructions, tracheostomy may be the only method of establishing a safe and secure airway. Finally, in some patients with chronic laryngeal incompetence, a tracheostomy may be performed to facilitate pulmonary cleansing.

Contraindications

There are few absolute contraindications to the placement of a tracheostomy except perhaps the presence of tumor or infection in the surgical field. Coagulation defects and unusual anatomic conditions (including significant tracheal obstruction by the innominate artery) make tracheostomy more difficult and may warrant delay until the underlying condition is corrected.

Instrumentation

Tracheostomy tubes may be constructed of metal or plastic; the plastic tubes are much more common today. Metal tubes and large plastic tubes used in adults typically have a removable inner cannula, which must be removed and cleaned several times each day. Because of the small diameter of the tubes used in infants and young children, most nonmetallic pediatric tracheostomy tubes do not have inner cannulas. The tube size (diameter and length) must be matched to the airway dimensions of the patient. There is a bewildering array of tube types on the market, and virtually all can be customized for the particular needs of the patient.

Technique

Tracheotomy is a surgical procedure; details of technique may be found in standard surgical texts. In brief, an incision is made over the cervical trachea, avoiding the thyroid isthmus and associated vessels. The incision is extended by blunt dissection to the anterior tracheal wall. The trachea is usually entered between the second and third (or third and fourth) tracheal rings; in children, one ring often must be divided. A suitable tube is inserted through the tracheal incision and secured in place.[76,77]

It may be difficult to reinsert the tracheostomy tube if it becomes dislodged before healing of the incision and establishment of a mature stoma, especially if the ends of the cartilage ring that was cut in the operation resume their normal position. Therefore it is customary to place retraction sutures around the ends of the cut cartilage ring; these are left in place until the tube is successfully changed (usually after 5 to 7 days) and it is verified that the stoma is stable. In an emergency recannulation, these retraction sutures can be used to pull the ends of the cartilage ring laterally, thus dilating the stoma so that the tube can be reinserted.

Alternative techniques exist for placing a tracheostomy tube, although they are not readily applicable in infants and young children. In brief, these involve transtracheal needle puncture followed by passage of a guidewire and a dilator; the tracheostomy tube is placed in much the same fashion as an over-the-wire vascular catheter.[78,79]

In an emergency, cricothyroidotomy[80] may be used to place an artificial airway into the trachea below the larynx. A horizontal incision is made directly over the cricothyroid membrane (identified by feel just at the inferior margin of the thyroid cartilage). After dilation with a suitable instrument, a tube is passed into the trachea. Because cricothyroidotomy risks laryngeal damage, the patient should undergo formal surgical revision and placement of a conventional tracheostomy as soon as it is feasible if there is a continuing need for the tracheostomy tube.

Complications

Immediate complications of tracheotomy include hemorrhage, air leak (pneumothorax, pneumomediastinum, or subcutaneous emphysema), and possibly damage to the recurrent laryngeal nerves. Displacement of the tube before the stoma has healed may have disastrous consequences if the patient does not have a functional airway.

Long-term complications include the development of granulation tissue, which may completely obstruct the suprastomal trachea; bleeding from the stoma, which is usually minimal but may be massive from the creation of a tracheoinnominate fistulas; respiratory distress resulting from obstruction or dislodgment of the tube; and trauma to the lower airways from suction catheter use. Infection is a constant risk because the normal defenses of the upper airway are bypassed.

Care of the Child with a Tracheostomy

A tracheostomy tube interferes with the normal humidification of inspired air. The inspired air should be humidified to reduce the risk of inspissation of secretions in the airways or the tracheostomy tube; a mist collar should be used in infants most of the time. After some months, many patients can tolerate nonhumidified air more easily, but some provision should still be made for adding humidification at least part of the time. "Artificial noses" are small devices that attach to the tracheostomy tube, condense some moisture during exhalation, and evaporate it on inspiration to partially humidify the inspired air; these may be useful,[81] and they also filter the inspired air.

Patients with tracheostomies require assistance clearing secretions from the airways and in keeping the tube patent. Dry mucus has the consistency of dry rubber cement and can occlude a tracheostomy tube, with lethal consequences. Therefore suctioning of the tube on a regular basis is essential. Suction catheters can traumatize the airway; this leads to increased mucus production, mucus stasis, and sometimes bronchial stenosis.[82] Suctioning should be performed only deeply enough to clear the tracheostomy tube; chest physiotherapy and cough should clear the bronchi of secretions.

Tracheostomy tubes should be changed at regular intervals (typically once a week). Caregivers must learn the techniques involved.[83] Metal tracheostomy tubes have very thin walls, and an obturator must be used during insertion to prevent the tube from cutting the tissue. However, obturators are not necessary with plastic tubes to prevent tissue damage and they obstruct the airway during insertion. If difficulty is encountered during attempted insertion of the tube (sterile, water-soluble lubricant should always be used), a suction catheter passed through the tube can be used as a guidewire in the same fashion as a guidewire with a vascular catheter. It is a good practice to have a spare tube one size smaller than the usual tube because in an emergency, it may be necessary to use a smaller tube to reestablish an airway.

The tracheostomy tube must be secured to the patient's neck with an appropriate strap. Various materials are used, ranging from adjustable Velcro straps to simple twill tape. The strap must be tight enough to prevent accidental decannulation but not so tight that it is uncomfortable. Materials must always be kept close at hand to cut or remove the strap and replace the tracheostomy tube quickly in case of emergency. An emergency kit should contain a clean tube of the appropriate size with straps already in place and ready to be secured, another tube one size smaller, a suction catheter, lubricating jelly, and scissors.

Because of the risk of catastrophic airway obstruction if the tracheostomy tube becomes dislodged or obstructed, infants and young children with tracheostomies must be monitored carefully. Unfortunately, there is no entirely satisfactory way to do this. Cardiorespiratory monitors may respond to airway occlusion only after the child has become sufficiently hypoxic to become apneic, whereas pulse oximeters have a very high rate of false alarms. Nevertheless, caregivers must be well trained to detect and respond quickly and appropriately to emergencies by suctioning, giving positive-pressure breathing, changing the tracheostomy tube on an emergency basis, and providing the basic elements of resuscitation. The preparation of a child and family for home care with a tracheostomy is complex and demanding.[84]

Tracheostomy tubes should be sized to fit the needs of the patient. In very young infants, the internal diameter of the tube should be large enough to minimize airway resistance, with relatively little concern for the child's ability to vocalize around the tube. Most full-term newborns do well with a tube with an internal diameter of 3 to 3.5 mm. The end of the tube must not touch the carina, but the tube must be long enough that it lies parallel to the tracheal axis. A short tube often pushes into the posterior membranous portion of the trachea, producing partial expiratory obstruction; this

also places the child at risk of developing granulation tissue at the tip of the tube. The tube size must be increased to keep pace with the child's growth. It also becomes more important to allow for some air movement around the outside of the tube to facilitate phonation.

At some point, it may become feasible to provide the patient with a one-way ("speaking") valve on the tracheostomy tube. This allows the child to breathe in through the tube but forces expired air through the glottis, thus facilitating both phonation and improved clearance of secretions.[85] There must be sufficient airway around the tube for effective airflow; expiratory pressures during quiet breathing greater than 10 cm H_2O are not well tolerated. On the other hand, some children with severe tracheomalacia or bronchomalacia benefit greatly from the enhanced expiratory resistance provided by the speaking valve.

Most patients with tracheostomies develop some granulation tissue at the superior margin of the stoma[86]; this may progress to complete obstruction of the suprastomal trachea with potentially lethal consequences. It is prudent to examine the airway with a bronchoscope at regular intervals[17,87] to assess for this complication as well as to evaluate the patient's readiness for possible decannulation.[88] Although there is controversy about how aggressively to remove small to medium suprastomal granulations, it is clear that near-total obstruction places the child at risk of serious complications.

Specific criteria for decannulation include the ability to breathe adequately without support and an anatomic and functionally patent airway.[87] Endoscopic examination of the airway before decannulation is virtually mandatory, and the airway should be examined with the tracheostomy tube removed. Some authors prefer to place a series of increasingly smaller tracheostomy tubes in preparation for decannulation, culminating in a small, plugged tube. In this author's experience, however, endoscopic evaluation followed if necessary by degranulation and immediate decannulation is almost always successful. If the airway is obstructed by granulation tissue or the collapse of the anterior tracheal wall,[89] then smaller tracheostomy tubes will not solve the problem. If the airway structure and dynamics appear adequate, the child should be observed in the hospital for 48 hours; the stoma usually closes very rapidly (often within hours), and a true emergency may arise if the child needs recannulation. In a small percentage of children, a persistent tracheocutaneous fistula requires surgical closure at a later date. Some children require laryngeal or tracheal reconstruction before successful decannulation.

THORACENTESIS

Indications

The accumulation of fluid in the pleural space often poses diagnostic problems that may be directly addressed by analysis of the fluid. Pleural effusions that are very small or that on clinical grounds are clearly the result of simple mechanical processes may not require thoracentesis. Examples of the latter include patients with congestive heart failure or severe hypoproteinemia. On the other hand, if infectious or malignant disease is suspected, then analysis of the fluid is warranted.[90]

Contraindications

If the diagnostic importance is sufficiently high, there are no absolute contraindications to thoracentesis. However, certain situations (i.e., thrombocytopenia) make the procedure more risky. Because children need sedation for thoracentesis, hypoxic patients are at greater risk from respiratory depression during the procedure. Careful attention to the patient's physiologic condition, continuous monitoring, and correction of risk factors amenable to correction (e.g., platelet transfusion) reduce the risk. It may not always be possible to determine the location of the diaphragm from simple radiographs, so there is some risk of puncturing the liver or spleen if the needle is placed too low.

Instrumentation

In brief, thoracentesis involves inserting a needle through the intercostal space and into the pleural space. If the goal is merely to obtain a specimen for diagnostic purposes, especially if the fluid is not loculated, then a simple needle of suitable length and diameter can be used. If the goal is to withdraw a substantial volume of pleural fluid, then use of a plastic catheter (passed over a small needle or through a larger needle) is more suitable. If an IV catheter (catheter over the needle) is used, it must be long enough to reach the pleural space and should be large enough that even highly viscous fluid can be withdrawn through it. Generally, a 16- or 18-gauge catheter should be used.

Radiographic or ultrasound evaluation before attempted thoracentesis is needed to determine the relative volume of fluid and its mobility or lack thereof. If the entire hemithorax is opacified, it may sometimes be difficult to ascertain the amount of fluid present and the position of the diaphragm; a computed tomographic or ultrasound scan can be very helpful. Small or loculated fluid collections are best located with ultrasound; the most appropriate site can be marked before skin preparation so that the needle can be inserted directly into the fluid.

Technique

The patient should be prepared with appropriate sedation and monitored carefully. Because fluid moves with gravity, it is usually most effective to perform the procedure with the patient sitting erect (usually leaning slightly forward and supported on pillows or an overbed table). Alternatively, in a supine patient the needle can be placed in the posterior axillary line with the patient very near the edge of the procedure table. The level of fluid is determined by percussion. The most common site for the insertion of the needle is the seventh intercostal space in the midaxillary or posterior axillary line; this may be modified according to the clinical situation (with ultrasound guidance if necessary).

After appropriate skin cleansing, disinfection, and sterile draping, a small-gauge needle is used to infiltrate lidocaine into the track intended for the larger needle. The needle, which is attached to a syringe containing 1 to 2 mL of lidocaine, is inserted perpendicularly to the skin and advanced to the rib and then up and over the top of the rib, thus avoiding the neurovascular bundle, which follows the inferior margin of the rib. The needle should be held with the fingers against

the skin so that if the patient moves, the operator's hand and the needle move in the same direction at the same time. The needle is carefully advanced with the other hand, which may be used to alternately gently withdraw and inject lidocaine. As soon as pleural fluid appears in the syringe, the depth of the needle is marked, and the needle is withdrawn. Then the larger needle/catheter is inserted in the same track, and gentle suction is applied as the needle reaches the marked depth. When fluid is obtained, the needle/catheter is advanced slightly into the pleural space, and the needle is withdrawn, leaving the catheter in the pleural space. A three-way stopcock is then attached to facilitate repeated aspiration with a syringe or drainage into a reservoir. When the desired amount of fluid has been withdrawn, the catheter is removed, and the site is dressed with a simple dressing; pressure dressings are seldom necessary. If fluid is not obtained with the probing needle, it may be because the fluid is loculated and the needle has been placed in the wrong position (the clinician should consider ultrasound guidance or try one interspace higher) or because what appears to be pleural fluid may in fact be pleural thickening.

An alternative technique is to use a large-bore needle (after the probing needle has been used to provide local anesthesia and locate the pleural fluid) through which a plastic catheter is passed. Once the needle enters the pleural space, the catheter is advanced and the needle withdrawn. Yet another technique is to use a catheter advanced over a guidewire that has in turn been passed into the pleural space through a needle[90,91] (see the section on the placement of chest tubes).

Complications

The complications of thoracentesis include bleeding, pneumothorax, and infection. Although the absolute risk of bleeding is small, it may be prudent to ensure that clotting mechanisms are normal before thoracentesis. Pneumothorax may occur if the needle is advanced too far, especially if the patient moves or coughs. An upright chest radiograph should be obtained after the procedure to evaluate for air leak. In patients with massive accumulations of pleural fluid, removal of large volumes can lead to unilateral pulmonary edema or hypotension. (As the pulmonary vascular bed in the previously collapsed or compressed lung fills with blood, the blood pressure may fall.) These complications seem to be more likely when the fluid has been present for a long time; there are no specific guidelines as to how much fluid may be safely withdrawn in a given patient.[92,93] Clearly, if the volume of fluid in the pleural space is sufficient to cause respiratory distress, then at least enough should be removed to relieve the distress. Purulent fluid should be drained as completely as possible; if the fluid is highly purulent it will also be highly viscous, and it may be necessary to insert a large-bore chest tube to achieve adequate drainage.

Specimen Handling

Specimens of pleural fluid should be sent for total and differential cell count, appropriate cultures, and determination of total protein content. Because pleural fluid often contains considerable amounts of fibrin, it is useful to collect some of the fluid into a tube containing an anticoagulant and to use this tube for cell counts and other determinations. Other analyses may be performed, including (but not limited to) amylase, glucose, and pH, depending on the clinical setting.

Interpretation of Findings

See Chapter 68.

TUBE THORACOSTOMY

Indications

A chest tube[90,91] is placed to remove air or fluid from the pleural space. In contrast to simple thoracentesis, which may also be used to treat pleural effusion or pneumothorax, a chest tube is left in place to enable drainage over a period of time. The size and type of tube are determined by the quantity and nature of the material to be drained; small tubes are suitable for the treatment of a pneumothorax, whereas much larger tubes may be required to drain an empyema. In rare circumstances, a chest tube may be placed prophylactically in anticipation of life-threatening pneumothorax or pleural fluid accumulation.

Contraindications

If the accumulation of pleural fluid or air is immediately life threatening, there are no contraindications to chest tube placement. Factors that make the procedure more risky include uncorrected thrombocytopenia, clotting factor deficiencies, extensive infections or tumors involving the chest wall, and severe scoliosis or other anatomic deformities.

Instrumentation

The essential instruments for chest tube placement include a suitable tube, the equipment with which the chest wall is penetrated, and a closed drainage system to which the tube is connected. Chest tubes, depending on their intended purpose, range in size from a 20-gauge IV catheter to 30-French (9.5-mm diameter) or larger. The tip of the tube is smooth to prevent trauma to the lung, and the proximal end must be capable of attaching to a drainage system. For a simple pneumothorax, a through-the-needle plastic catheter may be suitable, although such relatively thin-walled catheters may kink. Another disadvantage of such simple tubes is that there is only one hole (at the end); if the single hole becomes occluded, the tube becomes nonfunctional. In most cases, it will be more appropriate to use a tube designed to be passed over a guidewire because such tubes not only are stronger but also have more than one hole through which air or fluid may drain. When fluid is to be drained, a larger-diameter tube is more appropriate, depending on the viscosity of the fluid.

Drainage systems consist of tubing and a reservoir along with some mechanism to maintain a negative intrathoracic pressure. The most common (and simplest) system includes a chamber into which fluid drains; this chamber is connected to another reservoir containing sterile water, and the tubing from the first chamber extends some distance below the surface of the water in the second chamber. This arrangement allows fluid and air to escape, but prevents flow of air back

into the pleural space. The second chamber can be attached to a vacuum line to maintain a continuous negative pressure; this may be important in the management of pleural air leaks.

For emergency treatment of a pneumothorax when a closed, water-sealed drainage system is unavailable or inappropriate, a simple one-way valve may be attached to the chest tube.[94] When intrathoracic pressure increases, air escapes through the valve, but it cannot reenter the chest. Such systems can be lifesaving but should in most situations be converted to appropriate water-seal drainage as soon as feasible.

Technique

There are two general techniques for chest tube insertion: percutaneous placement and surgical placement.

PERCUTANEOUS INSERTION

Catheters may be inserted either through a large-bore needle or over a guidewire; in either case, the technique is very similar to that for simple thoracentesis. After suitable skin preparation and local anesthesia, the needle is inserted through the intercostal space along the superior margin of the rib. When the pleural space is reached, the catheter (or guidewire) is advanced and the needle withdrawn. The needle may be directed initially to guide the catheter or wire into the desired location (generally posteriorly for drainage of fluid and anteriorly for drainage of air).

The technique for placement of an over-the-wire catheter is analogous to that for a similar vascular catheter. After insertion of the guidewire through the probing needle, the needle is removed. A sharp scalpel (No. 11 blade) is used to make a small incision at the point of insertion, and a dilator is passed over the wire. Because the dilator is quite stiff, it should not be passed deeply into the thorax, but its tip must penetrate the parietal pleura. The dilator is removed, and the selected catheter is then threaded over the guidewire and advanced into the chest. The catheter should be grasped very close to the chest wall as it is advanced to prevent kinking of the guidewire. When the tube has been advanced to the desired depth, the guidewire is removed, and the tube is connected to a closed sterile drainage system.

SURGICAL INSERTION

The chosen site is prepared as for thoracentesis. After instillation of local anesthetic, a skin incision just long enough to accommodate the chest tube is made approximately 2 cm below the intended insertion site. The skin is pulled upward so that the incision overlies the intended puncture site. A surgical clamp is used to penetrate the intercostal space just above the rib and to dilate the wound so that the tube can be passed. The tip of the tube is grasped with the clamp, inserted through the track, and advanced into position after the clamp is removed. Alternatively, a chest tube with an internal trocar may be used instead of the surgical clamp. The trocar has a sharp point and may be used to penetrate the intercostal space as well as to facilitate the passage of the tube itself. Great care must be taken, however, when a trocar is used in this fashion so that penetration of the lung is avoided. The tube or trocar must be held with the gloved hand very close to the chest wall so that it cannot advance farther than intended once the pleura is penetrated. The tube is advanced over the trocar, which is then removed.

When the tube is in place, the tension on the skin overlying the insertion site is released, creating a subcutaneous track for the tube. This reduces the risk of air leakage around the insertion site and allows the tube to exit the chest on an oblique angle rather than perpendicularly. A purse-string suture should be placed around the tube, and the tube should be anchored to the chest wall with another suture or suitable taping. The tube should be secured so that accidental traction on the tube neither pulls the tube from the patient's chest nor moves the tube within the chest (which is painful).

Removal of Chest Tubes

A chest tube placed to drain a pleural effusion is usually left in place until the daily volume of drainage is minimal, whereas that placed for treatment of a pneumothorax is left until there has been no air leak for at least 24 hours. If the tube does not drain the pleural space adequately, it may require repositioning or replacement.

It is prudent to clamp a chest tube for some period of time before its removal. If fluid or air then reaccumulates within the pleural space, it is only necessary to unclamp the tube. When the tube is to be removed, any sutures attached to the tube are removed, the entrance site is covered with sterile gauze impregnated with petroleum jelly, and the tube is withdrawn. Before the tube is pulled, it should be rotated to break up adhesions between the tube and the lung. Gentle pressure is maintained over the insertion site during and after withdrawal. The tube should be withdrawn promptly to prevent entrance of air into the pleural space through the proximal side holes in the tube once they exit the chest. The purse-string suture, if used, is pulled tight and tied, and a pressure dressing is applied. A chest film with the patient sitting erect is obtained after removal of the tube to ensure that there is no residual pneumothorax.

Complications

The complications of chest tube insertion are essentially the same as those of thoracentesis, and include bleeding, damage to the neurovascular bundle, perforation or laceration of the lung, and infection. If the drainage system to which the tube is connected is mishandled, ascending infection may contaminate the pleural cavity. Likewise, disconnection of the tube from its underwater seal may result in a large pneumothorax.

PERCUTANEOUS NEEDLE ASPIRATION OF THE LUNG

Before the advent of flexible bronchoscopy and BAL, the only way to obtain a specimen from the distal airways involved rigid bronchoscopy, open lung biopsy, or percutaneous needle aspiration.[95-97] Although needle aspirations are seldom performed today, this is the only way except open biopsy to guarantee that there is no chance of contamination of the specimen by upper respiratory tract flora.

Indications

Percutaneous needle aspiration may be indicated when it is necessary to obtain a specimen from the distal airways and alternative methods, such as flexible bronchoscopy, are not available or for some reason are contraindicated. Patients with pulmonary consolidation or lesions located close to the pleura are the most appropriate candidates. Very small volumes of specimen are obtained and may be examined by microscope or a variety of microbiologic techniques. Percutaneous needle aspiration of lung lesions may be desirable in the investigation of possible malignancy or granulomatous disease. The site for the puncture can be guided by findings on radiographic studies.

Contraindications

Patients with noncorrectable bleeding disorders should not undergo percutaneous needle aspiration. Other factors that increase risk include pulmonary hypertension and positive-pressure ventilation. Percutaneous needle aspiration should not be performed through a pleural effusion.

Technique

The technique for percutaneous needle aspiration is very similar to that for thoracentesis. However, the object is for the needle to traverse the visceral pleura in the area of the parenchymal lesion. Sedation and local anesthesia are used as for thoracentesis. A needle of suitable size and length is attached to a syringe containing 1 to 2 mL of sterile, nonbacteriostatic saline. The needle is advanced to a position just short of the pleura. Cooperative patients are requested to hold their breath (most children will not do so, of course), and then the needle is rapidly advanced across the pleura. As quickly as possible, the contents of the syringe are injected, and then the plunger of the syringe is withdrawn to aspirate as much material as possible into the syringe (usually this amounts to only a few drops). The needle and syringe are then rapidly withdrawn. This entire process should take only 2 to 3 seconds; a longer time increases the risk of laceration of the pleura and pneumothorax.

Transtracheal aspiration[98] is a related procedure that has been performed for similar indications. This procedure, which is rarely performed since the advent of flexible bronchoscopy, involves passage of a catheter through a needle that has been inserted through the cricothyroid membrane, and then aspirating secretions from the airway. Fatal complications have been reported,[99] and the procedure does not guarantee that the specimen is not contaminated with oral secretions. Transtracheal aspiration should not be performed in infants and young children.

In the investigation of deeper parenchymal lesions for suspected malignancy, especially in older patients, a very thin, flexible needle can be used to reduce the risk of laceration of the lung. Fluoroscopy (preferably biplane fluoroscopy) or computed tomography should be used to guide the needle into the lesion. If warranted, a cutting needle may be used to obtain a small specimen of lung parenchyma for histologic examination. This procedure increases the risk of bleeding and air leak.

Complications

Pneumothorax is an obvious risk of percutaneous needle aspiration. Usually, the air leak is small and requires no therapy, but insertion of a chest tube is sometimes required. The risk of bleeding is somewhat higher than that for thoracentesis.

PLEURAL BIOPSY

Indications

Biopsy of the parietal pleura is indicated in the evaluation of pleural disease not diagnosed by thoracentesis or other methods. Most commonly, malignancy or mycobacterial disease is suspected. Pleural fluid is usually present when a pleural biopsy is considered.

Contraindications

Patients with uncorrectable bleeding disorders should not undergo pleural biopsy.

Instrumentation

A pleural biopsy needle (Cope or Abrams) consists of an outer cannula that is perforated near its tip, a cutting trocar, and a stylet. The Abrams needle is generally preferred.[90]

Technique

The patient is prepared as for thoracentesis. Because the biopsy needle is relatively large, a small skin incision is made with a scalpel (No. 11 blade). The needle with the cutting trocar and stylet in place is then passed through the parietal pleura. The stylet is withdrawn; a syringe can be attached to withdraw pleural fluid and confirm the position of the needle tip. The cutting trocar is rotated (Abrams) or withdrawn (Cope) to the open position, and the needle is withdrawn so that the opening in the outer cannula engages pleural tissue. The cutting trocar is then rotated (or advanced) to the closed position so that the biopsy specimen is held within the core of the trocar (it may be recovered by aspiration into the syringe or by removal of the cannula). Several specimens can be obtained in the same site by rotating the outer cannula and repeating the biopsy process. The operator should consider the orientation of the cutting port and avoid taking a biopsy toward the inferior aspect of the rib above the puncture site (to avoid cutting the neurovascular bundle).[100]

Complications

Pneumothorax and bleeding are the two most common complications. Care must be taken to avoid the neurovascular bundle by inserting the biopsy needle through the inferior part of the intercostal space and to avoid taking a biopsy in the superior aspect of the site.

THORACOSCOPY

There have been rapid advances in endoscopic instrumentation and technique in recent years. Many thoracic procedures that previously required open surgical approaches can now be performed with endoscopic visualization and manipulation. Continued miniaturization of instruments will ensure that

pediatric patients are not deprived of the benefits of such minimally invasive diagnoses and surgery.[101]

One potential limitation of thoracoscopy is that the patient must be able to tolerate one-lung anesthesia. The lung must be at least partially deflated to visualize the pleural surfaces. In pediatric patients, this may present technical problems in airway management. Patients with respiratory failure or insufficiency may be poor candidates for thoracoscopy. However, they are also poor candidates for thoracotomy, and in some cases, thoracoscopy can be informative even if the lung cannot be deflated.

Indications

Diagnostic thoracoscopy[102] is indicated in the evaluation of complicated pleural effusions (especially if malignancy is suspected), persistent pneumothorax, subpleural lung nodules, and mediastinal or pleural nodes or masses. In addition, thoracoscopic techniques may be indicated for lung biopsy or for the achievement of pleurodesis.[103,104]

Contraindications

As previously noted, the inability of the patient to tolerate one-lung anesthesia may make thoracoscopy inappropriate, and obliteration of the pleural space may make it impossible. As with other invasive procedures, uncorrected bleeding disorders increase the risk of hemorrhage.

Instrumentation

Thoracoscopy involves direct visualization of the intrathoracic contents through a rigid telescope inserted through the intercostal space. The telescopes are similar to those used for rigid bronchoscopy. A variety of ancillary instruments are available to manipulate the lung and intrathoracic contents. The telescopes and other instruments are passed through trocars, which allow an instrument to be removed and reinserted as necessary.

Technique

Thoracoscopy is a surgical procedure requiring general anesthesia. In general, more than one trocar (often three) is inserted into the thoracic cavity; one is used for a telescope, and others are used to manipulate the lung. Placement of the trocars depends on the area of interest. The lung is at least partially deflated, grasped with forceps, and pulled or pushed aside to achieve adequate visualization. The presence of pleural adhesions may complicate the inspection.

In addition to visual inspection, specimens of lung, pleura, or lymph nodes may be obtained with a variety of biopsy instruments. Hemostasis can be achieved by electrocautery, staples, sutures, or laser. Because the entire pleural surface can be visualized, thoracoscopy may be more versatile than limited thoracotomy when a lung biopsy is required.

LUNG BIOPSY

When other diagnostic methods have failed, histologic examination of lung tissue may be required. There are two techniques for obtaining such a specimen: transbronchial biopsy and open lung biopsy. Because of its technical limitations, transbronchial biopsy should rarely be used in pediatric patients, although it plays a critical role in the management of patients after lung transplant. Transbronchial biopsy specimens are very small, and histologic diagnosis is not as easily made as with an open biopsy.

Indications

Lung biopsy may be indicated in the evaluation of interstitial or other diffuse infiltrative diseases, nodular disease, and sometimes, suspected infection. Lung biopsy is indicated in the evaluation of suspected malignancy and suspected rejection after lung transplantation.[105,106] In general, bronchoscopy with BAL should be performed before open lung biopsy. In most cases, the pertinent diagnostic information from bronchoscopy and BAL is available within 24 hours, and the more invasive procedure (if it is necessary) is not delayed long. If the information is urgently required (as in a lung transplant) or if only a transbronchial biopsy is desired, then biopsy and BAL are performed at the same time.

Contraindications

If lung biopsy is the only way to achieve the necessary diagnosis, then there are no absolute contraindications to biopsy, but the technique may be dictated by the clinical circumstances. The risk of pneumothorax after transbronchial biopsy is much higher, for example, in patients on positive-pressure ventilation.

Instrumentation

Transbronchial biopsy is performed with flexible forceps passed through a bronchoscope.[107] These devices induce a substantial amount of crush artifact in the specimen obtained. The smallest available forceps are approximately 1 mm in diameter and can be used with the standard (2.8-mm) pediatric flexible bronchoscope. Unfortunately, the small size of the specimens obtained with this instrument severely limit the practical applications of the technique. The largest forceps available are approximately 2.5 mm in diameter and require the use of a flexible bronchoscope 6 mm in diameter.

Technique

Lung biopsy may be performed surgically or by thoracoscopy. An advantage of these techniques is that the lung surface can be examined and the specimen is much larger than that obtained by transbronchial biopsy. Automatic stapling devices are used to detach the specimen and seal the cut edges of the lung.

Transbronchial biopsy should be performed with fluoroscopic guidance, both to ensure that the selected area of the lung is being sampled and to reduce the risk of pleural perforation. The flexible bronchoscope is advanced to the desired bronchus, and the forceps are passed through the suction channel. The closed forceps are advanced to the desired depth, retracted slightly, opened, and then advanced to meet gentle resistance before closing. A slight tug should be felt and may be viewed on the fluoroscope if tissue is obtained. The specimen is placed immediately into either fixative or saline; if the specimen floats, it is more likely to contain

alveolar tissue. Multiple specimens are usually obtained to ensure that an adequate amount of tissue is available for analysis.

Complications

Lung biopsy always carries the risk of hemorrhage, air leak, or both, and the overall risks are higher in patients with respiratory failure or multiorgan failure. The incidence of pneumothorax after transbronchial biopsy is relatively small and depends somewhat on the technique used and the nature of the lung disease (the risk is higher in patients with poor pulmonary compliance). Deaths from massive hemorrhage have occurred after transbronchial biopsy. Infectious complications of transbronchial biopsy are those associated with bronchoscopy, and the incidence of complications may be increased if atelectasis results from bronchial obstruction caused by blood clots due to bleeding from the biopsy sites. Good pulmonary cleansing to clear the airways of clots after transbronchial biopsy reduces the incidence of complications.

NASAL MUCOSAL BIOPSY AND BRUSHING

The nasal mucosa consists of ciliated epithelium nearly identical to that of the trachea and bronchi. Therefore the nose is an important site for diagnostic evaluation of generalized mucosal abnormalities.

Indications

Patients suspected of having primary ciliary dyskinesia may undergo nasal mucosal biopsy for functional and ultrastructural evaluation of ciliary function.

Contraindications

There are essentially no contraindications to nasal biopsy. However, a biopsy taken during the course of a viral infection may reveal abnormalities that would not be present otherwise and that are not relevant to the patient's underlying condition.[108,109]

Instrumentation

Ciliated cells can be obtained with a small brush about 1 to 2 mm in diameter or with a small curette. The latter is more likely to yield intact pieces of epithelium.

Technique

Under normal circumstances, the anterior third of the nasal epithelium is squamous, whereas the more posterior two thirds is ciliated. The biopsy should be obtained from an area of ciliated epithelium; the most appropriate area is at least halfway along the inferior turbinate, preferably under this structure. The specimen is placed into tissue culture medium for examination by light microscopy for ciliary beat frequency and pattern or by electron microscopy. Functional analysis should take place as soon as possible because ciliary activity may decrease rapidly in traumatized cells; in general, ciliary activity is less likely to be demonstrable in individual cells than along the border of a patch of epithelial surface where the cells are more intact. Patients with primary ciliary dyskinesia have cilia that beat very slowly and incoordinately or not at all; the cilia may appear rigid. Specimens that appear to be abnormal should be processed for electron microscopy. A diagnosis of ciliary dysfunction should not be made in the absence of ultrastructural confirmation and may be complicated by environmental or infectious influences.

SPUTUM EXAMINATION

The examination of sputum is an important aspect of pulmonary diagnosis, at least in patients who produce sputum.[110] Invasive procedures to obtain specimens from the lower respiratory tract should usually be deferred until sputum has been evaluated. Unfortunately, sputum specimens may be difficult to obtain from children.

Indications

Sputum should be examined whenever productive cough is part of the complex of symptoms. A productive cough implies the presence of an abnormal quantity of respiratory secretions (or inadequate clearance). Induced sputum specimens may be useful in the diagnosis of diffuse lung diseases and certain infectious diseases such as tuberculosis. Sputum may be examined microscopically as well as by microbiologic methods.

Technique

There are two problems associated with sputum examination: obtaining a specimen and ensuring that the specimen comes from the lower respiratory tract. Even though they may have copious tracheal secretions and a cough that sounds productive, young children are usually unable to expectorate the specimen. A common practice therefore is to obtain a swab from the posterior pharynx while attempting to induce a cough. Although this may be successful (the swab will obviously have a sample of mucus, which may be green or yellow), it is not always certain that such a specimen comes from the lungs and not from the nasopharynx. There is a relatively poor correlation, at least in young children, between the results of such "gag sputum" specimens and specimens obtained by bronchoscopy and BAL. Microscopic examination of the specimen for the presence of alveolar macrophages can help determine whether the specimen is indeed from the lower respiratory tract.

In older patients who do not have a productive cough, it may still be possible to induce sputum by the inhalation of an aerosol (especially an ultrasonic aerosol) of saline (hypertonic or isotonic).[111] This procedure may place medical personnel at some risk, and they should be protected by appropriate procedures from the aerosol generated by the patient's cough.

To reduce the probability of contamination of the sputum specimen with oral secretions, the specimen should ideally be collected after the mouth is rinsed with water and not within an hour or so of a meal. The patient should be instructed to provide sputum rather than saliva, although it may be possible to separate material that appears to be sputum from saliva after expectoration. It is standard in many

microbiology laboratories to remove saliva by washing the sputum specimen with sterile saline before processing it.

Sputum may be examined microscopically as a wet mount by placing it under a coverslip on a microscope slide, or it may be smeared and stained with a variety of stains, depending on the purpose of the examination. Although Gram's stain is usually used in the microbiology laboratory, this is not an effective stain for study of cell types. Wright's or Giemsa stains are useful for evaluating inflammatory cells and eosinophils and identifying alveolar macrophages (the absence of which suggests that the specimen may not have come from the lower respiratory tract). The presence of numerous neutrophils does not in itself prove that the specimen came from the lungs, but the presence of large numbers of squamous epithelial cells does suggest heavy contamination with oral secretions.

CHAPTER 16 Pharmacology of the Lung and Drug Therapy

Joseph D. Spahn and Stanley J. Szefler

TEACHING POINTS

- Medication effect is determined by pharmacokinetic and pharmacodynamic properties.
- Effect of inhaled medications such as glucocorticoids is directly related to the delivery device, potency of the drug, and distribution and elimination.
- Variability in medication response should be anticipated and potentially related to medication adherence, pharmacogenetics, and the interaction of pharmacokinetics and pharmacodynamics.

Lung pharmacology is a diverse topic. Not only are a number of pharmacologic properties involved in the administration of drugs to the lung, but the lung itself is a complex site for drug delivery and metabolism. Simple factors such as the timing of doses can have a profound effect on the pharmacologic response to selected medications. In pediatric practice, age- and size-related patient variables must also be considered.

This chapter reviews basic principles of pharmacology that pertain to the lung and therapeutic dosing strategies in pediatric patients. Asthma, one of the most common chronic diseases in children, serves as the focus. Pharmacologic treatments of specific disease entities are covered in the relevant chapters.

THE LUNG AS A SITE FOR DRUG DELIVERY

The lung is a complex site for the administration of medications. The lung can be divided into four basic anatomic components—airways, vasculature, innervation, and interstitium—each of which has its own subcomponents. Successful delivery to these sites depends on a number of different variables that are directly affected by the relevant anatomic structures. The choice of target site is important in achieving the goal of therapy (e.g., eradicating infection, attaining bronchodilation, reducing inflammation).

Airways

The airways, simply thought of as a series of narrowing and branching tubes, consist of cartilaginous bronchi, membranous bronchioles, and terminal gas-exchanging ducts or alveoli.[1] These can be subdivided into their various cross-sectional components, which include the epithelium, lamina propria, smooth muscle, and submucosal connective tissue. The β-adrenergic receptors of smooth muscle serve as the target for the β-adrenergic agonist bronchodilators. Inflammatory cells or other cells such as epithelial lining cells or infectious organisms may also be the actual target cells for drug delivery. For example, lymphocytes, thought to play an important role in the pathogenesis and severity of asthma, are the target cells of glucocorticoid therapy. The bifurcations resulting from the branching of the airways and the reductions in airway caliber with each branching provide unique challenges to drug delivery by the inhaled route of administration.

Vasculature

The blood supply of the lungs and airways, the bronchial arteries, originates from either the aorta or the intercostal arteries. The functional pulmonary circulation is a complex network of arteries, arterioles, capillaries, venules, and veins. Blood flows from the pulmonary artery to the arteries of the lung and then to the capillaries, where gas exchange occurs in the alveoli. From there, the oxygenated blood returns via the venules, veins, and pulmonary vein and then to the circulation of the body. In general, the vasculature follows adjacent to the branching airways; however, at the periphery of the lung the veins branch away to pass between the lobules, whereas the arteries and bronchi continue down the centers of the lobules.[2] Because of the vast numbers of alveoli present, the majority of the total blood volume and surface area are present in the capillaries in the walls of the alveoli.[1] This has implications not only for drug therapy with regard to therapeutic effects but also for drug-induced toxicities because the entire blood volume circulates through the lungs and comes into contact with this vast surface area.

Innervation

Innervation of the lung has been well described with regard to the adrenergic and cholinergic pathways. Although abnormalities of these pathways have been described in asthma, such as enhanced α-adrenoreceptor function, impaired β-receptor function, and enhanced cholinergic responses, all of which ultimately result in bronchoconstriction, there is increasing evidence that neural mechanisms may contribute

to the airway inflammation associated with the disease.[3,4] In addition to the classic cholinergic and adrenergic pathways, the nonadrenergic, noncholinergic (NANC) pathway is also involved in regulating the tone and secretions of the airways and vasculature.[3,4] NANC nerves can either be excitatory (eNANC) or inhibitory (iNANC). Our knowledge of the neural regulation of the airways has greatly expanded over the past decade by applying molecular biology techniques, by using knockout and transgenic mice, and by the development of several neurotransmitter antagonists. It has also become increasingly clear that there is significant interaction between the neural and immune systems. Cholinergic nerves form the predominant bronchoconstrictors of neural pathway in humans. Excessive activity of cholinergic nerves may play an important role in asthma, particularly during acute exacerbations. The eNANC pathway also contributes to asthma with substance P and neurokinin A, the neurotransmitters involved in the eNANC system. These tachykinins are potent vasodilators and bronchoconstrictors. In addition, they are proinflammatory because they are involved in the stimulation of T and B lymphocytes, mast cells, and macrophages. They are also chemotactic agents for eosinophils and neutrophils. The iNANC pathway is the only neural-mediated system involved in bronchodilation with vasoactive intestinal peptide (VIP) and nitric oxide (NO)—the implicated neurotransmitters.[4,5]

Interstitium

Pulmonary interstitium, which surrounds the blood vessels, consists of loose connective tissue (primarily collagen and elastic fibers[6]) and is generally sparse under normal conditions. Although comprising a small volume, changes in vascular permeability may result in a dramatic expansion of the perivascular interstitium, which is a major storage compartment for excess extravascular fluid in the initial stages of pulmonary edema.[7] Thus, although it is not normally a target site for drug therapy, the interstitium can clearly be important in the pathogenesis of lung disorders.

ROUTES OF DRUG DELIVERY

Before any medication can be effective, it must be delivered to its site of action in the target tissues. A number of methods can be used to effectively deliver medication. These can be broadly divided into the topical and systemic routes of administration. Topical administration includes the inhalation of aerosols delivered by the commonly used metered dose inhalers, dry powder inhalers, and nebulized solutions. Systemic delivery consists of vascular distribution after oral and parenteral administration. Each of these routes has advantages and disadvantages. The inhaled route of administration is discussed in greater detail in Chapter 17.

Inhaled Administration

The inhaled route of administration is generally preferred over systemic routes because medications are delivered directly to the site of action, bypassing the need for absorption as with orally administered medications. Smaller doses are required, and a more rapid onset of action can be obtained.[8] Any potential systemic adverse effects can also be minimized or avoided, provided that the drug has a low degree of systemic activity and absorption. Thus, the inhaled route of administration appears to be advantageous over systemic delivery (Table 16-1).

The inhaled route for drug delivery is affected by a variety of physiologic and physicochemical factors. Not only must the inhaled medication be contained within particles small enough to be aerosolized, but the particles within the aerosol must also be of proper diameter to be inhaled, avoid impaction with the pharynx, and travel down through the bifurcations of the bronchi to the smaller airways, which is the target site for most inhaled medications.[9,10] Because infants and young children have smaller lungs and airways, the delivery of medications via inhalation can be considered more difficult in this population than in adults. Diseased airways, which have reduced conductance and airflow, may cause further difficulties in achieving adequate drug delivery.

Deposition of particles in the airways occurs via basic physical mechanisms. Large particles (those >5 μm in diameter) affect the pharynx and wall of the larger airways because of the inertia of the inhaled particle (inertial impaction), and small particles (those <5 μm in diameter) deposit in the small airways as a result of gravitational sedimentation.[9,10] Other factors, such as brownian movement and electrostatic forces, play lesser roles in the deposition of particles in the respira-

Table 16-1
Topical and Systemic Routes of Drug Delivery

Route	Advantages	Disadvantages
Topical: inhaled	Drug is delivered directly to site of action. Drug bypasses absorption. Route provides reduced incidence of adverse effects.	Coordination is often required for optimal use and delivery. Route may be inconvenient. Administration may be inconsistent.
Systemic: oral	Drug is easy to administer. Route is convenient. Drug can be inexpensive.	There are potential problems with absorption. There is potential for first-pass metabolism. Drug interactions can occur. There is increased incidence of adverse effects. There is limited exposure at site of action.
Intravenous	Drug has 100% bioavailability. Route provides rapid onset of action.	Route is inconvenient. Administration is costly. Aseptic technique is required. There is potential for drug interactions. There is increased incidence of adverse effects. There is limited exposure at site of action.

tory tract. Even smaller particles (those generally <1 μm in diameter) are often too small to be deposited and retained in the airways and are exhaled. Thus the "respirable range" of aerosol particles consists of those larger than 1 μm and smaller than 5 μm in diameter.

Drugs for inhalation must first be solubilized in a delivery vehicle which should not have adverse effects of its own.[11] Some highly desirable medications for inhaled administration are not water soluble and thus require unique and innovative delivery vehicles. Liposomes have been proposed as delivery vehicles for targeting various water-insoluble medications, such as glucocorticoids and cyclosporin, to the lung.[12,13]

The delivery device itself must produce aerosols containing particles of an appropriate size, between 1 and 5 μm in diameter, as previously mentioned. Several studies have demonstrated that the different brands of metered dose inhalers and nebulizers can produce varying aerosol characteristics, rates of output, output, and residual volumes[14-17] and that some single lots of nebulizers may even demonstrate widely variable characterstics.[18,19] This can have profound implications when the optimal delivery device is selected for critical medications, such as pentamidine.[20,21]

Each type of delivery device has advantages and disadvantages (Table 16-2). With drug delivery from metered dose inhalers, the potential for local or systemic adverse effects can be minimized with proper technique and spacer devices. The benefits of spacer devices include less need for coordinating inhalation and actuation for proper use (as with breath-actuated devices), the time needed for the propellant to evaporate, retention of the larger nonrespirable particles, and reduction of particle velocity.[22] If a drug has a poor topical-to-systemic potency ratio, however, an increase of systemic adverse effects can be observed because of better pulmonary deposition.

Metered dose inhalers that use chlorofluorocarbons (CFC) as the propellant are being replaced by metered dose inhalers that use hydrofluoroalkanes (HFA) because of the increasing concern over the effect of CFCs on the earth's ozone layer.[23] Although the CFC propellants used in metered dose inhalers represent a minute fraction of the total worldwide production and use, the Montreal Protocol has spurred the development of new methods for drug delivery.

Several such examples are the dry powder inhalers, which include the Turbuhaler (AstraZeneca LP, Wilmington, Del), and newer devices such as Diskus (GlaxoSmithKline, Research Triangle Park, NC), and Twisthaler (Schering-Plough, Kenilworth, NJ). All are similar in that they are breath-actuated devices that deliver a dry, micronized powder of medication to the lungs. Because they require some degree of coordination, these devices cannot be used in young children. A benefit of newer dry powder inhalers may be better lung deposition[24] with similar or even improved total bioavailability compared with metered dose inhalers[24,25]; however, some have suggested that these devices can provoke coughing and that increased bioavailability may alter the risk for systemic adverse effects. All of the aforementioned devices contain multiple doses.

The drug must be delivered to the site of action in concentrations sufficient to produce therapeutic effects. As mentioned previously, delivery of medications to the lung of pediatric patients can be considered more difficult because of the smaller airways. Complicating this issue further is the inability of young children to cooperate, as all of the delivery systems require good effort to be effective. Other topical delivery systems, such as the sublingual and transdermal routes, are available; however, these do not yet have applications in pediatric pulmonary practice.

Oral Administration

The oral route of drug administration requires absorption from the gastrointestinal tract as an initial step. Although this route may often be more convenient than the inhaled route, especially for younger children, a number of factors can adversely influence its use.

First, a drug given orally must be bioavailable from the gastrointestinal tract. Epinephrine, for example, is not administered orally because of rapid metabolism in the gastrointestinal mucosa and liver, making the drug ineffective. If a drug can be administered orally, other drugs or food can affect the gastric emptying time or the drug absorption itself. For

Table 16-2
Inhaled Drug Delivery Devices

Delivery Device	Advantages	Disadvantages
Metered dose inhaler	Standard of therapy	Need for coordination Phase-out of fluorocarbon propellants
Metered dose inhaler with spacer device	Reduced topical effects Reduced systemic drug absorption Need to clean spacer Increased pulmonary drug deposition	Cost of spacer Possible provocation of cough
Dry powder inhaler	Actuation by breath Possible increased pulmonary drug deposition	Possible requirement for high flow rates compared with metered dose inhaler Some single-dose units only
Nebulizer	Ease of use Efficient delivery	Inconvenience for some patients Need for water-soluble drug Need to clean nebulizer High cost (air compressors and ultrasonic) Possible inconsistent drug delivery (jet) Possibility of chemical breakdown of drug (ultrasonic) Potential mechanical difficulties (ultrasonic)

example, the bioavailability of theophylline can be affected by the specific sustained-release formulation, administration with meals, and patient variables such as gastric motility and absorption from the gastrointestinal tract.[26] Although sustained-release formulations are designed to affect the rate but not the extent of absorption, differences have been observed.[26] Patient factors that can affect gastrointestinal motility and absorption (e.g., dumping syndromes or ostomies, which greatly shorten gastrointestinal transit time) can also adversely affect the bioavailability of medications.

The second factor that influences oral administration is the incidence of adverse effects. The stimulatory effects of β-adrenergic agonists are greater after systemic compared with inhaled administration. For both terbutaline and oral albuterol, studies have shown significantly more adverse effects and increased heart rate and tremor but similar efficacy when intravenous administration is compared with inhaled administration.[27,28] Another example is the chronic administration of oral glucocorticoids. Although very effective in the long-term management of asthma, the adverse effects of chronically administered oral glucocorticoids preclude its use in all but the most severe asthmatic patients. A medication given orally must, therefore, not only be active, but it must also have a low degree of adverse effects.

Parenteral Administration

Parenteral routes of administration include the subcutaneous, intramuscular, and intravenous routes. For these routes to be viable, a medication must be water-soluble or in suspension. The intravenous route of administration bypasses the absorption step, resulting in 100% bioavailability. Another advantage is the rapid onset of action. These routes of drug administration may not always be viable because of inconvenience and cost. Also, the drug's adverse effects are not reduced compared with the effects after oral administration. Other disadvantages with parenteral routes are patient discomfort, the need for sterile conditions, and potential risks to health care practitioners from blood-borne pathogens. In some cases, however, these routes of administration may be the only way to achieve therapeutic concentrations at the target tissues, such as with some anti-infective agents and in emergency situations with asthmatic patients.

PHARMACOKINETICS

Drug Distribution

The following sections provide a brief overview of pharmacology. The first section deals with the various pharmacokinetic parameters such as volume of distribution and clearance (Box 16-1) whereas the second section deals with pharmacodynamics. *Pharmacokinetics* describe the relationship between the concentration of the drug at its site of action to time, whereas *pharmacodynamics* describe the relationship between the concentration of the drug to its clinical effects (Fig. 16-1). The distribution of systemically administered medications is important in that the drugs must be available to the target tissues. The *volume of distribution (Vd)* relates a drug's plasma concentration *(C)* to the concentration in the tissues and is defined by the following equation:

BOX 16-1 Definitions of Pharmacokinetic Parameters and Their Relevance to Inhaled Glucocorticoids in Asthma

Bioavailability. Bioavailability refers to the amount of drug systemically absorbed. In the case of inhaled glucocorticoid (GC) therapy, two routes of absorption are available. The drug can be absorbed via the oral route or via the lung. Both routes of absorption contribute to the systemic bioavailability.

Clearance. Clearance refers to the volume of blood that is cleared of the drug per unit of time. The clearance rates for all of the inhaled GC preparations are quite rapid and approach that of hepatic blood flow. This property contributes significantly to the high topical to systemic potency because these drugs are cleared quickly from the systemic circulation.

Volume of distribution. Volume of distribution refers to the distribution of the drug in the tissues of the body. Largely, this property is dependent on the lipophilicity of the drug: the greater the lipophilicity, the greater the apparent volume of distribution. The volumes of distribution among the available inhaled GCs vary greatly, but this parameter affects the topical-to-systemic potencies to a much lesser extent than that of systemic clearance.

Elimination half-life. The elimination half-life refers to the rate at which a drug is removed from the systemic circulation. It is derived from both the clearance and volume of distribution of the drug in question.

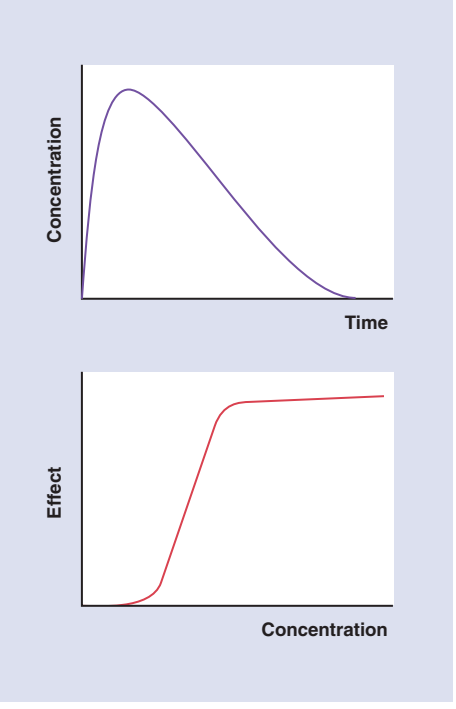

Figure 16-1 Graphic representations of the distinction between the pharmacokinetic and pharmacodynamic properties of a drug. The pharmacokinetics describe the concentration of a drug at the site of action over time, whereas the pharmacodynamics tries to relate the concentration of the drug to its clinical effects.

Eq 16.1

$$Vd = \frac{Dose}{C}$$

However, this does not provide insight into the drug's concentration at the relevant target tissue sites. A drug's volume of distribution, known from population values, allows calculation of the loading dose *(LD)* required to give a specified peak plasma drug concentration (C_p), as follows:

Eq 16.2

$$LD = Vd\ C_p$$

With oral dosing, the bioavailability of the particular drug and dosage form must also be considered. For some medications, such as theophylline, a "therapeutic range," which balances the desired therapeutic effects with the unwanted toxic effects, has been developed.[29,30] In the case of theophylline, the traditionally regarded therapeutic range (10 to 20 μg/mL) has been reassessed, and new guidelines recommend lower concentrations (5 to 15 μg/mL).[31,32]

The volume of distribution is related to the drug's lipophilicity, plasma protein binding, and route of elimination. A highly lipophilic medication, which tends to distribute and bind more widely to body tissues, generally has a larger volume of distribution and is metabolized in the liver.[33] Drugs that are highly protein bound or that have large molecules and thus remain primarily in the plasma, tend to have smaller volumes of distribution and are excreted unchanged by the kidney.[33] Factors affecting these parameters, such as competitive protein binding by other medications or metabolic changes that can affect protein binding (pH, serum albumin concentration, disease states that affect affinity of binding to albumin), can influence the drug's volume of distribution and can result in changes in therapeutic effect or toxicity.

For drugs that distribute to highly perfused tissues (versus adipose tissue), dosing is often based on ideal body weight. Examples of such drugs are aminoglycoside antibiotics and, on occasion, theophylline. Finally, differences among drugs themselves can manifest as differences in distribution to specific tissues. It has been demonstrated in an animal model that methylprednisolone achieves higher concentrations in the lung and persists for a longer period of time than prednisolone.[34,35] This may result in a therapeutic benefit of methylprednisolone over prednisolone during treatment of inflammatory conditions of the lung.

Drug Elimination

Drugs are eliminated from the body via two general pathways. They are either metabolized in the liver or excreted in the urine. As alluded to previously, the route of elimination is affected to some degree by the lipophilicity and size of the drug molecule. Drug metabolism can occur in body tissues other than the liver; however, this is usually to such a small extent that the effect on the total body clearance is minimal. A notable exception are glucocorticoids, which are thought to be metabolized in all body tissues.[36] In most instances, the total body clearance of a drug is the sum of both the hepatic and renal clearances. If a steady-state serum drug concentration *(Css)* is desired, the clearance *(Cl)* must be known so that the maintenance dose *(MD)* can be calculated, as follows:

$$MD = Cl \bullet C_{ss} \bullet t \qquad \text{Eq 16.3}$$

where *t* is the dosing interval. Clearance can also be calculated directly with detailed pharmacokinetics studies. After the serum concentration versus time curve is plotted after a dose of a given drug, the clearance is calculated as follows:

$$Cl = \frac{Dose}{AUC} \qquad \text{Eq 16.4}$$

where *AUC* is the area under the serum concentration versus the time curve. The AUC is most commonly calculated using the trapezoidal rule, which involves dividing the serum concentration versus the time curve into a series of trapezoids and calculating their areas (Fig. 16-2). The AUC is the sum of the areas of these trapezoids, and is approximated by the following equation[37]:

$$AUC = {}^1/_2(C_1 + C_2)(t_2 - t_1) + {}^1/_2(C_2 + C_3)(t_3 - t_2) + {}^1/_2(C_3 + C_4)(t_4 - t_3) + {}^1/_2(C_{n-1} + C_n)(t_n - t_{n-1}) \qquad \text{Eq 16.5}$$

Hepatic Clearance

Hepatic elimination of medications often occurs via the cytochrome P-450 pathway. There are approximately 50 active cytochrome P-450s of which 8 to 10 are involved in the majority of drug metabolism reactions. These isoforms are abbreviated using the term CYP. The following describes the medication used to treat asthma followed by the CYP isoenzymes involved in their elimination: glucocorticoids (CYP3A4), the long-acting beta agonist formoterol (CYP2A6, 2C9, 2D6), the leukotriene-modifying agents montelukast (CYP2C9, 3A4), zafirlukast (CYP2C9), and zileuton

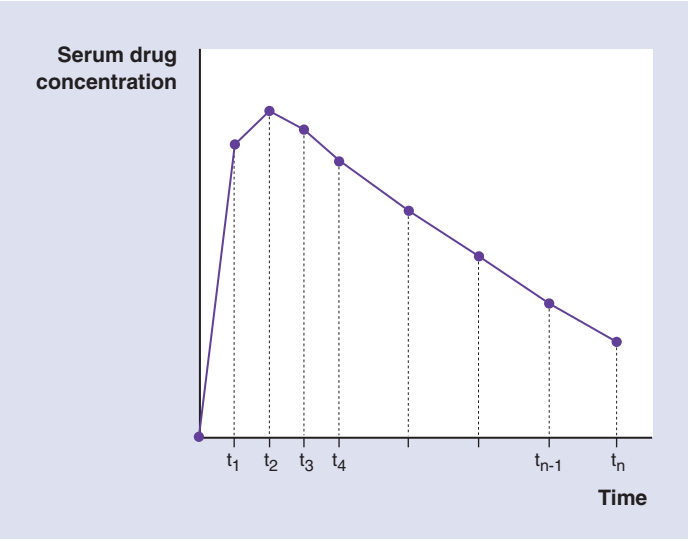

Figure 16-2 Division of a serum drug concentration versus time curve into a series of trapezoids for calculation of its AUC using the trapezoidal rule. AUC, area under the curve.

(CYP2C9, 1A2), and theophylline (CYP1A2, 2E1, 3A3).[33] This metabolic pathway is of importance because drugs metabolized by the P-450 system are susceptible to a number of drug interactions, resulting in either acceleration or reduction in metabolism based on whether the drug interaction results in inhibition or acceleration of the involved isoenzymes.

Theophylline is a good example of a medication significantly affected by drugs that either accelerate or inhibit the cytochrome-P-450 system. For example, the dose of theophylline must be reduced by ~50% in subjects receiving theophylline who are to be treated with a macrolide antibiotic such as erythromycin. Erythromycin is a potent inhibitor of the cytochrome P-450 system, and concomitant use with theophylline will substantially reduce theophylline metabolism, resulting in elevated serum concentrations and the potential for cardiac arrhythmias, seizures, and possible death. Theophylline has a narrow therapeutic index; concentrations below 5 μg/mL are ineffective whereas concentrations above 20 μg/mL can be associated with substantial toxicity. As a result, patients treated with theophylline require close monitoring and appropriate dosage adjustment to maintain levels within the therapeutic range. Of special consideration are the anticonvulsant agents phenytoin, phenobarbital, and carbamazepine, which enhance the metabolism of theophylline and glucocorticoids.[38-40] The macrolide antibiotics, troleandomycin, erythromycin, and clarithromycin, have also been shown to reduce methylprednisolone (but not prednisolone) clearance.[39-43]

Clearance and inactivation of drugs occur via other metabolic pathways. The short-acting β-adrenergic agonist albuterol, for example, undergoes conjugation in humans and glucuronidation in other species.[45] Drug clearance via these metabolic pathways is influenced by hepatic blood flow and the intrinsic capacity of liver enzymes to metabolize drugs.[44] Disease states that affect these factors can result in changes in drug metabolism. The most common disease state affecting the hepatic elimination of drugs is liver disease, which invariably results in reduced drug elimination. For example, theophylline elimination can be significantly altered by liver cirrhosis, acute hepatitis, cholestasis, and cor pulmonale.[25,46] Glucocorticoids, however, are extensively metabolized throughout the body.[36] Thus, liver disease has a minor impact on total body elimination, and dosage adjustments are not necessary. Other disease states can affect a drug's metabolism. Prednisolone elimination is enhanced in children with cystic fibrosis compared with children without the disease.[47] Elimination of other drugs metabolized via hepatic glucuronosyltransferase and biliary secretion are thought to be enhanced in cystic fibrosis as well, with oxidative metabolism unaffected.[48]

Renal Clearance

Renal drug clearance is a function of three mechanisms: glomerular filtration, tubular secretion, and tubular reabsorption. These mechanisms are influenced by plasma drug concentration and protein binding, urine flow and pH, and the general degree of kidney function and thus can affect the renal elimination of drugs.[45] For some drugs such as aminoglycoside antibiotics, estimates of creatinine clearance based on serum creatinine concentrations allow for a relatively accurate estimation of drug clearance and required dosing regimens.

First- and Zero-Order Elimination

Most drugs are metabolized by first-order elimination; that is, the rate of metabolism is proportional to the amount of drug in the body. A constant fraction of the drug in the body is metabolized per unit time. This constant is known as the *elimination rate constant* (k_e). The amount of drug removed *(R)* depends on the amount of drug present in the body *(A)* and is defined by the following equation:

$$R = k_e \bullet A \qquad \text{Eq 16.6}$$

The elimination rate constant can be calculated from a drug's clearance *(Cl)* and volume of distribution *(Vd)*, as follows:

$$k_e = \frac{Cl}{Vd} \qquad \text{Eq 16.7}$$

For some drugs, elimination pathways may become saturated. Thus, metabolism occurs at a fixed rate (k_m) or demonstrates zero-order elimination. With zero-order elimination, the amount of drug removed depends not on the amount of drug in the body but on the amount of time involved and can be described as follows:

$$R = k_m \bullet \text{Time} \qquad \text{Eq 16.8}$$

Most drugs demonstrate first-order elimination, with zero-order elimination observed in some patients as the dose is increased. A small fraction of the population may demonstrate zero-order theophylline metabolism even with therapeutic doses, and a number of instances of this phenomenon have been reported.[49] In such cases, changes in dosage do not correspond to proportional changes in serum concentration as they would if the drug demonstrated first-order elimination. Rather, small dosage increases can result in large increases in serum concentrations and possibly toxicity. Patients who demonstrate zero-order theophylline metabolism at concentrations within or close to the therapeutic range must be identified and then followed by close monitoring and careful dosage titration to maintain safe concentrations and prevent toxicities.

PHARMACOKINETICS AND PHARMACODYNAMICS OF INHALED MEDICATIONS

Glucocorticoids

By effectively delivering small quantities directly into the airway, inhaled glucocorticoids (GCs) maximize the beneficial effects while minimizing the unwanted systemic effects. In this way, one achieves a more favorable topical-to-systemic potency ratio or therapeutic index (Fig. 16-3). There are currently six inhaled GCs available for use in the United States: beclomethasone dipropionate (Qvar 40, 80 μg/inhalation), triamcinolone acetonide (Azmacort 100 μg/inhalation), flunisolide (Aerobid 250 μg/inhalation), budesonide (Pulmi-

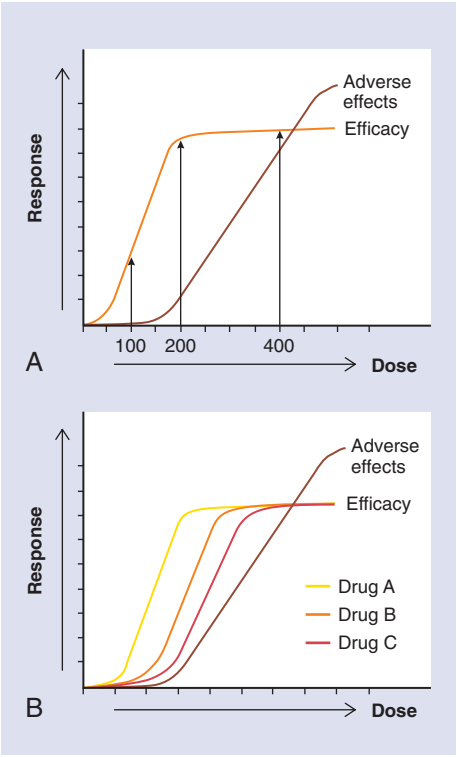

Figure 16-3 Graphic representation of the therapeutic index. The therapeutic index describes the relation between the wanted and unwanted effects of a drug. **A** demonstrates the point that the therapeutic index is dependent on the dose of the drug administered. The ideal dose is one that results in the greatest clinical effect with the smallest unwanted effect. **B** demonstrates the second important point—that the therapeutic index varies between members of a class of drugs. Drug A has the best therapeutic index; Drug B has a fair therapeutic index; Drug C has the poorest therapeutic index.

cort 200 µg/inhalation and 0.25 and 0.5 mg/2 mL solution), fluticasone propionate (Flovent 44, 110, 220), and mometasone furoate (Asmanex 220 µg/inhalation). A seventh product, ciclesonide, is currently undergoing phase III clinical studies. The pharmacokinetic and pharmacodynamic properties of inhaled GCs have received increasing attention as greater scrutiny has been placed on their potential adverse effects. The following discussion will provide an overview of how the pharmacokinetic and pharmacodynamic properties of inhaled GCs influence their effectiveness and potential for adverse effects.

DRUG DELIVERY

The delivery device and the propellant used to deliver inhaled glucocorticoids affect not only the amount of drug delivered to the lung, but also their deposition pattern within the lung.[50,51] Inhaled glucocorticoids can be delivered using three different devices. The most commonly used device is the pressurized metered dose inhaler (PMDI) that uses as a propellant either chlorofluorocarbon (CFC) or the "ozone friendly" hydrofluoroalkane (HFA). More recently, dry powder breath-actuated inhalers (DPIs), such as the Pulmicort Turbuhaler, Asmanex Twisthaler and the Advair Diskus, have been developed. The third type of device uses budesonide in a suspension for nebulization (Pulmicort Respules) for treatment in children 1 to 8 years of age.

The delivery device contributes significantly to the delivery of the inhaled GC to the lower airway. For example, budesonide delivered via the DPI Turbuhaler results in twice the lower airway deposition than that of the MDI.[24] The use of a holding chamber with MDIs can also significantly enhance the delivery of the drug into the lower airways while decreasing the amount of drug deposited on the oropharynx.[52,53] The mechanisms by which a holding chamber enhances drug delivery to the lungs are numerous. First, the holding chamber allows for a reduction in velocity of the ejected mass so that the majority of medication does not negatively affect the posterior oropharynx. Second, the aerosol has time to evaporate, thereby allowing for the generation of smaller particles from larger aggregate particles. Third, larger particles will deposit onto the chamber walls instead of the oropharynx.

In contrast to budesonide, where the DPI is a more efficient delivery device than the MDI, the opposite appears to be the case with fluticasone propionate. In a study published by the Asthma Clinical Research Network (ACRN), 111 µg/d of fluticasone propionate, delivered via a pMDI, resulted in a 10% suppression of plasma cortisol concentration area under the curve (AUC), whereas a fourfold greater amount (445 µg/d) was required when fluticasone propionate was delivered from a DPI device (Rotodisk).[51] The reason for discrepancy can be explained by differences in the fine particle dose (FPD) generated by the two devices. The FPD is considered to be the dose delivered to the lung. Fluticasone MDI provided an FPD of 52%, whereas DPI provided an FPD of only 11%.

The type of propellant used to power an MDI can have a profound effect on the amount of drug delivered and its deposition pattern within the airway. Glucocorticoids such as beclomethasone dipropionate, flunisolide, and ciclesonide dissolve into solution when HFA is the propellant, whereas all other inhaled glucocorticoids remain in a suspension, regardless of the propellant used. In solution, the average particle size is much smaller (1.1 µm), compared to an average particle size of 3.5 to 4.0 µm for glucocorticoids in suspension.[54] This is of clinical importance because smaller particles provide for greater drug delivery to the lung and greater delivery to the distal airways.[55] As a result, smaller concentrations of beclomethasone dipropionate–HFA have been shown to provide equivalent or superior efficacy compared to beclomethasone dipropionate–CFC.[56]

BIOAVAILABILITY

The systemic bioavailability of inhaled GCs is the sum of the absorption from both the oral and pulmonary routes (Fig. 16-4). The amount of drug swallowed is eventually absorbed from the gastrointestinal tract and is responsible for the oral bioavailability. Depending on the inhaled GC, oral bioavailability ranges from <1% for fluticasone propionate and mometasone furoate to 23% for triamcinolone acetonide.[57,58] Pulmonary bioavailability results from absorption of the inhaled GC that reaches the lung—with the amount of drug delivered determining the pulmonary contribution to systemic bioavailability. Thus, for fluticasone propionate, all of its systemic bioavailability comes from the pulmonary route, whereas for drugs such as triamcinolone acetonide and flunisolide, both oral and pulmonary bioavailability account for their systemic bioavailability (Table 16-3).

Table 16-3
Pharmacodynamic and Pharmacokinetic Parameters of Inhaled Glucocorticoids

Drug	RRA (L/hr)	Clearance (L)	Vd_{ss} (hr)	$t_{1/2}$ (%)	F_{oral} (%)	F_{inh} (%)
Mometasone furoate	2200	53.5	332	5.8	>1	NA
**Des-ciclesonide (active metabolite of ciclesonide)	1200	228	900	5.5	>1	52*
Fluticasone propionate	1800	69	318	7.8	>1	16
Beclomethasone monopropionate (active metabolite of BDP)	1345	120	400	2.7	26	55-60*
Budesonide	935	84	183	2.8	11	28
Triamcinolone acetonide	233	37	103	2.0	23	22
Flunisolide	180	58	96	1.6	20	39

*Delivered via hydrofluoralkanes-metered dose inhaler (HFA-MDI).
**Undergoing phase III clinical studies in the United States.
BDP, beclomethasone dipropionate; F_{inh}, inhalational bioavailability; F_{oral}, oral bioavailability; NA, not available; RRA, relative receptor affinity compared to dexamethasone (RRA = 100); $t_{1/2}$, plasma elimination half-life; Vd_{ss}, volume of distribution at steady state.

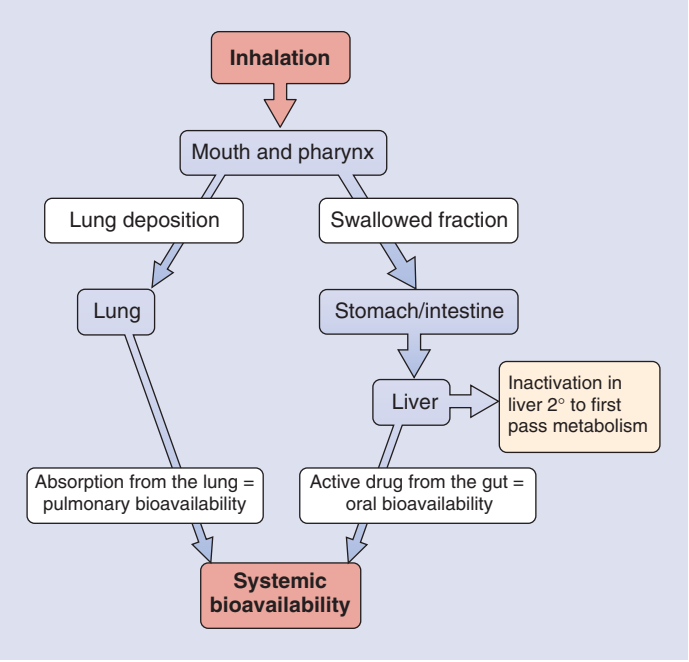

Figure 16-4 Flow diagram depicting the factors influencing the bioavailability of topically administered glucocorticoids. See text for details.

Airway diameter can also impact the bioavailability of an inhaled glucocorticoid. This point was demonstrated by Brutsche and colleagues,[59] who compared the pharmacokinetics of fluticasone propionate administered via MDI and spacer in asthmatics with significant airflow limitation (FEV_1 54% of predicted) to nonasthmatic controls (FEV_1 108% of predicted). The asthmatics, compared to the controls, had a significantly lower plasma fluticasone AUC (1082 versus 2815 pg/mL/hr), lower peak plasma fluticasone propionate levels (117 versus 383 pg/mL), and lower systemic bioavailability (10.1 versus 21.4%) following inhalation of fluticasone propionate.

Airway obstruction can also negatively influence efficacy. High-dose inhaled GC therapy administered over 1 to 2 weeks is often used to treat exacerbations of asthma.[60,61] Although inadequately studied, this form of therapy is thought to be efficacious in patients with mild to moderate exacerbations. Whether this practice is appropriate for severe exacerbations was recently examined.[62] In this study, 100 children with an acute severe asthma exacerbation (mean FEV_1 44% of predicted) who presented to the emergency department were randomized to receive high-dose fluticasone propionate (2000 μg) or prednisone (2 mg/kg) in addition to standard care, which included frequently administered albuterol and ipratropium. After 4 hours, the prednisone-treated subjects had a greater improvement in FEV_1 (18.9%) compared to those treated with fluticasone (9.4%). In addition, all subjects who received prednisone had stable or improved lung function, whereas 25% of the children treated with fluticasone actually had a decline in lung function. Of greatest importance, 31% of the children who received fluticasone required hospitalization compared to only 10% treated with prednisone. The authors concluded that fluticasone propionate was ineffective because of poor drug delivery as a result of significant airflow limitation. In this scenario, prednisone, although much less potent than fluticasone propionate on a microgram to microgram basis, was more effective because it reached sites of inflammation, perhaps the peripheral airways or deeper tissue layers, that were inaccessible via the inhaled route.

RECEPTOR AFFINITY

The affinity with which a GC binds to its receptor is an important pharmacodynamic parameter as receptor-binding affinity is closely linked to anti-inflammatory potency. Inhaled GCs with the highest receptor binding affinity have the greatest anti-inflammatory effects in vitro. Mometasone furoate has the greatest affinity, followed closely by fluticasone propionate and beclomethasone monopropionate (the active metabolite of beclomethasone dipropionate). The affinity of the remaining inhaled GCs in descending order is ciclesonide, budesonide, triamcinolone acetonide, and flunisolide (see Table 16-3).[63] Spahn and coworkers,[64] using an in vitro functional assay in which the concentration of GC required to inhibit lymphocyte activation by 50% was the pharmacodynamic parameter evaluated, found a similar hierarchy of potency. This pharmacodynamic assay has also been used clinically to assess GC responsiveness or resistance in adults and children with severe asthma.[65,66]

PULMONARY RETENTION TIME

Pulmonary retention is another important parameter to consider. Drugs with prolonged lung retention times have a

longer time within the lung to exert their anti-inflammatory effects and at the same time their absorption into the systemic circulation is delayed. Both of these factors are likely to contribute to a more favorable therapeutic index. Pulmonary retention is related to several factors including lipophilicity. The more lipophilic the GC, the greater the pulmonary retention time. FP is the most lipophilic GC; it also has a prolonged pulmonary retention time.[67] This finding was demonstrated by Esmailpour and coworkers,[68] who sought to investigate both the pulmonary retention and distribution of FP in vivo by having 17 subjects undergoing pneumonectomy or lobectomy for bronchial carcinomas inhale a single dose of fluticasone propionate (1000 μg) prior to surgery. The investigators were able to measure fluticasone propionate in the resected lung tissue for up to 16 hours. Of little surprise, central lung tissue had concentrations of fluticasone three to four times that of peripheral lung tissue, which in turn was approximately 100 times greater than that found in the serum.

Another method used to increase pulmonary retention time is to develop an inhaled GC that undergoes intracellular esterification with fatty acids. Fatty acid esterification within the lung has been demonstrated with both budesonide and ciclesonide. By creating fatty acid conjugates, a slow-release depot is produced which allows for a prolonged topical effect while minimizing systemic effects. In vitro studies have shown budesonide's pulmonary retention time to be as long or longer than FP owing to long-chain fatty acid conjugation within the airway epithelial cells.[69-71] This property likely explains why budesonide, although being less lipophilic and having a shorter half-life compared to fluticasone, has a once-daily indication, whereas fluticasone is administered twice daily.[72]

CLEARANCE AND VOLUME OF DISTRIBUTION

All of the available inhaled GCs display rapid systemic clearance with values approximating that of hepatic blood flow, which is the maximal rate at which hepatically metabolized drugs can be cleared.[63] As previously alluded to, the volume of distribution (Vd) is a measure of tissue distribution and is related to the lipophilicity of the drug (see Table 16-3).[73] Highly lipophilic drugs enter the tissues easily, resulting in a high Vd. The retention time in the various tissues of the body is dependent on the equilibrium that develops between the tissues and the systemic circulation. As a result, the volume of distribution is calculated by the ratio of the fraction unbound in the plasma (f_u) and in the tissue compartment (f_{uT}) and the volume of the plasma. Desisobutyryl-(des-)ciclesonide, the active metabolite of ciclesonide, has the highest Vd at 900 L, followed by beclomethasone monopropionate (the active metabolite of beclomethasone dipropionate) at 400 L, and fluticasone propionate at 318 L. The Vds of the other inhaled GCs are smaller with values ranging from 58 L for flunisolide to 84 L for budesonide (see Table 16-3).[75] It remains to be determined whether clinically significant correlations exist between Vd and measures of clinical efficacy and systemic adverse effects.

ELIMINATION HALF-LIFE

The elimination half-life varies substantially among the inhaled GCs and is dependent on both the systemic clearance rate and the volume of distribution (see Table 16-3). Given fluticasone propionate's large Vd, it is not surprising that it has the longest elimination half-life of 7.8 hours.[74] Desciclesonide has a larger Vd but its clearance is greater than that for fluticasone propionate. As a result, its half-life is shorter at 5.5 hours. The other inhaled GCs have values ranging from 0.1 to 0.2 hour for BDP to 5.8 hours for mometasone furoate (see Table 16-3).[24,57,76-78] Because fluticasone propionate has a long elimination half-life, it will take the drug longer to reach steady-state levels compared to the other inhaled GCs. This finding was supported by a recent study by Whelan and associates, who measured plasma fluticasone propionate concentrations following 1 and 6 weeks of fluticasone propionate 352 μg twice daily delivered via a CFC-containing MDI. The investigators found increasing fluticasone AUC from week 1 to week 6, suggesting that the time required to reach steady-state concentrations likely exceeds 1 week of treatment.[79]

Because FP is highly lipophilic, it has a larger volume of distribution and a longer elimination half-life. These properties have been used to explain fluticasone propionate's greater ability to suppress the HPA axis[80-82] compared to budesonide.[73] Although the greater Vd and longer terminal half-life of fluticasone propionate may contribute to its greater propensity to suppress the HPA axis, it should be noted that a large volume of distribution does not necessarily imply a greater potential for systemic effects. This is because GCs circulate primarily in an inactive protein-bound form. The active unbound form is independent of the Vd, with clearance and extent of protein binding the most important variables. Another potential explanation for fluticasone propionate's ability to suppress cortisol production especially at higher doses comes from the observation that fluticasone propionate binds to the GC receptor with greater affinity than the other inhaled GCs—with the exception of mometasone furoate. With increased receptor binding comes enhanced anti-inflammatory activity but also greater metabolic effects because all cells except red blood cells share the same GC receptor.

CICLESONIDE—A "THIRD GENERATION" INHALED GLUCOCORTICOID

Ciclesonide is currently undergoing phase III studies in the United States. It is considered a third generation inhaled GC because it has a number of unique features that distinguish it from other members of the class. First, it is a pro-drug. As it exists in the canister, ciclesonide is in an inactive form. Once it enters the lung, it is metabolized by lung esterases to its active form, des-ciclesonide. Des-ciclesonide has high GC receptor binding affinity, and as such, is likely to display significant anti-inflammatory effects. Second, because ciclesonide is inactive until it reaches the lung, there is less potential for local adverse effects such as oral candidiasis or dysphonia.[83] Third, ciclesonide undergoes lipid conjugation within the lung.[84] As previously discussed, inhaled GCs that undergo lipid conjugation have longer pulmonary retention times[69-71] and a greater potential to exert local anti-inflammatory effects. Fourth, once des-ciclesonide enters the systemic circulation, the majority (99%) is protein bound.[83] Because only the unbound or free fraction of a GC can bind to the GC receptor, drugs with extensive protein binding have little potential to exert systemic adverse effects. Des-

ciclesonide is 99% protein bound, whereas only 90% of fluticasone propionate is bound. This represents a 10-fold difference in protein binding (1% versus 10%) and a 10-fold difference in the concentration of drug available to exert systemic effects.[85] As a result, ciclesonide has fewer potential adverse effects than the other available inhaled GCs on a microgram-per-microgram basis. Ciclesonide has a relatively short half-life compared to the second-generation inhaled GC fluticasone (3.4 hours versus 8 to 10 hours).[83,86] The reason for its short half-life is its extremely rapid clearance from the systemic circulation. Ciclesonide is cleared from the circulation two to three times more rapidly than all the other inhaled GCs. This finding suggests that nonhepatic tissues must also contribute to its clearance. It should be stressed that much of the potential advantages of ciclesonide are yet to be proved in a clinical setting. These data will become available only when the drug is introduced for widespread use.

Inhaled Antibiotics for Cystic Fibrosis

Cystic fibrosis is the most common lethal inherited disease of whites—affecting 1 : 2000 to 1 : 2600 live births. It is a disorder of exocrine function involving multiple organs, but pulmonary disease is responsible for >90% of the morbidity and mortality in patients past the neonatal period. The defective gene has been identified and is located on chromosome 7q31.[87] The gene codes for a membrane-bound chloride channel called the cystic fibrosis transport regulator or CFTR. Patients with CF display increased viscosity of secretions from mucous glands and have undue susceptibility to chronic endobronchial colonization by *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and *Burkholderia cepacia*.

Chronic bronchopulmonary infection is thought to result in airway inflammation, which in turn leads to progressive loss of lung function.[88] Endobronchial colonization with *P. aeruginosa* occurs early in life (2 to 3 years), and once present it is difficult, if not impossible, to eradicate.[89] Thus, the mainstay of treatment in this disease is aggressive antibiotic therapy. Antibiotics are currently used in three distinct clinical situations: (1) antibiotics are used early in the course of the disease in an attempt to delay the onset of chronic colonization with *P. aeruginosa;* (2) intravenous antibiotics are used in combination with aggressive chest physiotherapy in a hospital setting to treat acute exacerbations; (3) once a child is colonized with *P. aeruginosa*, chronic antibiotics are administered in an attempt to slow the progressive decline in lung function associated with CF. Historically, the most frequent routes of delivery have been oral or intravenous, but over the past decade, inhaled antibiotic therapy has become increasingly utilized in an attempt to eradicate—or at least decrease the density of—*P. aeruginosa* in children who have become colonized.

Delivery of inhaled antibiotics such as tobramycin to patients with CF offers several potential advantages.[90] First, the drug is delivered directly to the site of infection. Second, much higher sputum concentrations can be achieved via the inhaled versus the oral or parenteral routes. Third, only a small fraction of the drug is absorbed from the lung and as a result, there is less potential for systemic toxicity. In addition, by delivering the antibiotic topically, there is less disturbance of the host's microorganisms. The following discussion will provide a brief overview of the pharmacokinetics and pharmacodynamics of inhaled tobramycin because it is the only inhaled antibiotic that is approved by the U.S. Federal Drug Administration (FDA) for use in children with CF.

INHALED TOBRAMYCIN (TOBI)

In 1997, TOBI (tobramycin solution for inhalation) was approved for use in children with CF 6 years of age and older. The recommended dose is 300 mg twice daily to be administered intermittently in 28-day cycles (28 days of therapy followed by 28 days off therapy). TOBI is dissolved in 5 mL of sterile preservative-free sodium chloride solution with an osmolality of 158 to 183 mOsm/kg and a pH of 6.0.[91] The manufacturer recommends TOBI to be administered using the PARI LC PLUS jet nebulizer with a DeVilbiss Pulmo-Aide compressor because this is the system that was used in the phase III studies designed to assess safety and efficacy.

As is the case with most inhaled medications, only a fraction of aerosolized tobramycin reaches the lower respiratory tract. Approximately 10% to 15% of the starting dose actually reaches the lung. As a result, the systemic bioavailability is also low with values ranging from 9% to 17.5%.[92,93] Ten minutes following administration of 300 mg of TOBI, the mean sputum tobramycin concentration was 1371 ± 1180 μg/g.[94] This value is much higher than the concentration thought to kill *P. aeruginosa* in sputum (100 μg/g).[95] Of importance, tobramycin concentrations 10 times the MIC may be required to suppress the growth and up to 25 times the MIC may be required to kill *P. aeruginosa* in sputum based on in vitro studies. In the two phase III placebo-controlled studies performed to gain FDA approval of TOBI, 464 patients received placebo or aerosolized TOBI 300 mg twice daily for 28 days (1 cycle) followed by 28 days off for a total of six cycles.[96] The mean sputum concentration 10 minutes after the initial dose was 1529 ± 1382 μg/g of sputum. TOBI was found to be more effective than placebo in improving lung function and decreasing the sputum density of *P aeruginosa.* Those who received tobramycin had a mean improvement in FEV_1 of 10%, whereas those who received placebo had a decrease in FEV_1 of 2% during the course of the study. The greatest improvement in FEV_1 came in the first 2 weeks, although improvement over placebo was maintained during the 20 weeks of the study. In addition, there was a significant decrease in sputum *P. aeruginosa* density in those who received tobramycin versus placebo at week 20. The mean serum tobramycin concentration 1 hour following the initial dose of TOBI was 0.94 μg/mL and unchanged 20 weeks later with a value of 0.98 μg/mL. Of note, sputum and serum concentrations were not related to age, gender, or baseline lung function. TOBI was well tolerated, although there was a trend toward increase in MIC in the *P. aeruginosa* isolates in the tobramycin-treated patients.

At present, there is some debate as to whether serum tobramycin concentrations should be monitored in children on chronic aerosol therapy. Most studies have shown serum concentrations to remain <2 μg/mL with no evidence for accumulation over time.[97] Nevertheless, nephrotoxicity should be assessed by obtaining serum creatinine, BUN, and urinalysis following 180 days of aerosolized tobramycin therapy.[98] Audiometric evaluation in the 500 to 8000 Hz

range has also been recommended after 180 cumulative days of therapy. Efficacy should be assessed by performing pulmonary function tests 2 to 4 weeks after institution of therapy. A lack of initial response does not preclude response later in the course because 30% of patients who did not have an immediate response were noted to have responded by 3 months of therapy.[96]

RECEPTOR PHARMACOLOGY

Receptors are biological units, specific protein recognition sites that bind or interact with molecules and determine the cellular response to such molecules at target tissues. These molecules commonly include drugs but also consist of endogenous hormones, neurotransmitters, mediators, and peptides. Receptor types include cell surface receptors and intracellular receptors. An example of each receptor site particularly relevant to respiratory diseases is the β-adrenergic receptor (cell surface) and the glucocorticoid receptor (intracellular).

Surface Receptors

Cell surface receptors, structurally consisting of polypeptide chains folded and crossing back through cell surface membranes several times, are known as *G-protein coupled receptors* because they interact with a guanine nucleotide regulatory protein.[99] Among these are the β-adrenergic receptors, adenosine receptor subtypes, and muscarinic receptor subtypes. The human β-adrenoceptor gene is located on chromosome 5 and codes for an intronless gene product of 1200 base pairs. The β-adrenoceptor family consists of at least three distinct groups, β_1, β_2, and β_3, which have been classically identified in heart, airway smooth muscle, and adipose tissue, respectively.[100]

Stimulation of β-adrenergic receptors results in a variety of effects. These include β_1 or chronotropic effects, and β_2 or smooth muscle relaxation effects. This stimulation of β_2-adrenergic receptors of the respiratory smooth muscle makes β-adrenergic agonist agents useful in the treatment of asthma. The mechanisms by which β-adrenergic agonists result in bronchodilation are well understood. Stimulation of the receptors activates adenylate cyclase and increases the level of intracellular cyclic adenosine monophosphate (cAMP). This is followed by activation of protein kinase A (PKA), inhibition of myosin phosphorylation, and lowering of intracellular calcium concentrations, which ultimately results in relaxation of airway smooth muscle.

Selectivity of an adrenergic agonist agent between β_1- and β_2-adrenergic effects results in a lesser incidence of the undesirable β_1 or chronotropic effects. Although it was once popular belief that β_1-adrenergic receptors existed only in heart tissue and β_2-adrenergic receptors were found only in lung tissue, radioligand-binding studies have demonstrated that each receptor subtype exists in both cardiac and lung tissue in almost equal proportions.[101] Stimulation of β_3-receptors, which are found in adipose tissue, is thought to result in the metabolic responses of adipocytes, muscle, and the gastrointestinal tract.[102]

The assessment of the pharmacodynamics of short-acting β-adrenergic agents is influenced by the development of tolerance (also referred to as *tachyphylaxis* or *desensitization*). Continuous exposure to a β_2-adrenergic agonist leads to reduced efficacy associated with diminished receptor density on the cell surface.[103] This is due to several intracellular mechanisms. Repeated receptor activation by agonist results in phosphorylation of serine and threonine amino acid residues on the intracellular carboxy terminus by serine-threonine kinase (also termed *β_2AR kinase*, *GPCR kinase*, or *GRK2*). This action, in combination with β-arrestin enzyme and cAMP protein kinase, results in internalization of the receptor into endosomes. The receptor in the endosomes may, in time, be recycled to the membrane surface, or may be degraded. With desensitization, decreased gene transcription (due to mRNA destabilization) of the β_2-adrenergic receptor also occurs.[104] Decreased response with the same or greater concentration of albuterol is consistent with tolerance to the drug, and may be characterized as a pharmacodynamic property termed *clockwise hysteresis*.[105]

Although receptor downregulation may play a role in tachyphylaxis to β-adrenergic agonists and perhaps the widely publicized potential for detrimental effects after regular use of these agents in treating asthma,[106,107] the clinical importance of such effects remains to be elucidated. Other factors, such as the inflammatory mediators phospholipase A_2, platelet activating factor, leukotrienes B_4 and C_4, 15-lipoxygenase products, oxygen metabolites, and cytokines, may also affect β-adrenergic receptor expression and function and, ultimately, control of severe asthma.[108]

Conversely, the upregulation of β-adrenergic receptors by GCs and thyroid hormones has been described.[103] Functionally, GCs, which are necessary for normal β-adrenergic receptor function, reduce the threshold for receptor stimulation and potentiate the bronchodilatory effects of agonist agents.[109-112] A twofold to threefold increase in the number of lung β-adrenergic receptors has been observed after the administration of GCs.[113-115] This is thought to result from increases in the rate of transcription- and receptor-specific messenger ribonucleic acid in cells.[116,117] GCs can also increase the responsiveness of desensitized cells to β-adrenergic agonists.[103,118,119]

Intracellular Receptors

The glucocorticoid receptor is an example of an intracellular receptor (Fig. 16-5). This receptor is located in both the cytoplasm and the nucleus of the cell. Because glucocorticoids are lipophilic molecules, they easily diffuse across the plasma membrane and enter the cytoplasm, where they interact with the glucocorticoid receptor and begin the chain of events that results in their biological effects. Once in the cell, binding of the glucocorticoid molecule to the receptor is preceded by a number of processes.

The first step involved in the binding of free glucocorticoid within the cell to the glucocorticoid receptor appears to be phosphorylation of the soluble receptor.[120-122] The next step is the binding of two 90-kD proteins,[123] which are from the family of heat-shock proteins elicited by stressors,[124,125] to the receptor, with binding of one hsp56 protein to the two hsp90 proteins.[126,127] Once it is bound to these proteins, the receptor complex can bind to the GC. It is thought that the receptor, when bound to hsp90, is stabilized in a high-affinity

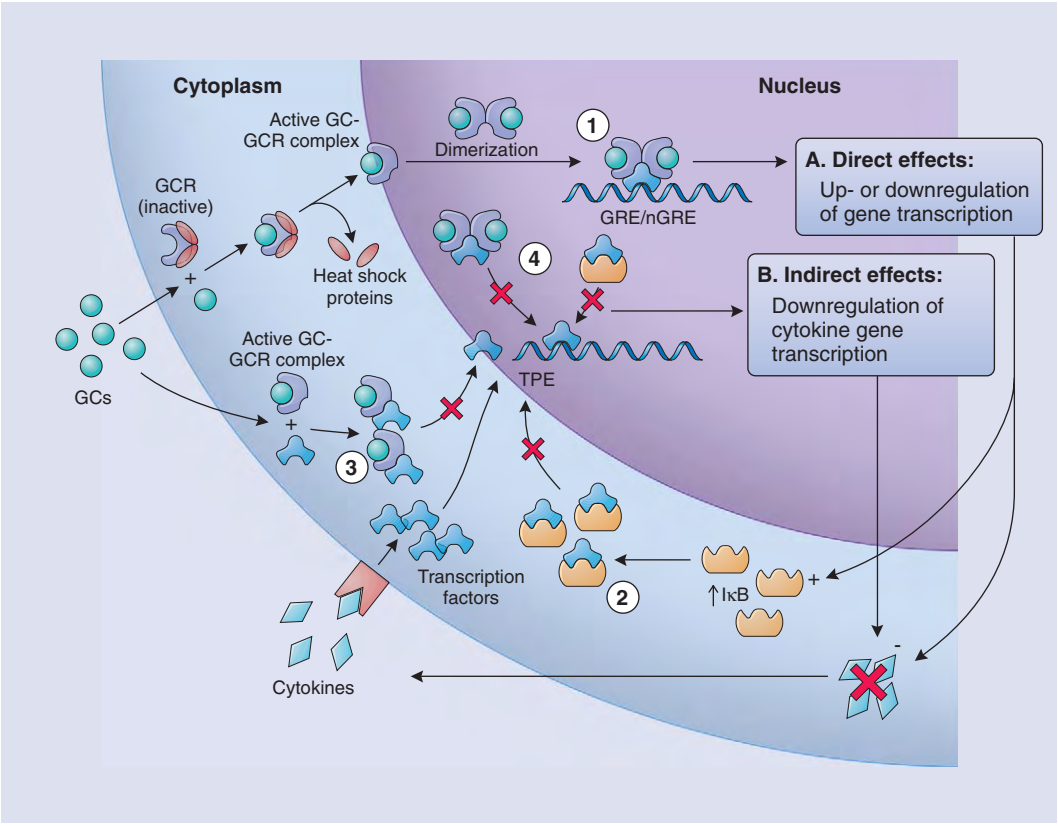

Figure 16-5 Model of glucocorticoid action. Glucocorticoids (GCs) easily diffuse across the plasma membrane of inflammatory cells where they bind to a cytoplasmic receptor, termed the *glucocorticoid receptor* (GCR). The GC-GCR complex is then transported to the nucleus where it dimerizes. GCs exert their anti-inflammatory effects in two major ways. By a process termed *trans*-activation, the GC-GCR complex binds to specific sites on the DNA called *glucocorticoid response elements* (GRE) and either up- or downregulates gene transcription (1). Second, in a process termed *trans*-repression, GCs inhibit transcription factor function. GCs can also inhibit the transcription of proinflammatory cytokines indirectly by either stimulating the production of Iκb, which then interferes with the ability of transcription factor function (2), or by binding to transcription factors directly (3). Transcription factors are essential in the transcription of proinflammatory cytokine genes. By interfering with the ability of transcription factors to bind to their binding sites, termed *transcription factor response elements* or TREs, GCs prevent transcription factor–induced gene transcription from occurring (4). *Trans*-repression is thought to be responsible for the majority of the anti-inflammatory effects of GCs, whereas *trans*-activation is thought to mediate many of the adverse effects associated with chronic GC use.

state for GCs.[128] Activation or transformation, the next step, is thought to result from a conformational change in the receptor that may result from dissociation of the receptor-hormone from the heat-shock proteins. Dimerization of two receptor-hormone complexes may also occur before nuclear translocation.[129]

When translocated into the nucleus, the GC receptor hormone complex can now exert its biological effects. We now know that two distinct processes account for the anti-inflammatory actions of GCs. By a process termed *trans*-activation, the GC-glucocorticoid receptor (GCR) complex binds to specific sites on the DNA called *glucocorticoid response elements* (GREs) and either up- or downregulates gene transcription. Once inside the nucleus, the "active" GC-GCR complex binds to specific DNA sites upstream from promoter regions, the GRE.[130] Binding of the GC-GCR to the GRE results either in upregulation or downregulation of gene products.[131] In this way, GCs inhibit the transcription of proinflammatory cytokines and inflammatory mediators. Alternatively, and more importantly, GCs, in a process termed *trans*-repression, inhibit transcription factor function.[132,133] Transcription factors such as AP-1 and NFκb are essential molecules in the upregulation of the inflammatory response. It is through this pathway that GCs exert the majority of their anti-inflammatory effects. In contrast, many of the adverse effects associated with chronic oral GC use likely come from *trans*-activation. Insight into the dichotomous effects of GCs has led many investigators to believe that the adverse effects of GCs could some day be separated from their anti-inflammatory effects.[134]

PHARMACODYNAMICS

Pharmacodynamics relates to the chemical and biochemical effects of a drug as they pertain to its mechanism of action. A drug's pharmacodynamics can be measured with regard to its onset of action, peak effect, duration of effects, and offset of action. For example, a number of factors alter the pharmacodynamics of GCs. Changes in the basic glucocorticoid structure, which result in differences in absorption, distribu-

tion, receptor affinity, and elimination, can affect the magnitude and duration of the drug's effects.[135] Thus, a drug's pharmacokinetics influences its pharmacodynamics, although this relationship is not always well understood. One might assume that changes in a drug's concentration or the dose administered would result in proportional changes in its clinical effect.

In a study investigating GC response as tyrosine aminotransferase activity in an animal model, a 10-fold increase in dose resulted in only a 50% increase in peak effect and a doubling of the duration of effect.[135] Further study using a similar model demonstrated that frequent smaller doses were more effective than larger single doses in prolonging the duration of effect.[136] Other studies have demonstrated a similar disproportion between changes in dosage and response. A study using lymphocytopenic effect as a measure of GC response showed a 33% increase in peak effect and a 20% increase in duration of effect after a sixfold increase in prednisolone dose.[137] In a model of methylprednisolone pharmacodynamics measured by whole blood histamine suppression, similar durations of effect were observed with a single 40 mg dose and a 20 mg dose followed by a 5 mg dose 8 hours later.[138] Therefore, it is not entirely surprising that low doses of GCs can achieve similar therapeutic effects compared with higher doses.[139,140] This may be one factor that explains the greater beneficial effect of inhaled GC therapy compared to oral therapy.

Although numerous cellular and biochemical effects of GCs have been demonstrated, it is still unclear as to which are important in the mechanism of action. Thus, there are no good markers of the effects of GCs at their site of action. Clinicians treating asthmatic patients are left with functional markers, such as bronchial hyper-responsiveness and pulmonary function, and changes in airway cellularity as measures of the effects of glucocorticoid therapy. Peripheral (blood, sputum) markers of lung inflammation that bypass the need for invasive procedures such as bronchoalveolar lavage and bronchial biopsy would be useful in determining the response to GC treatment.[141-143]

Exhaled nitric oxide is a noninvasive measure of allergic inflammation that has received increasing attention. It is a gas produced in large quantities by airway epithelial cells that have been damaged by eosinophilic inflammation. Studies have demonstrated exhaled nitric oxide to be a useful tool in establishing the diagnosis of asthma[144,145] and it can provide information regarding asthma severity and control.[146,147] More importantly, it can serve as a pharmacodynamic parameter because exhaled nitric oxide levels fall in asthmatic patients treated with inhaled and oral GCs.[148,149] In addition, elevated nitric oxide levels are predictive of response to GC therapy.[150] This technology is FDA-approved for treatment of asthma.[151]

CHRONOPHARMACOLOGY

For disease processes that exhibit biological rhythms, a relatively new discipline known as *chronopharmacology* has emerged. In this discipline, the timing of therapeutic modalities is used to optimize their effect on disease control. Asthma is an example of such a disease because many patients demonstrate nocturnal worsening of pulmonary function. Etiologies for this nocturnal worsening and therapies designed to prevent the deterioration of pulmonary function during the evening hours have been investigated.

In patients with nocturnal asthma exacerbations, the following occur:

1. The number of peripheral blood eosinophils is higher than in asthmatics without nocturnal symptoms.[152]
2. Eosinophil counts are higher during the night than during the day.[153]
3. A lower concentration of methacholine is required to elicit a 20% drop in the forced expiratory volume in 1 second at 4 AM compared with 4 PM.[154]
4. The leukocytes demonstrate a reduced β-adrenergic receptor density and responsiveness at 4 AM versus 4 PM.[155]
5. The total number of leukocytes, neutrophils, and eosinophils in bronchoalveolar lavage fluid is elevated at 4 AM versus at 4 PM, corresponding to the observed reduction in the 1-second forced expiratory volume.[156]

Thus, therapies designed to prevent these changes may be useful in treating nocturnal asthma. Early studies have demonstrated that the timing of GC doses is important in the overall daytime control of asthma.[157,158] Alternative modalities include single daily doses of theophylline given in the evening to protect against the nocturnal decline in pulmonary function[159] and doses of GCs given at the unconventional time of 3 PM, which provides greater protection from nighttime worsening than when given at 8 PM or the more conventional 8 AM dosing.[157,160,161]

AGE-RELATED CHANGES

A number of variables, which may change with growth and development, can affect the absorption, distribution, and elimination of drugs. The airways are developed by week 16 of gestation, and growth in terms of the multiplication of alveoli occurs during the first few years after birth.[162] The changes in pulmonary arteries, primarily a reduction in the thickness of the vessel walls, occur rapidly during the first 3 days of life.[162] Thus with the exception of growth (in terms of size), no major changes in lung development would affect drug disposition.

Absorption

Absorption of drug from the gastrointestinal tract is influenced by a number of factors, including gastric acidity, gastrointestinal motility, mucosal membrane permeability, bacterial flora, enzyme activity, biliary function, and diet.[163] These factors change with aging and, in turn, affect the rate and extent of drug absorption.[164] As acid secretory capacity matures during the first few days of life, gastric acidity changes from a pH of 8 to 6 during the neonatal period, nears adult values for the first month of life, and then increases until adult values are attained at age 3 to 7 years.[163,165] Therefore, drugs that are weak acids should be more slowly absorbed in children than in adults because of the decreased gastric acidity. Conversely, better gastric absorption of weak bases should be observed in pediatric patients. Data consistent with these theories include increased bioavailability of penicillin

and ampicillin in children compared with adults and delayed absorption and reduced bioavailability of phenobarbital, phenytoin, and acetaminophen.[165] Phenobarbital absorption has also been correlated to age.[166]

Although much is known regarding gastric acidity in neonates and young children, limited information is available regarding other factors that may affect drug absorption. Gastric emptying time is prolonged in the neonate and infant and approaches adult values at 6 to 8 months of age.[165] Similarly, intestinal transit time can be prolonged because peristalsis is irregular,[167] a potential problem for sustained-release products such as theophylline and oral albuterol. These factors can influence drug absorption, as can the episodes of diarrhea common in this age group. Biliary function, which develops during the first month of life,[168] and the development of intestinal bacterial flora may also influence the absorption of drugs.

Distribution

A drug's volume of distribution relates to its plasma concentration, which is affected by body composition. Thus, age-related changes in body composition can affect the distribution of drugs. Neonates have a higher proportion of body mass in the form of water compared with older children and adults. The proportion of total body water decreases from 75% to 85% in the neonatal period to 55% in adulthood.[165] The result of such differences is manifested as higher loading dose requirements for drugs that distribute to total body water in infants and young children. Unlike total body water, body fat increases with age.[163] This results in smaller volumes of distribution for lipophilic drugs in young children.

Protein binding, as discussed in a previous section, also influences the distribution of drugs. Neonatal serum concentrations of albumin, the major binding protein, is approximately 80% of adult values and increases to normal within the first year of life.[163] Because only free drug is considered active, a lower serum albumin concentration and a lower proportion of bound drug can result in greater pharmacologic and possibly toxic effects with drug concentrations that appear to be therapeutic. The binding affinity of albumin for some drugs, including theophylline, appears to be decreased in the neonate as well.[164]

Elimination

In general, neonates are thought to demonstrate a reduced enzyme capacity for metabolizing drugs, which increases with age.[163,165] Insufficiencies of elimination pathways are often compensated for by metabolism via alternative pathways, as seen in neonatal methylation of theophylline to caffeine.[169] The expression of the cytochrome P-450 isoenzymes changes dramatically over time. The expression of CYP3A7 peaks soon after birth, followed by a rapid decline so that levels are undetectable by adulthood. CYP2E1 and CYP2D6 become detectable soon after birth, whereas CYP3A4 and CYP2C appear during the first week of life. CYP1A2 is the last CYP to appear at 1 to 3 months of life.[163] The differences in renal drug clearance between children and adults may not result from intrinsic enzyme capacities or quantity but can be attributed to changes in body composition (i.e., proportion of liver tissue).

Like hepatic enzyme activity, renal function (renal blood flow, glomerular filtration, and tubular function), when normalized for body surface area, is reduced in infants and children compared with adults. After birth, increased cardiac output and reductions in intrarenal vascular resistance result in increased kidney perfusion and increased renal function. However, this increase in renal function during the first week of life is not observed in premature newborns. Glomerular filtration, which is developed to a greater degree than tubular function at birth, gradually increases to adult values by 3 years of age. Premature infants have lower filtration rates than do full-term infants, and their filtration capacity develops more slowly. Differences in renal drug clearance between children and adults are thought to correspond to maturation of renal function.[165] These points highlight the need for individualization of doses based on desired drug concentrations and therapeutic and toxic effects for drugs cleared primarily by the kidney.

SUMMARY

Understanding the pharmacokinetic and pharmacodynamic properties of medications for use in childhood is required for rational and optimal drug therapy. Not only are the pharmacokinetic and pharmacodynamic properties important in the treatment of childhood pulmonary diseases, but equally important are the numerous factors involved in delivering a medication directly to the airway. Great strides have been made in our ability to deliver potent anti-inflammatory agents such as inhaled GCs to the airways of asthmatic children. We have come close to approaching the "ideal" inhaled GC—that being a medication that displays potent anti-inflammatory effects; displays high retention time in the lung and as a result produces long-lasting therapeutic effects; has little to no oral bioavailability; and displays little to no potential for adverse effects. All of the inhaled GCs in use today display these properties to varying degrees and because of this, they display significant efficacy while minimizing the potential for systemic effects.

Despite the strides in our understanding and treatment of pulmonary diseases, issues remain. First, drug delivery in infants and toddlers continues to present a challenge as none of the current devices provide efficient delivery. In addition, none of the available inhaled glucocorticoids is entirely devoid of adverse effects, especially at higher doses. We have also learned that there is significant variability of response to medications. As a result, a great deal of time and energy has been placed on the development and implementation of pharmacogenetics. Throughout the enzymatic and signaling pathways are several polymorphisms including beta-adrenergic receptors, enzymes involved in the synthesis and degradation of leukotrienes, and the CYP-metabolizing enzymes. These polymorphisms have the potential to influence the response to drugs on both the pharmacokinetic and pharmacodynamic levels. It is hoped that by better understanding the pharmacokinetics, pharmacodynamics and pharmacogenetics of a medication, clinicians may tailor medications to maximize benefit while minimizing unwanted and potentially harmful effects.

Acknowledgments

The authors would like to thank Alan Kamada, PharmD, currently at GlaxoSmithKline, for his work on the chapter included in the first edition. His insight into organizing this complex literature and providing the base for this update is greatly appreciated. We would also like to thank Gretchen Hugen for work in preparing the manuscript.

CHAPTER 17

Aerosol Therapy and Delivery Systems

Sunalene G. Devadason, Mark L. Everard, and Peter N. Le Souëf

TEACHING POINTS

- Advances in delivery systems have rendered traditional nebulizers obsolete for use in asthma.
- Pressurized metered dose inhalers attached to a spacer (pMDI-spacer) are the delivery method of choice for children with asthma.
- pMDI-spacers must be rendered static-free to perform adequately. For plastic spacers, coating with detergent is the most efficient and cheapest method of achieving this.
- To treat a plastic spacer for static, the spacer should be immersed in water containing detergent and left to drip dry without rubbing or rinsing. Rinsing will remove the detergent and render the exercise useless.
- Dry powder inhalers are not recommended for use in young children and, in all patients, require a mouthwash and gargle when used with inhaled steroids.
- Current drug delivery systems in children do not require that a lower dose be prescribed for younger children because the dose that children receive from a given device is reasonably proportional to the size of the child.
- Care must be taken to avoid side effects of inhaled drugs and to use the lowest possible dose.
- Newer nebulizer systems are likely to become the delivery system of choice in the future.

Inhalational drug therapy is the primary mode of treatment for asthma as well as other respiratory diseases such as cystic fibrosis. The efficiency of aerosol therapy, both for adults and children, has improved greatly in recent times. Factors such as the development of pro-drugs with greater topical activity and fewer adverse systemic effects[1]; new formulations to maximize the delivery of drug particles within inhalable size ranges; improved delivery systems to optimize airway targeting, minimize lung deposition, and decrease drug wastage have resulted in marked increases in clinical efficacy. However, the requirement for affordable and disposable inhalers, particularly for the more widespread treatment of asthma, has limited the advances that could be made in this field.

Greater advancements have been made in the optimization of aerosol devices and drug formulations for the treatment of cystic fibrosis and for the delivery of aerosolized drugs for systemic therapy. The use of aerosols as a noninvasive vehicle to permit rapid absorption of drug into the systemic circulation for the treatment of nonrespiratory diseases such as diabetes is becoming increasingly important.[2] Because the drugs used to treat these conditions are more costly and tend to have narrower margins between therapeutic efficacy and deleterious side effects, highly efficient aerosol delivery systems are required to deliver strictly quantified doses to targeted lung regions.

PRINCIPLES OF AEROSOL DELIVERY

An aerosol is a biphasic system containing a gaseous phase and a particulate phase. In other words, it is a gaseous suspension: a gas containing solid and/or liquid particles.[3] The definition of a particle is a body with a defined solid or liquid boundary bordering its gaseous environment.[3] The advantage of using aerosol therapy for the treatment of respiratory disease is that the drug is delivered directly to the site of action, allowing more rapid therapeutic effects using a lower nominal dose.

The most important consideration with aerosolized drugs is to maximize drug deposition in the required areas of the respiratory tract. Deposition of aerosolized particles in the respiratory tract is governed by three main factors: inertial impaction, gravitational sedimentation, and diffusion. In addition, the electrostatic charge on both the aerosol and the respiratory mucosa may also affect drug deposition.[2,4-6]

The degree of influence of each of these factors on aerosol deposition in the lungs is dependent on the particle size of the aerosolized particles (Fig. 17-1). The optimal particle size for deposition in the smaller airways is less than 3 μm,[4,6] although particles larger than 5 μm are still considered "respirable" particles.[4] Particles larger than 5 μm generally deposit in the oropharynx or upper airways.[4]

Particle size measurement is complicated by the fact that some of the aerosolized droplets may be irregularly shaped rather than strictly spherical. For convenience, particles of different shapes that behave in a similar aerodynamic manner are grouped together and visualized as spherical droplets with a common diameter. This is termed the aerodynamic diameter, which is defined as the diameter of a sphere of unit density with the same terminal sedimentation velocity in air as the particle or droplet in question[2] and is usually determined by the mass of the droplet.

Monodisperse aerosols consist of particles with the same aerodynamic diameter. However, aerosols generated by most forms of aerosol therapy are generally polydisperse in nature in that the aerosol is made up of particles of widely variable aerodynamic diameters. Polydisperse aerosols are usually

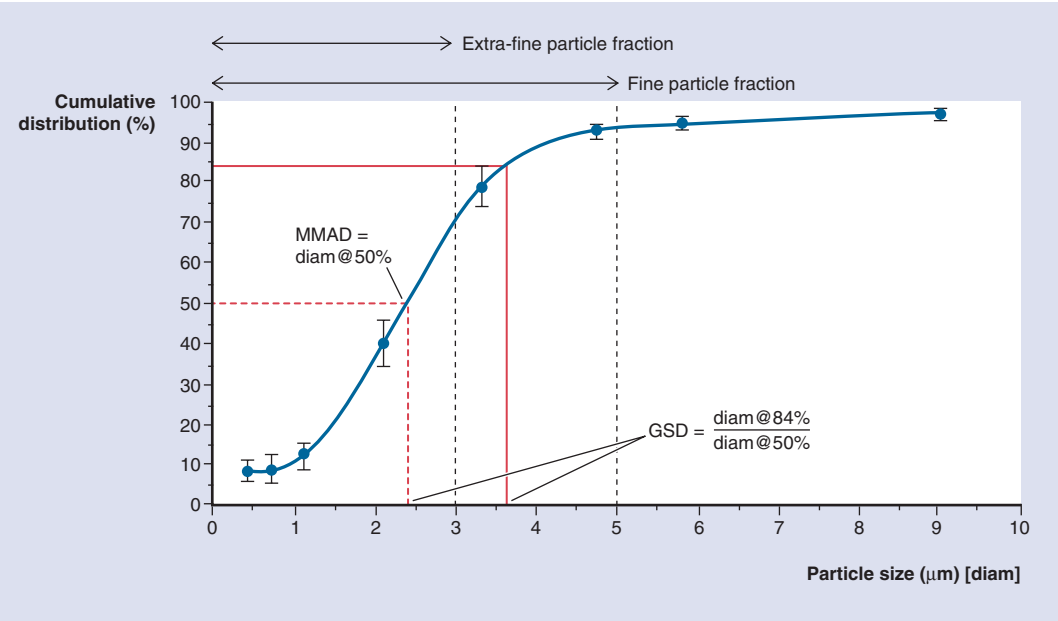

Figure 17-1 Aerosol particle size. GSD, geometric standard deviation; MMAD, mass median aerodynamic diameter.

characterized by their mass median aerodynamic diameter (MMAD) and geometric standard deviation (GSD).[4] That is, one half the mass of the aerosol will have an aerodynamic diameter below the MMAD, and one half of the mass will be in particles with diameters greater than the MMAD. Lung deposition for a highly polydisperse aerosol with an MMAD of 3 μm would be much lower than that for a monodisperse aerosol of the same diameter, and the reverse would occur if the MMAD was >5 μm.[7]

Minimizing the particle size of aerosolized drugs is essential because larger particles carry a much greater volume of drug than smaller particles owing to the cubic increase in volume with a unit increase in the diameter of the particles. Hence, aerosols that contain a large proportion of particles >15 μm in diameter will deliver most of the drug available for inhalation to the oropharynx—resulting in little therapeutic effect and increased systemic availability.

Physical Mechanisms of Deposition

INERTIAL IMPACTION

Inertial impaction has a greater effect on larger particles (>3 μm),[8] and in the oropharynx and upper airways where the velocity of the inhaled particles is highest. This is because particles carried by a gas or propellant possess momentum, which is determined by both the mass and the velocity of the particle.[5,6] When the particles approach a surface such as the back of the throat or a bifurcation of the airways, the direction of air flow will change. Inhaled particles may not follow the direction of air flow, and will instead accumulate on the surface. Particles with a higher momentum (i.e., larger particles or those with higher velocities) are more likely to accumulate in the oropharynx or the larger airways.

Particles >15 μm are unlikely to enter the trachea.[7] Even for particles <15 μm, further deposition of the larger particles will occur at airway bifurcations.[6] As the larger particles get filtered out and as the velocity of the particles decreases, impaction becomes less important as a mechanism of deposition in the smaller airways.[7]

SEDIMENTATION

Particles <3 μm will probably not deposit owing to inertial impaction. Sedimentation caused by gravity is the most important mechanism for deposition in the smaller airways. The effect of sedimentation is greatest on the larger particles (>0.5 μm)[6] that have escaped deposition owing to inertial impaction. Breath-holding after inhalation of the aerosolized particles helps deposition in the airways owing to sedimentation.[46]

DIFFUSION

Particles <0.5 μm will move by diffusion (impaction with gas molecules) toward the surface of the respiratory tract. Movement of particles by diffusion decreases with increasing particle diameter, and hence has a greater effect on small particles (<0.1 μm).[6] Deposition in the airways due to diffusion is helped by breath-holding after inhalation. Without breath holding, most small particles <0.1 μm are likely to be exhaled rather than deposited.

ELECTROSTATIC ATTRACTION

Deposition may occur because of attraction between charged particles in the inhaled aerosol and an induced charge on the mucosa of the respiratory tract.[5] The importance of this factor for aerosol therapy has not been investigated in detail but will presumably vary greatly depending on the drug formulation being administered.

In addition to the factors just discussed, irregularities in airway structure and inhalation flow patterns lead to nonuniform deposition of aerosolized drugs. "Hot spots" usually occur at airway bifurcations,[4,5] where large amounts of drug tend to deposit. The greater the degree of airway obstruction due to disease, the more central the deposition in the

airway—thereby reducing the therapeutic efficiency.[9] The depth of penetration of aerosolized particles in the airways also depends on physiologic factors such as tidal volume, respiratory rate, and breath-hold capability.[10]

Therapeutic Aerosol Devices

The relative merits of the devices used in children are summarized in Table 17-1. The pressurized metered dose inhaler with valved holding chamber or spacer (e.g., Aerochamber [ForestPharmacaticals, St. Louis, Mo], Volumatic [GlaxoSmithKline, London]) continues to be the delivery system of choice for use by children (Figs. 17-2 and 17-3), particularly in the younger age groups (infants and children younger than 6 to 7 years of age). Pressurized metered dose inhalers (pMDIs) are inexpensive, easy to use, and disposable; in particular pMDIs require no inspiratory effort on the patient's part in order for the metered dose to be dispensed.

When used without a spacer, pMDI actuation must be closely coordinated with the start of the patient's inhalation; a difficult feat for many older children, and impossible for young children to achieve. Valved holding chambers or spacers eliminate the need for coordination, but are less convenient and portable. However, spacers must be used with pMDIs when treating children younger than 6 to 7 years of age, and are highly recommended for all patients when using corticosteroids. Facemasks must be used for infants and toddlers (less than 3 years of age); however these encourage nasal inhalation which will filter out much of the aerosolized drug. Children more than 3 years of age can be taught to use a mouthpiece; this greatly increases the amount of drug delivered to the lungs.

Comparison of bronchodilator delivery with pMDI-spacer and nebulizer has shown increased efficiency of drug delivery via pMDI-spacer[11] and equivalent clinical outcomes in both adults and children,[12-14] even during severe exacerbations. The use of pMDI-spacers for delivery of bronchodilators in hospital emergency departments is becoming much more widespread.

Electrostatic charge greatly reduces drug delivery from plastic spacers,[15] but this problem can be reduced or eliminated by coating the inner surface of the spacer with detergent,[16] use of a metal spacer,[17] or by constructing spacers from patented plastic materials, which are more resistant to the build-up of electrostatic charge (Aerochamber Max, Trudell Medical, London, Ontario, Canada). Proper care must be exercised in using a detergent-coated plastic spacer. The spacer should be washed in water containing a diluted ionic detergent and then left to drip dry. The surfaces of the spacer should not be rubbed or touched and, most importantly, the spacer should NOT be rinsed because this will remove the detergent. A detergent-coated plastic spacer will have minimal static and detergent coating has been shown to

Figure 17-2 Spacers for use with pressurized metered dose inhalers.

Figure 17-3 Child inhaling from a pressurized metered dose inhaler and spacer.

Table 17-1
Relative Merits of Devices for Aerosol Delivery in Children

	Nebulizer	Pressurized Metered Dose Inhaler	Pressurized Metered Dose Inhaler-Spacer	Dry Powder Inhaler
Age Range	All	6 Years and over	All	6 Years and over
Expense	High	Low	Low	Low
Efficiency	Low	Moderate to good	Good to excellent	Good to excellent
Dependency on Technique	Low	High	Low	Low to moderate
Major Disadvantage	Inefficient, expensive, slow	Reliance on technique	Bulky, must be designed or treated to reduce static	High oropharyngeal deposition, gargle with steroids
Major Advantage	Delivery of drugs in cystic fibrosis	Portability, use for bronchodilators	Easy and efficient to use in children with asthma	Portability
Recommended for Use in Children with Asthma	No	Yes, but only for bronchodilators	Yes, device of choice	Yes, but limited age range

last for a month without static returning. Plastic spacers should not be stored in plastic bags or wrappings.

Breath-actuated pressurized inhalers, such as the Autohaler (3M, St. Paul, Minn), eliminate the need for patient coordination of actuation with inhalation, without the use of a holding chamber. Once the device has been primed, the patient's inhalation flow triggers actuation and release of the drug, which has been shown to improve drug delivery in adults with poor coordination.[18] Breath-actuated devices still require a 2 to 4 second inspiratory time, which may be difficult for some children (particularly those younger than 6 years of age) to achieve.[19]

Most older children and adolescents prefer dry powder inhalers (DPIs) because of their convenience and portability, and giving them a choice of inhalation device may be an important factor in improving adherence in this age group. However, the more common DPIs available for asthma therapy (e.g., Turbuhaler [AstraZeneca, London], Accuhaler/Diskus [GlaxoSmithKline]) require a forced inspiratory maneuver for the drug dose to be dispensed. Hence, the patient must be able to remember and consistently reproduce the optimal inhalation technique when using these devices. The higher the inspiratory flow, the greater the amount of respirable drug delivered, particularly when using the Turbuhaler. Because of the high resistance when inhaling through the Turbuhaler, greater inspiratory effort may be required from the patient to achieve an equivalent dose compared to the Accuhaler.[20] DPIs generally result in a higher oropharyngeal drug dose and patients should wash their mouths and gargle after inhaling corticosteroids. In addition, younger patients may not be able to consistently generate a sufficiently high inspiratory flow through DPIs—hence these devices are not recommended for children younger than the age of 6 to 7 years.

Much more efficient dry powder delivery systems have been developed (e.g., Pulmonary Inhaler, Nektar, San Carlos, Calif)—the patient's inspiratory effort is not required to dispense the metered dose because the drug is automatically dispensed into a holding chamber. These devices would not be cost effective when compared to current inhalers used for asthma therapy. A similar concept (namely, the use of a holding chamber) was tested for use with the Turbuhaler,[21] but did not achieve widespread use.

The use of jet nebulizers for asthma treatment has now ceased in many places in the world and is decreasing in most other places. Nebulizers still have a role in the treatment of cystic fibrosis. This has occurred as traditional nebulizers are less efficient in delivering drug to the lower airways, and are expensive, inconvenient and cumbersome as they generally require an external compressor and power supply. Ultrasonic nebulizers are not widely used, as they are not suitable for delivery of some drugs, particularly those in suspension formulations. Several new generation nebulizers or liquid aerosol delivery systems (e.g., Aeroneb [Nektar], eFlow [PARI Pharma, Munich], AERx [NovoNordisk, Hayward, Calif], I-neb [Respironics, Murrysville, Pa) have been developed that address most of these problems. These vibrating menbrane devices are battery powered and compact, and may even be breath actuated (i.e., releasing drug only during the optimal portion of the patient's inhalation). These devices are too costly to compete with pMDIs for the treatment of asthma, but may have a role in the treatment of cystic fibrosis for the delivery of DNase and antibiotics because the increased delivery efficiency of these expensive medications easily justifies the use of a more costly delivery system.

Drugs for Pediatric Use

ASTHMA THERAPY

When prescribed and administered correctly, inhaler therapy is able to control asthma symptoms in most patients by reversing airway obstruction and reducing airway inflammation.[22] The primary aerosolized medications currently used to treat asthma include short-acting beta$_2$ agonists, long-acting beta$_2$ agonists, and corticosteroids. These medications are generally delivered using either pressurized metered dose inhalers, or dry powder inhalers. Nebulizer use for asthma therapy has decreased significantly over the last decade and traditional nebulizers may now be obsolete for use in asthma.

Beta$_2$ Agonists

Short-acting beta$_2$ agonists such as salbutamol (albuterol) provide immediate relief of acute asthma symptoms by binding to the beta$_2$ receptors on the smooth muscles of the bronchioles, causing them to bronchodilate. Symptom relief lasts up to 3 to 4 hours.[23,24] Short-acting beta$_2$ agonists should be used only to relieve acute symptoms, and if required more than three times a week, anti-inflammatory therapy should be commenced. Long-acting beta$_2$ agonists such as salmeterol or eformoterol enhance bronchodilation for up to 12 hours after administration.[23] Eformoterol also has an immediate bronchodilatory effect, similar to salbutamol, whereas salmeterol has a more delayed onset of action and must be used with short-acting bronchodilators for acute relief of symptoms. Long-acting beta$_2$-agonists are often prescribed with corticosteroids in combination inhalers for treatment of severe, chronic, or refractory asthma.

Corticosteroids

Long-term therapy for chronic or severe asthma in children requires the use of prophylactic inhaled corticosteroids for suppression of airway inflammation. Corticosteroids are the most potent and effective form of anti-inflammatory treatment for severe asthma.[25] Long-term use of inhaled corticosteroids reduces airway inflammation and bronchial hyper-responsiveness, thereby decreasing asthma exacerbations and symptom severity.[26,28]

Fluticasone propionate (FP), currently one of the most widely used corticosteroids available, combines the advantage of high topical activity with low gastrointestinal bioavailability.[29] Adverse local effects[30] and systemic effects due to the systemic absorption of fluticasone via the airway mucosa have been reported[31-33] even within therapeutic dose ranges, particularly in children. Budesonide is still widely used, particularly via Turbuhaler, but it has lower gastrointestinal bioavailability than beclomethasone dipropionate (BDP) and is less topically active than FP.[29,34] However, budesonide is highly protein bound in plasma, reducing the effect of absorption through the airway mucosa into the systemic circulation.[34]

The development of newer synthetic steroids for inhalation may alleviate some of these concerns.[1] Ciclesonide is

one of the more promising candidates, having already been granted regulatory approval in many countries for use in adults and children older than 4 years of age for the treatment of asthma. Ciclesonide is inhaled as an inactive pro-drug and is activated intracellularly within the airways to a highly topically active form.[35] Because of a number of factors (low oral and gastrointestinal bioavailability of the inactive pro-drug and high protein binding of the active drug in plasma prior to hepatic inactivation), ciclesonide appears to have markedly reduced local and systemic effects,[36,37] even in children.[38]

Currently, inhaled corticosteroids are the most widely used drugs of concern in the pediatric age group. BDP has been reformulated as an extra-fine propellant-based aerosol (QVAR) that maximizes lung deposition in both adults[39] and children.[19] However, there is the potential for increased adverse side effects using this formulation because of high gastrointestinal bioavailability and increased absorption through the airway mucosa. The recommended prescribed dose of BDP is halved when switching to QVAR.[40]

Although administering corticosteroids via inhalation is associated with fewer adverse effects when compared to oral administration, local and systemic effects can still occur particularly when children are prescribed high daily doses over a prolonged period. Thus, to reduce unwanted side effects, the lowest effective dose required for effective symptom control should be used, and the delivery of drug to the lungs should be optimized. Local adverse effects in both adults and children can include dysphonia and oropharyngeal candidiasis due to deposition of drug particles in the mouth and throat. These effects can be minimized by rinsing the mouth and gargling after inhaler use. Other adverse side-effects include adrenal suppression and decreased bone density.[27,28,37]

Long-term use of inhaled corticosteroids in young children is of concern because of the potential impact on bone turnover and growth. These effects may include inhibition of new bone formation and bone reabsorption.[27] However, studies examining the effects of moderate corticosteroid use (<400 μg/day of FP) have found little effect on bone turnover[41] and final height.

CYSTIC FIBROSIS THERAPY

A number of different drugs for cystic fibrosis (CF) therapy (antibiotics, recombinant human DNase, mucolytics, hypertonic saline) are delivered via aerosol—generally using jet nebulization. Bronchodilators and corticosteroids are also sometimes prescribed for CF patients (via pressurized or dry powder inhaler). This section will focus primarily on inhaled antibiotics and DNase delivery.

Recombinant Human Deoxyribonuclease (rhDNase)

The presence of excessive levels of DNA has been found to contribute to the increased viscosity of the sputum of CF patients.[42] In addition, by binding to aminoglycoside antibiotics in sputum, DNA could reduce their efficacy.[43] The use of recombinant human deoxyribonuclease 1 (dornase alpha, rhDNase, Pulmozyme), delivered via jet nebulizer, has been shown to reduce the viscosity of CF sputum,[42] improve lung function, and reduce exacerbations in CF patients.[44] rhDNase can be aerosolized using a number of different jet nebulizer-compressor combinations; however, a small particle size, high-output system is recommended.[45]

Inhaled Antibiotics

Chronic bacterial infection of the lower airways is present in most CF patients from early life. Early prophylactic antibiotic treatment can reduce lung damage caused by these infections, and improve quality of life. The use of inhaled antibiotics such as tobramycin has been shown to improve clinical outcomes in patients chronically infected with *Pseudomonas aeruginosa*.[46,47] Other antibiotics, such as colomycin, are also widely used, although controlled trial evidence supporting the use of colomycin is not as convincing as for tobramycin.[48] A number of jet nebulizer-compressor systems may be used for aerosolization of antibiotics.

Ventilator Circuits

Traditionally, jet nebulizers were used to deliver medication to patients through ventilator circuits, but there are many problems with this form of therapy, since only a small proportion of the nebulized drug is actually delivered to the patient. The use of pMDIs with suitable adaptors allows more efficient delivery, particularly when used with small-volume chambers, which appear to be suitable for all patients from preterm baby to adult.[49-51] Medication delivery via endotracheal tubes is also possible using ultrasonic nebulizers.[51,52] Doses approaching 100% of the nominal dose can be delivered into the lower respiratory tract by actuating the medication through a catheter passed through the endotracheal tube.[53] However, not all drugs required for delivery to ventilator patients are available in pMDI formulations, requiring the continued use of nebulizers for this purpose.[54] More recently, vibrating membrane nebulizers have been investigated for use in ventilator circuits, and have been shown to markedly improve drug delivery.[55]

DOSE CONSIDERATIONS

Given that lung deposition studies for most inhalation devices in children from infancy up to about 10 years of age show that the amount reaching the lung is generally proportional to the size of the child, the same prescribed dose can be used in all children. Most drug dosage schedules recommend progressively lower doses with reducing age of the child, but these schedules appear to have been designed without reference to the available scientific data and with no proper evidence basis to this practice. Extreme care should be taken with prescribing high doses of inhaled drugs to all children, regardless of age, and every attempt should be made to ensure that side effects are avoided and that the lowest possible therapeutic dose is used.

CONCLUSIONS

In recent times, pMDI-spacers have become the most commonly used approach to aerosol therapy in children. They can be used for all ages and for both long-term, preventive therapy, and for short-term treatment of acute exacerbations. One of the main advantages of pMDI-spacer use is that normal tidal breathing can be used during aerosol administration, which makes them ideal for infants and younger children. However,

newer and more innovative devices are gradually becoming available and these may offer therapeutic advantages in terms of increased efficacy, convenience, and compliance—particularly for older children and adolescents. The ability of a child to utilize an inhaler device and to perform the required inhalation technique consistently must be evaluated when making the choice of an appropriate delivery system for children of different ages.

CHAPTER 18 Chest Physiotherapy

Maximilian S. Zach and Béatrice Oberwaldner

TEACHING POINTS

- Chest physiotherapy (CPT) for airway clearance is a spectrum of mechanical techniques for the noninvasive clearance of excessive secretions or aspirated material from the airways.
- Efficient intervention by CPT should be preceded by a detailed analysis of the patient's disease situation. Targeted CPT should be based on prevailing pathophysiology rather than on general diagnostic classifications.
- Therapist-administered techniques such as postural drainage, chest percussion, vibration, and compression, with assisted coughing or suction (conventional CPT) remain the only available CPT approach for infants and small children.
- Patients can be trained in self-administered CPT techniques from an age of 5 to 6 years and older.
- CPT has a traditional position in the treatment of cystic fibrosis and other chronic suppurative lung disorders.
- In addition to airway clearance, chest physiotherapists may offer assistance in a spectrum of other diagnostic and therapeutic procedures and programs such as breathing exercises, muscle training, rehabilitation and exercise programs, aerosol therapy, lung function testing, oxygen therapy, tracheostomy care, and long-term home mechanical ventilation.

The term *chest physiotherapy* (CPT) stands for a spectrum of physical and mechanical interventions aimed at interacting therapeutically with acute and chronic respiratory disorders. Experience shows that CPT in children differs in many aspects from that in adults.[1] Consequently, pediatric CPT is a specialized branch of the entire CPT spectrum that is tailored to the specific needs of newborns, infants, and children. In practice, a major part of pediatric CPT is dedicated to airway clearance, but many chest physiotherapists have also acquired competence in a variety of other caregiving strategies.

CPT FOR AIRWAY CLEARANCE

CPT for airway clearance is a spectrum of mechanical techniques for the noninvasive clearance of excessive secretions or aspirated material from the airways. Because it physically addresses the respiratory tract, CPT can be seen as a therapeutic application of respiratory physiology.

CPT is used to prevent or treat the mechanical, infectious, and biochemical sequelae of accumulated intrabronchial material.[2] Such obstructive material (in most cases, secretions) increases the resistance to airflow and the work of breathing and can cause hyperinflation and atelectasis, maldistribution of ventilation, and ventilation-perfusion mismatch. Accumulation of secretions and the resulting complications facilitate infection. Microorganisms and host-mediated inflammatory responses release proteolytic enzymes that damage the airway epithelium and wall, further impairing mucociliary and cough clearance.[3] Thus intrabronchial accumulation of secretions may initiate a vicious circle of infection, impaired clearance, and progressive airway damage. In such conditions, CPT may not only have antiobstructive effects but also prevent or delay tissue damage. A theoretical third therapeutic benefit from CPT should be improved access to the bronchial mucosal surface; after effective removal of secretions, a larger portion of inhaled medications should penetrate to the airway epithelium.

The most important features of each CPT technique are its effectiveness and safety. Techniques for long-term treatment should be easy to teach to patients and caregivers; they should not fatigue the patient but rather should be time efficient and comfortable.[4] Practical applicability and cost effectiveness demand that techniques be based on patient participation rather than on expensive equipment. One possible exception to this rule could be the very ill and exhausted patient; in this case, each technique that offers some benefit is acceptable, even if it involves expensive machinery, regular expert assistance, or both.

CPT Techniques

CONVENTIONAL CPT

The term *conventional CPT* is used for a spectrum of traditional techniques that were described in the early 1960s and, at least in part, stem from practices developed as early as 1934.[5] Basically, conventional CPT is a therapeutic regimen intended to be applied by a physiotherapist or trained caregiver. However, some techniques can be self-administered by the patient.

Techniques

The techniques can be differentiated into those for mobilizing secretions and those for transporting secretions. They are combined for tailoring individually targeted treatment sessions.

Postural Drainage

Postural drainage is based on the concept of gravity-assisted mobilization and transport of secretions. The patient is positioned to drain each segment of the lungs or a group of segments. These traditional positions, established by practical experience and guided by the anatomy of the bronchial tree, have been summarized and illustrated in relevant textbooks.[5,6] For older children and adults, positioning for postural drainage is assisted by using frames, tilt tables, or pillows; postural drainage for an infant is administered by positioning the child over the knees of the therapist. In the actively cooperating patient, postural drainage can be complemented by thoracic expansion exercises and by breathing control. In infants and toddlers, chest percussion, vibration, and compression can be applied during postural drainage.

Thoracic Expansion Exercises

Intended to aid in the mobilization of secretions, thoracic expansion exercises are deep inspirations with a 3-second hold at total lung capacity followed by a relaxed expiration. To expand particular areas of the patient's rib cage, the physiotherapist using proprioceptive stimuli teaches locally emphasized inspirations. Consequently, one can distinguish unilateral lower, bilateral lower, posterior lower, and apical thoracic expansion. Experienced therapists can effect thoracic expansion in preterm and newborn infants by positioning with manual inspiratory assistance. Laughing and crying are effective for thoracic expansion in infants and children.

Manual Hyperinflation

In mechanically ventilated lungs, an increase in volume is achieved by manual hyperinflation. The size of the bag, flow rate of gas, level and control of inspiratory pressure, and use of positive end-expiratory pressure are all important technical details that determine the efficacy and safety of this technique.[1]

Breathing Control

Breathing control is needed to help the patient recover between other, more energy-consuming CPT maneuvers and reduce breathlessness; it is tidal breathing with the patient using the lower chest while relaxing the upper chest and shoulders. The terms *diaphragmatic breathing* and *abdominal breathing* are often used for describing this technique.

Chest Percussion

Intended to mobilize secretions, clapping is manual percussion with cupped hands. In infants, the therapist's cupped hand is replaced by the fingertips or a small, cushioned face mask. Although chest percussion is essentially a physiotherapist-administered technique, patients can be taught to do self-clapping. In addition, mechanical percussors have been developed to allow for percussion administered by the patient or by a caregiver who is less experienced or is physically handicapped.

Chest Vibration

Chest vibration also aims to mobilize secretions. With the hands on the patient's thorax, the therapist produces vibrations of the chest wall during expiration. This technique can be combined with chest compression.

Chest Compression

As a support for the patient's own expiration, chest compression is intended to mobilize and transport secretions. In older patients, the chest is compressed by the therapist's arms that are wrapped around it or by manual pressure on the sternum, the lateral lower parts of the rib cage, or both. In infants, the chest is compressed by one or both hands; after the expiratory squeeze, the subsequent inspiration can be supported by thoracic expansion.

Assisted Coughing

Usually, a patient coughs spontaneously as soon as secretions have been mobilized. An attending physiotherapist can manually support the patient's chest during coughing. Frequently, the pressure waves produced by chest percussion, vibration, or both techniques, also activate the cough reflex. Experienced therapists can induce coughing by applying gentle digital pressure to the trachea in the suprasternal notch. Coughing should continue until airways have been cleared from all mobilized sputum. Care must be taken to avoid mobilization without complete expectoration because this leads to erroneous shifting of secretions from one part of the lower respiratory tract to the other.

Suction

In patients with artificial airways, the transport of secretions is mechanically hampered by the endotracheal tube or the tracheostomy cannula. In addition, the underlying disease, concomitant medication, or both can reduce the activity of the cough reflex. In these cases, suction must substitute for coughing. The catheter is introduced into the artificial airway and advanced no more than 1 cm beyond without suction. Then suction is applied while the catheter is slowly rotated and withdrawn. Correct performance of the suction procedure is essential for minimizing negative side effects. Details to be considered are preoxygenation, instillation of saline before the suction procedure, diameter of the suction catheter in relation to the size of the trachea, length and gradation of the catheter, position and number of the side holes, magnitude of the negative pressure applied, duration of the suction procedure, and manual or mechanical hyperinflation after suctioning.[1,7] Suction procedure policies regarding most of these technical details differ among centers.[8] In some patients whose lungs have not been intubated and who cough ineffectively or not at all, the larynx and upper trachea can be cleared by deep pharyngeal suctioning.

Physiologic Background

The efficacy of postural drainage for clearing the lower respiratory tract and improving lung functions has been documented in several studies.[9-15] However, it has remained unclear whether this improved drainage results from gravity or depends on a posture-effected redistribution of ventilation.[16,17] Such posture-induced redistribution of ventilation is age dependent and differs between children and adults.[18] With few exceptions,[19] the therapeutic value of postural drainage has been established by studies of adults; thus it remains unclear whether and to what extent these findings are also valid for children. It was shown that in some infants postural drainage with a head-down tilt may cause gastroesophageal reflux.[20] Whether these findings are

of clinical relevance or not has remained subject to discussion.[1,21]

The rationale for using thoracic expansion exercises is based on the concept that high lung volumes enhance air entry behind partially obstructing mucous plugs. With a deep inspiration, airways are distended enough for inspired air to pass on toward the periphery; furthermore, airflow through collateral channels is enhanced.[17] Breathing control is a strategy for economizing the energy cost of breathing (i.e., for achieving the necessary gas exchange with minimal effort).[5]

The scientific and physiologic bases of chest percussion have remained undefined. Some researchers have shown a deterioration of lung function and arterial oxygen tension with clapping,[22,23] but others, by incorporating clapping into more complex CPT regimens, did not observe such negative effects.[24,25] Pressure waves produced by clapping, vibrations, and compression may induce bronchospasm in patients with hyperreactive airways.[12,26] Although the relevant literature has thus far focused on whether chest percussion has negative side effects, it has remained unclear whether and how percussion achieves a therapeutic effect. Conclusive studies to document the efficacy of clapping per se are lacking. Whether clapping produces transthoracic pressure waves that shake secretions from the airway walls or mobilizes secretions by stimulating the cough reflex remains to be shown. Experienced pediatric chest physiotherapists claim that chest percussion has its maximal efficacy in infants and loses its therapeutic value progressively with increasing age. This observation complies with a concept of transthoracic pressure waves that decrease in efficacy with increasing size and stiffness of the chest. There is no evidence that CPT performed with mechanical percussors is more effective than manual clapping.[27-29] Consequently, patients and parents may choose between these two percussion techniques based on their personal perception of comfort, benefit, convenience, and practicability.[29]

Isolated mechanical chest vibration as a technique for mobilizing excess bronchial secretions was investigated in a radioaerosol study, but results remained inconclusive.[30] Another investigation of patients with atelectasis documented a vibration-effected increase in the partial pressure of arterial oxygen.[31] It appears that many of the existing questions related to chest percussion may also apply to chest vibration.

Chest compression also lacks a specific scientific background; as a technique for supporting the patient's expiration, however, it finds some physiologic basis in the mechanisms of a forced expiratory maneuver.

The efficacy of coughing for transporting secretions is also based on the mechanisms of forced expiration; these mechanisms are discussed in more detail in the next section. In some patients, coughing may be as effective as more complex CPT techniques for clearing secretions from airways.[32-34] Such findings, however, might not apply to patients with instability of the airway wall (i.e., bronchiectatic airway wall damage).[35] In such a situation, the high positive transthoracic pressures, which are developed during a cough, can result in complete airway collapse, thereby effectively interrupting the expiratory airstream through the bronchus.[36] Because this occurs frequently, the forced expiration technique (FET) and other related CPT methods might be more effective than coughing; this speculation is based on the finding that the transpulmonary pressures developed with coughing exceed those occurring in a forced expiratory maneuver.[37]

Suction interrupts mechanical ventilation and thereby affects gas exchange, can facilitate bacterial contamination of the lower respiratory tract, and can cause atelectasis and other complications.[38] Deep suctioning damages the airway by effecting suction biopsy of the mucosa.[39] If it occurs repeatedly, such suction trauma can result in airway obstruction by granulation tissue and scarring, a complication most frequently found at the entry into the segmental bronchi of the right lower lobe. Consequently, suction depth is a critical detail of the procedure. In addition, suctioning should be performed only when necessary; any suction routine with fixed time intervals should be avoided. Manual or mechanical hyperinflation after suctioning is recommended to prevent suction-induced atelectasis; bagging increases the compliance of the respiratory system.[40]

Practical Aspects

For clinical application, these techniques can be combined into different individually tailored CPT sessions. Therapist-administered techniques such as postural drainage, chest percussion, vibration, and compression, with assisted coughing or suction, are routinely applied in infants and small children and remain the only available CPT approach in this age group. Older patients can cooperate with breathing control and thoracic expansion exercises, or they can be trained in one of the self-administered techniques discussed later. Parents of children with chronic conditions are trained by an experienced therapist to competently administer conventional CPT at home.

Properly performed conventional CPT is neither painful nor unpleasant for children; thus after a short adaptation period, it is usually well tolerated. To familiarize the small patient with this therapeutic routine, it seems important to reach adherence to regular therapy at an early age.[41] A treatment session can be time consuming, especially with generalized lung disease.

FET AND ACTIVE CYCLE OF BREATHING TECHNIQUES

The FET was first described in England in the late 1970s.[42,43] As a self-administered technique for clearing the airways, it was first and most extensively studied in patients with cystic fibrosis (CF), but it can also be applied to other chronic disorders with abundant intrabronchial secretions.

Technique

In the FET, the forced expiratory maneuver used for mobilizing and transporting secretions has the form of a "huff." For producing a huff, the patient, using chest wall and abdominal muscles, exhales forcefully, but not violently, through the open mouth. Care must be taken to keep the glottis open. For loosening secretions in the periphery, a huff should cover the range from middle to low lung volume; subsequently, lung volume of huffing can be adjusted to the momentary location of the transported secretions. As soon as secretions reach the upper airways, they can be raised by a huff from high lung volume. The expiratory flow rate used varies individually with the airflow obstruction and compressibility of airways;

huffs must be long enough to effectively move secretions. The FET is performed while the patient is in gravity-assisted positions or sitting.

The active cycle of breathing techniques adheres to the following sequential protocol[44]: breathing control, thoracic expansion exercises, breathing control, thoracic expansion exercises, breathing control, FET (one or two huffs), and breathing control. This sequence can be repeated until all secretions are removed; individual modifications can adapt the protocol to each disease situation.

Physiologic Background

Like coughing, the FET uses expiratory airflow for mobilizing and transporting secretions, thus applying the physiology of a forced expiration.[45,46] The technique attempts to mobilize secretions from the periphery by having the patient huff in a low lung volume. The efficacy of the technique depends on the upstream movement of the equal pressure points in the airways. With an ongoing forced expiration, the dynamic compression of airways creates a wave of choke points that run upstream toward the periphery. A mucous plug, once reached and caught by such a choke point, is propelled downstream by the airflow (Fig. 18-1). In addition, the airflow velocity increases locally with this dynamic compression of the airway; accumulated intrabronchial secretions are mobilized by markedly increased shearing forces and intensified gas-liquid interactions. Radioaerosol studies indicate that coughing and the FET lose effectiveness progressively from the central airways to the periphery of the lung.[34]

The FET is a well-investigated technique. It produces more sputum than conventional CPT in a shorter period of time.[42] Two studies comparing the efficacy of the FET and positive expiratory pressure (PEP) mask therapy have arrived at somewhat contradictory results.[14,47] Airway clearance by the FET can result in a statistically significant improvement of lung function.[15] A fall in oxygen saturation, occasionally observed with conventional CPT, can be prevented with the use of the entire active cycle of breathing techniques.[48]

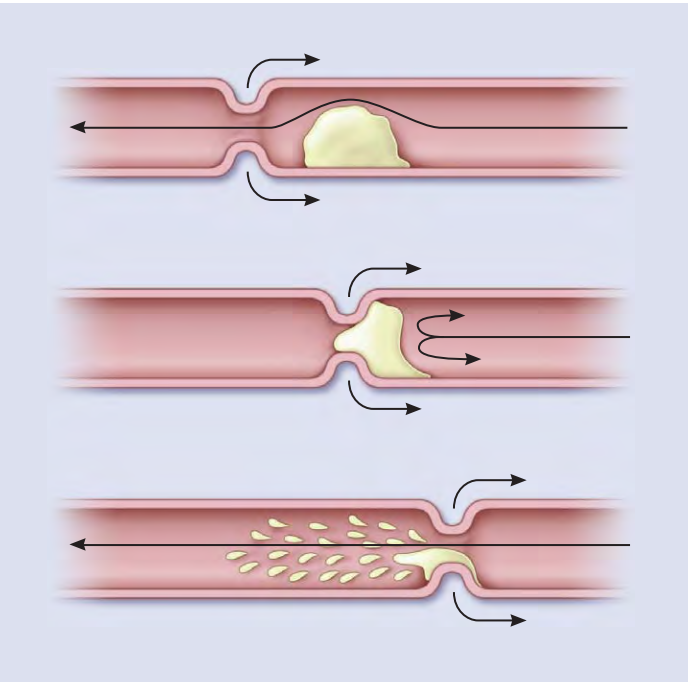

Figure 18-1 Mobilization of mucus by a forced expiration. *Top*, The choke point moves upstream and approaches the mucous plug. *Middle*, The mucous plug is caught in the choke point. *Bottom*, The expiratory airstream ejects the mucus through the choke point.

Practical Aspects

The FET is an effective, self-administered CPT technique that remains independent of any mechanical adjunct. Children as young as 3 to 4 years of age can be taught to huff; blowing games can assist training in this age group.

AUTOGENIC DRAINAGE

Autogenic drainage (AD) is a self-administered CPT technique developed in Belgium and first described in the early 1980s.[49] The accumulated clinical experience with this technique stems mainly from its application in the treatment of CF.

Technique

AD is a special breathing technique that commences at low lung volumes (i.e., in the expiratory reserve volume) and then, with mobilization of secretions, is first elevated to the level of tidal breathing. With the accumulation of secretions in more central airways, the AD breathing level is further elevated into the inspiratory reserve volume, and finally, secretions are raised by a huff. The single inspiration and expiration of AD breathing exceeds the tidal volume dimension. Each inspiration is followed by a short pause; each expiration, performed with an open mouth and glottis, is mildly forced but simultaneously tries to avoid compression-induced interruption of airflow. Massively forced expiratory maneuvers and coughing are avoided. AD is usually performed with the patient in a sitting position.

Physiologic Background

AD can be seen as a modification of the FET, so comparable physiologic principles apply. The technique aims to individually determine an "ideal" expiratory flow rate that is high enough for mobilizing and transporting secretions but still low enough for avoiding positive transthoracic pressures of such magnitude that destabilized bronchi are occluded. Clearly, such a compromise is determined by the most collapsible airway segments in the system. By commencing at low volumes and by approaching high lung volumes in a stepwise manner, the technique tries to follow the movement of mobilized secretions.

There is a discrepancy between the widespread clinical application of this technique in Europe and the paucity of controlled investigations of its value. One prospective study in CF patients indicates that the technique is clearly more effective than spontaneous coughing.[50] Another investigation found AD to be as effective as the active cycle of breathing techniques at clearing mucus in patients with CF.[51] Other relevant articles are descriptive.[52] So far, the relative value of AD compared to most other self-administered techniques remains to be defined.

Practical Aspects

Because the patient must develop significant proprioceptive abilities for feeling the movement of secretions and the occlu-

sion of bronchi, it takes considerable time to properly learn this technique. Furthermore, a daily AD routine also tends to require more time than CPT by some other techniques. On the other hand, AD is less energy consuming and is less prone to induce bronchospasm than more aggressive forms of CPT.[50]

PEP MASK THERAPY

PEP mask therapy uses the same concept as pursed-lips breathing; as a CPT technique, it was developed in Denmark in the late 1970s[47] and has found widespread acceptance. Basically, it is a self-administered CPT technique for the treatment of CF, but it may also be of some value in other conditions that produce abundant endobronchial secretions.

Technique

The PEP mask is a cushioned anesthesiology mask connected to a one-way breathing valve. An endotracheal tube adaptor for neonates is plugged into the outlet of the valve and serves as an expiratory resistor. A set of such resistors with different internal diameters allows for individual variation of the stenosis. Other types of resistors are also offered by some manufacturers.

Therapy is performed with the patient seated with the elbows resting on a table and the mask pressed tightly but comfortably over the mouth and nose. Using diaphragmatic breathing, the patient inspires a volume larger than the tidal volume and then exhales actively, but not forcefully, to functional residual capacity. The resistor is chosen individually for achieving a PEP from 10 to 20 cm H_2O and an inspiratory-to-expiratory ratio of 1:3 to 1:4. A manometer connected to the outlet part of the valve allows monitoring of expiratory pressures and serves as a visual feedback to the patient. From 10 to 20 such breathing cycles are performed with the mask in place; then the mask is removed, and secretions are raised by a huff. Ideally, this sequence of PEP breaths, followed by huffing, is repeated until the airways are cleared from all mobilized secretions. In an attempt to facilitate aerosol distribution to the peripheral airways, PEP breathing can be combined with aerosol inhalation.[53] In such a case, a mouthpiece can substitute for the mask.

Physiologic Background

It is believed that exhaling against resistance can create enough backpressure to maintain the patency of unstable airways. This theory is supported by work that demonstrated a marked attenuation of dynamic airway compression by PEP.[54] Thus, PEP mask therapy can be used to treat patients with obstructive lung disease complicated by instability of the airway wall (i.e., bronchiectasis). PEP mask therapy is thought to increase collateral airflow to areas where the airways are obstructed by secretions, thereby facilitating subsequent expiratory mobilization of mucus.

PEP mask therapy is a well-studied technique. In some comparative investigations, it was found to be superior to other CPT techniques in terms of sputum production and other clinical measures.[47,55,56] A radioaerosol study showed PEP mask therapy in combination with FET to be more effective in terms of mucus clearance than FET alone.[57] Other authors either failed to find significant differences when comparing PEP mask therapy with other forms of CPT or found PEP mask therapy to be somewhat less effective.[14,58-62] PEP mask therapy has been reported to cause various changes of lung functions, such as an increased partial pressure of oxygen and tidal volume and a decreased residual volume and work of breathing.[47,55,63,64] From the sum of these published data, one can conclude that PEP mask therapy is effective for clearing airways of excess secretions in chronic lung disorders, especially CF. However, its relative value, when compared to other CPT techniques, needs to be more clearly defined.

Practical Aspects

PEP mask therapy is an attractive technique for patients with chronic lung disease who depend on a self-administered method that is not time consuming. PEP mask therapy sessions typically take only half of the time required for a conventional CPT session but raise equivalent quantities of sputum.[65] In addition, the patient does not depend on cumbersome equipment for effective self-treatment. PEP mask therapy can be taught to children beginning at approximately 4 years of age.

HIGH-PRESSURE PEP MASK THERAPY

High-pressure PEP mask therapy, developed in Austria in the early 1980s, incorporates forced expiratory maneuvers into the PEP mask technique.[66] It can be used by patients with CF and other chronic respiratory conditions that produce excessive bronchial secretions.

Technique

The instrument used for this technique is the same as that described in the previous section, but it is equipped with another manometer for monitoring higher pressures. Therapy is performed with the patient seated with the elbows resting on a table and the shoulders moved close to the neck to cover and support the lung apexes. PEP breathing for 8 to 10 cycles is done as described in the previous section; then the patient inhales to total lung capacity and subsequently performs a forced expiratory maneuver against the stenosis. Effected mobilization of secretions usually results in coughing at low lung volume. After expectorating sputum, the patient repeats the same sequence of breathing maneuvers until no more sputum is produced. Care must be taken not to terminate these forceful expirations before residual volume is reached; the sustained expiratory pressures achieved usually range between 40 and 100 cm H_2O.

The dimension of the expiratory resistor is determined individually by a spirometer-assisted method.[66] For this purpose, the outlet of the PEP mask is connected to a spirometer, and the patient performs forced expiratory vital capacity maneuvers through a series of resistors with different internal diameters (Fig. 18-2).

Physiologic Background

The effects of high-pressure PEP mask therapy are speculatively explained by increased collateral airflow to underventilated lung regions; air expired from there mobilizes obstructing secretions. In addition, a forced expiration against a marked resistive load tends to squeeze pendelluft from hyperinflated into obstructed and atelectatic lung units. Mobilization of mucous plugs might be supported by backpressure-effected dilation of airways. The same backpressure

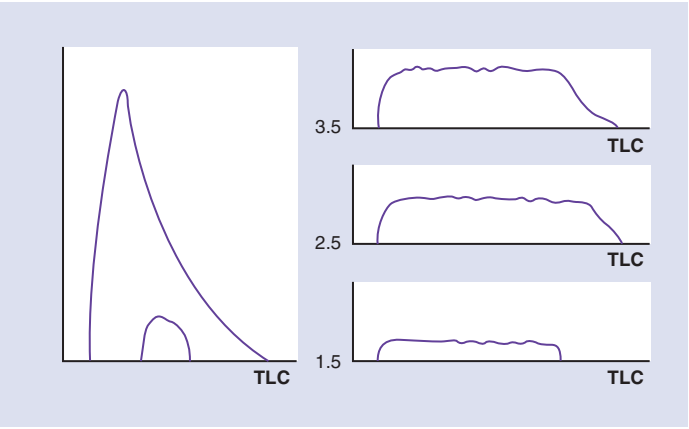

Figure 18-2 Finding the optimal expiratory resistor for high-pressure PEP mask therapy. Patient with CF, age 15 years. *Left,* Maximum expiratory flow-volume curve of the patient. *Right, top,* With a 3.5-mm internal diameter resistor, there is a stenosis-effected plateau formation, but the terminal portion of the tracing is still curvilinear (inhomogeneous emptying of different lung units). *Right, middle,* With a 2.5-mm internal diameter resistor, there is a plateau at a lower flow rate, and the terminal portion of tracing has straightened. *Right, bottom,* With a 1.5-mm internal diameter resistor, the patient terminates expiration before the residual volume is reached. The 2.5-mm resistor is chosen for further treatment. TLC, total lung capacity.

will prevent collapse and occlusion of those airways with instable walls owing to bronchiectatic destruction. As in the FET, upstream movement of the equal pressure points with the ongoing forced expiration and a progressive incorporation of the peripheral airways into the compressed downstream segment appear to be prerequisites for efficacy. Consequently, incomplete maneuvers, either caused by the choice of an inappropriate resistor or by an incorrectly performed technique, result in impaired clearance.[66]

High-pressure PEP mask therapy is a relatively well investigated technique, but studies published so far have been limited to CF patients. In a long-term investigation, the technique decreased airway obstruction and hyperinflation.[66] In hospitalized patients, high-pressure PEP mask therapy resulted in a stepwise improvement of lung function, and these changes correlated to the weight of produced sputum.[67] When compared to AD, the technique produced more sputum in a shorter period of time.[50]

Practical Aspects

To avoid prolonged use of suboptimal resistors, patients using this technique need regular reevaluation by specialized therapists who are supported by a well-equipped center. Backpressure-induced airway distention imposes some stress on airway walls; consequently, high-pressure PEP mask therapy occasionally induces bronchospasm in patients with airway hyperreactivity.[50,68] Such patients should use another CPT technique or adopt a routine of bronchodilator premedication. As evident from substantial clinical experience, the technique carries no increased risk of pneumothorax.[68] Because it takes considerable expiratory muscle strength and endurance to repeatedly exhale forcefully against a marked resistive load, high-pressure PEP mask therapy is an energy-consuming technique that does not meet the needs of an exhausted patient.

From the viewpoint of the patient, the technique is attractive because it involves highly effective but brief treatment sessions. The technique can be used properly and safely by most patients older than 5 years.

ORAL HIGH-FREQUENCY OSCILLATION THERAPY

In oral high frequency oscillation and intrapulmonary percussive ventilation, an eccentric cam piston or the diaphragm of a loudspeaker produce pressure waves that are superimposed on normal tidal breathing. Oscillation of airway walls is thought to mobilize secretions. In contrast to high-frequency oscillations of the chest wall, however, oral high-frequency oscillation therapy does not enhance tracheal mucus clearance in relevant animal studies.[69] In one study of healthy subjects, oral high-frequency oscillation increased mucociliary clearance.[70] In patients with CF, this technique was as effective as conventional CPT in enhancing sputum expectoration.[71,72] Another study has shown this technique to be no more effective than other CPT methods.[73] It follows that the relative efficacy of this technique remains to be defined. No guidelines have yet been established on how to fine-tune the technique to the patient or the disease state.

HIGH-FREQUENCY CHEST COMPRESSION THERAPY

High-frequency chest compression therapy has been developed, introduced, and investigated in the United States.[74] It is applied by a device that consists of a vinyl-coated polyester inflatable vest, which covers the entire torso of the patient, and a variable air-pulse delivery system. This apparatus applies high-frequency compressions to the patient's chest to mobilize secretions. The "best" compression frequencies for an individual are thought to be those associated with the highest expiratory flow rates and the largest expired volumes. These frequencies are determined by measuring the airflow and volume at the mouth during tidal breathing while the patient receives high-frequency chest compression therapy at frequencies between 5 and 22 Hz.

One long-term study found this technique to be superior to conventional CPT in terms of the lung function of CF patients.[74] Other investigators found both techniques equally effective in improving lung functions and sputum expectoration in hospitalized patients with CF.[72,75] In patients whose lungs were mechanically ventilated, this technique was as effective and safe as conventional CPT.[76] The relative value of high frequency chest compression, when compared to other self-administered CPT techniques, remains to be evaluated. One practical drawback is that this technique depends on expensive and cumbersome equipment.

OSCILLATING PEP

Oscillating PEP or "flutter therapy" tries to combine PEP breathing and oral high-frequency oscillation. Self-administered flutter treatment is performed by breathing through a pipelike instrument; in the pipe's outlet, a steel ball oscillates in the expiratory airstream and thus serves as a variable resistive load. Results of a comparative study indicated that the active cycle of breathing techniques raises more sputum than flutter therapy in patients with CF.[77,78] Another study in CF patients found the flutter technique to be more effective than conventional CPT in raising sputum.[79] There might be an optimal oscillation frequency for each

individual, and patients might benefit from fine-tuning the technique to their disease situations; so far, however, there are no objective guidelines for determining an individual optimal frequency.

PHYSICAL EXERCISE

Strenuous physical exercise and sports can facilitate expectoration of sputum in patients with CF.[80] Several mechanisms may contribute to this effect: Exercise-induced hyperventilation accelerates mucociliary clearance[81,82] and increases gas-liquid pumping in airways filled with secretions; subtle, submersion-induced chest compression occurs with swimming, and other sports occasionally cause chest shaking and vibration.

In some children with CF, regular physical exercise may effectively substitute for CPT.[83] In adults with CF, however, CPT produces more sputum than does exercise.[84] From these seemingly discrepant study results, one can conclude that sports may probably substitute for CPT in some patients with mild to moderate lung disease. However, these patients still need to be trained in a CPT technique to clear their airways when they are unable to exercise. For more severely diseased patients, CPT and physical exercise should be considered complementary rather than competing treatment strategies.

Indications and Contraindications

GENERAL ASPECTS

Indications

In general, CPT for airway clearance should be considered in all disease situations that have expected or already established complications from accumulated intrabronchial secretions or aspirated material. CPT is then prescribed to substitute for the patient's failing mucociliary and cough clearances. Efficient intervention by CPT should be preceded by a clear analysis of the prevailing mechanisms of the patient's disease. Because several pathophysiologic variations can occur within the frame of one diagnostic entity, it seems prudent to base the use of pediatric CPT on an analysis of disease mechanisms rather than on general diagnostic classifications.

CPT is targeted to the intrathoracic airways and thus can interact only with bronchial pathology. It is effective mainly for the clearance of the central airways and loses its efficacy progressively toward the periphery. With the possible exception of some breathing exercises and positioning, CPT has no place in the treatment of alveolar, interstitial, vascular, and pleural disease.

CPT is also indicated on diagnostic grounds when secretions from the lower respiratory tract are a more relevant substrate for bacteriologic investigation than a throat swab. Effective clearance of airways by CPT is a prerequisite for the application of therapeutic aerosols that address the bronchial mucosa.

Contraindications

The decision against applying CPT, like the decision for applying CPT, should be based on a detailed understanding of the disease. When contemplating contraindications, the clinician should remember that CPT involves a variety of mechanical interventions with different and specific risks and benefits. For example, some disease situations might preclude the use of chest percussion, vibration, and compression but not thoracic expansion exercises.

Some components of CPT are contraindicated when they threaten to cause significant hemorrhage (in bleeding disorders, some cases of vascular or cardiac surgery, massive intrabronchial bleeding) or cardiac dysrhythmias (in various forms and stages of cardiac disease or surgery). Occasionally, conditions of the chest wall (trauma, infections, neoplasms, rickets, and other disorders with increased risk of rib fracture) reduce or even forbid effective mechanical access to the patient's thorax.

The critically ill child with raised intracranial pressure presents a special CPT problem in that CPT might be needed to prevent deterioration in respiratory functions but might also cause further acute rises in intracranial pressure. In this case, special CPT management with more frequent, but shorter, treatment periods is advisable.[85] The head-down position is contraindicated, and any handling and endotracheal suction should be reduced to a minimum.[1]

Some forms of CPT might cause bronchospasm in patients with airway hyperreactivity.[12,26] Such cases can be managed by bronchodilator premedication or by tailoring of an individual CPT regimen to avoid more aggressive mechanical irritations of the intrathoracic airways.

SPECIFIC DISORDERS

Acute Conditions

With few exceptions, CPT should always be considered for the treatment of atelectasis or local hyperinflation despite whether the condition occurred as a complication of bronchiolitis, bronchial asthma, aspiration pneumonitis, bronchial stenosis, or intubation and mechanical ventilation.[24,86,87]

Children with uncomplicated acute bronchiolitis or acute severe asthma do not benefit from CPT.[88,89] Similarly, there is no reason to prescribe CPT for children with croup or epiglottitis.[1] CPT is, at best, useless in acute pneumonia with lobar or segmental consolidation,[90,91] a finding that is not surprising when the predominantly alveolar localization of the inflammatory process is considered. Foreign-body aspiration is routinely treated by bronchoscopy; however, CPT performed over several days after the removal of the foreign body often supports an uncomplicated recovery.[1]

Because an endotracheal tube interrupts the mucociliary escalator and hampers cough clearance, CPT should be considered for any child whose lungs are ventilated mechanically for more than a few hours. In mechanically ventilated lungs, intrabronchial accumulation of secretions is further enhanced by mucus inspissation, which is caused by fluid restriction and the use of diuretics, by the suppression of cough resulting from sedatives and neuromuscular blockage, and by poor humidification of inspired gas. Thus, CPT is important in neonatology, pediatric intensive care, and pediatric surgery. For cases of lobar atelectasis or unilateral lung collapse in newborns, infants, and children whose lungs are mechanically ventilated, most centers have developed some routine of nonendoscopic bronchial lavage; such procedures usually consist of saline instillation, bagging, expiratory vibration, and chest compression followed by endotracheal suctioning.[92]

In neonatology, CPT might be prescribed for premature infants with hyaline membrane disease whose lungs are ventilated and for neonates with meconium aspiration syndrome, aspiration of food, and any other disorder requiring mechanical ventilation. Because CPT has potentially serious side effects in this patient group,[93,94] it should always be applied on an as-needed and not on a routine basis. Properly performed CPT removes secretions, improves oxygenation, and may prevent postextubation atelectasis in newborns with respiratory disease.[87,95,96] A prerequisite for applying CPT effectively and safely in premature infants and newborns is a profound knowledge of the special respiratory anatomy and physiology in this age group; specifically, the therapist should modify the approach to match an extremely compliant thorax, a special mechanical situation of the diaphragm, the closing airways, an age-specific interrelation of body position and distribution of ventilation, and an actively elevated functional residual capacity. Respiratory care of the newborn is described in more detail in relevant textbooks and manuals.[1,97]

In the pediatric intensive care unit, CPT is often needed after the repair of congenital cardiac defects, after pulmonary surgery, and for patients with congenital diaphragmatic hernia, gastroschisis, exomphalos, and tracheoesophageal fistula.[1] In addition, patients with intubated and ventilated lungs and with severe neurologic disorders or various critical medical conditions benefit from CPT. The preoperative and postoperative CPT management of children undergoing cardiac and transplantation surgery requires specialized knowledge and experience.[1] Treatment frequency should be determined and adjusted on the basis of careful and repeated reassessment of the individual. Any chest physiotherapist working in a pediatric intensive care unit must be profoundly familiar with the special environment, its staff, machinery, and techniques. CPT strategies for intensive care are described and discussed in special texts.[1,98]

Chronic Diseases

CPT has a traditional position in the treatment of CF.[3] A meta-analysis of relevant studies confirmed that CPT effects significantly greater sputum clearance in CF patients than no treatment.[99] Other forms of chronic suppurative lung disease, such as localized bronchiectasis, primary ciliary dyskinesia, and some cases of agammaglobulinemia, also benefit from daily CPT. In addition, neurologically handicapped children, who chronically aspirate secretions and food, often need regular CPT. Occasionally, CPT should be prescribed for a child with bronchopulmonary dysplasia or any other chronic respiratory problem characterized by excess intrabronchial secretions. In contrast, the asthma syndrome constitutes no routine indication for CPT.

Increasingly, chest physiotherapists provide care for children with neuromuscular disease. In addition to long-term home ventilation and airway clearance, some of these patients may benefit from individualized respiratory muscle training.[100] Because of muscle weakness, the effectiveness of cough is often severely impaired; chest physiotherapists can augment cough in these patients by using special cough-simulating machinery for insufflation and subsequent exsufflation.[101]

OTHER FACETS OF CPT

In addition to airway clearance, the CPT team of a pediatric respiratory center may be involved in other caregiving programs as well as diagnostic and therapeutic procedures. Such involvement differs substantially among hospitals and centers and regions and countries, the most relevant modifying factor being the availability of other specialized health care professionals such as respiratory therapists, specialized technicians, nurses, and medical doctors. Thus the subsequent list, which is based on local experience, intends to stimulate a possible wider perspective on the job description of pediatric chest physiotherapists. In the United States, the respiratory therapist is responsible for many of the same areas as the chest physiotherapist in Europe.

Breathing Exercises

Breathing exercises encompass a wide spectrum of therapeutically applied breathing patterns and body positions. One end of this spectrum is characterized by the breathing maneuvers for airway clearance, maneuvers needed for properly inhaling an aerosol, and maneuvers for adapting a patient's breathing pattern to various physical activities. On the spectrum's other end are ill-defined and occasionally obscure breathing maneuvers that have managed to survive in some institutions and physiotherapy schools in spite of lacking any physiologic basis or scientific proof of efficacy.

Muscle Training and Exercise Programs

Training programs, especially when targeted on chest and shoulder girdle, can increase respiratory muscle endurance.[102] In addition, body-building exercises may increase upper body muscle mass. By disguising disease-related chest deformities, this effect might improve a patient's body image. Chronic obstructive lung disease affects posture and thoracoabdominal musculature; targeted exercise programs may counteract this development and help the patient maintain good posture and mobility. Under the guidance of an experienced chest physiotherapist, any patient may find an easier and safer access to such programs. These interventions should start early when postural deficits are just emerging.[103]

Exercise programs, either organized in the form of repeated sports lessons or as a training camp, can improve the respiratory status of pediatric patients with chronic lung disease.[80,83] Relatively simple training programs were shown to improve cardiopulmonary fitness in children with CF.[104] In addition, the chest physiotherapists conducting these programs gain valuable insight into patients' respiratory status, exercise tolerance, compliance with medication, and psychosocial problems and habits.

Aerosol Therapy

A pediatric respiratory center must provide a wide spectrum of techniques for aerosol delivery, ranging from nebulizers to dry powder or metered dose inhalers to spacers. The efficacy and safety of aerosol therapy depend on the meticulous standards for the maintenance of equipment, hygiene, dosing, and training patients and parents to perform inhalation techniques. Within a medical center, many health care profession-

als administer aerosol therapy, but quality control and adoption of new techniques are the responsibilities of the center's chest physiotherapists. Other responsibilities include updating other health care professionals on new techniques and equipment and organizing individual or group training sessions for patients and parents.

Lung Function Testing

Pediatric chest physiotherapists should be trained in recording and interpreting several simple and straightforward lung function tests such as spirometry, flow-volume curves, peak expiratory flow, transcutaneously measured blood gas tension, and pulse oximetry. This enables them to closely monitor the patient's therapy, thereby introducing an additional factor of control and safety. Because of their special expertise in training children to perform complex breathing maneuvers, they frequently succeed in obtaining valid lung function recordings in very young children.

Assistance with Other Diagnostic and Therapeutic Procedures

With the widespread introduction of flexible fiberoptic bronchoscopy, the pediatric airway has become more easily accessible for the pediatric pulmonologist. Incorporation of the chest physiotherapist into the endoscopy team provides the opportunity to further improve personal knowledge about this organ system. With time, the chest physiotherapist develops into a valuable assistant for the endoscopist. Occasionally, bronchoscopic lavage is performed for the removal of impacted intrabronchial secretions.[105] In such cases, simultaneously performed CPT might increase the sputum yield of the procedure. In addition to endoscopy, the chest physiotherapist can offer assistance with exercise testing and in the sleep laboratory.

Long-Term Oxygen Therapy

Long-term oxygen therapy can be applied via a concentrator or, for supporting the patient's mobility, via a portable system (small tank or liquid oxygen container). Minitracheostomies may facilitate oxygen delivery to the patient. The caregiving system required for prescribing long-term oxygen therapy may be set up, maintained, and updated by the center's CPT team.

Tracheostomy Care

A small group of children with complex congenital or acquired lesions of the upper respiratory tract or progressive neuromuscular disease require tracheostomy for securing the patency of the upper airway or for applying long-term mechanical ventilation. Pediatric tracheostomy care is a comprehensive treatment encompassing many details such as selection of the ideal cannula, the changing and proper fixation of cannulas, suction, humidification, the use of filters and valves, and the training of parents and other caregivers. Chest physiotherapists can be responsible for such a program; in fact, some current concepts for pediatric tracheostomy care have been developed by chest physiotherapists.[106]

Home Mechanical Ventilation

Home mechanical ventilation has been widely accepted as a caregiving strategy for children with chronic respiratory insufficiency related to etiologies such as bronchopulmonary dysplasia, spinal muscular atrophy, phrenic nerve paralysis, diaphragmatic hernia, thoracic and abdominal wall deformities, high-level myelodysplasia and spinal cord injury, childhood myopathies, and central hypoventilation syndrome.[107] Home mechanical ventilation can be applied via a tracheostomy or noninvasively through the nose or the mouth. Guidelines for home mechanical ventilation have been developed.[108] As with tracheostomy care, the success and safety of a home mechanical ventilation program depend on the availability of a comprehensive and highly specialized treatment plan and on the meticulous training of parents. Again, such programs can be organized and carried out by a center's CPT service.

Psychologic Support

Many pediatric chest physiotherapists find themselves as patient- and parent-elected troubleshooters for psychosocial problems. By frequently talking to patients and by touching them, they gain the confidence of patients and parents and become profoundly familiar with their personal problems, which is especially important when working with children who suffer from chronic respiratory disease. With this type of knowledge, the chest physiotherapist often provides a vital, albeit unofficial, link among patients, parents, and staff.

SCIENTIFIC BASIS OF CPT

Relevant Problems and Misconceptions

EFFICACY

More than three decades ago, a conference on the scientific basis of CPT was opened by the statement that CPT lacks an established scientific basis and evidence of lasting clinical benefit.[109] Since then, various aspects of CPT have been subject to prospective and controlled clinical studies. However, many techniques and methodological details have thus far remained empirical. That the proponents of specific techniques tend to champion their methods at symposia and meetings has not helped clarify the situation; thus controversy reigns in the field. It follows that the scientific basis of CPT is still fragile and incomplete.

Evaluating the efficacy of CPT is a difficult task because numerous confounding variables cannot be eliminated from such studies. Each CPT technique consists of several methodological components; different therapists and centers often tend to emphasize different parts of the technique and neglect others. When comparing the performance of CPT among centers, one finds major technical differences, a situation that illustrates an urgent need for standardization. Consequently, comparative studies of different techniques frequently find that a technique is most effective where it was developed or is most intensively practiced. Because of the pathophysiologic heterogeneity of diagnostic entities and the methodological heterogeneity of CPT techniques, the "best" CPT technique appears to be a misconception, and the

ongoing search for such a technique is ineffectual. It may be more appropriate to evaluate which CPT regimens are more effective for individuals rather than evaluating whether any one technique is the most effective for all patients and disease situations.[110] However, research aimed at improving the efficacy of CPT by better matching the specific pathophysiologic and methodological details does not exist yet.

PHYSIOLOGIC BASIS

Another handicap for establishing a more substantial scientific basis of CPT is the incomplete understanding of each technique's physiologic basis. Most techniques have been developed by trial and error at the bedside; traditionally, therapists have focused on *whether*, not *how*, a specific technique works. Any future concept of tailoring specific CPT techniques to individual patients and disease situations requires a clearer understanding of the mechanisms responsible for each technique's efficacy.

CPT Studies

SHORT-TERM STUDIES

Short-term studies evaluate the effects of one or a few treatment sessions. Their potential clinical relevance is based on the speculation that a specific, documented short-term effect of CPT might alter the disease course. So far, clinicians have been unable to determine which diagnostic technique can most accurately assess the CPT-effected removal of secretions.

Sputum Weight

One of the simplest and most straightforward strategies is to quantify expectorated sputum by its weight. Contamination by saliva might introduce some error, but such an error progressively loses significance with increasing sputum volumes. Clearly, one cannot investigate a technique for emptying a ketchup bottle when the bottle contains hardly any ketchup in the first place.[111] For adolescents and adults, a daily sputum volume in excess of 30 mL must be obtained for documenting the efficacy of CPT.[111,112]

Lung Function Measurements

Assessment of lung function and blood gases is another traditional approach to the evaluation of short-term CPT effects. Numerous studies have documented beneficial lung function changes after the application of different CPT techniques, but many attempts to correlate the dimension of lung function changes to the weight of raised sputum have remained unsuccessful.[9,12,33] One study of CF patients, however, finally established such a cause-and-effect relationship.[67] This traditional difficulty in documenting a lung function-sputum weight correlation is most likely explained by airway-related noise. CPT-effected shifting of secretions from one lung unit to the other without complete expectoration, therapy-induced bronchospasm in patients with airway hyperreactivity, and occasionally applied concomitant medications are all confounding variables that tend to disguise the potentially beneficial effects of sputum expectoration on lung function. Blood gas measurements might be particularly sensitive to this type of airway-related noise.

Radioaerosol Studies

Radioaerosol studies are considered a promising strategy for assessing the effects of CPT.[113] Treatment-effected movements of the inhaled tracer are observed directly with a gamma camera. One handicap of this diagnostic approach, which particularly applies to children, is the radiation. Another caveat relates to the maldistribution of ventilation that invariably develops with any intrabronchial accumulation of secretions: Inhaled tracer particles tend to deposit least in the most obstructed lung units, which on the other hand, should benefit most from CPT.

Other Diagnostic Techniques

Occasionally, the effects of CPT can be directly observed when CPT is applied in the course of an endoscopic investigation. With few exceptions, conventional chest radiographs are too insensitive for direct visualization of accumulated intrabronchial secretions. However, they remain the routine diagnostic approach for assessing the effects of CPT on segmental or lobar atelectasis.

LONG-TERM STUDIES

The long-term effects of repeatedly applied CPT on chronic respiratory disease can be evaluated only by long-term studies. Such studies are extremely difficult to perform because the long-term course of chronic respiratory disease is usually variable and characterized by exacerbations, remissions, and the effects of other concomitant treatment strategies. Another limitation is introduced by patients, who often do not comply with CPT recommendations.[114] For obvious ethical reasons, it is frequently impossible to set up an equally diseased control group without CPT. In spite of all these limitations, a few studies, performed mainly with CF patients, have tried to establish a scientific basis for the long-term prescription of CPT in chronic pediatric lung disease.[66,74,115,116] Systematic reviews of this literature, however, are invariably hampered by the present paucity of well-designed, sufficiently powered, long-term studies.[117]

CONCLUSIONS

The relevant literature provides some first fragments for a scientific basis of pediatric CPT but also illustrates the urgent need for additional controlled investigations. Thus clinical and scientific audits should be an integral part of CPT practice.[118]

ORGANIZATIONAL ASPECTS

Professional Situation

At present, CPT-related organizational concepts, required level of specialization, interaction with other health care professionals, legal and administrative basis for practice, and employment conditions all differ widely among countries, medical schools, and hospitals. For example, some overlap exists, but there are also some important differences between the professional concepts of *CPT* and *respiratory therapy*, the former being of predominantly European and the latter of North American origin. One end of the professional spectrum is characterized by a profoundly structured and highly trained CPT team in the organizational framework of a pediatric respiratory center; on the other end, a specialized CPT service

is completely absent. In the latter case, some CPT techniques are applied by other health care professionals or, occasionally, by physiotherapists from other pediatric subspecialties. Whether such CPT, which might lack quality and therapeutic intensity, should be prescribed at all or whether it threatens to produce more complications than benefits remains a matter of discussion. In some countries, employment of chest physiotherapists is characterized by hospital-based services; in other countries, many physiotherapists, including those who specialize in CPT, work in private practice—a situation that may impede the intensive interaction between other caregivers and the physiotherapist. The prerequisites for establishing an effective pediatric CPT service are the specialized theoretical and practical training courses that are offered by physiotherapy schools and training hospitals and that include a major pediatric component.

Improving the Efficacy of CPT

When pediatric CPT is based within the framework of a pediatric respiratory center, intensive interaction between the chest physiotherapists and all other health care professionals is mandatory for improving the efficacy of treatment. A "respiratory progress chart" for each patient can assist the health care team in monitoring the disease and patient responses to CPT.[119] Such written documentation also intensifies the flux of information between medical physicians and physiotherapists. In addition, all members of the CPT team should take part in patient- and problem-related staff conferences for maximal integration into all relevant caregiving programs. Various delivery systems aimed at correcting CPT misallocations are developed and evaluated.[120]

Other health care professionals, including medical physicians, often have no clear knowledge of CPT and its potential indications, contraindications, and risks. Thus, the build-up of an effective CPT service includes ongoing education of professionals and administrators. Another important factor for improving the efficacy of a center's CPT team is an intensive exchange of thoughts and visits with other pediatric CPT groups.

CHAPTER 19

Respiratory Failure and Acute Respiratory Distress Syndrome

Juan A. Gutierrez, Trevor Duke, Robert Henning, and Mike South

TEACHING POINTS

- Hypoxemia is present in the two main types of respiratory failure: nonventilatory, or type 1, and ventilatory, or type 2. Hypercarbia is present in the second, most common type. Clinically significant hypercarbia is always associated with hypoxemia, unless supplemental oxygen is provided.
- The causes of hypoxemia are multiple, but the most common type is caused by increased venous admixture, especially in the form of ventilation/perfusion inequality.
- Pulmonary edema can be of hydrostatic origin, sometimes called cardiogenic, or it can be caused by increased capillary permeability. In practical terms, especially in the critically ill patient, elements of both types of pulmonary edema may be present.
- ARDS is a type of respiratory failure caused by acute lung inflammation with pulmonary edema resulting from increased permeability. Advances in critical care, including the use of protective lung strategies, are improving the outcome of this serious condition.

RESPIRATORY FAILURE

This chapter covers the pathophysiologic mechanisms involved in respiratory failure, with particular emphasis in the clinically relevant aspects. In this context, we will discuss how these factors lead to specific pulmonary conditions, such as acute respiratory distress syndrome and acute lung injury. Respiratory failure is the cause for a significant proportion of deaths during infancy and childhood, even more in underdeveloped countries. As we will review in this chapter, there are specific anatomic and functional characteristics that place the pediatric patient at risk, in particular, when compared with adults.

Definition

Respiratory failure is defined as the impaired ability of the respiratory system to maintain adequate oxygen and carbon dioxide homeostasis.[1] In respiratory failure, the respiratory system may be unable to mobilize enough oxygen and carbon dioxide required by the body's metabolism.

Commonly used criteria are a partial pressure of arterial carbon dioxide ($PaCO_2$) of 50 mm Hg or higher, or a partial pressure of arterial oxygen (PaO_2) of less than 60 mm Hg in a subject breathing air at sea level. However, these are arbitrary criteria of limited utility in the clinical context, in particular in pediatric patients. For example, patients with congenital heart defects with right-to-left shunt (cyanotic heart defects), live with baseline PaO_2 well below the 60 mm Hg limit. We have to take into account the prior status of the patient, the inspired oxygen concentration (FIO_2), the barometric pressure, and the age of the patient.[2]

As indicated in Boxes 19-1 through 19-3, respiratory failure may be caused by disorders at any point in the respiratory system, which includes the central and peripheral nervous system, the respiratory muscles; the thoracic cage and pleura; the large and small airways; the pulmonary epithelium and interstitium, and the pulmonary circulation. Although an abnormality at a single point can produce respiratory failure, such as the acute obstruction of the trachea by a foreign body, more commonly we see combined abnormalities at different levels of the respiratory system. When the subject has a chronic condition affecting one of the levels, such as tracheobronchomalacia, a disorder affecting a second level, for example central nervous system depression by sedatives, is often responsible for precipitating or aggravating respiratory failure.

Respiratory failure can be acute or chronic. **Acute respiratory failure** is an immediately life-threatening condition that develops over minutes to hours. **Chronic respiratory failure** is a potentially life-threatening condition that develops over months to years (e.g., the gradually deteriorating gas exchange in a child with kyphoscoliosis and diaphragmatic weakness resulting from Duchenne-type muscular dystrophy).

Classification of Respiratory Failure

Respiratory failure has been traditionally divided into two types. Although this classification is useful from a conceptual point of view, they are usually both present in different degrees in most patients.

- Type 1, or hypoxemic or nonventilatory: There is hypoxemia, but the $PaCO_2$ is low or normal. This situation is rare as a pure entity.
- Type 2, or ventilatory or global respiratory failure: hypoxemia and hypercapnia are present.

Hypoxemia is present in both types of respiratory failure. From a clinical point of view, it may be more useful to consider the causes of the hypoxemia rather than the type 1 or 2 classification.

BOX 19-1 Central Nervous System Causes of Respiratory Failure

Medications
- Narcotics
- Sedatives
- General anesthetic agents
- Diuretics that cause metabolic alkalosis (e.g., furosemide)
- Sodium bicarbonate
- Prostaglandin E_1
- Poisoning

Metabolic conditions
- Hypoxia
- Extreme hypercapnia
- Severe alkalosis
- Hyperglycemia
- Hypoglycemia
- Hyponatremia
- Hypocalcemia
- Hyperammonemia, including Reye's syndrome and urea cycle disorders, and some organic acidemias, including maple syrup urine disease
- Medium-chain acyl-coenzyme A dehydrogenase deficiency
- Leigh disease
- Cerebral edema of any cause

Infections
- Meningitis
- Encephalitis
- Brain abscess
- Bulbar poliomyelitis
- Postinfectious demyelinating disorders of the brain stem

Brain stem malformations
- Syringobulbia

Arnold-Chiari malformation
- Encephalocele
- Joubert syndrome
- Dandy-Walker syndrome

Bony abnormalities affecting the brain stem
- Achondroplasia
- Osteogenesis imperfecta

Bulbar hemorrhage

Brain stem trauma and raised intracranial pressure of any cause

Seizures

Central alveolar hypoventilation

BOX 19-2 Neuromuscular Disorders Causing Respiratory Failure

Medications
- Muscle relaxants
- Anticholinesterases
- Aminoglycosides
- Dantrolene
- Glucocorticoids
- Heavy metal poisoning

Metabolic Conditions
- Severe hypophosphatemia
- Hypokalemia or hyperkalemia
- Hypermagnesemia
- Uremia
- Carnitine deficiency
- Acid maltase deficiency
- Acute intermittent porphyria

Infections
- Poliomyelitis
- Tetanus
- Botulism
- Diphtheria

Trauma
- Spinal cord trauma
- Phrenic nerve trauma
- Diaphragm trauma

Other
- Myasthenia gravis
- Muscular dystrophy
- Hoffman-Werdnig syndrome
- Kugelberg-Welander syndrome
- Guillain-Barré syndrome
- Prolonged starvation
- Multiple sclerosis
- Polyneuropathy of critical illness
- Dermatomyositis or polymyositis
- Envenomations (tick, tetrodotoxin, snake)

CAUSES OF HYPOXEMIA

There are basically two causes of hypoxemia: hypoventilation and increased venous admixture. Hypoventilation will be discussed first. Increased venous admixture is more complex and includes the following mechanisms: right-to-left shunt; ventilation/perfusion ($\dot{V}/\dot{Q}$) inequality; and diffusion block.

These mechanisms can combine and their contribution to the hypoxemia varies from one disease to another, from one patient to another with the same disease, and even from one time to another in the same patient. The physiology of these entities is discussed in detail in Chapter 14; however, although some redundancy will be unavoidable, this chapter will frame these concepts into a clinical context.

Hypoventilation

Hypoventilation (reduced alveolar ventilation) causes hypoxemia by increasing the partial pressure of carbon dioxide in alveolar gas (P_{ACO_2}) (type 2 respiratory failure). As P_{ACO_2} increases, it displaces oxygen from the alveolar gas so that the partial pressure of oxygen in alveolar gas (P_{AO_2}) (and therefore Pa_{O_2}) decreases, as is shown from the alveolar gas equation, which follows:

BOX 19-3 Pulmonary Causes of Respiratory Failure

Disorders of Bellows Function

Chest wall
- Kyphoscoliosis
- Asphyxiating thoracic dystrophy
- Collodion skin
- Circumferential chest burns
- Chest wall edema

Pleura
- Hemothorax
- Pleural effusion
- Pneumothorax: open or closed
- Bronchopleural fistula

Lung
- Pulmonary hypoplasia

Airway Disorders

Upper airway obstruction
- Nose
- Pharynx
- Larynx
- Trachea
- Bronchi

Small airway obstruction
- Asthma
- Viral bronchiolitis
- Bronchiolitis obliterans
- Inhalation injury to small airways

Lung Parenchymal Disorders

Pneumonia
Pulmonary edema
Pulmonary fibrosis
Pulmonary alveolar proteinosis

Pulmonary Vascular Disorders

Primary pulmonary hypertension
Pulmonary arteriovenous malformations
Pulmonary embolism

Eq 19.1 $$P_{AO_2} = P_{IO_2} - P_{ACO_2}/R + [P_{aCO_2} \times F_{IO_2} \times (1 - 1\ R)/R]$$

where P_{IO_2} is the partial pressure of oxygen in inspired gas, and R is the respiratory quotient (approximately 0.8 in children on a normal diet). This equation is often simplified to:

Eq 19.2 $$P_{aO_2} = F_{IO_2} \times (P_B - PH_2O) - P_{aCO_2}/R$$

Where: FIO2 = fractional concentration of oxygen in room air ≈ 0.21; P_B = barometric pressure at sea level ≈ 760 mm Hg; P_{aCO_2} = partial pressure of arterial carbon dioxide ≈ 40 mm Hg; R = respiratory quotient ≈ 0.8

A patient who is hypercapnic is always hypoxemic unless he or she is receiving supplemental oxygen. Pure hypoventilation may result from neuromuscular, central nervous system, or chest wall disease. However, if these conditions persist, especially if they lead to reduced tidal volume (V_T) and reduced sighing, small airway closure and atelectasis are likely to ensue, with consequent $\dot{V}/\dot{Q}$ inequality, shunt, or both. Thus hypoventilation alone is a relatively uncommon cause of hypoxemia, except in acute conditions.[3,4] In hypoventilation the individual fails to increase the ventilation in the face of rising CO_2. The inadequate response to hypercapnia may result from abnormalities at the following three levels:

- At the sensor level: chemoreceptors fail to generate and communicate the order to increase the ventilation to the central and peripheral nervous system. Insensitivity of the chemoreceptors of the respiratory center to changes in the P_{aCO_2} may be the primary problem, such as in central alveolar hypoventilation syndrome.
- At the effector level: disorders of the airways, lung parenchyma, chest wall, and/or respiratory muscles prevent these structures from responding to increased neural output from the respiratory center. This is the most commonly affected level.
- Hypoxemia and extreme hypercapnia may themselves depress central respiratory drive. The immaturity of the respiratory system can also be part of the problem, such as apnea in newborns. Although the newborn's ventilatory response to carbon dioxide is similar to the older child's and adult's, the carbon dioxide response in the newborn is depressed by hypoxemia.[5-7] The newborn with recurrent apnea is also less able than older infants to sustain inspiratory effort in the face of increased inspiratory loads.[8,9]

MECHANICAL FACTORS

The respiratory drive and the resulting neuromuscular response may be adequate when the dynamic compliance of the respiratory system is high but may become inadequate when compliance decreases. This is especially important in a young infant, whose compliant rib cage and horizontal rib position reduce the mechanical efficiency of the respiratory muscles in expanding the thoracic volume. Respiratory muscle fatigue and distortion of the chest wall may also impair the ability of the respiratory system to increase the minute ventilation and restore P_{aCO_2} in the presence of $\dot{V}/\dot{Q}$ inequality, shunt, or diffusion defects.[10]

Airway obstruction: As hyperinflation increases in obstructive conditions such as asthma and bronchiolitis, the precontraction length of the diaphragmatic muscle fibers decreases, so the force of contraction decreases, resulting in a reduced V_T and raised P_{aCO_2}.[11,12] At any level of alveolar ventilation, depending on the mechanical characteristics of the respiratory system, there are combinations of respiratory rate and V_T at which respiratory work is minimized but at which gas exchange is not optimal.[13] When alveolar ventilation and work of breathing are low, the combination of rate and V_T selected may optimize gas exchange, but at higher levels of V_T and work of breathing, mechanical loading is adjusted to reduce respiratory work at the expense of gas exchange.[13] For example, when the respiratory system elastance decreases in pneumonia, the work of breathing is minimized when the respiratory pattern is a shallow tachypnea. In this pattern, however, the dead space to tidal volume ratio (V_{DS}/V_T) is

high. When elastance is severely increased, the increase in the dead space to tidal volume ratio resulting from extreme tachypnea may result in reduced alveolar ventilation and, therefore, raised $PaCO_2$ and reduced PaO_2.

Respiratory muscle failure: The integrity of the pumping action of the respiratory muscles is as essential to life as the actions of the cardiac muscle.

RESPIRATORY MUSCLE FUNCTION

The muscles of the respiratory pump have a large reserve, and they can sustain high levels of ventilatory work over prolonged periods. The primary muscle of inspiration is the diaphragm, which is innervated from cervical spinal roots 3 to 5. At rest, only 10% to 15% of diaphragmatic muscle motor units are active.[14] Diaphragmatic contraction leads to inspiration by two main mechanisms: a simple, piston-like caudal displacement of the dome of the diaphragm, and elevation of the lower ribs into which the diaphragm inserts as the muscle sheet contracts across the relatively incompressible abdominal contents. The upper ribs are raised by mechanical coupling, and because of the oblique attachments of the ribs, the transverse diameter of the chest increases as the ribs rise. In infants, the compliant chest wall limits the latter effect.[15] During quiet respiration, usually only the diaphragm is active, but as the need for alveolar ventilation increases (e.g., in exercise) or the work required to maintain ventilation increases (e.g., in obstructive airway disease), first the accessory inspiratory muscles and then the so-called expiratory muscles are recruited into use. The accessory inspiratory muscles include the sternocleidomastoid, scalene, internal intercostal, and external intercostal muscles. They are usually inactive during quiet respiration but become recruited as increased effort is required by exercise or pulmonary disease. They make the ribs more horizontal and raise the rib cage. In infants, these muscles have a limited ability to support inspiration because the ribs are almost horizontal at rest.[16-18] The rib cage develops a more adult configuration by about 2 years of age, but before this age, the intercostal muscles play an important role in preventing deformation of the compliant chest wall during inspiration.[19-22] The abdominal muscles (external and internal oblique, rectus abdominis, and transversus abdominis) and the interosseous internal intercostal muscles cause expiration and are used in forced expiratory activities such as coughing. However, they also increase the efficiency of inspiration by two mechanisms: pulling the rib cage down and inward beyond the point at which the elastic recoil of the chest wall exceeds the collapsing force of the lungs, so that this recoil will assist the next inspiration, and by pushing the diaphragm upward to a point where the muscle fibers reach their optimal resting length for maximal contraction.

The stimulus for muscle contraction begins in the central nervous system and is transmitted as an axonal action potential to the neuromuscular junction. The release of acetylcholine from the small neuronal end plate at its synapse with the muscle cell membrane greatly amplifies the signal and, by opening cationic channels, causes muscle cell depolarization. The change in membrane polarity reaches the tubular sarcoplasmic reticulum, and calcium ions are released. Free calcium ions combine with troponin, a protein that prevents actin and myosin filaments from reacting. Calcium causes troponin to change its physical configuration, and the actin and myosin filaments can then slide over one other, shortening the muscle and generating force. Relaxation occurs when calcium is pumped back into the sarcoplasmic reticulum. Both the sliding reaction of actin and myosin filaments and the return of calcium to the sarcoplasmic reticulum are active steps requiring hydrolysis of adenosine triphosphate (ATP). In addition to producing ventilation of the alveoli, the respiratory muscles have a number of other functions, including stabilization of the compliant chest wall in infants; expulsive efforts such as coughing, sneezing, vomiting, and defecation; and stabilization of the chest and abdomen in motor activities involving the trunk.

The respiratory muscles may become weak and fail under a number of conditions. Respiratory muscle weakness may be the primary and sole cause of alveolar hypoventilation, for example, in severe infantile botulism. More commonly, the problem is respiratory muscle fatigue from increased work of breathing. For example, in a child with severe acute asthma, the progression to respiratory failure occurs when the diaphragm becomes fatigued and cannot maintain the increased work of breathing caused by increased airway resistance. The causes of respiratory muscle fatigue include diseases of the central and peripheral nervous system, the neuromuscular junction, and skeletal muscle (see Boxes 19-1 and 19-2), which affect diaphragmatic muscle function and, in some cases, cause alveolar hypoventilation. Compression caused by lung hyperexpansion may impair blood flow to the diaphragm (e.g., in severe asthma). Low cardiac output, such as that occurring in several severe pulmonary conditions (see later section on cardiorespiratory interactions) may also limit the required increase in diaphragmatic blood flow.[23]

The force of diaphragmatic contraction is proportional to the mass of the muscle. Low diaphragmatic muscle mass may occur in states of malnutrition,[24] and provision of sufficient nutrition to achieve positive nitrogen balance can be difficult in ill infants, particularly preterm babies.[25] Reduced body muscle mass is a feature of some chronic respiratory disorders. The mass of the diaphragm and the maximal force of contraction are reduced in some adults with chronic obstructive airway disease. Respiratory muscle function in chronic pediatric respiratory disorders, such as cystic fibrosis, has not been studied in as much detail as in adult COPD.

Hypoxemia and hypercapnia lead to reduced muscle contractility and increase the tendency to fatigue.[26,27] If these abnormalities exist as a result of pulmonary disease, a vicious cycle of deterioration ensues.

Metabolic derangements, including hypophosphatemia,[28] hypocalcemia,[29] and hypomagnesemia,[30] can all lead to reduced diaphragmatic contractility. The levels of sodium and potassium are essential for the normal function of all muscles, including the respiratory muscles. Viral infection may reduce skeletal muscle force generation, and one study showed significant reductions in respiratory muscle strength during acute viral upper respiratory tract infections in normal adults.[31] The impact of viral infection on respiratory muscle function in patients with chronic pulmonary disease or in children has not been studied. Respiratory muscle weakness has been described for human immunodeficiency virus infections.[32] Bacterial infections, including pneumococcal sepsis,[33] and gram-negative infection with endotoxic shock[34] signifi-

cantly reduce diaphragmatic contractile force in experimental models.[35]

Ventilator-induced diaphragmatic dysfunction is an ill-defined entity associated with the use of mechanical ventilation. The mechanisms involved include muscle atrophy, oxidative stress, and structural injury. The implications for the ventilator weaning of critically ill patients have been reviewed by Vassilakopoulos and colleagues.[36]

The biochemical events leading to muscle fatigue are complex. Fatigue may occur in a number of ways, including depletion of acetylcholine at the neuromuscular junction, depletion of ATP or of substrates used to generate ATP within muscle (glycogen, glucose, free fatty acids), reduced rate of calcium release from the sarcoplasmic reticulum, and reduced supply of substrate to the muscles because blood flow does not match demands. When subjected to greatly increased workloads, the diaphragm may require a blood flow rate that is 10 to 20 times greater than resting rates to meet its metabolic demands.[37,38] Some evidence indicates that once the diaphragm begins to fatigue, there is a reduction in central nervous system respiratory drive to this muscle. This limits fatigue but may contribute to respiratory failure if other respiratory muscles cannot help maintain the ventilatory requirements.

A mixture of weakness and fatigue may occur. For example, a patient with Duchenne muscular dystrophy may be able to sustain the work of normal breathing but may not be able to do so when the work of breathing is increased by pulmonary disease, such as pneumonia. Alveolar hypoventilation occurs with less severe pulmonary consolidation than it would in a previously normal patient.

DEVELOPMENTAL ISSUES

As noted earlier, differences in chest wall configuration and compliance between young infants and older children can place normal infants at a disadvantage when trying to meet the increased ventilatory requirements imposed by pulmonary disease or increased metabolic demands. Differences in the microstructure and properties of the respiratory neuromuscular system of infants may also be important. In older children and adults, each muscle fiber in the diaphragm is innervated by only one motoneuron, and each motoneuron innervates 200 to 300 muscle fibers. Each fiber of the neonatal diaphragm receives innervation from several motoneurons, and this persists for the first few weeks of life.[39] The significance of this polyneural innervation is unknown, but it may have a role in reducing the susceptibility to diaphragmatic fatigue. Skeletal muscle fibers, including those of the diaphragm, may be classified into two basic groups, type I or II, according to histochemical and electrophysiologic characteristics. Type I fibers do not stain in the myofibrillar adenosine triphosphatase reaction, have a high capacity for oxidative phosphorylation, develop their maximal force generation slowly ("slow-twitch"), and are resistant to fatigue.[40] Type II fibers rapidly develop their maximal force generation ("fast-twitch"), but this group may be subdivided according to other properties. Type IIa fibers have intermediate oxidative phosphorylation and are fatigue resistant. Type IIb fibers have poor oxidative phosphorylation and fatigue easily. Type IIc fibers are found only in fetal and neonatal diaphragmatic muscle; they are highly oxidative and resistant to fatigue.

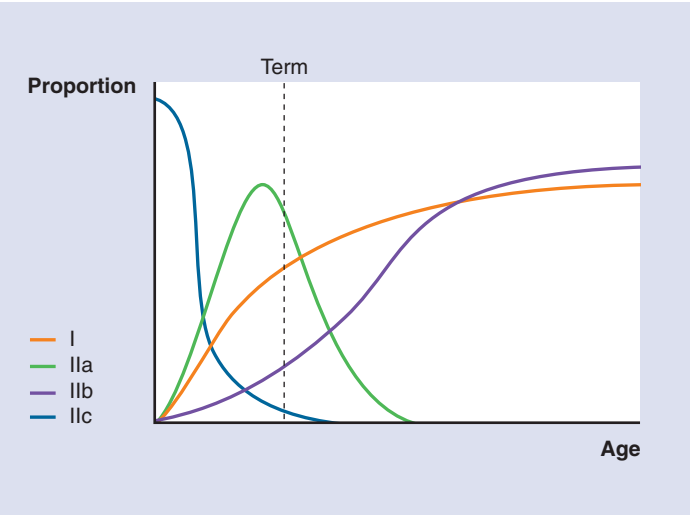

Figure 19-1 Graphic representation of changes with age in the proportion of the skeletal muscle fibers in the baboon diaphragm. Data are unavailable for the human diaphragm but are thought to be similar.

Type IIh fibers are also found only in fetal and neonatal muscle and probably represent a transition phase from type IIa to IIb fibers[41,42] (Fig. 19-1). There are certainly differences in the fiber composition between adults and newborns, but the extent and importance of these differences, particularly with regard to the fatigability of the diaphragm, has been the subject of some controversy. Initial investigations suggested that young infants have lower proportions of type I fibers and that overall, the neonatal diaphragm has a reduced ability for oxidative phosphorylation and hence an increased tendency to fatigue. More recently, it has been demonstrated[41-43] that some of these observations may have resulted from postmortem changes. In fresh specimens of neonatal diaphragm, there are fewer type I fibers, but these are replaced by the highly oxidative and fatigue-resistant type IIc fibers.

In newborn rats, the quantity of acetylcholine released by the diaphragmatic neuronal end plates in response to an action potential is less than that released in adult rats.[44] At high frequencies of stimulation, the neonatal diaphragmatic neuromuscular junction may be prone to transmission failure.

In vitro and in vivo studies of diaphragmatic action in humans and animals also have conflicting results. There is some evidence that the infantile diaphragm can generate forces as great as those in adults,[45] but other evidence suggests that the maximal force generated increases with postnatal age.[41] In vitro, fetal diaphragm muscle strips suffer fatigue less than strips from adults.

Many researchers now believe that diaphragmatic fatigue is a more common feature of thoracopulmonary disease in infants than in adults, but that this is probably a result more of the mechanical disadvantages caused by chest wall configuration and compliance than of an increased tendency to fatigue in the diaphragm muscle itself.

Increased Venous Admixture

Disorders of oxygenation increase the difference in the partial pressure of oxygen between alveolar gas and arterial blood

($P_{AO_2} - P_{aO_2}$). This difference may be considered equivalent to an admixture of venous blood to the oxygenated blood emerging from the pulmonary capillaries. Venous admixture includes the effects of anatomic shunt, diffusion defects, and ventilation of lung units with low perfusion (low $\dot{V}/\dot{Q}$).[46]

ANATOMIC EXTRAPULMONARY SHUNT

Anatomic right-to-left shunt (Fig. 19-2) occurs when venous blood enters the aorta through anatomic structures that bypass the pulmonary circulation. This includes desaturated blood from the bronchial and thebesian veins as well as abnormal extrapulmonary shunts (intracardiac shunts and shunts via the ductus arteriosus) and intrapulmonary shunts.

The bronchial and thebesian veins drain into the pulmonary circulation distal to the gas-exchanging vessels in the alveoli (physiologic shunt), reducing the P_{aO_2} below the partial pressure of end-capillary oxygen ($P_{c'O_2}$). The bronchial veins (which contain deoxygenated blood) drain into the pulmonary veins (which contain oxygenated blood), and the thebesian veins drain into the cavity of the left ventricle. In normal adults, this obligatory shunt represents less than 1% of the cardiac output and reduces the P_{aO_2} by approximately 5 mm Hg.[47]

In children with congenital heart disease, venous blood may enter the arterial circulation at the level of the atria via a patent foramen ovale or an atrial septal defect; this may also occur across a ventricular septal defect or a patent ductus arteriosus when the pulmonary artery pressure is high or if there is common mixing of venous and arterial blood (e.g., in a univentricular heart or a truncus arteriosus).

In the absence of structural cardiac abnormalities, venous blood may enter the arterial circulation via the foramen ovale or ductus arteriosus, provided that these structures are not permanently closed, when the pulmonary vascular resistance is high (e.g., in meconium aspiration syndrome[48] or hyaline membrane disease [HMD] in the newborn). The foramen ovale is closed functionally by 2 hours of age in the normal human but retains the ability to open in 30% of children and adults when right atrial pressure exceeds left atrial pressure.[49] Extrapulmonary right-to-left shunts of 27% to 73% (mean, 52%) have been measured by cardiac catheterization in meconium aspiration syndrome,[50] and a $P_{AO_2} - P_{aO_2}$ difference of more than 610 mm Hg has been reported resulting from these shunts.[51]

In most cases of HMD, shunting via the ductus arteriosus plays a minor role in the production of arterial hypoxemia, representing only 4% of cardiac output and less than 10% of total venous admixture,[52] although in some cases of persistent pulmonary hypertension of the newborn associated with HMD, shunting via the ductus arteriosus is responsible for significant right-to-left shunting in the presence of severe hypoxemia, hypercapnia, or acidosis. The improvement in P_{aO_2} with increasing F_{IO_2} in these circumstances is attributable to a reduction in pulmonary vascular resistance, which

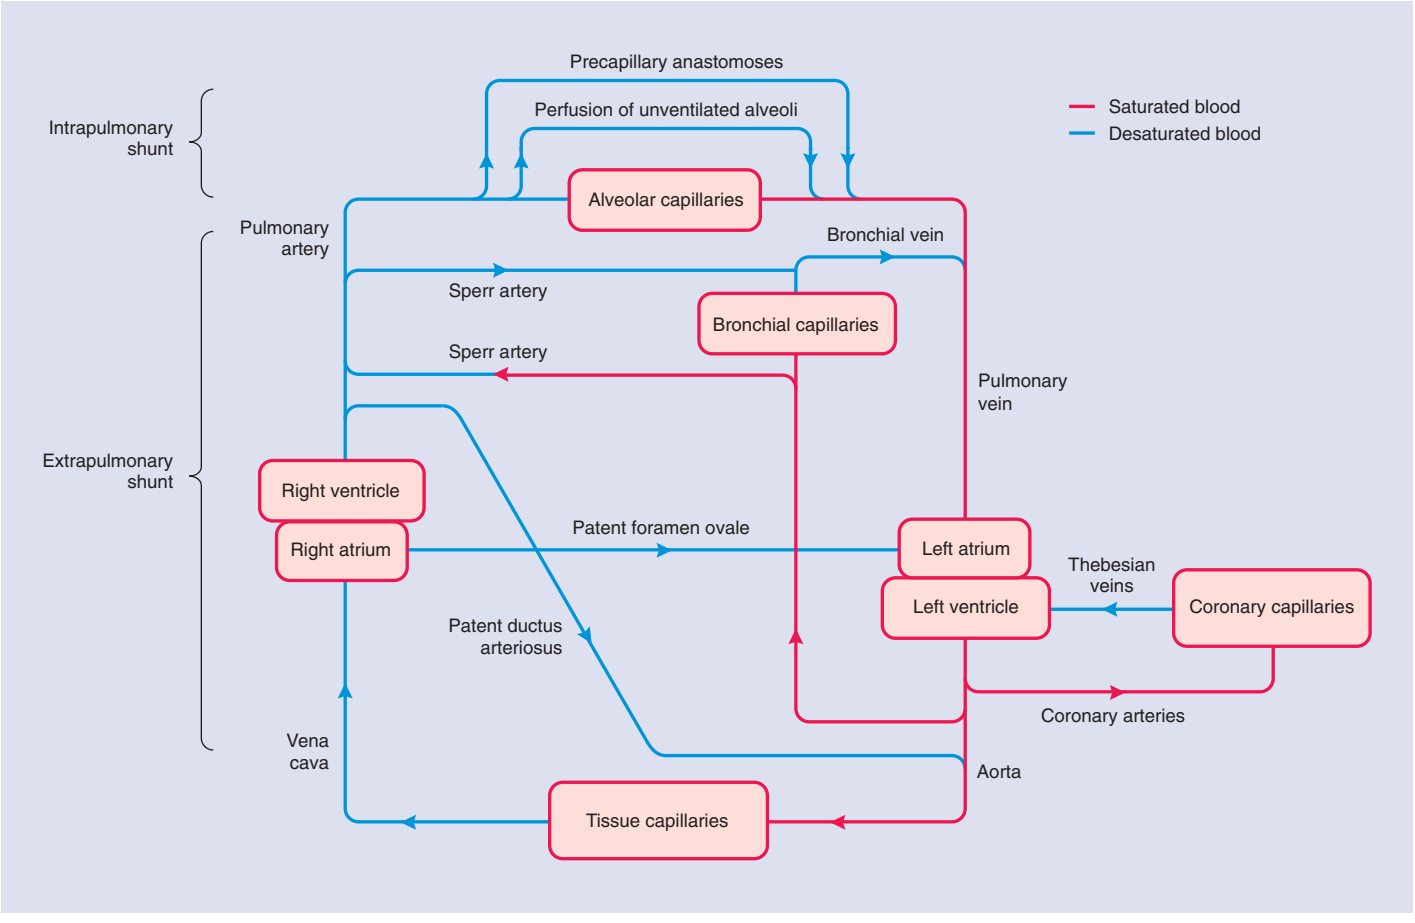

Figure 19-2 Diagram of the circulation showing the intrapulmonary and extrapulmonary right-to-left shunts.

is caused by the increased F_{IO_2} with consequent reduction in the shunt.[53]

ANATOMIC INTRAPULMONARY SHUNT

An intrapulmonary shunt may take the form of discrete extra-alveolar arteriovenous connections or may involve blood that traverses completely unventilated alveoli. Except in the case of pulmonary arteriovenous malformations, the most common malformations of the pulmonary circulation, the existence of true anatomic shunt vessels passing from the pulmonary artery to the pulmonary vein remains controversial. Some 36% to 47% occur as part of Osler-Weber-Rendu disease, whereas others appear as isolated congenital abnormalities. Shunts as large as 79% of the cardiac output have been reported in children with pulmonary arteriovenous malformations, and the Pa_{O_2} is less than normal in 80% of cases.[54] Von Hayek,[55] in 1960, reported the existence of "Sperr" arteries that form a network linking the bronchial arteries to the pulmonary artery and the pulmonary artery to the bronchial veins (and thence to the pulmonary veins, bypassing the alveoli). These muscular bypass channels may regulate the flow of desaturated blood into the systemic circulation (see Fig. 19-2).

Although some investigators have described muscular arterial connections between the bronchial and pulmonary arteries that appear in infancy and disappear by adulthood[56] and the presence of vessels that transmit 60- to 200-μ glass microspheres has been shown in postmortem specimens,[57-59] a careful histologic study by Hislop and Reid[60] did not find any precapillary arteriovenous connections in the lungs of 18 normal children. However, a study using intravenously infused krypton-81m in infants and children with recurrent apnea appeared to show blood traversing the lung without perfusing gas exchanging surfaces during apneic episodes.[61] This finding may imply that functional pulmonary arteriovenous connections exist, although the histologic evidence is inconclusive. It has been suggested that functional arteriovenous shunts, opening acutely, may explain the rapid onset of arterial desaturation occurring early in apneic spells.[62]

Intrapulmonary shunting in infants is due mainly to the perfusion of airspaces not involved in gas exchange.[63] In the normal term neonate, the $P_{AO_2} - Pa_{O_2}$ is greater than it is in adults, mainly because of intrapulmonary shunting, although in normal term babies, unventilated alveoli are not found after the first few hours of life.[64] In preterm infants breathing 100% oxygen in whom there is no clinical or radiologic evidence of lung disease, the $P_{AO_2} - Pa_{O_2}$ is 400 mm Hg at 26 weeks of conception and 250 mm Hg at 32 weeks of conception.[65] Perfusion of immature terminal airspaces where there are few alveoli may contribute to this venous admixture.[65,66]

The collapse of small airways in infants as a result of incomplete smooth muscle and cartilage development in the bronchial wall[67] and low airway conductance is thought to predispose to the closure of some small airways in expiration.[68,69] The pressures needed to open a closed airway are greater than those that caused it to close: The reduction in airway pressure distal to a point of closure and the stability of a fluid meniscus formed at the site of an airway closure tend to keep the airway closed.[70] Airway closure prevents the ventilation of alveoli supplied by that airway: The blood perfusing those alveoli is an intrapulmonary right-to-left shunt.

Routes of collateral ventilation among groups of alveoli (which might assist in the re-expansion of collapsed alveoli) are poorly developed in infancy. Kohn's pores appear gradually with increasing postnatal age, and Lambert's channels between terminal bronchioles and adjacent alveoli appear after the age of 7 years.[71]

Gas trapping resulting from small airway closure appears to be common in small infants (especially in preterm infants,[72] in whom it is associated with a large $P_{AO_2} - Pa_{O_2}$ that decreases with increasing age as the thoracic trapped gas volume decreases).[72] Intrapulmonary shunt resulting from perfusion of the unventilated trapped gas compartment contributes to the $P_{AO_2} - Pa_{O_2}$ in these infants. In healthy full-term infants, the $P_{AO_2} - Pa_{O_2}$ approaches zero by 2 weeks of age as thoracic gas volume (and gas trapping) decreases, whereas in preterm infants, the $P_{AO_2} - Pa_{O_2}$ remains elevated despite a decreasing thoracic gas volume at several months of age, presumably because atelectasis contributes both to the declining thoracic gas volume and to the $P_{AO_2} - Pa_{O_2}$.[72]

In neonates with meconium aspiration syndrome, right-to-left shunting is the main cause of arterial hypoxemia.[48] Total shunts of 27% to 73% of cardiac output have been measured in these infants.[50] Although some of the venous admixture occurs at the level of the ductus arteriosus and foramen ovale in the presence of pulmonary hypertension, much venous admixture is attributable to intrapulmonary shunt, with perfusion of collapsed lung segments or of lung units containing trapped gas whose composition approaches that of mixed venous blood.[48]

Intrapulmonary shunt accounts for much of the $P_{AO_2} - Pa_{O_2}$ in atelectasis, pneumonia, and ARDS in children and adults, mainly because of continued perfusion of unventilated alveoli. In pneumococcal pneumonia, this continued perfusion is due to impairment of hypoxic pulmonary vasoconstriction, possibly by bacterial products or by immune mediators.[73,74] The cause of venous admixture in cystic fibrosis varies from patient to patient. In some patients, intrapulmonary shunt accounts for most of the $P_{AO_2} - Pa_{O_2}$ difference, and the degree of shunt may increase with exercise.[75]

$\dot{V}/\dot{Q}$ INEQUALITY

$\dot{V}/\dot{Q}$ inequality, sometimes called $\dot{V}/\dot{Q}$ mismatch, is the most important cause of arterial hypoxemia in practice. The concentration of oxygen in the alveoli of a lung unit and in the pulmonary venous blood draining that unit depends on the partial pressure of oxygen in the inspired gas and desaturated pulmonary artery blood perfusing that unit as well as on the ratio of $\dot{V}/\dot{Q}$. The same applies to carbon dioxide.[47]

The P_{AO_2} is determined by the pressure of inspired oxygen, the P_{ACO_2}, and the respiratory quotient; whereas Pa_{CO_2} is determined largely by alveolar ventilation and the body's rate of producing carbon dioxide (see earlier section). When the blood flow to a lung unit decreases (and therefore the $\dot{V}/\dot{Q}$ ratio increases), the P_{AO_2} and the Pc'_{O_2} of that unit approach the partial pressure of oxygen (P_{O_2}) of inspired gas (150 mm Hg when breathing room air). When the ventilation of a lung unit decreases (and the $\dot{V}/\dot{Q}$ ratio decreases), the P_{AO_2} and Pc'_{O_2} of that unit approach the P_{O_2} of mixed venous

blood. When all the units in a lung have a $\dot{V}/\dot{Q}$ ratio of 1, the P_{aO_2} is approximately 100 mm Hg, and the $P_{AO_2} - P_{aO_2}$ is 10 to 20 mm Hg in adults breathing room air at sea level[76] in the absence of shunt or diffusion defect.

When some units have a $\dot{V}/\dot{Q}$ ratio less than 1, the blood emerging from those units has a P_{O_2} approaching 40 mm Hg and a partial pressure of carbon dioxide (P_{CO_2}) approaching 45 mm Hg. Because of the shape of the oxygen-hemoglobin dissociation curve, increasing the $P_{c'O_2}$ of high $\dot{V}/\dot{Q}$ units cannot significantly increase the content of oxygen in end-capillary blood (C_{cO_2}) and, therefore, cannot compensate for the low C_{cO_2} of blood emerging from low $\dot{V}/\dot{Q}$ units, particularly because low $\dot{V}/\dot{Q}$ units contribute more blood flow than high $\dot{V}/\dot{Q}$ units.

In a spontaneously breathing subject, increased alveolar ventilation stimulated by chemoreceptors prevents the P_{aCO_2} from rising. (Indeed the P_{aCO_2} may be lower than normal because of a ventilatory response to arterial hypoxemia.) Because the carbon dioxide response curve is approximately linear in the working range—in fact it is hyperbolic (Fig. 19-3)—increasing alveolar ventilation to the high $\dot{V}/\dot{Q}$ units can remove enough carbon dioxide to compensate for the high P_{aCO_2} in the low $\dot{V}/\dot{Q}$ units (see section on the effect of $\dot{V}/\dot{Q}$ inequality on carbon dioxide). However, if alveolar ventilation does not increase in response to a raised P_{aCO_2} (e.g., because of a central nervous system or neuromuscular disorder or because of mechanical ventilation in a child), increased $\dot{V}/\dot{Q}$ inequality also increases P_{aCO_2}.

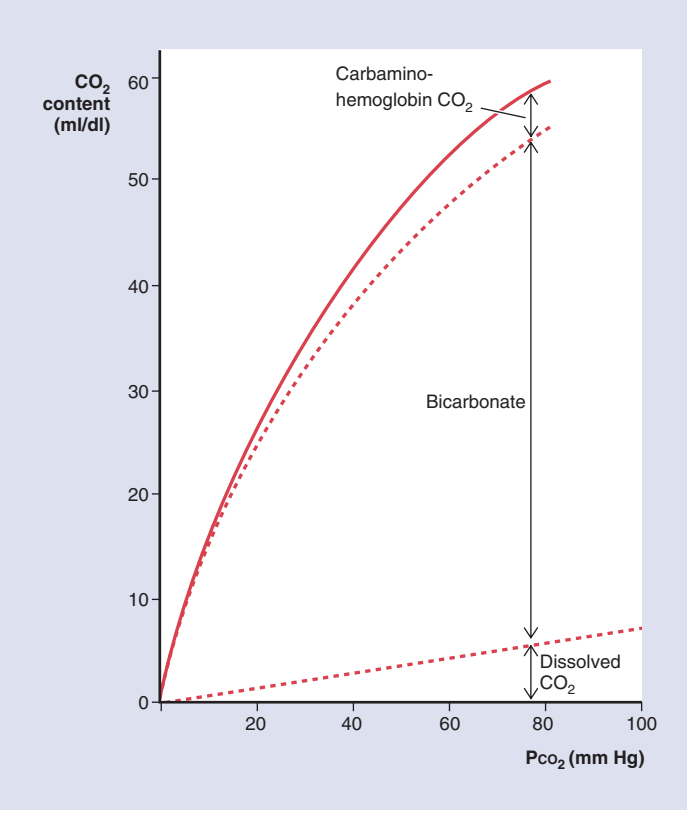

Figure 19-3 Carbon dioxide dissociation curve for whole blood *(continuous line)*. Oxyhemoglobin *(upper dotted line)* carries less carbon dioxide as carbamino compounds than reduced hemoglobin (Haldane effect). The dissociation curve is virtually a straight line over the normal physiologic range of P_{CO_2}. (Adapted from Swenson ER, Hlastala MP: Carbon dioxide transport and acid-base balance: Tissue and cellular. In Chernick V, Mellins RB [eds]: Basic Mechanisms of Pediatric Respiratory Disease: Cellular and Integrative. Philadelphia, BC Decker, 1991, p 148.)

Effect of $\dot{V}/\dot{Q}$ Inequality on Carbon Dioxide Transfer

Although carbon dioxide transfer is less affected by $\dot{V}/\dot{Q}$ inequality than oxygen transfer, $\dot{V}/\dot{Q}$ inequality is the most common cause of hypercapnia in lung disease.[2] The main reasons follow:

1. Both oxygen and carbon dioxide are gases of intermediate solubility; their transfer is less efficient in the presence of $\dot{V}/\dot{Q}$ inequality than the transfer of very soluble or very insoluble gases (Fig. 19-4).
2. Although in the presence of $\dot{V}/\dot{Q}$ inequality, increasing the ventilation of high $\dot{V}/\dot{Q}$ units can lower the P_{ACO_2} and thereby the P_{aCO_2} in these units, the carbon dioxide dissociation curve is hyperbolic rather than linear in the normal operating range so that high $\dot{V}/\dot{Q}$ units may be unable to wash out enough carbon dioxide to compensate for the failure of low $\dot{V}/\dot{Q}$ units to eliminate carbon dioxide.[2]

Furthermore, the altered P_{aO_2} and pH and the increased work of breathing associated with lung disease contribute to respiratory muscle fatigue and limit the maximal alveolar ventilation of which the patient is capable.

A lung with $\dot{V}/\dot{Q}$ inequality cannot transfer as much oxygen and carbon dioxide as a lung with a $\dot{V}/\dot{Q}$ ratio of 1, all else being equal. If the same amounts of oxygen and carbon dioxide are being transferred, the P_{aO_2} will be lower and P_{aCO_2} will be higher than in a lung with homogeneous $\dot{V}/\dot{Q}$ ratios—all else being equal.[47]

In a computer model of a lung in which some compartments were ventilated in series (e.g., via *pendelluft* or Kohn's pores or in which some alveoli arise from more proximal

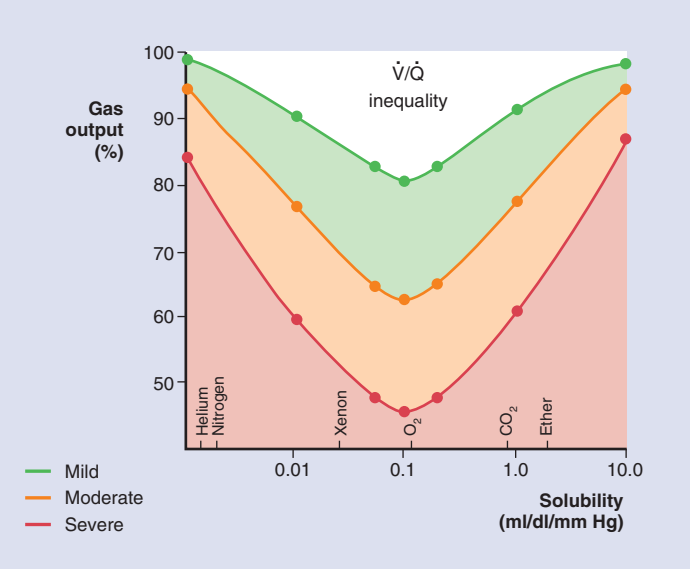

Figure 19-4 Effect of $\dot{V}/\dot{Q}$ inequality on the transfer of gases of different solubilities in the lung. $\dot{V}/\dot{Q}$ inequality has a greater effect on the transfer of gases of intermediate solubility, such as oxygen, than on the transfer of more soluble gases, such as carbon dioxide, or less soluble gases. (From West JB: Causes of carbon dioxide retention in lung disease. N Engl J Med 284:1232-1236, 1971.)

bronchioles), West[77] found that carbon dioxide transfer is reduced more than oxygen transfer. This was because a "parasitic" alveolus that receives all of its inspired gas from a second alveolus is effectively rebreathing gas with a P_{O_2} of approximately 110 mm Hg and a P_{CO_2} similar to that of mixed venous blood. Although oxygen transfer from this parasitic alveolus is almost normal, carbon dioxide transfer is low. Carbon dioxide removal may be less efficient in a lung in which series ventilation of alveoli is prominent (e.g., centrilobular emphysema) than in a lung with other forms of $\dot{V}/\dot{Q}$ mismatch.

If all of the observed $P_{AO_2} - P_{aO_2}$ is due to $\dot{V}/\dot{Q}$ inequality and none is due to shunt, breathing 100% oxygen should correct the hypoxemia. This is because if the low $\dot{V}/\dot{Q}$ units are ventilated even a little, their nitrogen content is washed out over several minutes so that their alveoli contain only oxygen, carbon dioxide, and water vapor, as follows:

Eq 19.3 $$P_{AO_2} = P_B - P_{H_2O} - P_{ACO_2}$$

where P_B is barometric pressure and P_{H_2O} is the saturated vapor pressure of water at 37° C (47 mm Hg). This method may be used to determine how much of the observed $P_{AO_2} - P_{aO_2}$ is due to $\dot{V}/\dot{Q}$ inequality and how much is due to shunt.[78] Inaccuracy may be introduced into this method, converting some low $\dot{V}/\dot{Q}$ units with partly obstructed airways to true shunt because of absorption atelectasis. This has been predicted in theory and observed in adults using the multiple inert gas technique of $\dot{V}/\dot{Q}$ quantitation[79] and in newborn lambs,[80] but it is not seen in adults with bacterial pneumonia.[74]

In a patient with a given degree of $\dot{V}/\dot{Q}$ inequality, the P_{aO_2} is reduced further by a low partial pressure of venous oxygen (P_{vO_2}). P_{vO_2} particularly influences lung units with a low $\dot{V}/\dot{Q}$ ratio or shunt. Measures aimed at raising the P_{vO_2} (e.g., by raising cardiac output or reducing whole-body oxygen consumption [D_{O_2}]) may raise P_{aO_2} in conditions in which shunt and low $\dot{V}/\dot{Q}$ ratio are prominent (e.g., pneumonia, ARDS).[74,81] Cardiac output may be increased (at the expense of increased myocardial oxygen demand) by the use of plasma volume expansion, vasodilator medications (which improve left ventricular performance by reducing afterload), or inotropic medications such as dopamine.

None of these methods is ideal, however. Plasma volume expansion may increase the water content of the lung, thereby increasing respiratory system elastance and impairing gas diffusion. Vasodilator medications dilate systemic and pulmonary vessels indiscriminately and may increase perfusion and oxygen delivery (D_{O_2}) to nonessential tissues such as muscle at the expense of essential tissues such as the brain and heart. Some vasodilator medications such as glyceryl trinitrate and sodium nitroprusside may impair hypoxic pulmonary vasoconstriction (HPV), increasing $P_{AO_2} - P_{aO_2}$ in the presence of lung disease.[82] Catecholamines such as dopamine, which are used for their inotropic effect, also increase the body's rate of producing oxygen and carbon dioxide, mainly by their effect on fat catabolism.[83] Dopamine and dobutamine both reduce P_{aO_2} by about 10 mm Hg in patients with severe lung disease by increasing the perfusion of unventilated lung units (shunt) and of low $\dot{V}/\dot{Q}$ lung units.[84]

The use of any of these measures intended to improve oxygenation by raising mixed venous P_{O_2} depends on whether the potential gains are greater than the potential disadvantages. Trial and error—titrating dose against effect with close observation of blood gases, mixed venous P_{O_2}, and indicators of organ function (conscious state, urine output, and plasma lactate concentration)—is the method generally used.

Causes of $\dot{V}/\dot{Q}$ Inequality

The phasic nature of alveolar ventilation and pulmonary blood flow and the difference in frequency of these two flows mean that instantaneous ventilation and perfusion of the lung are frequently unequal,[85] although the $\dot{V}/\dot{Q}$ ratio averaged over a period of minutes may be equal to 1. In fact, at low inspiratory flow rates, the ratio of ventilation per alveolus at the lung apex compared to ventilation at the base is about 0.6, but this ratio approaches 1 (i.e., ventilation becomes more evenly distributed) as inspiratory flow rate increases.[86] As underperfused areas may become more ventilated with an equally distributed ventilation, the effect of this is an even greater maldistribution of the $\dot{V}/\dot{Q}$ ratio throughout the lungs at high inspiratory flow rates.

The effect of short-term fluctuations in the $\dot{V}/\dot{Q}$ ratio on gas exchange is buffered by the functional residual capacity (FRC).[76] For example, after a stepwise reduction in the $\dot{V}/\dot{Q}$ ratio of a lung unit, the P_{O_2} and P_{CO_2} in the alveolar gas and end-capillary blood in that lung unit exponentially approach values closer to those in mixed venous blood. The larger the alveolar gas volume in relation to the alveolar ventilation and blood flow, the slower the exponential change. When a series of stepwise changes in the $\dot{V}/\dot{Q}$ ratio in alternating directions occur, the larger the alveolar gas volume (or FRC), the smaller the amplitude of the fluctuations in P_{O_2} and P_{CO_2} in alveolar gas and end-capillary blood.

Regional $\dot{V}/\dot{Q}$ Inequality.

In the adult lung, blood flow decreases rapidly from the base to the apex, whereas alveolar ventilation decreases less rapidly (Fig. 19-5). Thus the $\dot{V}/\dot{Q}$ ratio is much higher at the lung apex than at the base, and much of the pulmonary blood flow passes through lung units whose $\dot{V}/\dot{Q}$ ratio is less than 1 and whose end-capillary P_{O_2} is correspondingly low.[46] This means that in the normal upright adult, gas exchange is less efficient than it would be if the $\dot{V}/\dot{Q}$ ratio were 1 in all lung units. Similarly, in the adult lying supine, both ventilation and blood flow increase from ventral to dorsal, whereas in the adult subject lying on one side, both ventilation and blood flow are greater in the dependent lung.

Children differ in the following respects:

1. Because a child's pulmonary artery pressure is similar to an adult's but the child's lung is smaller, more of the child's lung is perfused continuously throughout the cardiac cycle because the pressure in the pulmonary capillaries remains higher than the intra-alveolar pressure surrounding the capillaries, even close to the apex of the lung. Because of the child's smaller lung dimensions, the head of hydrostatic pressure that is distending vessels in the lung base is less than that in the adult, so the difference in the vascular radius between the lung base and apex—and therefore the difference in pulmonary vascular

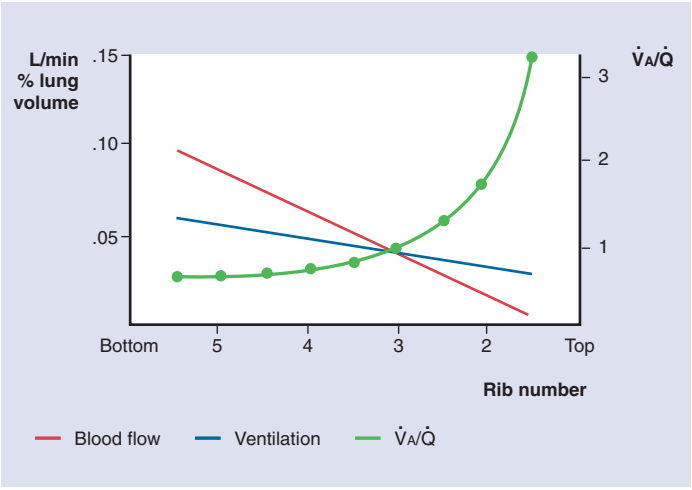

Figure 19-5 Distribution of ventilation, blood flow, and $\dot{V}/\dot{Q}$ ratio from the base to the apex of the upright lung. $\dot{V}/\dot{Q}$, alveolar ventilation/perfusion ratio. (From West JB: Ventilation, Blood Flow and Gas Exchange, 3rd ed. Oxford, Blackwell, 1977, p 30.)

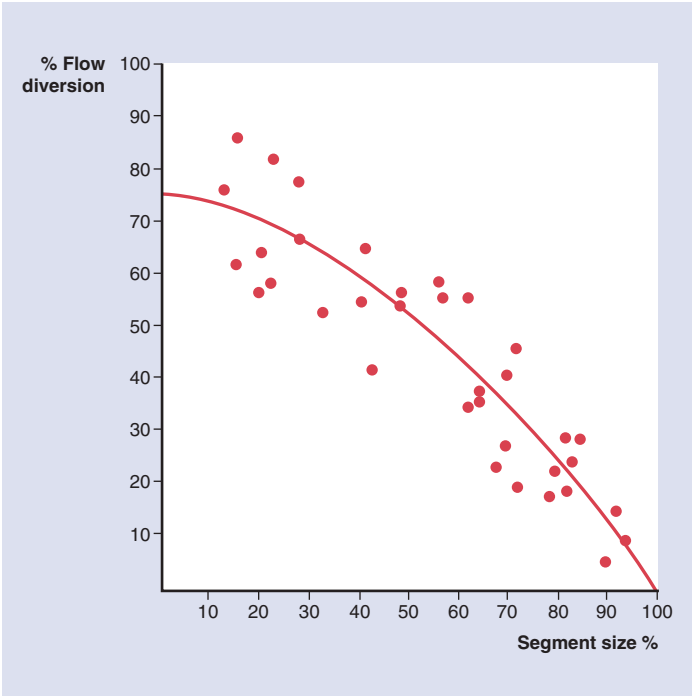

Figure 19-6 Effectiveness of hypoxic pulmonary vasoconstriction as the size of the hypoxic segment of lung increases. (From Marshall BE, Marshall C, Benumof J, Saidman LJ: Hypoxic pulmonary vasoconstriction in dogs: Effects of lung segment size and oxygen tension. J Appl Physiol 51(6):1543-1551, 1981.)

resistance between the lung base and apex—are less and pulmonary blood flow is more evenly distributed over the lung.[64] This effect is often seen in children with high pulmonary artery pressures resulting from left-to-right cardiac shunt or from pulmonary venous hypertension. In these children, blood flow to the lung apex is increased, and flow to the lung bases is reduced.[87]

2. In children younger than 18 years of age, ventilation is distributed preferentially to the upper areas of lung and away from dependent areas.[88]

In young children, the closing volume is higher than the FRC.[89] Airways in dependent areas of the lung are the first to close during expiration and the last to reopen during inspiration—so in infants, inspired gas preferentially ventilates nondependent areas of lung. In humans of all ages, as preinspiratory lung volume decreases below the closing volume, ventilation inhomogeneity increases. Regional variability in static mechanical properties within the lung (especially in elastic recoil) may explain some of the reduced ventilation of the lung bases in children.[90]

The net effect of these two differences is that there is less $\dot{V}/\dot{Q}$ inequality in the lungs of the normal child and adolescent than in the adult. Also, in an adult with unilateral lung disease, the $P_{AO_2} - P_{aO_2}$ is greater with the diseased lung in a dependent position, but in a child up to the age of 18 years, the $P_{AO_2} - P_{aO_2}$ is greater with the diseased lung in uppermost position.[91,92]

In an adult with unilateral drug disease, gas exchange (especially oxygenation) is consistently better when the patient lies with the normal lung dependent than when the patient lies supine or with the diseased lung dependent. This strategy results in a greater improvement in oxygenation than in carbon dioxide elimination.[93] In contrast, children with unilateral lung disease are managed with the diseased lung dependent, in which position the P_{aO_2} is usually higher than when the diseased lung is uppermost. Conventional treatment of unilateral pulmonary interstitial emphysema includes managing the child in the decubitus position with the abnormal lung down.[94]

In some newborns, gas trapping in the first few days of life is associated with a raised $P_{AO_2} - P_{aO_2}$.[49,72] This gas trapping may occur in narrow compliant airways in which occlusive bubbles readily form, and the relative lack of collateral ventilation channels in the newborn lung may contribute to the resulting regional hypoventilation[95] and to $\dot{V}/\dot{Q}$ inequality.

ROLE OF HYPOXIC PULMONARY VASOCONSTRICTION (HPV) IN $\dot{V}/\dot{Q}$ INEQUALITY

Constriction of pulmonary vessels in response to alveolar hypoxia decreases the arterial hypoxemia that occurs with regional alveolar hypoventilation and thereby reduces the $P_{AO_2} - P_{aO_2}$ in situations of $\dot{V}/\dot{Q}$ inequality and shunt. The smaller the hypoxic segment of lung, the more powerful the HPV and the greater the diversion of blood flow from the hypoxic segment.[96] Thus HPV plays a greater role in the reduction of venous admixture when the hypoxic segments are small and scattered than when a lobe is hypoxic (Fig. 19-6).

According to micropuncture studies, the vessels that constrict in response to hypoxia are the small pulmonary arteries and veins,[97] with the precapillary pulmonary arteries being the most important site of HPV.[98] The principal stimulus to HPV is low alveolar oxygen (P_{AO_2}).[64] A major reduction in the mixed venous P_{O_2} can reduce the effectiveness of HPV by reducing the P_{aO_2} in well-ventilated areas of lung more than in less well-ventilated regions and diverting blood flow to hypoxic areas of the lung, thereby reducing the P_{aO_2}.[99] Measures that increase the P_{VO_2} by increasing cardiac output or by reducing the $\dot{V}_{O_2}$ (e.g., by cooling or the use of muscle relaxants) may therefore be expected to increase the P_{aO_2} in patients with shunt or $\dot{V}/\dot{Q}$ inequality.[99]

Although the adequate stimulus to HPV (low P_{AO_2}) is known, the nature of the sensor and the mode of stimulus transmission to the vascular smooth muscle cells have not been identified for certain. It appears that some form of chemical messenger is involved: A pulmonary artery to which some lung tissue is adherent contracts in response to hypoxia, and a pulmonary artery from which all lung has been stripped will not contract.[100] Possible chemical messengers include leukotrienes C_4 and D_4 (inhibitors of which suppress HPV),[101] the calcium slow channel (facilitation of calcium entry into cells augments HPV),[102] and oxygen radicals.[98,103]

Inhibition of endothelial nitric oxide (NO) production by hypoxia is likely to be a major contributor to HPV. NO is an important endothelium-derived relaxing factor that is produced in the pulmonary vascular endothelium and diffuses into the subjacent smooth muscle cells. There it activates guanylate cyclase, which increases the intracellular level of cyclic guanosine monophosphate and results in relaxation of vascular smooth muscle.[104,105] The relaxation of pulmonary vascular smooth muscle induced by NO is impaired by chronic hypoxia but may be restored by the administration of L-arginine, a NO precursor.[106] NO production is reduced by hypoxia in both the adult and the fetal pulmonary arteries.[107,108] However, because the primary stimulus to HPV is in the alveolar gas phase, it is not clear how the stimulus is transmitted to the vascular endothelium to inhibit NO production.

In adults with ARDS, inhaled NO (iNO) acts as a selective pulmonary vasodilator, reducing pulmonary artery pressure without reducing systemic blood pressure. Because it is delivered by inhalation, iNO dilates the pulmonary arteries supplying the well-ventilated lung units more than the pulmonary arteries in less well-ventilated units, thereby improving $\dot{V}/\dot{Q}$ matching and increasing P_{aO_2}.[109]

Lung units with low $\dot{V}/\dot{Q}$ ratios have high P_{ACO_2} values as well as low P_{AO_2} values. An increased P_{CO_2} acts as a pulmonary vasoconstrictor in these lung units, augmenting the effect of the low P_{AO_2}, although the raised P_{CO_2} and its accompanying low pH are each a weaker vasoconstrictor stimulus than hypoxia. The P_{CO_2} in the pulmonary artery, not the alveoli, is the main carbon dioxide vasoconstrictor stimulus.[110]

HPV in the newborn is more vigorous than in the adult and is triggered at a higher P_{AO_2} threshold;[111] despite this, the $P_{AO_2} - P_{aO_2}$ in the newborn remains higher than in the adult for some days after birth.[65]

$\dot{V}/\dot{Q}$ Inequality in Lung Disease

NEONATES

In HMD, early studies using urinary-alveolar nitrogen gradients were unable to demonstrate significant $\dot{V}/\dot{Q}$ mismatch,[112] so all of the observed $P_{AO_2} - P_{aO_2}$ was attributed to right-to-left shunt—both intrapulmonary shunt and that at the level of the foramen ovale and ductus arteriosus. More recent data show the existence of appreciable $\dot{V}/\dot{Q}$ inequality as well as a shunt component in HMD; up to 40% of the cardiac output passes through high $\dot{V}/\dot{Q}$ lung units, and about 3% passes through low $\dot{V}/\dot{Q}$ units.[113,114] It has been suggested that the commonly observed reduction in P_{AO_2}, which follows a decrease in F_{IO_2} in infants with HMD, means that $\dot{V}/\dot{Q}$ inequality is a major cause of hypoxemia in this condition.[115] However, because extrapulmonary shunting occurs in both HMD and meconium aspiration syndrome and because the amount of shunting is greater at high pulmonary artery pressures, the reduction of F_{IO_2} may increase venous admixture by lowering the P_{AO_2} and thereby increasing HPV, total pulmonary vascular resistance, and the amount of the extrapulmonary shunt. Continuous positive airway pressure increases the total perfusion of lung units with high $\dot{V}/\dot{Q}$ in HMD by recruiting the alveoli of low $\dot{V}/\dot{Q}$ units into the high $\dot{V}/\dot{Q}$ compartment,[113] although it does not appear to recruit completely unventilated alveoli, whose perfusion continues to represent intrapulmonary shunt.[114]

A low $\dot{V}/\dot{Q}$ contributes significantly to venous admixture in meconium aspiration syndrome,[63] although extrapulmonary shunting at the level of the ductus arteriosus and foramen ovale as well as intrapulmonary shunt cause most of the venous admixture in this condition. In atelectasis and pneumonia in the newborn, there is evidence from animal experiments that inflammatory mediators suppress the local HPV response and thereby exacerbate the arterial desaturation caused by $\dot{V}/\dot{Q}$ inequality to a greater extent than in adults.[95]

CHILDREN

Asthma

$\dot{V}/\dot{Q}$ inequality is the major source of hypoxemia in asthma, with very little contribution from shunt.[116-118] As the severity of the asthma attack increases, the proportion of the cardiac output that traverses low $\dot{V}/\dot{Q}$ units increases from 10% to 28%.[117,118] In some asymptomatic asthmatic adults, up to 50% of lung units lie behind closed airways. These units have a small $\dot{V}/\dot{Q}$ ratio (i.e., nonshunt) because of collateral ventilation.[116] Although this issue has not been addressed in children, it is possible that shunt may be more prominent in infants, whose collateral ventilation pathways are less well developed.[95]

Adults with moderately severe asthma have a bimodal distribution of $\dot{V}/\dot{Q}$ ratio in the lungs even when their condition is asymptomatic (Fig. 19-7): one peak at $\dot{V}/\dot{Q} = 1$ and another of low $\dot{V}/\dot{Q}$ ratio (approximately 0.1).[116] During an acute asthma attack, it appears that there is no relation between the 1-second forced expiratory volume (absolute or percent predicted) and measures of $\dot{V}/\dot{Q}$ inequality,[118] possibly because spirometric findings are determined by the resistances of large airways, whereas gas exchange may be more influenced by edema, mucus production, and muscular contraction in small airways.[119] There is also little relation between the clinical severity of asthma and the degree of $\dot{V}/\dot{Q}$ mismatch, so a patient with the most severe clinical evidence of asthma may have the same $\dot{V}/\dot{Q}$ inequality as a patient with the least clinically severe attack.[119]

Inhaled albuterol abolishes $\dot{V}/\dot{Q}$ inequality in asthmatic children after histamine challenge.[120] Increased perfusion caused by vasodilation with albuterol could worsen $\dot{V}/\dot{Q}$ matching; however $\dot{V}/\dot{Q}$ inequality is unaffected by nebulized albuterol[118] but is exacerbated by intravenous albuterol, intravenous terbutaline,[121] and nebulized isoproterenol[116,118] in adult asthmatics. The difference in effect on $\dot{V}/\dot{Q}$ distribution between the inhaled and the intravenous route is thought to result from the fact that pulmonary vaso-

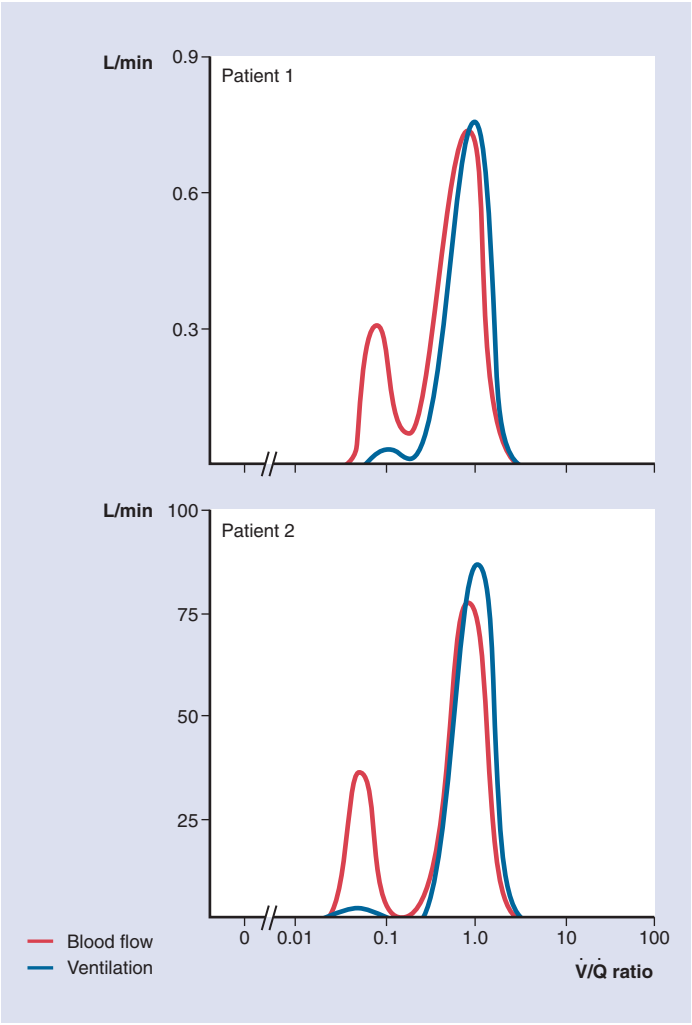

Figure 19-7 Distribution of ventilation and blood flow between lung units of different $\dot{V}/\dot{Q}$ ratios in two patients with asthma. Note that there is some perfusion of lung units with low $\dot{V}/\dot{Q}$ ratios ($\dot{V}/\dot{Q} = 0.1$) but that there was no perfusion of lung units with $\dot{V}/\dot{Q} = 0$ (shunt). (From Wagner PD: *Am Rev Respir Dis* 118:511-524, 1978.)

dilator medications given intravenously dilate the vessels supplying all lung units, including underventilated units, impairing HPV, whereas inhaled pulmonary vasodilator medications act preferentially on well-ventilated lung units to which they have greater access. Thus inhaled NO reduces the $\dot{V}/\dot{Q}$ inequality and $P_{A}O_2 - PaO_2$ in ARDS,[109] and inhaled halothane causes less $\dot{V}/\dot{Q}$ inequality than intravenous sodium nitroprusside for the same total reduction in pulmonary vascular resistance[122] in dogs with pulmonary atelectasis. Infusion of glyceryl trinitrate or prostaglandin E_1 increases the $\dot{V}/\dot{Q}$ inequality and $P_{A}O_2 - PaO_2$ in patients with ARDS.[82] Inhalation of 100% oxygen in asthma increases the $P_{A}O_2 - PaO_2$, either by causing absorption atelectasis in low $\dot{V}/\dot{Q}$ units or by reducing HPV.[117]

Cystic Fibrosis

Although intrapulmonary shunt is the main source of $P_{A}O_2 - PaO_2$ in some patients with cystic fibrosis, $\dot{V}/\dot{Q}$ inequality makes a major contribution to hypoxemia in others. The effect of exercise also varies from patient to patient. In some, exercise reduces $\dot{V}/\dot{Q}$ inequality, whereas in others, $\dot{V}/\dot{Q}$ inequality is increased or converted to shunt. Despite an apparent increase in venous admixture with exercise in cystic fibrosis, the PaO_2 is not necessarily reduced.[79] Vasodilator medications reduce the PaO_2 by impairing HPV in cystic fibrosis.[123]

Pneumonia

The role of $\dot{V}/\dot{Q}$ inequality in producing venous admixture varies from patient to patient. In about one half of patients with pneumonia, $\dot{V}/\dot{Q}$ inequality makes the major contribution, and shunt is less important.[74] HPV is relatively ineffective at reducing the perfusion of underventilated alveoli in pneumonia—perhaps because of inflammatory mediators.[73,74]

ARDS

Although the majority of patients with ARDS show evidence of some $\dot{V}/\dot{Q}$ inequality,[124] most of the venous admixture found in this condition is due to shunt, and only a small proportion comes from $\dot{V}/\dot{Q}$ mismatch[75] (Fig. 19-8). The shunt fraction appears to be directly related to the amount of pulmonary edema present.

The use of positive end-expiratory pressure (PEEP) ventilation does not reduce the amount of extravascular lung water in ARDS,[119,125] but improves PaO_2 by reducing the blood flow to unventilated alveoli, and probably by decreasing atelectatic areas, in particular after the application of a recruitment maneuver.[125] However, it also increases alveolar dead space by increasing the ventilation of unperfused alveoli.[75] During the resolution of ARDS, shunts gradually decrease via conversion to normal $\dot{V}/\dot{Q}$ units without passing through a phase of low $\dot{V}/\dot{Q}$ ratio.[119] As the cardiac output increases in ARDS, the shunt fraction also increases, possibly because the raised PvO_2 resulting from increased cardiac output suppresses HPV in unventilated areas of the lungs. In fact, the effects of raised PvO_2 on shunt fraction and on end-capillary PO_2 tend to cancel each other out, so PaO_2 does not change as cardiac output increases.[119]

DIFFUSION BLOCK

In practice it is difficult to separate the contribution of diffusion block to hypoxemia from that of $\dot{V}/\dot{Q}$ inequality because the two almost always occur together. The rates of diffusion of oxygen and carbon dioxide between blood and alveolar gas follows Fick's law:

$$\dot{Q} = k(P_1 - P_2) \times A/T \qquad \text{Eq 19.4}$$

where $\dot{Q}$ is the rate of diffusion of the gas in milliliters per minute, k is a constant, $P_1 - P_2$ is the partial pressure difference of the gas between the alveolus and blood, A is the total area of the alveolar membrane, and T is the thickness of the alveolar membrane. Thus any reduction in the partial pressure gradient for a gas (e.g., resulting from high $P_{A}CO_2$ or low $PvCO_2$ in the case of carbon dioxide), thickened alveolar capillary membrane (e.g., resulting from pulmonary edema), or reduced surface area (e.g., resulting from atelectasis) reduces the rate at which that gas is transferred. Carbon dioxide diffuses through the alveolar membrane 20 times faster than oxygen.

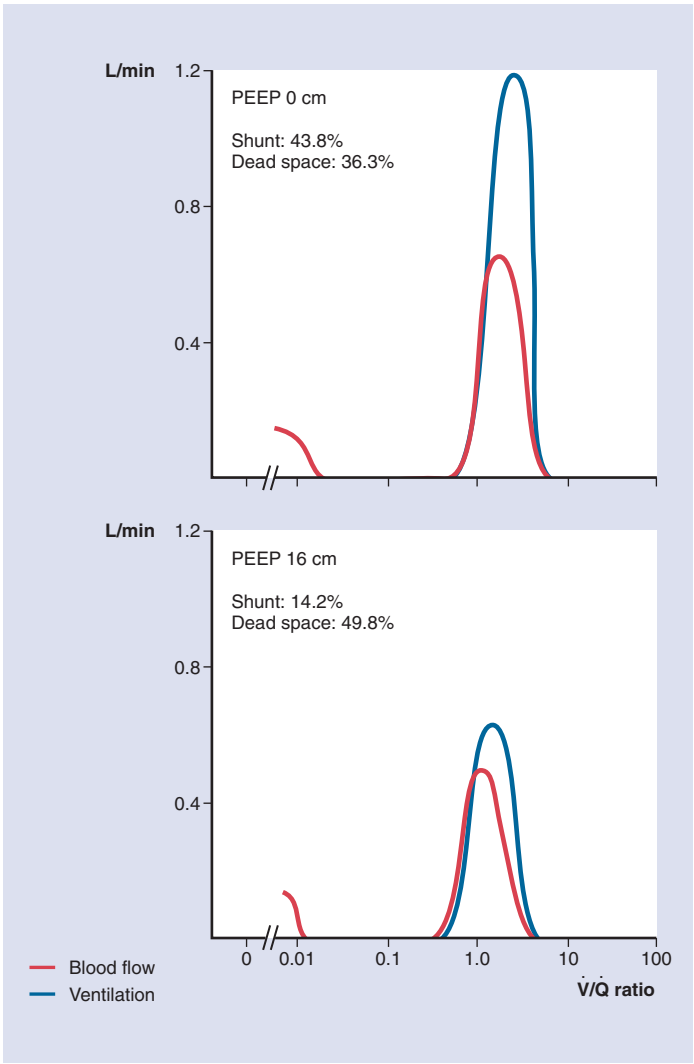

Figure 19-8 Distribution of ventilation and blood flow between lung units of different V̇/Q̇ ratios in acute respiratory distress syndrome (ARDS), showing the large contribution of shunt (**A**). Positive end-expiratory pressure (PEEP) improves oxygenation in ARDS by reducing the perfusion of shunt blood flow at the expense of an increase in dead space ventilation (**B**). (From Dantzker DR, Brook CJ, Dehart P, et al: Ventilation-perfusion distributions in the adult respiratory distress syndrome. Am Rev Respir Dis 120(5):1039-1052, 1979.)

The passage of oxygen from the alveolus into the blood and thence into red cells to attach to hemoglobin takes a finite minimum time. Each red cell remains in the pulmonary capillary an average of 0.75 second.[47] Normally the hemoglobin is loaded with oxygen by the time it is a third of the way through the pulmonary capillary. However, the time taken for hemoglobin loading is greater when the alveolar membrane is thickened or its area reduced, when the partial pressure gradient is reduced by a low P_{AO_2} (e.g., at high altitude), and when the circulation transit time is reduced (e.g., in a hyperdynamic circulation).

The diffusion characteristics of the normal lung as measured by the diffusing capacity for carbon monoxide ($\dot{D}_{LCO}$) remain almost constant throughout life.[49] In HMD (in which the alveolar membrane is thickened and the total alveolar area reduced by atelectasis), some studies have shown a reduction in the $\dot{D}_{LCO}$ lasting more than 72 hours after birth despite an increase of the FRC to normal in that time.[126] However, other studies have demonstrated no difference in the $\dot{D}_{LCO}$ between babies with HMD and normal newborns.[76]

A significant reduction in the $\dot{D}_{LCO}$ standardized for total lung capacity has been demonstrated in a variety of childhood illnesses in which the lungs are affected. These include interstitial pulmonary fibrosis,[127] Henoch-Schönlein purpura,[128] the active phase of childhood connective tissue disorders (including juvenile rheumatoid arthritis, systemic lupus erythematosus, and dermatomyositis),[129] interstitial pneumonitis after bone marrow transplantation,[130] amiodarone-induced pneumonitis,[131] and the acute phase of histoplasmosis.[132]

Because $\dot{D}_{LCO}$ and V̇/Q̇ inequality have not been studied simultaneously in these conditions, the contribution to hypoxemia of a reduced diffusion capacity independent of V̇/Q̇ inequality is not certain. In adolescents and young adults with cystic fibrosis, the presence of a reduced diffusion capacity is associated with marked airflow obstruction and severe arterial desaturation on exercise,[133] although V̇/Q̇ inequality makes a much greater contribution than impaired diffusion to hypoxemia in cystic fibrosis.[75]

LUNG WATER AND PULMONARY EDEMA

Pulmonary edema is the accumulation of abnormal amounts of fluid in the extravascular spaces of the lung and is common in many conditions. The primary site of pathology may be pulmonary (e.g., aspiration pneumonitis) or elsewhere (e.g., cardiomyopathy). Although many diverse conditions can lead to pulmonary edema, they all do this via at least one of a small number of mechanisms. The presence of excess fluid in the airspaces decreases lung compliance, increases airway resistance, and impedes gas exchange; hence respiratory failure is a common endpoint.

Water Turnover in the Normal Lung

The normal lung is approximately 80% water by weight. Approximately 25% of this water is within the pulmonary circulation, and the remaining (extravascular) water is within the interstitial spaces and pulmonary lymphatics.[134] Less than 0.5 μm of tissue separates water that is under hydrostatic pressure in the capillary circulation from the alveolar airspaces; therefore maintenance of the barrier that prevents water from flooding the airspaces is critical to the preservation of alveolar gas exchange.

Water distribution at the level of the alveolar-capillary gas exchange unit can be considered as being in four compartments: vascular, interstitial, alveolar, and lymphatic. There is a continual flux of water from the vascular compartment, via the interstitial compartment, to the lymphatic compartment. This compartmental model allows consideration of normal and pathologic mechanisms but is an oversimplification of the real situation. In the normal lung, alveolar arterioles and venules contribute significantly to the water flux from the circulation to the pulmonary lymphatic system, and some of the water that passes from the vascular compartment to the interstitium is reabsorbed into the circulation at other locations.

The vascular compartment is separated from the interstitial space by the capillary endothelium, which is thought to

be relatively permeable to water and small molecules but not to circulating proteins. The alveolar compartment is separated from the interstitial space by its epithelium, which is much less permeable to fluids and solutes. The alveolar-capillary interstitial space is continuous with that of the perivascular and peribronchial regions and thus with the lymphatic system that drains these spaces.

Pulmonary arterial pressure produces a positive hydrostatic pressure within the vascular compartment, whereas the forces of elastic recoil probably produce a subatmospheric pressure within the lung interstitium. This hydrostatic pressure difference tends to move fluid out of the capillary circulation into the interstitial space. However, because the endothelial membrane is impermeable to macromolecules, an osmotic gradient tends to keep water within the vascular compartment. The hydrostatic force varies considerably from the highest to the lowest point in the lungs, but on average, it exceeds the osmotic force. Hence there is a small, continuous flux of fluid from the vascular compartment to the interstitial space. Because the alveolar epithelial membrane is relatively impermeable, this fluid tracks to the perivascular and peribronchial interstitium, where it flows into the pulmonary lymphatic system.

The capillary endothelial and alveolar epithelial membranes are composed of single layers of cells. At the point where the two layers touch, the basement membranes are fused, and there is no true interstitial space. Where the two layers are not in direct contact, there is an interstitial space consisting of a matrix of proteins and proteoglycans.[135,136] The passage of water and solutes between the compartments is determined by the membrane structures, and the flow through the interstitium is affected by the properties of the matrix. Substances may cross membranes either between the cells or through them. The endothelial and epithelial membranes vary in both their transcellular and pericellular permeability.

The endothelial membrane is formed from a homogeneous cell type with relatively permeable cell-to-cell junctions (gap junctions, tight junctions, and zonula adherens), and most flux occurs between the cells. Transcellular fluid and solute flux can occur,[137] but the degree to which it contributes to the permeability of the endothelial membrane is controversial.

The alveolar epithelial membrane is made up from two different cell types (types I and II), and they vary in their mechanisms of transcellular fluid transport. The epithelial membrane is characterized by tight apposition at the cell-to-cell junctions. The membrane has well-developed mechanisms for the active transcellular transport of ions and hence water. In fetal life, the active transport of chloride into the alveolar space leads to the secretion of fluid into the alveoli. This is the source of the "lung fluid" that passes up the airway and into the amniotic cavity.[138] In postnatal life, the active transport of sodium out of the airspace results in reabsorption of water that may have leaked into the alveolus.[139] This mechanism becomes more active during healing after alveolar injury. Type II alveolar cells may be more active in the reabsorption of sodium and water than the type I cells, and this fits with the observation that type II cells are not prominent until toward the end of fetal maturation but are very prominent in the healing lung.

Pulmonary edema occurs when the rate of fluid flux out of the vascular compartment exceeds the rate at which it can be cleared from the lung. A number of safety mechanisms help prevent the accumulation of excessive amounts of extravascular water. First, if an increased amount of fluid but not protein passes from the vascular to the interstitial compartment, then the osmotic gradient between the compartments increases and encourages fluid to remain within the circulation. This mechanism cannot occur if there is a pathologic increase in endothelial protein permeability. Second, the perivascular interstitium has limited capacitance, and fluid accumulation quickly increases the interstitial hydrostatic pressure and thus reduces the flux of water. Third, the pulmonary lymphatic system has a tremendous reserve capacity and can clear interstitial fluid formation at a rate at least 10 times the basal level.[134,140] Fourth, accumulation of interstitial fluid leads to hyperpnea (possibly by the stimulation of juxtacapillary J receptors), and increased breathing movements augment pulmonary lymphatic flow.

Formation of Pulmonary Edema

Pulmonary edema occurs when the rate of fluid flux from the vascular to the interstitial compartment exceeds the rate at which it can be cleared by reabsorption or by the lymphatic system. It is thought that a phase of interstitial edema appears first and that, later, fluid leaks through the epithelial membrane to form alveolar edema.

The route by which interstitial fluid leaks into the alveolus is still uncertain. It may be that fluid breaches the cell-to-cell junctions of the alveolar epithelial membrane,[141] or it may be that fluid tracks to the peribronchiolar interstitium and then through the more permeable epithelium of the terminal bronchioles and back into the alveoli.[140-143] In lung injury from noxious substances that have been inhaled (e.g., toxic gas) or aspirated (e.g., gastric acid), direct leak through the damaged alveolar epithelium is most likely.

Etiology of Pulmonary Edema

The various causes of pulmonary edema (Box 19-4) may be classified by primary abnormality into two types: increased hydrostatic pressure (Box 19-5) or increased permeability. The increased hydrostatic pressure pulmonary edema is sometimes called cardiogenic pulmonary edema, as one of the main causes in adults is a left ventricular function failure, with the consequent elevation in the end-diastolic left ventricular pressure and left atrial pressure. In general, left atrial pressures of more than 25 mm Hg are associated with overt pulmonary edema. The two forms of pulmonary edema are sometimes difficult to distinguish clinically. Tools useful for the differentiation are some radiographic criteria (such as the width of the vascular pedicle, the vascular distribution, etc.),[144] echocardiographic evaluation,[145] pulmonary artery catheterization,[146] and, more recently, brain natriuretic peptide.[147] Although convenient,[148] this classification ignores the fact that in many conditions, both types of edema coexist. For example, the edema associated with increased pulmonary microvascular hydrostatic pressure in left-sided heart failure is often exacerbated by an increase in capillary endothelial permeability brought about by stretching of the porous cell-

BOX 19-4 Causes of Pulmonary Edema Classified by Mechanism

Increased Hydrostatic Pressure Gradient

Increased capillary pressure (see Box 19-5)
Decreased interstitial pressure
- Upper or lower airway obstruction
- Lung re-expansion

Increased Permeability

Pneumonia (bacterial or viral)
Acute respiratory distress syndrome (ARDS)
Generalized sepsis
Aspiration
Near-drowning
Inhalation of smoke or toxic gases
Thermal inhalation injury
Oxygen toxicity
Hypersensitivity reactions

Decreased Oncotic Pressure Gradient

Decreased intravascular oncotic pressure
- Hypoalbuminemia
- Water overload

Increased interstitial oncotic pressure secondary to increased permeability

Decreased Lymphatic Drainage

Congenital pulmonary lymphangiectasis
Decreased drainage after lung transplantation

Uncertain or Mixed Pathogenesis

Neurogenic pulmonary edema
Narcotic abuse

BOX 19-5 Causes of Increased Capillary Pressure Classified by Primary Site

Increased Systemic Arterial Pressure

Aortic coarctation
Renal hypertension

Increased Left Atrial Pressure

Mitral valve disease
Cor triatriatum

Increased Pulmonary Venous Pressure

Obstructed anomalous pulmonary venous drainage
Pulmonary veno-occlusive disease
Mediastinal tumor or fibrosis

Increased Left Ventricular End-Diastolic Pressure

Aortic valve disease
Left ventricular outflow obstruction
Cardiomyopathy (including anthracycline toxicity)
Myocarditis
Myocardial ischemia
Pericarditis or effusion
Dysrhythmias

to-cell junctions. In inflammatory lung diseases such as ARDS and pneumonia, in which the permeability of the capillary endothelium to proteins increases, the osmotic gradient that resists fluid flux into the interstitium is reduced. The resulting increase in extravascular lung water is greatly exacerbated by increases in capillary hydrostatic pressure (e.g., resulting from left ventricular dysfunction or the administration of plasma expanders). If colloid plasma expanders are infused as the capillary permeability is increased, the colloid molecules (human serum albumin, gelatin, dextran, and starch) enter the interstitial space; when the endothelium again becomes impermeable to protein and colloids, the osmotic gradient between the plasma and lung interstitium remains low, and the duration of pulmonary edema is prolonged.[149] Additionally, it has been well demonstrated that high levels of brain natriuretic peptide are not as useful in critically ill patients, in whom they could be elevated even in the absence of congestive heart failure.[150] There is no consensus on the usefulness of brain natriuretic peptide in pediatric patients,[151] although there are reports that indicate that there is also considerable overlap in pediatric critically ill patients with and without left ventricular dysfunction.[152] More details on the mechanisms of pulmonary edema formation, clinical features, and management are given in the chapters dealing specifically with the relevant conditions, but some miscellaneous conditions are covered here.

Increased Permeability of the Alveolar-Capillary Membrane

Increased permeability of the alveolar-capillary membrane may occur as a direct result of the primary disease mechanism (e.g., inhaled toxins, bacterial toxins) or the effects of circulating mediators (e.g., cytokines, eicosanoids, complement). Neutrophil adhesion to the pulmonary capillary endothelium, which is mediated by selectin or integrin complexes or by platelet-activating factor on the endothelial cell membrane, leads to the release of proteases or oxygen-derived free radicals. Depletion of endothelial cell ATP production caused by oxidant damage impairs the membrane sodium-potassium pump, leading to osmotically induced cell swelling. Disassembly of the cytoskeleton as a result of paucity of ATP contributes to the endothelial cells' becoming globular in shape, opening up intercellular tight junctions, and increasing microvascular permeability.[153]

Decreased Oncotic Pressure Gradient

Hypoproteinemia, either as a primary condition (e.g., in liver disease or malnutrition) or as a result of water overload, does not usually lead to pulmonary edema. However, it may exacerbate the edema associated with other conditions. For example, excessive infusion of crystalloid solutions greatly increases extravascular lung water in a patient with raised capillary hydrostatic pressure caused by left ventricular failure.

Decreased Interstitial Pressure

A small number of children with acute obstruction, particularly of the upper airway (e.g., laryngotracheobronchitis, epiglottitis, laryngospasm), develop pulmonary edema.[154] This can occur after even very brief periods of obstruction[155,156] and is often manifested only after the obstruction has been relieved by endotracheal intubation. A simplistic view of the etiology suggests that decreased interstitial hydrostatic pressure tends to draw water across the capillary endothelium into the interstitial space. The reason that fluid enters the alveolar airspace is less clear, as is the reason that often the edema appears only after removal of the obstruction. Other factors that may be important include an increase in capillary endothelial permeability caused by hypoxia and a shift of blood from the systemic to the pulmonary circulation as a result of circulating catecholamines.

Neurogenic Pulmonary Edema

Brain injury from a variety of causes (e.g., trauma, hypoxia, ischemia, meningitis) is sometimes complicated by the development of pulmonary edema. The mechanisms have not been well studied in humans, but a number of experimental animal models of brain injury have given some insight into the causes.

The pathogenesis of neurogenic pulmonary edema is thought to result mainly from increased capillary hydrostatic pressure, probably from a component of myocardial dysfunction,[157] but the relatively high protein content of the edema fluid suggests that the increased permeability of the alveolar-capillary membrane may also be important. The main feature of neurogenic pulmonary edema is the activation of both the neural and humoral components of the sympathetic nervous system.[158,159] Generalized vasoconstriction leads to a shift of circulating volume to the pulmonary circulation. Systemic vasoconstriction increases left ventricular afterload, and relative left ventricular failure tends to increase pulmonary capillary pressure. The increased permeability, previously documented, may result from stretching of the porous cell to cell junctions or from endothelial damage caused by some circulating mediators (not yet proved). The hemodynamic disturbances described can be transient, yet the features of pulmonary edema can persist for much longer. This suggests that the circulatory changes may be the initial event and that damage to the capillary endothelium with protein leakage causes the condition to persist.

Disturbances in Lung Function Caused by Pulmonary Edema

The development of pulmonary edema profoundly affects the mechanical and gas-exchanging properties of the lungs. Lung compliance is reduced by several mechanisms. The presence of large amounts of interstitial edema reduces the distensibility of the lungs and promotes the collapse of the alveoli and small airways. Flooding of the alveoli with fluid physically disrupts the surfactant layer at the air-fluid interface, and the presence of protein and cellular debris impairs the activity of surfactant.[160,161] These effects lead to greatly increased surface tension in the fluid lining of small airspaces and tend to collapse these spaces (atelectasis). Airway resistance is increased by the physical presence of fluid in the small airways and by the compression of the small airways by fluid that has accumulated in the peribronchial interstitium. The combined effects of reduced lung compliance and increased airway resistance greatly increase the work of respiration, which may lead to respiratory muscle fatigue and respiratory failure.

The gas-exchanging properties of the lung are impaired by the presence of pulmonary edema. Interstitial edema probably causes only a small reduction in gas exchange because the fused basement membranes of the alveolar-capillary membrane prevent accumulation of fluid at this point. Alveolar edema significantly impairs oxygenation. Lung units may be unventilated because they are flooded with fluid or because the airways supplying them are obstructed. Blood flow to unventilated lung units may be reduced by hypoxic vasoconstriction, but significant $\dot{V}/\dot{Q}$ mismatch usually remains with consequent hypoxemia.

Hyperventilation with hypocapnia is a common feature in the early course of pulmonary edema. Arterial hypoxemia and anxiety probably provoke increased ventilation. Stimulation by edema of the J receptors in the airways also leads to rapid, shallow respirations.

Pulmonary arterial hypertension is a frequent feature of pulmonary edema. It may lead to right-sided heart failure if sufficiently severe. Pulmonary hypertension is probably a result of hypoxic vasoconstriction in poorly ventilated lung units and direct vascular compression from edema in the perivascular interstitium.

Summary

Pulmonary edema is a feature of many conditions of diverse etiology. The effects on lung mechanics and gas exchange make it one of the common causes of respiratory failure.

CARDIORESPIRATORY INTERACTIONS

Interactions among the functions of the circulatory and respiratory systems are very complex.[162] The functions of the respiratory system have a modest effect on cardiac function under normal conditions, and this effect may vary qualitatively or quantitatively if there is respiratory or cardiac disease.

Physiologic Cardiorespiratory Interactions

Diagrams of the circulatory and respiratory system often show the right and left sides of the heart as two separate pumps connected in series via the circulation of the lungs. This is obviously a gross oversimplification. The facts that the two sides of the heart share a common muscular septum, share common circular muscle fibers, and are enclosed together in the pericardial cavity (Fig. 19-9) mean that they do not act independently. Similarly, the fact that the two sides of the heart and the pulmonary circulation are contained, along with the rest of the lung tissues, within the closed thoracic cavity means that changes in lung volume and intrathoracic pressure influence circulatory function.

The output from either cardiac ventricle is determined by its venous filling (preload), the force of muscular contraction (contractility), and the pressure gradient against which it has

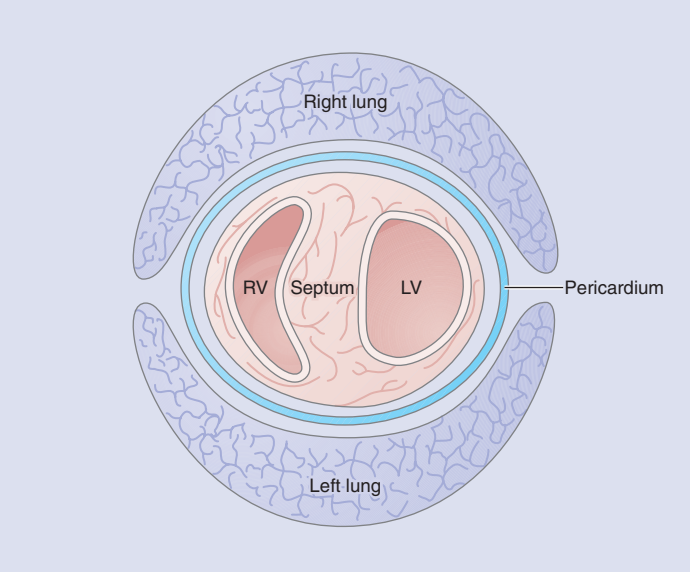

Figure 19-9 Diagrammatic cross section of the cardiac ventricles and lungs, which interact during respiration and the cardiac cycle. The right ventricle (RV) and left ventricle (LV) share a common septum, and the right is wrapped around the left. The muscle fibers of the free walls of the two ventricles are in continuity. The pericardial sac surrounds the two ventricles and in turn is surrounded by the lungs, pleura, and chest wall. See text for details of this interaction. (From Robotham JL: Hemodynamic events: A physiological approach. In Montenegro HD [ed]: Chronic Obstructive Pulmonary Disease, New York, Churchill Livingstone, 1984, pp 183-217.)

to eject (afterload). The afterload is determined by the transmural pressure gradient, which is the difference in pressure between the ventricular cavity and the surrounding intrathoracic pressure. The output of either ventricle may also be influenced by the pressure or volume of the other ventricle. The anatomic reasons for this ventricular interdependence have already been outlined.

Changes in intrathoracic pressure have differing effects on the preload and afterload of the two ventricles. The capacitance vessels (veins), which supply the right ventricle, lie outside the thoracic cavity, whereas the arterial circulation that the ventricle supplies is within this cavity. The reverse is true for the left ventricle.

EFFECTS OF SPONTANEOUS RESPIRATION IN A HEALTHY SUBJECT

Table 19-1 outlines how inspiration and a fall in intrathoracic pressure affect circulatory function in a healthy subject. Several of the effects cancel each other out, but the overall results are a transient increase in right ventricular output and a decrease in output from the left ventricle. The cyclic respiratory effects are easily seen in the pressure waveform trace from a peripheral systemic arterial catheter in a spontaneously breathing subject. Systolic arterial pressure varies up to 10 mm Hg between inspiration and expiration.

Because the ventricles are connected in series, such differences in output cannot be sustained. In a prolonged inspiration, the output from the left ventricle falls initially (because of the mechanisms previously outlined), and then within three or four cardiac cycles, it rises again as the increased output from the right ventricle reaches the left. The effects of expiration and a rise in intrathoracic pressure are essentially the reverse of those seen in inspiration.

Table 19-1
Effects of a Normal Inspiration

Effect	Mechanism (Because of a Fall in Intrathoracic Pressure)
Increase in right ventricular preload	Increase in the pressure gradient from the systemic veins to the right atrium
Increase in right ventricular afterload	Increase in the transmural pressure gradient of the right ventricle
Decrease in right ventricular afterload	Distention of the pulmonary vascular bed and reduction in its resistance to flow
Decrease in left ventricular preload	Distention of the pulmonary vasculature and a fall in the pressure gradient from the pulmonary veins to the left atrium
Increase in left ventricular preload	Fall in left atrial pressure and increase in the pressure gradient from the pulmonary venous return to the left atrium
Decrease in left ventricular filling	Increased right ventricular filling with ventricular interdependence from septal shift
Increase in left ventricular afterload	Increased transmural pressure gradient of the left ventricle

Apart from breath-holding (apnea), neither respiratory phase is prolonged. The cyclic changes in ventricular output with respiration merge from one breath into the next, and the observed changes in cardiac output depend to some degree on the relative cardiac and respiratory rates.

Cardiovascular Effects of Pathologic Pulmonary Conditions

Many respiratory conditions are complicated by pulmonary arterial hypertension. The way that pulmonary hypertension reduces left ventricular filling and increases right ventricular afterload can profoundly affect cardiac function, and this subject is discussed in detail in Chapter 53.

Respiratory conditions that lead to reduced lung compliance (e.g., pneumonia, HMD, pulmonary fibrosis) or increased airway resistance (e.g., asthma, bronchiolitis, emphysema) lead, for any given level of respiratory effort, to greater swings in intrathoracic pressure than would occur in a child with normal lungs. These swings are manifested as indrawing of the soft tissues and even the ribs in the relatively compliant chest wall of a child with these conditions. These large swings persist while normal or increased respiratory effort is maintained but diminish as respiratory muscle fatigue ensues.

The effects of obstructed expiration on the cardiovascular system are similar to those of the Valsalva maneuver. Venous return and flow in the pulmonary system are severely reduced by the high intrathoracic pressure early in expiration, but there is a small initial increase in cardiac output and blood pressure as a result of expulsion of blood from the lungs and compression of the left ventricle and thoracic aorta. The reduced venous return then reduces the cardiac output and blood pressure, provoking a baroreceptor response to tachycardia and vasoconstriction that causes a rebound hypertension when the forced expiration is released and venous return increases.

Obstructed inspiration causes cardiovascular effects similar to those of a Müller maneuver (forced inspiration against a closed glottis). Low intrathoracic pressure increases systemic venous return and expands the pulmonary blood volume, but venous return to the left ventricle, the systemic cardiac output, and the blood pressure decrease early in inspiration but approach normal later in inspiration.

Conditions causing hyperinflation of the lungs and high airway resistance (e.g., asthma) can lead to substantial changes in cardiac performance. Increased negative pressure during inspiration and positive pressure during active expiration lead to big swings in intrathoracic pressure and exaggeration of the normal cyclic changes in right and left ventricular preload and afterload.[163] The variation in left ventricular stroke volume leads to a palpable swing in systolic systemic arterial pressure with respiration.[164] This *pulsus paradoxus* is an exaggeration of the normal pattern, and it can be used as a tool to evaluate the severity of the hyperinflation.[165] Pulsus paradoxus can also be observed in other conditions, such as pericardial tamponade.[166] In severe airway obstruction, pulmonary vascular resistance is increased by elevated lung volume, hypoxic vasoconstriction, and acidosis.

Respiratory Effects of Cardiovascular Disorders

Increased left atrial pressure resulting from reduced left ventricular contractility or compliance, pulmonary venous obstruction, mitral valve disease, pericardial disease, or hypervolemia causes pulmonary edema and affects lung mechanics and gas exchange (see earlier section). As the cardiac output decreases, increased tissue oxygen extraction reduces the mixed venous P_{O_2}. The consequent reduction in pulmonary end-capillary P_{O_2} (and therefore Pa_{O_2}) is greater for lung units with normal $\dot{V}/\dot{Q}$ ratios than in those with high or low $\dot{V}/\dot{Q}$ ratios.[167] Although the mixed venous P_{CO_2} also increases when the cardiac output is low, the rapid diffusion of carbon dioxide across the alveolar membrane means that the Pa_{CO_2} is not normally increased by a reduction in cardiac output.[168]

Reduction in cardiac output also decreases the pulmonary pressure, decreasing the perfusion to the uppermost parts of the lung and increasing the alveolar dead space. In practice, this is only important in the upright position. As previously described, a decrease in respiratory muscle blood flow as a result of low cardiac output contributes to respiratory muscle fatigue when the work of breathing is increased. If the decrease in cardiac output is predominantly caused by left ventricular failure, then the pulmonary artery occlusion pressure will be elevated and pulmonary edema may develop, as discussed in the previous section. It must be noted that the cardiorespiratory interactions are highly complex and do not follow a linear pattern, implying that more sophisticated nonlinear mathematical analysis may be superior for their evaluation.[169]

Effects of High Cardiac Output

In severe exercise, the cardiac output is very high, and pulmonary transit time is reduced. Diffusion limitation reduces the pulmonary end-capillary P_{O_2} and increases the $P_{AO_2} - Pa_{O_2}$. During short bursts of severe exercise in trained athletes, the Pa_{O_2} falls below 75 mm Hg.[170] The high cardiac output found in septic shock is associated with reduced oxygen extraction and a high mixed venous P_{O_2}, so the effect on Pa_{O_2} of diffusion limitation as a result of high cardiac output is not as pronounced in these patients. In the presence of lung disease, inotropic drugs that increase the cardiac output tend to increase the $P_{AO_2} - Pa_{O_2}$ and reduce the Pa_{O_2} by increasing the perfusion of unventilated alveoli and of low $\dot{V}/\dot{Q}$ lung units.[84]

ACUTE RESPIRATORY DISTRESS SYNDROME

ARDS is a clinical syndrome with multiple etiologies.[171] The hallmark is an acute change in lung function characterized by pulmonary edema resulting from increased alveolar-capillary permeability. This results in severe hypoxemia, decreased lung compliance, and the appearance of bilateral pulmonary infiltrates on chest radiograph. Inflammation plays a part in the pathogenesis, and fibrosis occurs in the lung parenchyma during resolution. Alveolar injury is diffuse but not uniform throughout the lung.[171] ARDS can be considered the pulmonary manifestation of the systemic inflammatory response syndrome (SIRS).[172]

ARDS may occur after direct or indirect lung injury. Septicemia, near-drowning, hypovolemic shock, and closed-space burn injury were the most common antecedent illnesses in children reported by Pfenninger and colleagues.[173] ARDS is also seen in immunocompromised children after treatment for malignancy[174]; in association with respiratory infections, including mycoplasma,[175] respiratory syncytial virus,[176] and herpesvirus[177] infections; and after major head injury,[178] multiple trauma,[179] asphyxia,[180] and chemical aspiration.[181] Studies of adults indicate that patients with multiple predisposing conditions (e.g., trauma, multiple transfusions, disseminated intravascular coagulation) are at a much greater risk of developing ARDS than those with a single risk factor.[182] The lung injury associated with cardiopulmonary bypass and ECMO support has the pathophysiologic features of ARDS.[183]

Disease Mechanisms

The pathology of ARDS has been extensively reviewed by Bachofen and Weibel,[184] and more recently by the American-European Consensus Conference on ARDS.[171] In the initial stage, there is damage to and edema of the interalveolar septa. There is extensive destruction of type I alveolar epithelial cells. Although on electron microscopy, the endothelial cell basement membrane appears relatively intact, this barrier becomes permeable to plasma proteins, and interstitial edema results. Proteinaceous fluid first collects within the peribronchial and perivascular connective tissue, then within the alveolar septa, and later in the alveoli. Edema fluid contains erythrocytes, leukocytes, fibroblasts, macrophages, cell debris, albumin, globulins, and amorphous material comprising strands of fibrin. Hyaline membranes form along the inner surface of the alveoli. As the alveoli and interstitium fill with exudate, the gas-exchanging and mechanical properties of the lung deteriorate. There are reduced lung volumes and poor compliance with $\dot{V}/\dot{Q}$ mismatching, intrapulmonary shunting, and increased dead space.[185,186]

Microthrombosis of pulmonary vessels occurs as a result of intravascular coagulation, pulmonary vascular congestion,

and the sequestration of neutrophils and platelets that plug the pulmonary capillaries. This further exacerbates endothelial damage, high pulmonary vascular resistance, and $\dot{V}/\dot{Q}$ mismatching.

In the first days of ARDS, the capillary endothelial and alveolar epithelial barrier are reduced in thickness by cellular necrosis. By the end of the first week, there is regeneration of the endothelium, and the destroyed type I pneumocytes that line the alveoli are replaced by the marked proliferation of thicker, cuboidal, type II pneumocytes. This phase of ARDS may result in complete resolution of the process or may progress to interstitial fibrosis. Fibrosis commences after the first week and particularly involves the alveolar walls. Pulmonary fibrosis rapidly and progressively obliterates the alveoli, alveolar ducts, and pulmonary interstitial space, which also is expanded by edema fluid and inflammatory cells. The apposition between the alveolar epithelium and capillary endothelium is then separated by bulky type II pneumocytes and fibroblasts in the alveolar septum and interstitium. In advanced cases of ARDS, when thickening of the alveolar wall is extensive, gas exchange is too impaired to support life. Intra-alveolar hemorrhage may be focally present in some cases but is generally not severe. Although alveolar damage is widespread in ARDS, the lung is not uniformly affected. Computed tomography of patients with ARDS shows the distribution of lung collapse to be mainly in the dependent regions.[187]

Although the predisposing causes of ARDS are known and the histopathologic changes well characterized, there is still uncertainty as to the exact role and timing of the mediators involved. Neutrophils probably have a central role in the genesis of endothelial injury[188] and lung injury associated with ARDS.[189] They are sequestered early into the lung, drawn to the lung by chemotactic components of the complement cascade (C5a), prostaglandins, tumor necrosis factor, leukotrienes, and platelet activating factor (PAF). Neutrophils release interleukin-1 and toxic oxygen radicals that cause cell destruction. Oxygen-derived free radicals, such as hydrogen peroxide and the hydroxyl radical, are bactericidal agents, which may produce host membrane damage by causing lipid peroxidation or by making target proteins more susceptible to proteolytic cleavage. Oxygen radicals also inhibit the action of α_1-antitrypsin, allowing unopposed activity of elastase and other proteolytic enzymes, which are capable of degrading elastin, collagen, proteoglycans, fibronectin, and structural components of basement membranes and the intercellular matrix. The role of oxygen radicals in ARDS has been recently reviewed by Zhang and coworkers.[190] Neutrophils stimulate the production of arachidonic acid metabolites—prostaglandin, thromboxanes, and leukotrienes—some of which cause increased capillary permeability, vasoconstriction, and platelet aggregation and are chemotactic for neutrophils.[191] Leukotriene levels in plasma and bronchoalveolar lavage have been associated with the inflammation and the risk of mortality from ARDS.[192,193]

Large numbers of platelets are present in pulmonary capillaries in ARDS. They aggregate, causing increased microvascular hydrostatic pressure, and release arachidonic acid metabolites. The number of alveolar macrophages increases greatly. These cells produce cytokines such as tumor necrosis factor and the interleukins, which cause tissue damage.

The role of PAF in acute lung injury has been reviewed by Anderson and associates.[194] PAF is produced by endothelial cells, type II pneumocytes, marginating neutrophils, and alveolar macrophages. PAF causes microvascular leakage and margination of leukocytes and contributes to the development of intravascular coagulation in lung capillaries. PAF seems to be essential in the macrophage response to endotoxin.[195] The levels of PAF and those of the enzyme that metabolizes it, PAF-acetylhydrolase, are increased in the bronchoalveolar lavage fluid of patients with ARDS.[196,197]

Role of Pulmonary Hypertension

Zapol and Snider[186] found pulmonary artery hypertension and elevated pulmonary vascular resistance in 30 patients with ARDS associated with increased right ventricular stroke work. In adults[186] and children[185] with ARDS, pulmonary artery pressure and vascular resistance gradually fall after several days in survivors but increase progressively in those who die. Severe pulmonary hypertension can result in right ventricular failure and a low cardiac index. Right ventricular dilation leads to a leftward septal shift, impairing left ventricular diastolic filling. Coronary blood flow to the right ventricle decreases, producing myocardial ischemia and further compromising right ventricular function.

Inhaled nitric oxide administered by inhalation to children with ARDS causes a significant fall in pulmonary artery pressure and intrapulmonary shunting and an increase in the cardiac index, up to a dose of 20 ppm.[198] Intrapulmonary shunting decreases because inhaled nitric oxide preferentially dilates the pulmonary vessels that supply ventilated alveoli, increasing their blood flow at the expense of less well ventilated parts of the lung. Above 20 ppm, there was no further increase in oxygenation or beneficial effect on pulmonary hemodynamics. A randomized controlled trial in adults with ARDS revealed that nitric oxide, at doses of 5 ppm, did not improve the outcome, either in terms of survival or duration of mechanical ventilation, although there were short-term improvements in oxygenation.[199]

Role of Secondary Infection and Multiple Organ Failure

ARDS may be associated with organ failure of other systems as a result of the same insult (e.g., brain failure and ARDS after the hypoxic-ischemic injury of near-drowning). Renal failure, gastrointestinal hemorrhage, disseminated intravascular coagulation, impaired liver function, bone marrow suppression, and altered cerebral function are commonly associated with severe ARDS,[200] especially during the late stages. In the initial description of the sepsis syndrome by Bone and colleagues,[201] 25% of 191 patients developed ARDS. Pfenninger and associates[173] described 20 children with ARDS, of whom 60% had coagulation failure, 40% had renal failure, 40% had brain dysfunction, and 30% had hepatic or gastrointestinal failure. Nonsurvivors had more organ systems failing than those who survived. Interventions aimed to decrease the inflammatory impact of noxious stimuli, such as lung protective strategies or tight glucose control, may be associated with a decreased incidence of both ARDS and multiple organ failure in at-risk patients.[202]

Infection may occur in children with ARDS as part of the manifesting illness, or it may be nosocomially acquired from indwelling catheters or endotracheal tubes or endogenously

acquired secondary to gut ischemia or the use of broad-spectrum antibiotics. Bacteremia was present in 45% of Bone's patients but did not influence the patient's outcome.[201] In Pfenninger's study,[173] 15% of the children with multiple organ dysfunction developed culture-proven septicemia and died. Although culture-proven bacterial infection is common in patients with multiple organ system failure, it is not a prerequisite. The lung is the most common source of sepsis at autopsy in adults with clinical sepsis but negative blood cultures. The high risk of secondary infections in the ARDS patient may stem from a functional immunodepression, likely caused by the up-regulation of anti-inflammatory mediators after the acute phase of injury.[203,204]

The roles of gastrointestinal tract mucosal ischemia and loss of barrier function in the development of multiple organ failure are yet to be fully elucidated, but there is evidence that gut ischemia is associated with the translocation of bacteria, endotoxin, and other bacterial toxins and the activation of neutrophils, which may affect distal organs, including the lungs.[205,206] This has been sometimes called the *gut hypothesis*. Gut mucosal ischemia may occur in ARDS secondary to hypoxemia or inadequate cardiac output with redistribution of blood flow away from the gut and toward other vital organs such as the brain and heart. The gut hypothesis has been recently modified to emphasize the role of gut-derived factors in the intestinal lymph, more than in the portal blood. This is now called the *gut-lymph hypothesis*.[207,208]

CLINICAL MANIFESTATIONS

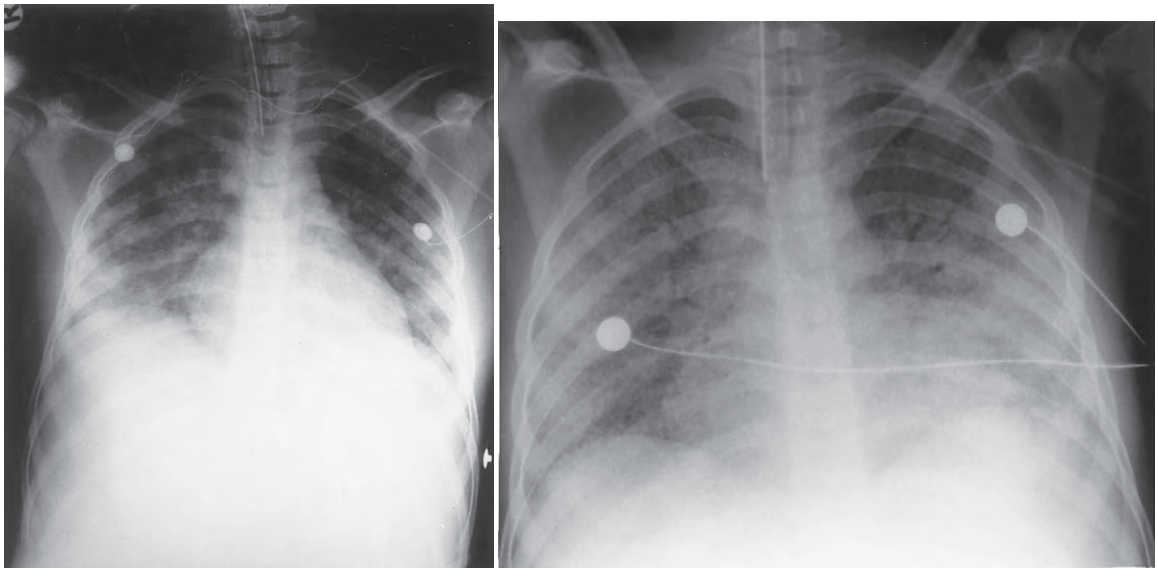
After the event or illness that precipitates ARDS, there may be clinical signs of respiratory distress, or the signs may develop later, commonly in the first 48 hours. Tachypnea is the first sign, at which stage the chest radiograph is often normal. Chest retractions, expiratory grunt, alar flaring, and cyanosis may also be present. Initially, there is respiratory alkalosis. Later, there is severe hypoxemia with a large $P_{AO_2} - P_{aO_2}$ difference and a rising P_{aCO_2}. The lungs become noncompliant with diffuse bilateral infiltrates on the chest radiograph (Fig. 19-10). The final phase involves widespread bilateral consolidation with hypoxemia in 100% oxygen and severe hypercarbia as well as respiratory and often metabolic acidosis. Multiple organ failure often ensues. Not all patients progress at the same rate or to the same extent. The condition may partially or completely resolve at any stage.

MANAGEMENT

The prevention of ARDS should be one aim of the treatment of all critically ill children. The principles of management are to treat the underlying cause if possible, ensure adequate tissue oxygenation, and prevent complications.

Investigating for Treatable Causes

Many factors cause a child's ARDS. For some children, there is no specific treatment. Treatable causes such as infection should be identified and treated. The search for primary or secondary lung infection may require culture of tracheal aspirates, bronchoalveolar lavage (BAL) fluid, or lung biopsy specimens. Lung biopsy may be clinically useful in adults with ARDS who are on ventilators, but lung biopsy has not been compared with less invasive methods in prospective trials.[209] BAL can be performed safely in such patients.[210] The most common finding in BAL fluid in patients with ARDS is increased numbers of polymorphonuclear leukocytes, making up nearly 80% of the total cell population (normal, <5%). The one type of ARDS that may respond to corticosteroid therapy is characterized by an increased number of eosinophils in BAL fluid or by peripheral eosinophilia.[211] Prophylactic antibiotics are not beneficial in ARDS, but potential bacterial pathogens found in BAL fluid should be treated. Lung fluid should also be cultured for viruses.



A B

Figure 19-10 Chest radiographs of a 12-year-old girl with acute respiratory distress syndrome (ARDS) associated with acute hepatic failure. **A,** Radiograph 2 days after onset. There are widespread alveolar opacities, mostly in the lower zones. **B,** Radiograph 4 days after onset. There is widespread consolidation with air bronchograms and alveolar and interstitial opacities.

Herpes simplex virus was identified in the tracheal aspirates of 30% of 46 adults with ARDS, in whom it was associated with the need for more prolonged respiratory support and an increased mortality rate than was the case in patients in whom the BAL fluid did not grow the virus.[177] Herpes simplex virus has also been found in the lungs of patients with burn injury.[212] The role of reactivation of this virus in ARDS is unclear, and prophylactic antiviral agents are not indicated, but acyclovir may be useful if the virus is present. BAL fluid may also have other opportunistic pathogens, such as *Pneumocystis jiroveci*, which may present with acute respiratory failure in children with known or unsuspected impaired immunity.

Ensuring Adequate Tissue Oxygenation

The therapy for ARDS is based on support for the cardiorespiratory system to maintain adequate P_{AO_2}, P_{ACO_2}, and tissue perfusion. This involves attention to ventilation strategy as well as cardiac output and tissue oxygenation. Ventilatory support maintains arterial oxygenation at a safe level while preventing pulmonary oxygen toxicity and additional lung trauma resulting from excessive ventilatory volumes or pressures. PEEP was first used successfully to treat pulmonary edema in 1938[213] and has since improved the outcome in ARDS.[214] Despite this initial success in a controlled trial of adults at risk of ARDS, the early application of PEEP at 8 cm H_2O did not reduce the incidence of the syndrome.[215] PEEP is applied to increase lung volume, keep alveoli open, and recruit collapsed alveoli and small airways. It improves arterial oxygenation in ARDS. The theoretically optimal level of PEEP would be one that allows a reduction in F_{IO_2} to a safe level (less than 0.5), does not impair venous return to the heart or reduce cardiac output, does not impair cerebral venous drainage or increase intracranial pressure, and optimizes arterial oxygenation.

PEEP may reduce cardiac output in children[216] and adults[217] with ARDS. The mechanism is likely to be both a decrease in systemic venous return and an increase in right ventricular pressure load. The latter causes a leftward shift of the interventricular septum with a reduction in filling[217] and an impaired systolic ejection function of the left ventricle. By increasing alveolar volume, PEEP increases the resistance to flow through the alveolar capillaries and thereby increases right ventricular afterload. PEEP of at least 15 cm H_2O reduces the cardiac index in adults.[217] In children without cardiorespiratory disease, Clough and coworkers,[216] using Doppler measurements of cardiac output, found a fall in cardiac output of 3.7% at 5 cm H_2O of PEEP, 6.7% at 10 cm H_2O, and 15.9% at 15 cm H_2O. There was a wide variation in subjects studied, but there was a trend toward a greater fall in cardiac output for a given level of PEEP with increasing age. Ideally, the level of PEEP chosen would be based on the measurement of cardiac output and calculated oxygen delivery. PEEP levels should be gradually increased to achieve acceptable arterial saturation with nontoxic F_{IO_2} levels (<0.5), and the effect of PEEP on hemodynamics should be monitored clinically, if measurement of cardiac output, mixed venous P_{O_2}, or oxygen consumption are unavailable.[218] Titration of PEEP against clinical measures is inexact. Hypotension often does not become apparent until cardiac output substantially falls.[219] A recent large trial in adults with ARDS found no differences in mortality with high and low PEEP while using low tidal volumes.[220]

PEEP improves compliance by opening collapsed alveoli. If PEEP levels are too high, however, overdistention of already opened alveoli may lead to a reduction in compliance. According to Sivan and associates,[221] in children with acute respiratory failure, the level of PEEP that normalized the functional residual capacity was within 4 cm H_2O of the PEEP at which static respiratory compliance was maximal; in most cases, this was the same value. Their data also showed that the best compliance was not achieved when the PEEP level was chosen by clinical judgment alone. In addition to an assessment of optimal tissue oxygen delivery, an assessment of maximal static compliance may be helpful in choosing the level of PEEP. Despite intensive research, the PEEP goals and the methods for titrating to that goal remain unclear.[222]

PEEP may increase cerebral venous pressures and intracranial pressure by increasing the intrathoracic pressure and impairing cerebral venous drainage. This is particularly important in children with brain injury. In an animal model,[223] when a lesion causing raised intracranial pressure is associated with diffuse lung injury, the rise in intracranial pressure and reduction in cerebral perfusion pressure with increasing levels of PEEP are not as great as when the lungs are normal.[224] However, the high levels of PEEP that reduce cardiac output and require blood volume expansion may lead to reduced cerebral perfusion pressure with resultant cerebral ischemia as well as volume overload, which may cause cerebral edema.

Other strategies of ventilation include a control-assist mode of ventilation, intermittent positive-pressure ventilation (IPPV) with or without paralysis, intermittent mandatory ventilation, permissive hypercapnia, inverse ratio ventilation, and high-frequency oscillatory ventilation (HFOV). Some form of synchronized, triggered, pressure-limited ventilation has been advocated[218] (e.g., pressure support, synchronized intermittent mandatory ventilation). The potential benefits of these modes of ventilation are limitations of acute rises in intrapulmonary pressures that occur with unsynchronized patient breaths, improved patient comfort, and avoidance of adverse effects of muscle relaxant medications, such as prolonged muscular weakness after the medications have been ceased. Many children with severe ARDS are unable to achieve adequate oxygenation at safe levels of F_{IO_2} and peak pressures without muscle relaxation, in which case, pressure-limited IPPV is required. Inverse-ratio ventilation increases the mean airway pressure by prolonging the inspiratory time.[225] This type of ventilation can enhance oxygenation after conventional ventilation has failed in some patients with ARDS[226] but may require heavy sedation and paralysis.[218]

HFOV has been used as an alternative to conventional ventilation in ARDS. In a randomized trial of HFOV versus conventional ventilation in children with ARDS, Arnold and collaeagues[227] found that HFOV produced greater increases in oxygenation with less barotrauma. There was no difference in other outcomes, including survival. Other studies in adults with ARDS also suggest that although high-frequency forms of ventilation may achieve preset ventilation criteria for oxygenation and gas exchange at lower inspired oxygen concentrations and lower peak pressures, there is no beneficial effect

on survival.[228] HFOV may be more likely to improve outcome if instituted as an early, rather than a late, rescue therapy.[229,230] The use of high-frequency ventilation in pediatric respiratory disease has been recently reviewed by Froese.[231]

Ventilation in the prone position in infants and children with ARDS has resulted in improved oxygenation at lower levels of inspired oxygen.[232] This strategy is based on the findings of Gattinoni and coworkers[187] that atelectasis occurred mainly in dependent parts of the lung. Regular turning from the supine to the prone position may reduce dependent atelectasis and intrapulmonary shunt. In older children who need mechanical ventilation, the lateral decubitus position can be used; this position has been advocated for patients with hypoxemia unresponsive to other medical interventions.[218] However, a well-designed randomized controlled trial using prone positioning in pediatric patients with ARDS found no improvement in any of the outcomes.[233]

Large tidal volumes, high peak airway pressures, and inspired oxygen concentrations above 0.6 have been implicated as causes of lung injury. Because of the smaller lung volume available for gas exchange in ARDS, the use of tidal volumes as small as 6 mL/kg is likely to be associated with fewer pulmonary and hemodynamic complications.[234] These small, relatively normal areas of lung are overinflated and are exposed to high positive inspiratory pressures unless low volume and pressure-limited ventilation are used. The now famous ARDS Network trial demonstrated an improvement in the survival of patients treated with low tidal volumes (6 mL/kg of predicted body weight), leading to an early stop of the trial and widespread recommendation to adopt this "protective lung strategy."[235] Although the study has been criticized for having too high tidal volumes in the control group, it stands as the best evidence in favor of using low tidal volumes. Low tidal volumes have been combined with relatively low ventilatory rates to produce controlled hypoventilation with permissive hypercapnia. Permissive hypercapnia (accepting a $PaCO_2$ up to 80 mm Hg and arterial pH above 7.15) is aimed at avoiding barotrauma and volutrauma. It is now an established and widely recommended strategy.[218]

The fluid management of patients with ARDS has also been a matter of controversy. A recent randomized controlled study compared two strategies, liberal and conservative, in the fluid management of adult patients with ARDS. There was no improvement in the survival at 60 days, but the conservative strategy was associated with shorter duration of mechanical ventilation and intensive care stay.[236]

OUTCOME

The mortality rate from ARDS in adults was about 50%,[237] and the morbidity in survivors is substantial. The new published trials have shown reductions in the mortality to 25% to 31%, reflecting the cumulative effects of improvements in critical care over the last 10 to 15 years.[238] The most recent trial in pediatric patients with ARDS reports a mortality rate of 21%.[233]

At long-term follow-up of respiratory function in nine children who survived ARDS,[239] three had recurrent respiratory symptoms consisting of moderate exertional dyspnea and cough, two had radiographic evidence of pulmonary fibrosis, and all had abnormal pulmonary function tests. The abnormalities consisted of ventilation inequalities in eight patients. The ventilation inequalities shown by multiple-breath nitrogen washout curves and obstructive airway disease were found in two patients. One child had residual restrictive lung disease. There was a mild degree of hypoxemia in seven of the children. The results were more favorable in a more recent series of pediatric long-term survivors of ARDS, with normal or near-normal pulmonary function, albeit the number of patients studied is still very small.[240]

CHAPTER 20 Cardiopulmonary Resuscitation

Robert A. Berg and Vinay M. Nadkarni

TEACHING POINTS

- Cardiac arrests in children are uncommon, but not rare.
- Ventricular fibrillation occurs in ~25% of pediatric cardiac arrests.
- There are four phases of cardiac arrest: pre-arrest, no flow (untreated arrest), low flow (CPR), and post-resuscitation.
- Excellent advanced life support depends on excellent basic life support.
- PUSH HARD, PUSH FAST, minimize interruptions, allow full chest recoil, and avoid overventilation.

Pediatric cardiopulmonary resuscitation (CPR) has a rich history. For example, Kouwenhoven and colleagues first described closed chest cardiac massage in small dogs with compliant chest walls, and then established that this technique could provide circulation and result in resuscitation from cardiac arrest in children.[1] Only later did they extend the technique to adults.

CPR in children differs from that in adults.[2,3] Infants and children are anatomically, physiologically, and developmentally different from adults. In particular, the chest wall configuration and compliance of an infant are quite different from that of an adult. Perhaps more important, the etiology and pathogenesis of cardiac arrests in children are different.[2-21]

In contrast to adults, children rarely suffer sudden ventricular fibrillation (VF) cardiac arrest from coronary artery disease. Cardiac arrests in children are typically precipitated by progressive respiratory insufficiency or circulatory shock.[2-21]

Coping with a sudden unexpected death is always difficult; however, when the victim is a child, the loss tends to be more devastating. Although we know that each life is temporary, we do not expect children to die and thus are not prepared for it. Therefore, health care providers who are otherwise able to deal with most devastating problems often become emotional, and occasionally dysfunctional, when faced with a dying child. The experience for the family is naturally more intense and longer lasting. Children are the family's future. Many families never overcome the grief associated with the premature death of a child.

Definition of Pulseless Cardiac Arrest

Pulseless cardiac arrest is typically defined as the documented cessation of cardiac mechanical activity, determined by the absence of a palpable central pulse, unresponsiveness, and apnea. Differentiating severe hypoxic-ischemic shock with poor perfusion from the nonpulsatile state of cardiac arrest can be challenging at any age. This differentiation can be especially difficult in babies because of smaller size and lower blood pressures. A rescuer's ability to determine cardiac arrest by a pulse check is neither sensitive nor specific in adults.[22-29] Not surprisingly, the pulse check is even more problematic in children.[27-29] In adults, pulses can typically be palpated until the systolic pressure is <50 mm Hg. Because the normal systolic blood pressure in neonates is generally 60 to 70 mm Hg, a decrease in blood pressure to "nonpalpable pulse" may occur earlier in the continuum from hypoxic-ischemic shock to nonpulsatile cardiac standstill. Furthermore, the best arterial pulse to palpate in an adult is the carotid pulse; however, the short, fleshy neck of a baby with potential to compress the airway and impede respiration limits the effectiveness of carotid pulse palpation in infants. Therefore, palpation of the brachial, femoral, or axillary pulse may be easier.[3,27-29]

EPIDEMIOLOGY

Pediatric In-Hospital Arrests

Cardiac arrests were reported in 3% of children admitted to one children's hospital,[5] in ~2% of children admitted to pediatric intensive care units (PICUs) in the United States, in 6% of children admitted to one PICU in Finland,[6] and in 4% of children admitted to a pediatric cardiac intensive care unit.[8] The most common causes of the arrests were progressive respiratory failure and progressive shock.

Several well-designed, relatively small single institution in-hospital pediatric CPR investigations with long-term follow-up have established that pediatric CPR and advanced life support can be remarkably effective.[4-10] Almost two thirds of these cardiac arrest patients were initially successfully resuscitated (i.e., attained sustained return of spontaneous circulation). Most of these arrests/events occurred in PICUs after progressive life-threatening illnesses that had not responded to treatment despite critical care monitoring and supportive care. The 1-year survival rates of 10% to 44% are substantially better than reported outcomes following out-of-hospital pediatric CPR. Almost three quarters of survivors to discharge have good neurologic outcomes.

The largest published reports of in-hospital pediatric cardiac arrests (880 patients and 1005 patients, respectively)

emanate from the American Heart Association's multicenter National Registry of Cardiopulmonary Resuscitation (NRCPR).[11,12] Most of these arrests occurred in children with progressive respiratory insufficiency and/or progressive circulatory shock.[11] These children often had progressive underlying critical illnesses and suffered cardiac arrest despite aggressive critical care monitoring and therapy. Therefore, 95% of these arrests were witnessed and/or monitored, and only 14% occurred on a general pediatric ward. Before the arrest, 57% of these children were mechanically ventilated, 38% had continuous vasopressor infusions, and 29% had continuous direct arterial blood pressure monitoring.

Despite the diverse and complex clinical circumstances leading to their arrests, 52% attained sustained return of spontaneous circulation, 36% survived for 24 hours, and 27% survived to hospital discharge. Outcomes for these children were substantially better than reported outcomes for adults in this registry (adjusted odds ratio, 2.3 [95% CI, 2.0 to 2.7]).[11] Approximately two thirds of the patients had relatively good neurologic outcomes. Interestingly, the better survival rate compared with adults is primarily because of better survival rates among infants and preschool children, presumably in part because their compliant chest walls allow for more effective blood flow during external chest compressions.[13]

Pediatric Out-of-Hospital Arrests

Outcomes following pediatric out-of-hospital arrests are much worse than in-hospital arrests.[4,14-21] Survival to hospital discharge typically occurs in less than 10% of these children, and many have severe neurologic sequelae. Two diseases have especially poor outcomes: traumatic arrests and sudden infant death syndrome (SIDS). Traumatic cardiac arrests typically result from either severe, prolonged hypoxic episodes or exsanguination. SIDS patients are often "long dead" before resuscitation is attempted. In most series of out-of-hospital pediatric cardiac arrests, more than one third of the children have the diagnosis of SIDS. For other pediatric cardiac arrests in the prehospital setting, CPR and advanced life support from EMS providers are typically applied after prolonged periods of profound hypoxia and hypoperfusion of vital organs.

Pediatric Ventricular Fibrillation

Ventricular fibrillation is an uncommon, but not rare, electrocardiographic rhythm during out-of-hospital pediatric cardiac arrests, generally occurring in ~10% of cases.[4,21,30-33] The incidence of VF varies by setting and age. In special circumstances, such as tricyclic antidepressant overdose, cardiomyopathy, postcardiac surgery, and prolonged QT syndromes, VF is a more likely rhythm during cardiac arrest. Another special circumstance, commotio cordis, or mechanically-initiated VF because of relatively low-energy chest wall impact during a narrow window of repolarization, occurs predominantly in children 4 to 16 years old.[34,35] Out-of-hospital VF cardiac arrest is uncommon in infants, but occurs more frequently in children and adolescents. The variance of VF by age was highlighted in a study documenting VF/VT in only 3% of children in cardiac arrest 0 to 8 years old versus 17% of children 8 to 19 years old.[32]

Although the initial ECG rhythms during most pediatric in-hospital cardiac arrests are asystole and pulseless electrical activity (PEA), in approximately one quarter of arrests the rhythms are VF or pulseless VT.[11,12] Among the first 1005 pediatric in-hospital cardiac arrests in the American Heart Association's National Registry of CPR, 10% had an initial rhythm of VF/VT, an additional 15% had subsequent VF/VT (i.e., some time later during the resuscitation efforts), and another 2% had VF/VT but the timing of the arrhythmia was not clear.[12] Therefore, 27% of children with in-hospital cardiac arrests had VF/VT—not an uncommon phenomenon. Even in the setting of progressive respiratory failure and shock with an initial ECG of asystole or PEA, a substantial number of these children developed subsequent VF/VT during CPR. After initial VF/VT, 35% survived to hospital discharge.[12] Surprisingly, the subsequent VF/VT group had worse outcomes than children with asystole/PEA who never developed VF/VT during the resuscitation: 11% survival to discharge with subsequent VF/VT during resuscitation from asystole/PEA versus 27% with asystole/PEA alone.[12] Traditionally, VF and VT have been considered "good" cardiac arrest rhythms, resulting in better outcomes than asystole and PEA. However, these data have resulted in a paradigm shift: outcomes after initial VF/VT are "good," but outcomes after subsequent VF/VT are substantially worse, even when compared with asystole/PEA rhythms.

THE PHASES OF CARDIAC ARREST AND CPR

There are at least four phases of cardiac arrest: (1) pre-arrest, (2) no flow (untreated cardiac arrest), (3) low flow (CPR), and (4) post-resuscitation. Interventions to improve outcome from pediatric cardiac arrest should be targeted to optimize therapies according to the timing, duration, intensity, and "phase" of resuscitation as suggested in Table 20-1. The prearrest phase represents the largest potential opportunity for

Table 20-1
Phases of Cardiac Arrest and Resuscitation

Phase	Interventions
Pre-arrest (Prevention)	Community education regarding child safety Patient monitoring and rapid response teams Recognize and treat respiratory failure and/or shock
No-flow	Minimize interval to BLS and ACLS (organized response) Minimize interval to defibrillation, when indicated
Low-flow (CPR)	PUSH HARD, PUSH FAST Allow full chest wall recoil Minimize interruptions in compressions Avoid overventilation Titrate CPR to optimize coronary perfusion pressure Consider ECMO if standard CPR/ACLS is not promptly successful
Post-resuscitation	Optimize cardiac output and cerebral perfusion Treat arrhythmias, if indicated Avoid hyperthermia, hyperventilation, hyperglycemia Consider induction of post-resuscitation systemic hypothermia

ACLS, advanced cardiac life support; BLS, basic life support; CPR, cardiopulmonary resuscitation; ECMO, extracorporeal membrane oxygenation.

patient survival by preventing pulseless cardiopulmonary arrest. Interventions during the prearrest phase focus on prevention. Infant safety seats and safe driving to prevent traumatic arrests, water safety programs to prevent drowning arrests, medication safety caps to prevent drug poisoning arrests are well known, highly effective efforts to prevent cardiac arrests. Because many pediatric cardiac arrests are due to progressive respiratory failure and shock, the main focus of the Pediatric Advanced Life Support (PALS) course is the early recognition and treatment of respiratory failure and shock in children (i.e., prevention of cardiac arrest in the prearrest phase).[36] Increasingly, medical emergency teams (or rapid response teams) are utilized in hospitals to recognize and treat respiratory failure and shock before cardiac arrests occur.

Interventions during the no-flow phase of untreated pulseless cardiac arrest focus on early recognition of cardiac arrest and prompt initiation of basic and advanced life support. When there is insufficient oxygen delivery to the brain or heart, CPR should be initiated. The goal of effective CPR is to optimize coronary perfusion pressure and blood flow to critical organs during the low-flow phase.[2,3] Basic life support with continuous effective chest compressions is the emphasis in this phase. The focus should be to *PUSH HARD, PUSH FAST, allow full chest wall recoil, minimize interruptions, and don't overventilate.*

The post-resuscitation phase is a high-risk period for brain injury, ventricular arrhythmias, and other reperfusion injuries. Overventilation is frequent and can impede blood return to the thorax during and following CPR.[37,38] Induced hypothermia (32° to 34° C) can improve outcome for comatose adults after resuscitation from out-of-hospital ventricular fibrillation cardiac arrest.[39,40] In addition, myocardial dysfunction and fatal hypotension are common during the post-resuscitation phase.[41-46] Thoughtful attention to management of temperature, glucose, blood pressure, myocardial function, coagulation, and optimal ventilation may improve outcome in this phase.

Interventions During the Low Flow Phase: CPR

AIRWAY AND BREATHING

One of the most common precipitating events for cardiac arrests in children is respiratory insufficiency. Adequate oxygen delivery to meet metabolic demand and removal of carbon dioxide is the goal of initial assisted ventilation. Effective bag-mask ventilation skills remain the cornerstone of providing effective emergency ventilation. Effective ventilation does not necessarily require an endotracheal tube. In one randomized, controlled study of children with out-of-hospital respiratory arrest, children who were treated with bag-mask ventilation did as well as children treated with prehospital endotracheal intubation.[47] During CPR, cardiac output and pulmonary blood flow are approximately 10% to 25% of that during normal sinus rhythm.[3] Consequently, much less ventilation is necessary for adequate gas exchange from the blood traversing the pulmonary circulation during CPR in contrast to normal sinus rhythm with a normal cardiac output. Animal and adult data indicate that overventilation during CPR is common and can substantially compromise venous return and cardiac output because of increased intrathoracic pressure.[37,38] Most concerning, these adverse hemodynamic effects from overventilation during CPR, combined with the interruptions in chest compressions typically necessary to provide airway management, rescue breathing, vascular access, and rhythm analysis, can inadvertently contribute to worse survival outcomes.

CIRCULATION

Basic life support with continuous effective chest compressions is generally the best way to provide circulation during cardiac arrest. Basic life support is often provided poorly or not provided at all.[3,48-53] The most critical elements are to PUSH HARD, PUSH FAST (100 compressions/minute). Because there is no flow without chest compressions, it is important to minimize interruptions in chest compressions. To allow good venous return in the decompression phase of external cardiac massage, it is important to allow full chest wall recoil, and to avoid overventilation. The American Heart Association recommends compressing the chest of an infant or child one third to one half of the total depth of the chest.[3] When the rescuer can reach his/her hands around the infant's chest, the American Hospital Association (AHA) recommends the two thumb-encircling hand technique (Fig. 20-1). For a larger child, the rescuer can use the one-hand or two-hand technique to compress the chest.

The effectiveness of chest compressions can be monitored in several ways. If direct monitoring of arterial pressure is being performed, the aortic relaxation, or diastolic, pressure should be maintained at more than 20 to 30 mm Hg.[54-56] If direct monitoring of arterial and central venous pressure is being performed, the coronary perfusion pressure can be calculated. The coronary arteries are perfused during the relaxation phase of CPR (diastole).[57] The coronary perfusion pressure is the aortic diastolic pressure minus the right atrial diastolic pressure. Data from adults and young animals suggest that maintaining a coronary perfusion pressure of more than 15 to 25 mm Hg is important for effective resuscitation.[55,56]

For most patients, direct arterial and central venous pressure monitoring is unavailable at the time of cardiac arrest. Traditionally, the presence of a palpable pulse during CPR has been used to determine the effectiveness of CPR. Data from

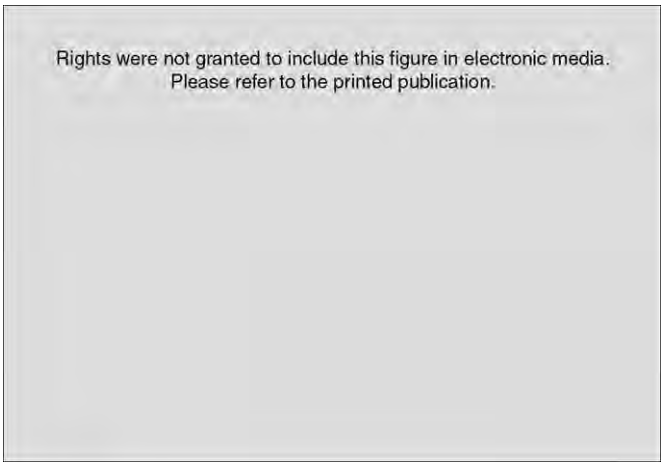

Figure 20-1 Infant CPR using the two thumb-encircling hand technique. (Reprinted with permission from the American Heart Association.)

animal studies and children demonstrate that pulsations may result from retrograde flow in the venous system as well as antegrade flow in the arterial system.[58] Nevertheless, the strength of peripheral pulsations may reflect the force and therefore the effectiveness of chest compressions.

Data from animal models and adult cardiac arrest victims suggest that measurements of end-tidal carbon dioxide (CO_2) are useful predictors of coronary perfusion pressure, cardiac output, and effective resuscitation.[59-63] During the low-flow state of CPR, the major determinant of end-tidal CO_2 level is pulmonary blood flow. Pulmonary blood flow, in turn, reflects the cardiac output produced by chest compressions. When the end-tidal CO_2 concentration is less than 10 mm Hg, CPR is inadequate, and the victim almost never survives.[62,63] End-tidal CO_2 monitoring can also verify appropriate endotracheal tube placement.[64]

Capnometry during CPR after asphyxial cardiac arrest is somewhat different from that after VF. Experimental data suggest that the end-tidal CO_2 value may be very high during the first few breaths after an asphyxial cardiac arrest. During asphyxia, alveolar CO_2 may rise, thereby resulting in high end-tidal CO_2 levels for several breaths.[65] After the first few breaths, capnometry reflects pulmonary blood flow and cardiac output and is a useful monitor of the effectiveness of CPR; however, the administration of sodium bicarbonate during cardiac arrest may spuriously increase the end-tidal CO_2 concentration without reflecting any increase in pulmonary blood flow because of increases in the level of pulmonary venous CO_2.[3]

CIRCULATION: ECMO-CPR

Dalton and colleagues[66] first reported the use of emergency extracorporeal membrane oxygenation (ECMO) during CPR for 11 children who suffered intractable cardiac arrest in their pediatric intensive care unit. Six of these 11 survived to hospital discharge.

More recently, Morris and coworkers reported 66 children who were placed on ECMO during CPR at Children's Hospital of Philadelphia over a 7-year period.[67] The median duration of CPR prior to establishment of ECMO was 50 minutes, and 35% (23 of 66) of these children survived to hospital discharge. It is important to emphasize that these children had brief periods of "no flow," excellent CPR during the "low flow" period, and a well-controlled post-resuscitation phase. Moreover, most of the survivors had reversible cardiac etiologies for their arrests. Many pediatric centers now provide ECMO-CPR for selected patients who fail to respond to initial advanced life support techniques. In addition, there is growing evidence that provision of ECMO in the post-resuscitation phase may also improve outcome from in-hospital cardiac arrests.[68]

VASCULAR ACCESS

Establishing vascular access during pediatric cardiac arrest is difficult, yet necessary, for the administration of medications and fluids.[3] Theoretically, vascular access into a large vein that drains into the superior vena cava is optimal for the delivery of medications during CPR. The lack of valves in the inferior vena cava results in to-and-fro blood flow during external chest compressions. Valves in the superior vena caval system tend to minimize this problem. Therefore, medications infused into the inferior vena caval system can take longer to reach the heart and systemic circulation. In some models, medication administration via the central venous route results in a more rapid onset of action and higher peak concentrations than administration via the peripheral route.[69] Any potential minor benefits of central venous or superior vena caval drainage on medication administration are probably less important than the rapid and safe administration of intravascular medication. Inferior venal caval access via the saphenous vein, tibial bone marrow, or femoral vein may be easier and safer than venous access near the head or neck while ventilation and chest compressions are being provided. Medication administered via the peripheral or femoral vein during CPR should probably be followed by a fluid flush to more rapidly move the medications into the central circulation.[3]

Physicians and prehospital personnel can usually attain intraosseous access for pediatric arrest victims in less than 1 minute.[70,71] Intraosseous vascular access should be strongly considered for any child in cardiac arrest without vascular access, allowing not only medication delivery but also rapid volume infusion when indicated.[3] The technique for intraosseous access is relatively easy and safe. The bone marrow cavity is effectively a noncollapsible vein, even in the presence of shock or cardiac arrest. Although almost any needle can be used, a bone marrow needle with a stylet is recommended to prevent needle obstruction from a core of bony cortex. The proximal tibia, distal femur, and anterior superior iliac spine are all acceptable sites that are easily accessible during resuscitation. The needle should be twisted into, rather than shoved through, the bone marrow. Evidence of successful entry into the bone marrow includes the lack of resistance (or "give") after the needle passes through the cortex, the needle's ability to remain upright without support, aspiration of bone marrow into a syringe, and free flow of the infusion without significant subcutaneous infiltration.[70,71]

Almost any medication that can be administered into a vein can be safely infused into the bone marrow. All medications recommended for pediatric advanced life support can be safely and effectively administered via the intraosseous route. The onset of action of medications and plasma concentrations is similar after intraosseous and peripheral venous administration during CPR.[3,70,71]

Even this relatively safe procedure can result in rare complications. Osteomyelitis, fractures, extravasation of toxic medications (e.g., epinephrine, calcium, sodium bicarbonate), and compartment syndrome with resultant amputation have been described.[3] Microvascular pulmonary fat and bone marrow emboli have been demonstrated but do not appear to be clinically significant.[72]

ACUTE FLUID VOLUME RESUSCITATION

As noted in the "Definition of Pulseless Cardiac Arrest" section, differentiating severe hypoxic-ischemic circulatory shock with poor pulses from the nonpulsatile state of cardiac arrest can be challenging. The initial treatment of choice for the former is rapid intravascular fluid volume resuscitation with 20 mL/kg of isotonic crystalloid (e.g., normal saline or

Ringer's lactate solution).[36] For hypotensive circulatory shock, the 20 mL/kg volume bolus should be provided as rapidly as possible (in less than 5 minutes). The child should be immediately reassessed and a repeat volume bolus should be provided if the circulatory shock has not resolved. In fact, a second volume bolus is nearly always needed for hypotensive circulatory shock (and often a third and fourth volume bolus). If the child has a less severe fluid deficit, volume resuscitation can be provided with a 10 mL/kg isotonic fluid bolus (especially if significant myocardial dysfunction is suspected).

Some experts recommend colloid solution fluid resuscitation (e.g., 5% albumin) rather than crystalloid; however, colloid fluid resuscitation did not improve outcome in adults compared with crystalloid resuscitation in a large randomized controlled trial or in meta-analyses of other smaller studies.*Nevertheless, because of excellent outcomes with the use of 20 mL/kg volume boluses of 5% albumin for children with meningococcemia, some leaders recommend colloid resuscitation for initial treatment of pediatric septic shock.†

Volume resuscitation may also be lifesaving for some children in cardiac arrest. CPR is unlikely to be effective when preload is insufficient (e.g., when septic shock or other hypotensive circulatory shock states progress to cardiac arrest). Importantly, hypotensive shock is the immediate precipitating factor for more than one half of in-hospital cardiac arrests in children.[11] Perhaps there should be greater emphasis on intravascular volume resuscitation during CPR for children in cardiac arrest.

ENDOTRACHEAL MEDICATION ADMINISTRATION

Endotracheal intubation may be easier to obtain than vascular access during pediatric CPR. Lidocaine, epinephrine, atropine, and naloxone (mnemonic: LEAN) are common resuscitation medications that have been successfully administered via the endotracheal tube.[3] On the other hand, sodium bicarbonate and calcium are poorly absorbed and may be very irritating to the airways and lung parenchyma, so they should not be administered via the endotracheal route. Absorption of medications into the circulation after endotracheal administration depends on dispersion over the respiratory mucosa, pulmonary blood flow, and matching of ventilation to perfusion.[73] Droplets of medication that remain on the endotracheal tube obviously do not help the patient's condition. Poor cardiac output with inadequate chest compressions results in inadequate pulmonary blood flow and, therefore, poor delivery of the medication to the heart and systemic circulation. Pulmonary edema, pneumonitis, and airway disease also affect the pharmacokinetics of endotracheally administered medications. The vasoconstrictive effects of epinephrine may limit local pulmonary blood flow and thereby diminish medication uptake and delivery.[74-76]

Case reports and the authors' clinical experiences have indicated that endotracheal administration of epinephrine can be effective and lifesaving.[77,78] However, in animal studies, plasma epinephrine concentrations and physiologic effects vary widely after endotracheal administration.[73,75,79,80] An endotracheal epinephrine dose approximately 10 times higher than that reached during intravenous administration is generally needed to obtain peak plasma concentrations. This higher dose is not without danger. After resuscitation, a prolonged depot effect occurs and may result in profound hypertension and tachycardia. After an asphyxial episode, the extra myocardial oxygen demand resulting from tachycardia and the increased afterload may not be well tolerated. On the other hand, the usual intravenous dose of epinephrine is generally ineffective via the endotracheal tube in asystolic adults.[74]

Based on these data, the AHA recommends that any route of vascular medication administration, including intraosseous or peripheral access, is preferable to endotracheal administration.[3] If, however, epinephrine is to be administered via the endotracheal tube during the resuscitation of children, the suggested initial dosage is 10 times the usual intravenous dose. However, for neonates the recommended endotracheal epinephrine dose is the same as the intravenous dose, 0.1 mL/kg of 1:10,000 solution, because (1) the depot effect can result in prolonged severe hypertension, (2) severe hypertension can lead to intracranial hemorrhage in neonates, (3) most neonatal resuscitations are successful with the present recommendations, and (4) there are limited data regarding the safety or efficacy of high-dose epinephrine via endotracheal tubes in neonates.[3]

MEDICATIONS

Medications commonly used for CPR in children are vasopressors (epinephrine or vasopressin), calcium chloride, sodium bicarbonate, and antiarrhythmics (amiodarone or lidocaine). The doses and indications for these medications are listed in Table 20-2.

Vasopressors

During CPR, epinephrine's α-adrenergic effect on vascular tone is most important.[81,82] The α-adrenergic action increases systemic vascular resistance, increasing diastolic blood pressure, which in turn increases coronary perfusion pressure and blood flow and increases the likelihood of the return of spontaneous circulation (ROSC).[81-83] Epinephrine also increases cerebral blood flow during CPR because peripheral vasoconstriction directs a greater proportion of flow to the cerebral circulation.[84] The β-adrenergic effect increases myocardial contractility and heart rate and relaxes smooth muscle in the skeletal muscle vascular bed and bronchi, although this effect is of less importance. Epinephrine also increases the vigor and intensity of VF, increasing the likelihood of successful defibrillation.

High-dose epinephrine (0.05 to 0.2 mg/kg) improves myocardial and cerebral blood flow during CPR more than standard-dose epinephrine (0.01 to 0.02 mg/kg), and may increase the incidence of initial ROSC.[85-89] Administration of high-dose epinephrine, however, can worsen a patient's

Table 20-2
Common CPR Medications

Medication	IV Dose	Indications
Epinephrine	0.1 mL/kg of 1 : 10,000 (0.01 mg/kg) Dose via ETT: 0.1 mL/kg of 1 : 1000 (0.1 mg/kg)	Cardiac arrest: asystole, pulseless arrest; symptomatic bradycardia
Atropine	0.2 mL/kg = 0.02 mg/kg (minimum: 0.1 mg; maximum: 1.0 mg)	Symptomatic bradycardia unresponsive to effective oxygenation, ventilation, and treatment with epinephrine
Calcium chloride 10%	0.2 mL/kg = 20 mg/kg	Hypocalcemia, hyperkalemia, hypermagnesemia, calcium channel blocker toxicity
Sodium bicarbonate	1 mEq/kg = 1 mL/kg of 8.4% solution = 0.5 mL/kg of 4.2% solution	Hyperkalemia, tricyclic antidepressant toxicity, severe metabolic acidosis unresponsive to oxygenation and hyperventilation
Amiodarone	5 mg/kg bolus	Symptomatic VT or ventricular ectopy, VF/pulseless VT unresponsive to defibrillation and epinephrine
Lidocaine	1 mL/kg	Symptomatic VT or ventricular ectopy, VF/pulseless VT unresponsive to defibrillation and epinephrine

ETT, endotracheal tube; VF, ventricular fibrillation; VT, ventricular tachycardia.

post-resuscitation hemodynamic condition with increased myocardial oxygen demand, ventricular ectopy, hypertension, and myocardial necrosis.[90-92] Prospective studies in adults indicate that use of high-dose epinephrine does not improve survival compared with standard-dose epinephrine.[85-89] In addition, a retrospective study in adults suggests higher total epinephrine dose may be associated with a worse neurologic outcome.[93]

Although enthusiasm for the initial use of high-dose epinephrine waned after these studies, high-dose epinephrine was still recommended as a reasonable option if the initial standard dose failed.[36] A randomized, blinded controlled trial of rescue high-dose epinephrine versus standard-dose epinephrine following failed initial standard-dose epinephrine for pediatric in-hospital cardiac arrest demonstrated a worse 24-hour survival in the high-dose epinephrine group (1/27 versus 6/23, $P<0.05$).[94] In particular, high-dose epinephrine seemed to worsen the outcome of patients with asphyxia-precipitated cardiac arrest. High-dose epinephrine is no longer recommended for initial therapy or rescue therapy. Nevertheless, high-dose epinephrine may be considered as an alternative to standard-dose epinephrine in certain special circumstances of refractory pediatric cardiac arrest (e.g., patient on high-dose epinephrine infusion prior to cardiac arrest) and/or when continuous direct arterial blood pressure monitoring allows titration of the epinephrine dosage to diastolic (decompression phase) arterial pressure during CPR.[3]

Vasopressin is a long-acting endogenous hormone that acts at specific receptors to mediate systemic vasoconstriction (V1 receptor) and reabsorption of water in the renal tubule (V2 receptor).[3] In experimental models of cardiac arrest, vasopressin increases blood flow to the heart and brain and improves long-term survival compared to epinephrine. Vasopressin may decrease splanchnic blood flow during and after CPR. In randomized controlled trials of in-hospital and out-of-hospital arrests in adults, vasopressin had comparable efficacy to epinephrine.[95-97] Vasopressin did not improve outcome compared with epinephrine in two large trials. However, a small randomized, blinded controlled trial demonstrated that vasopressin was superior to repeated epinephrine doses in adults after the initial epinephrine dose had failed.[97] A case series of four children who received vasopressin during six prolonged cardiac arrest events suggests that the use of bolus vasopressin may result in return of spontaneous circulation when standard medications have failed.[98] Although vasopressin will not likely replace epinephrine as a first line agent in pediatric cardiac arrest, there are preliminary data to suggest that its use in conjunction with epinephrine in pediatric cardiac arrest deserves further investigation.

Calcium

For in-hospital pediatric cardiac arrests, hypocalcemia is not uncommon. Although calcium administration is recommended only during cardiac arrest for hypocalcemia, hyperkalemia, hypermagnesemia, and calcium channel blocker overdose, it is commonly used for in-hospital pediatric cardiac arrests, especially those occurring postcardiac surgery.[3] The administration of calcium has not been demonstrated to improve outcome in cardiac arrest. Animal

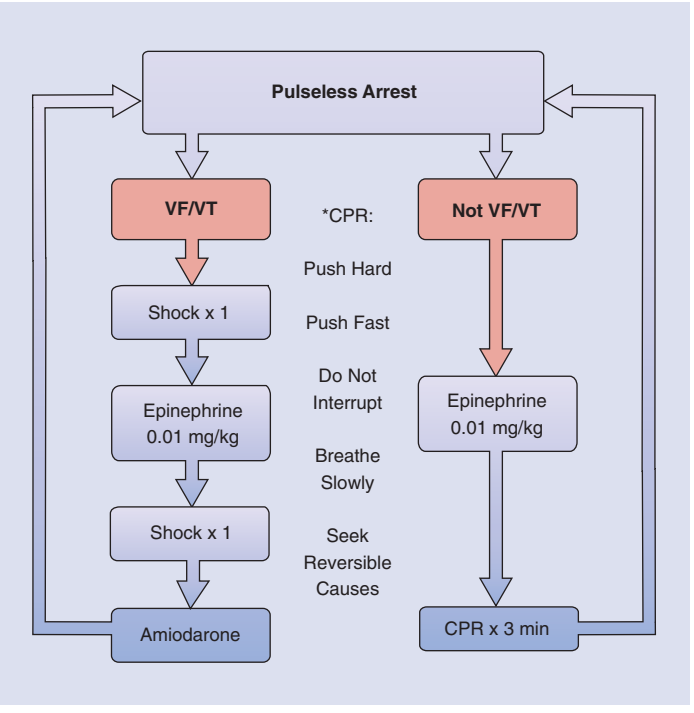

Figure 20-2 A pulseless arrest flow chart.

studies suggest that calcium administration may worsen reperfusion injury.

Buffer Solutions

Cardiac arrest results in lactic acidosis from inadequate organ blood flow and poor oxygenation. Acidosis depresses myocardial function, reduces systemic vascular resistance, and inhibits defibrillation. Nevertheless, the routine use of sodium bicarbonate for a child in cardiac arrest is not recommended.[3] Retrospective clinical series have not demonstrated a beneficial effect of sodium bicarbonate.[99] However, the presence of acidosis may depress the action of catecholamines, so the use of sodium bicarbonate seems rational in an acidemic child who is refractory to catecholamine administration. The administration of sodium bicarbonate is more clearly indicated in the patient with a tricyclic antidepressant overdose, hyperkalemia, hypermagnesemia, or sodium channel blocker poisoning.[3]

The buffering action of bicarbonate occurs when a hydrogen cation and a bicarbonate anion combine to form carbon dioxide and water. If carbon dioxide is not effectively cleared through ventilation, its build-up will counterbalance the buffering effect of bicarbonate. Other side effects with sodium bicarbonate include hypernatremia, hyperosmolarity, and metabolic alkalosis.[3,99] THAM is a non-carbon dioxide generating buffer that can be used during cardiac arrest. Note that excessive alkalosis decreases calcium and potassium concentration and shifts the oxyhemoglobin dissociation curve to the left.

An important practical matter during cardiac arrest is physicochemical medication incompatibility. Frequently the patient has only one venous access site. Administration of bicarbonate can inactivate catecholamines, and more importantly, calcium precipitates when mixed with bicarbonate. Therefore, intravenous tubing must be carefully irrigated before and after infusions of sodium bicarbonate.

Antiarrhythmic Medications: Amiodarone and Lidocaine

Administration of antiarrhythmic medications should not delay administration of a shock for a patient with VF. However, after unsuccessful attempts at electrical defibrillation, medications to increase the effectiveness of defibrillation should be considered. In both pediatric and adult patients, the first administered medication for VF is epinephrine.[2,3] If epinephrine with or without vasopressin and a subsequent repeat attempt to defibrillate are unsuccessful, the antiarrhythmic agents amiodarone or lidocaine should be considered.[2,3]

Lidocaine has been recommended traditionally for shock-resistant VF in adults and children. However, the only antiarrhythmic agent that has been prospectively determined to improve survival to hospital admission in the setting of shock-resistant VF when compared to placebo is amiodarone.[100] Furthermore, patients who received amiodarone for shock-resistant out-of-hospital VF had a higher rate of survival to hospital admission than patients who received lidocaine alone.[101] Neither of these randomized controlled trials included children. There are no published comparisons of antiarrhythmic medications for pediatric refractory VF. Nevertheless, extrapolation of the adult studies has led to the recommendation of using either amiodarone or lidocaine for shock-resistant VF in children.[2,3]

CONCLUSIONS

Outcomes from pediatric cardiac arrests were once thought to be dismal. Prompt recognition, immediate provision of excellent CPR (PUSH HARD, PUSH FAST, minimize interruptions, allow full chest wall recoil, and avoid overventilation), defibrillation of shockable rhythms, appropriate advanced life support, and excellent post-resuscitation care can result in good outcomes. More recent data indicate that ~27% of children survive to hospital discharge after in-hospital cardiac arrests.

CHAPTER 21 Lung Transplantation

Trevor J. Williams*, Glen Westall, and Gregory I. Snell

TEACHING POINTS

- Donor availability is the major limiting factor to lung transplantation, thus only a small proportion of those who may benefit will be transplanted.
- Cytomegalovirus and Epstein-Barr virus (CMV/EBV) serologic mismatch is the rule in pediatric lung transplantation.
- The small airway caliber presents technical challenges at the time of surgery and follow-up bronchoscopy.
- Consent (and commitment) to the procedure of parents and child is crucial because compliance to the complex post-transplant regimen is a major issue.
- The experience can be emotionally charged and arduous but the final outcome well worthwhile.

Transplantation is one of the true miracles of modern medicine. Although the concept of exchanging severely damaged body parts dates back at least 1500 years, the 20th century saw the fulfillment of this idea. Transplantation for end-stage pulmonary and pulmonary vascular disease in children remains one of the most complex, demanding forms of solid organ transplantation. As a consequence, very few centers around the world perform pediatric lung transplantation in any substantial number. Specific issues include obtaining informed consent, compliance with complex treatment regimens, technical problems due to small size, the developing and often brisk immunologic response as well as a lack of preformed immunity to important DNA viral infections. Those factors all combine to make pediatric lung transplantation both extremely challenging and ultimately very rewarding (see Teaching Points).

HISTORY

On his return from World War II, Vladimir Demikhov, a Russian surgeon and physiologist, performed a remarkable series of experiments in the second half of the 1940s. Demikhov performed canine auto- and allogenic transplantation of heart, heart/lung, and single lung, demonstrating the technical feasibility of transplanting these organs.[1,2] Of particular note was that these procedures were performed prior to the availability of cardiopulmonary bypass. Furthermore, animals receiving heart/lung transplants died rapidly from acute respiratory failure believed to be a result of bilateral pulmonary denervation.

Demikhov's findings resulted in the first attempts at human lung transplantation utilizing a single lung transplant technique. In 1963 Hardy[3] performed a single lung transplant in an adult with obstructive lung disease and lung cancer thought to be unresectable owing to physiologic considerations. Although the patient died of sepsis and anastomotic breakdown some 18 days following transplant, the ability of the transplanted lung to participate in gas exchange was confirmed. Over the next 2 decades, approximately 40 further unsuccessful attempts at lung transplantation were made.

Important studies by the Stanford University group confirmed that in primates, bilateral denervation of the lungs did not result in the development of acute hypercapnic respiratory failure.[4] This set the stage for the first attempt at heart/lung transplantation, which was performed by Denton Cooley and colleagues at the Texas Heart Institute[5] (performed on a child) in 1968. This appears to be the first (albeit unsuccessful) attempt at lung transplantation in a child.

The first long-term survivors of any form of lung transplantation were the culmination of decades of work by the Stanford University group led by Bruce Reitz. In 1980, this group reported extended survival of primates receiving heart/lung auto- and allo-heart/lung transplantation.[6] This paralleled the meticulous work under the leadership of Norman Shumway to develop the techniques now used in heart transplantation.

The Stanford University group reported long-term survival in two patients with pulmonary vascular disease receiving heart/lung transplantation in the *New England Journal of Medicine* in 1982.[7] This landmark report began the era of modern lung transplantation. The success was based on a decade or more of meticulous basic and applied research, the newly available immunosuppressive drug cyclosporine A, and a better understanding as to what represented a suitable candidate for lung transplantation.

Heart/lung transplantation can be applied to most patients with severe pulmonary or pulmonary vascular disease. The rapid evolution of cardiac transplant programs—as well as the concern that in these combined organ transplants the likelihood of rejection of one organ would be significantly

*Financial support provided by Margaret Pratt Heart and Lung Transplant Research Trust, Ronald MacDonald House Charities, and Bennalong Foundation.

increased—led other groups, particularly the Toronto Lung Transplant group, to try to develop techniques of isolated lung transplantation.

Lung transplantation was unusual in that not all major vascular structures were routinely re-anastomosed. The bronchial circulation, providing blood supply to the large intrathoracic airways down to terminal bronchioles, was not re-anastomosed, and grave concerns for the viability of the bronchus below the anastomosis were raised.[8] This did not appear to be a problem in heart/lung transplantation where collaterals from the coronary circulation and posterior pericardium meant that anastomotic breakdown was a rare phenomenon.

Successful, isolated single lung transplant was first performed by the Toronto Lung Transplant group in 1983.[9] The patient had idiopathic pulmonary fibrosis and ultimately lived more than 6 years post transplant. The complete avoidance of corticosteroids pre- and early postoperatively, as well as wrapping of the bronchial anastomosis with a pedicle of greater omentum (bronchial omentopexy) was performed with the intention of reducing or preventing bronchial anastomotic breakdown. Initially, single lung transplantation was performed almost exclusively for patients with pulmonary fibrosis, although subsequently patients with severe pulmonary hypertension—both primary and secondary to intracardiac defects—have received single lung transplantation. In 1989, the first single lung transplant for emphysema was performed,[10,11] disproving concern that overwhelming hyperinflation of the native lung would make this procedure impossible. The first successful pediatric isolated single lung transplant was performed in a 16-year-old with familial pulmonary fibrosis in 1987.[12]

Toward the end of the 1980s, the first reports of the successful application of heart/lung transplantation in the pediatric age group,[13] particularly in patients with cystic fibrosis,[14-16] appeared. After reporting the development of an appropriate operative technique,[17] the Toronto Lung Transplant group reported the first successful double lung transplant procedure[18] in 1988. Initially this procedure was performed as an en bloc procedure with a tracheal anastomosis. This approach was associated with a very high mortality because of tracheal anastomotic breakdown.[19] Working in parallel, the Toronto group, St. Louis, and San Antonio (Texas) Lung Transplant Programs modified the procedure to the presently utilized bilateral sequential lung transplant.[20] This procedure is performed through a horizontal clam shell incision typically running below the fifth rib and transecting the sternum. One lung is transplanted with the patient generally supported on their remaining lung without the requirement of cardiopulmonary bypass.[21] Subsequently the patient is supported on the new transplanted lung allowing transplantation of the second lung—again often without the requirement for cardiopulmonary bypass.

Further improvements in the technique of bronchial anastomosis including telescoping[22] have led to a dramatic reduction in airway anastomotic complications. This is despite now almost universal pre- and perioperative corticosteroid use and discontinuation of the use of omentopexy. Worldwide, bilateral sequential lung transplantation is the most common form of double lung replacement, although some groups have continued to utilize the en bloc technique in combination with revascularization of the bronchial circulation using an internal mammary artery pedicle.[23,24]

By the early 1990s, there had been a substantial increase in the number of lung transplants performed worldwide, with more than 500 procedures having been performed. However, the International Society for Heart and Lung Transplantation/United Network of Organ Sharing (ISHLT/UNOS) Paediatric Lung Transplant Registry noted still only 30 U.S. pediatric transplants in total by the end of 1991.[25] Nevertheless, particularly in countries where a time priority organ allocation system (first come, first served system) was the system of organ allocations, children and young adults with rapidly progressive pulmonary diseases were dying without reaching a position on waiting lists where they would be realistically transplanted.

Vaughan Starnes at the University of Southern California developed a technique of utilizing the lobe from a live donor (initially a close relative) to allow transplantation, particularly of children and young adults.[26,27] The first reported successful transplant was a 12-year-old girl with bronchopulmonary dysplasia receiving a lobar transplant from her mother.[28] This procedure has now evolved to a bilateral procedure using the right lower lobe and the left lower lobe from two living donors so that bilateral transplantation can be performed. This procedure is most commonly performed for young children and adults with cystic fibrosis. Initially the donors were first-degree relatives, although more recently unrelated lobar donors have been used.[29]

In patients, particularly with cystic fibrosis, severe lung disease and end-stage liver disease occasionally coexist. Successful transplantation using en bloc heart/lung and liver or bilateral lung/liver transplants have been more recently reported.[30]

PATIENT SELECTION

Presently, the great majority of heart/lung and isolated lung transplants are performed using donors who have sustained irreversible and complete cessation of brain and/or brain stem function (brain death). Their vital organs remain ventilated and perfused because of continued mechanical ventilation and circulatory support. This is an unusual circumstance and the number of potential donors remains substantially less than the number of potential recipients.

The objective of the assessment process is, thus, not only to identify patients that might benefit from transplantation, but also to assess those who realistically will obtain a durable high quality outcome. The transplant process is onerous to the recipient and extended family and thus an assessment of the likelihood of a good outcome is an important part of the assessment process. Units vary as to precise details of their assessment process. Nevertheless, most programs have developed a process of evaluation of potential recipients that has several key features in common (Fig. 21-1). These features include an initial screening process and up-front discussion to make sure there are no absolute contraindications to lung transplantation. Integral to the process is the recognition that lung transplantation should be the last option after all other suitable treatment options have been considered. Where there are no absolute contraindications, then more detailed evaluation, typically as an inpatient, occurs. Both the

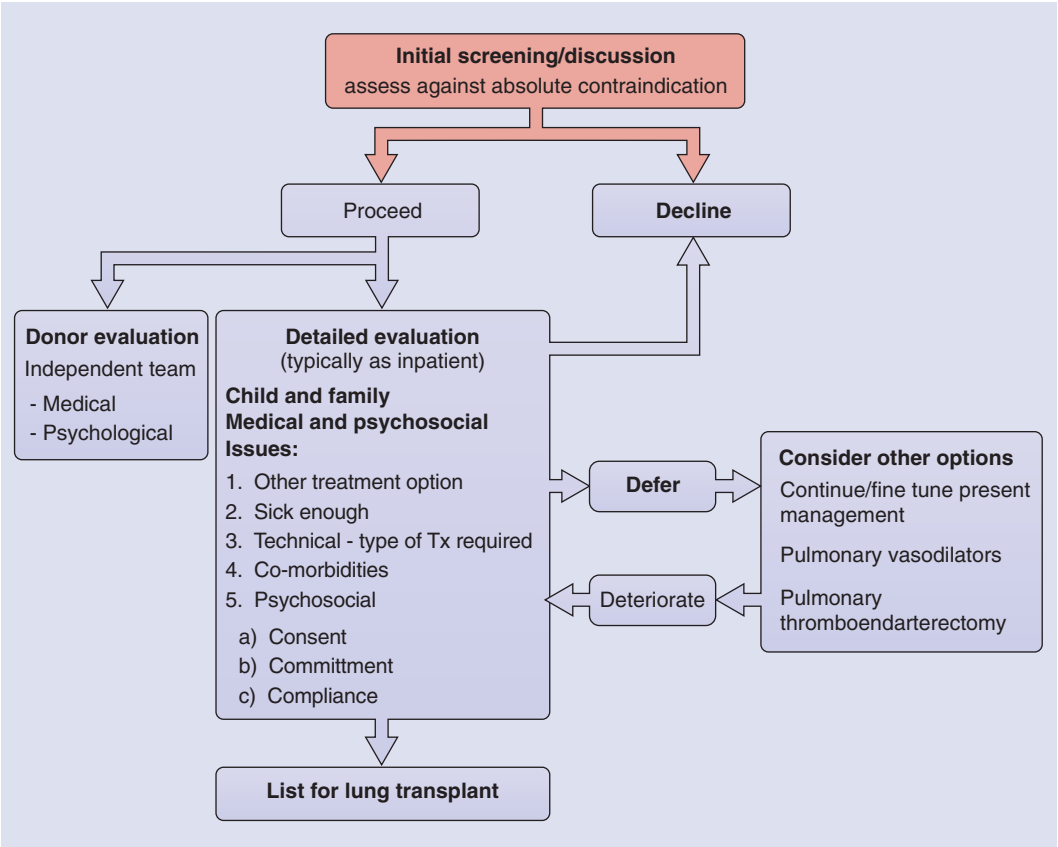

Figure 21-1 A general schema adopted by most programs outlining the process of initial screening and evaluation of potential lung transplant recipients.

child and family are evaluated as part of this process. The evaluation would typically occur with both child and family together but also with periods of separate discussion and evaluation.

The key issues that need to be addressed are the availability of other suitable treatment options; whether the patient is sick enough to warrant the risks of transplantation; technical aspects of the transplantation including which transplant procedure is most suitable; detection and evaluation of comorbidities, and detailed psychosocial evaluation of child and family to resolve issues of informed consent, commitment to the transplant procedure, and ability to comply with a complex treatment regimen.

It is evident that such an important and potentially emotionally charged decision should not be made by a single individual. It is normal practice for the details of this formal evaluation to be presented to a multidisciplinary assessment team for a final determination with respect to suitability for transplantation.

Broadly, however, patients are selected for transplantation on two grounds (Table 21-1). First, suitability may be on prognostic grounds. Lung transplantation is offered for patients with end-stage pulmonary or pulmonary vascular disease where survival is enhanced by transplantation and typically median survival is anticipated to be less than 2 years. Some patients with very poor quality of life may also be offered transplantation in the absence of a clear prognostic advantage. Those offered transplantation, however, are generally New York Heart Association Functional Class III or IV.

There continues to be evolution as to what are regarded as contraindications to lung transplantation. Generally accepted absolute contraindications[31,32] to lung transplantation are shown in Table 21-2. Important contraindications include malignancy (unless in complete remission for 5 years, the exception being non-melanotic skin cancers), serious incurable infection (e.g., HIV, which is almost universally regarded as an absolute contraindication, but in the antiretroviral era lung transplantation for pulmonary arterial hypertension may enhance prognosis for the individual). Other serious systemic illnesses and major psychiatric illness (such as uncontrolled psychosis or substance addiction) are regarded as absolute contraindications. More difficult are patients with multiple relative contraindications that would lead the assessment team to believe the likelihood of a sustained period of enhanced quality of life after transplantation

Table 21-1
General Criteria for Lung Transplantation

Prognosis	Quality of Life
End stage disease (pulmonary & pulmonary vascular) No suitable alternative treatments <2 Year median survival	NYHA Functional Class III-IV

Table 21-2
Contraindications to Lung Transplantation[31,32]

Absolute
Uncontrolled malignancy
Uncontrolled infection
- HIV

Psychosocial
- Poor support
- Lack of commitment
- Demonstrated poor compliance

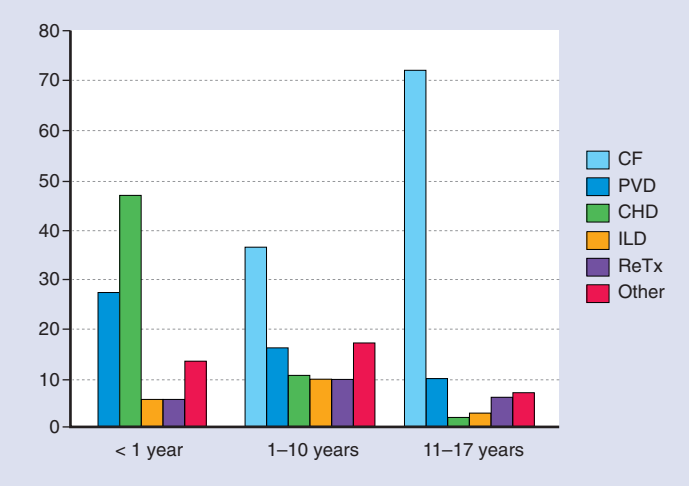

Figure 21-2 Indication for pediatric lung transplantation by recipient age. In the neonatal age group congenital heart disease is the predominant indication for lung transplantation; thereafter, cystic fibrosis is the most common indication. CF, cystic fibrosis; CHD, congenital heart disease; ILD, interstitial lung disease; PVD, pulmonary vascular disease; ReTx-repeat transplantation.

was low. Factors that would be considered include previous surgery (particularly pleurectomy or pleurodesis) but also complex cardiac repairs and infections with significant pathogens that are difficult to control post-transplant (see Table 21-2). Of particular note are *Burkholderia cepacia*,[33] atypical mycobacteria (e.g., *Mycobacterium abscessus*)[34] and fungi (such as *Aspergillus* spp.) which are of considerable concern, but colonization would not be regarded universally as a contraindication to lung transplantation. In vitro and in vivo resistance to antibiotics would be of great concern to the transplant assessment team. Other comorbidities such as chronic liver disease, renal impairment, and psychosocial aspects where there is demonstrably poor support, lack of commitment to transplantation, or demonstrably poor compliance would be considered as relative contraindications. In pediatric recipients, it is often these psychosocial aspects that require the greatest care and consideration.

The age distribution of pediatric lung transplantation is bimodal with one peak at <1 year of age and a second much larger peak at 17 years of age.[35] Each year 60 to 80 pediatric lung transplants (recipient age <18 years) from approximately 25 centers worldwide are reported to the ISHLT/UNOS international registry (compared to a yearly adult lung transplant activity of 1500 to 1600). The most common indication for lung transplantation is cystic fibrosis, which in the 11- to 17-year age group accounts for 72% of lung transplants; other indications include pulmonary vascular disease (10%) and re-transplants (6%). In the neonatal age group (<1 year old), congenital heart disease (47%) and pulmonary vascular diseases (27%) are the most common indications for lung transplantation (Fig. 21-2).

LUNG TRANSPLANT DONORS

At the outset of human lung transplantation, a very conservative approach to donor suitability was developed. In part, this came out of concerns for the cardiac allograft in heart/lung transplantation[36,37] Age (younger than 55 years), nonsmoking status, absence of history of respiratory disease, a normal chest radiograph, minimal airway secretions bronchoscopically, and a PaO_2 greater than 300 mm Hg on 100% FIO_2 and 5 cm of PEEP have conventionally been the organ-specific criteria for donor suitability. Other more general criteria for organ donation must also be fulfilled, including establishment of brain death according to the requirements of the local jurisdiction, consent from the appropriate authority (e.g., the coroner), no identifiable risk factors for serious viral infections (including hepatitis B and HIV infection) and absence of a history of malignancy, have formed part of the general donor suitability criteria. More recently this conservative approach has been progressively challenged by the use of so-called "marginal" donors.[38-40] Specific factors such as long ischemic time,[41] donor history of asthma,[42] and moderate smoking history,[43] have been investigated and found to still be compatible with good recipient outcome. It is now increasingly understood that previously defined marginal or unacceptable donors can be successfully utilized in lung transplantation.[44]

The recognition that the lungs are more resilient to prolonged periods of warm ischemia[45-47] has led to the development of lung transplantation using so-called non-beating-heart donors or donation after cardiac death. In an important recent report from Steen and coworkers from Sweden[48] successful lung transplantation was performed after a period of 4 hours of circulatory arrest, using topical cooling of the lungs through intercostal catheters inserted 2 hours after complete circulatory arrest. This raises the prospect of much more extensive use of donation after cardiac death for lung transplantation with a significant increase in rates of lung transplantation worldwide.

Programs using live donor lobar transplantation have developed protocols for detailed evaluation of the potential donors. Overall, live (lobar) donor lung transplantation accounts for 12% of pediatric lung transplantation (88% are cadaveric donors)—with the youngest recipient in the last 8 years being 7 years old.[35] Lobectomy carries a significant morbidity and mortality and so medical, surgical, and psychological evaluation are crucial in detailed evaluation of a potential live donor. Generally, a team independent of the team assessing the recipient would make a determination of the suitability of such donors.

The allocation system for organs varies quite substantially from country to country. Broadly, systems are based on time priority (a first-come, first-served approach utilized until recently in the United States) or systems based on clinical urgency and utility (as is reported in Australia), but with significant overlap in other places. The basic donor-to-recipient matching is determined by ABO and size compatibilities. The use of donor-predicted total lung capacity (TLC), recipient-predicted and measured TLC, height/weight, chest circumference, and chest radiograph-derived measurements from donor and recipient are all used in various combinations by individual programs. Generally, multiple measures are used, particularly if relying on predictive equations to determine predicted TLC in children. Where possible, matching for CMV and EBV serostatus is undertaken (although often not achievable in children). Many units routinely perform lymphocytotoxic antibody cross, matches to detect preexisting antibodies to HLA-class 1 and 2 antigens. HLA matching as performed for renal transplantation is generally not practical.

The Lung Transplant Procedure

Heart/lung, single lung, and bilateral lung transplantation have all been extensively used in pediatric recipients (Table 21-3). The trend in recent years, however,[35] has been for most pediatric recipients to receive bilateral lung transplantation—although some surgeons prefer for heart/lung transplantation to try to avoid the difficult problem of anastomotic complications in the small pediatric recipient. Particularly in the United States and Japan, live-donor lobar transplantation has also been quite extensively applied in the pediatric age range.

The time constraints around donor organ procurement often mean the patient spends no more than 1 to 2 hours in hospital before going to the operating room. Thus the patient and family need to be well prepared in advance. After arrival in the operating theater, the patient will be prepared by the anesthetic team for the surgery. This will usually include insertion of an intravenous line and epidural catheter. Once anesthetized, a central line, pulmonary artery catheter, urinary catheter, and arterial line can be inserted.

The bilateral sequential lung transplant procedure is performed through a clam shell incision which starts from the axilla, runs under the fifth or sixth intercostal space, transecting the sternum and extending along the fifth or sixth intercostal space to the contralateral axilla. This incision allows good access to the apices of the lung and appears to be well suited—particularly for transplantation of patients with cystic fibrosis.[49] Dissection of the lung is usually performed prior to initiating cardiopulmonary bypass to minimize bleeding complications. The first lung transplanted is generally the lung deemed to be most severely affected as judged on quantitated ventilation perfusion scan. Single lung ventilation is established either with a double lumen tube or bronchial blocker and the pulmonary artery is temporarily clamped to assess whether the recipient is sustainable on single lung ventilation. If hypoxia or cardiovascular instability occurs, then cardiopulmonary bypass would be used to support the recipient through the procedure. Once the appropriate anastomoses are performed, the clamps are released and perfusion to the organ is reestablished. After a period of stability, attention is switched to the contralateral lung, which is then excluded from ventilation; the pulmonary artery is then clamped and assessment is made as to whether the patient can be supported on the newly transplanted lung. Again a decision about the use of cardiopulmonary bypass will need to be made and the implantation of the second lung will then proceed. At the end of the operation at least two large drains are placed into each pleural space and the incision is closed with wiring of the ribs and sternum.

Table 21-3
Lung Transplant Options in Pediatrics

	Heart/Lung Transplant	Bilateral Lung Transplant	Single Lung Transplant	Living Donor Lobar Transplant
Potential Indication	All	All except: Severe irreversible coexisting cardiac disease	All nonseptic lung disease	All except: Severe irreversible coexisting cardiac disease
Common Indications	Pulmonary vascular disease Congenital heart disease with pulmonary hypertension	Cystic fibrosis Pulmonary vascular disease Interstitial lung disease	Rarely used in pediatrics. Interstitial lung disease	Cystic fibrosis Many rare indications
Anastomoses	Aortic Right atrial or caval Tracheal	Bilateral pulmonary arterial Left atrial Bilateral bronchial	Unilateral pulmonary arterial Left atrial bronchial	Lobar artery to pulmonary artery Lobar pulmonary vein to pulmonary vein Lobar bronchus to main bronchial
Survival (Pediatric/Adult)				
1 yr	64/62	77/76	54/76	85
5 yr	39/43	47/52	27/45	NA
Comment	Still performed where heart-lung allografts available	Most commonly performed procedure in pediatrics	Now infrequently performed	Performed particularly in U.S. and Japan

Heart/lung transplantation necessitates cardiopulmonary bypass in all recipients. Efficiency of organ utilization can be maintained by using the heart/lung transplant recipient's heart in a second recipient, the so-called heart/lung domino procedure.[50] The live donor lobar transplant procedure is generally performed using cardiopulmonary bypass and requires more difficult anastomoses between the lobar airway, artery, and vein with the main bronchial and vascular trunk on the appropriate side.

Crucial to the success of these procedures are an experienced surgical team and anesthetic team working in close cooperation with the perfusion team running cardiopulmonary bypass as required. The transplant procedure is coordinated with the donor procedure to try to minimize the period of cold ischemia. Generally cold ischemic times of less than 6 hours have been regarded as acceptable.[36]

Recipient Management

PREOPERATIVE MANAGEMENT

Once listed for transplantation, the key objectives of management are:

1. Survival through to transplantation.
2. Maintaining physical condition including optimization of weight, maintenance of physical activity, monitoring for the development of comorbidities (e.g., osteoporosis, colonization with resistant organisms).
3. Continuing to inform and educate the patient and family as to the ongoing management of the lung transplant recipient.
4. Continuing to reevaluate the patient and—if rapidly deteriorating—discussion should be undertaken addressing issues including the use of marginal or nonconventional donors.

This can be an extremely difficult and complicated time. Substantial psychosocial support is often required because the normal approach to palliative care may become inappropriate in a patient awaiting lung transplantation.

EARLY POSTOPERATIVE CARE

All patients following transplantation will be sent to the intensive care unit (ICU). The phases of postoperative management include:

- Intensive care management
- Early postoperative management
- Rehabilitation
- Long-term care of the transplant recipient

These are not mutually exclusive periods of care. In patients with severe early graft dysfunction rehabilitation may start while ventilated in the ICU.

The principal objectives of intensive care management are ventilatory support through to weaning and extubation and circulatory support—generally with an objective of keeping the recipient dry,[51] using inotropes where needed to support the circulation. Fluid management can be particularly difficult because over-generous fluid resuscitation can exacerbate primary graft dysfunction pulmonary edema[52]; conversely, hypovolemia can be associated with poor cardiac output, renal hypoperfusion, and potentially renal failure.

The most common early problem is primary graft dysfunction–related pulmonary edema which typically starts within hours of transplantation and generally reaches its peak 48 hours post-transplant.[52] If severe, advanced strategies of mechanical ventilation or support may be required, including the use of high-frequency ventilation and even periods of support using extracorporeal membrane oxygenation (ECMO).[53] In single lung transplant recipients with severe primary graft dysfunction (particularly in single lung transplantation for obstructive lung disease) differential lung ventilation through a double lumen endotracheal tube can be lifesaving—this is a rare problem in pediatric lung transplantation.

Immunosuppression can generally be discussed in three phases: induction, maintenance, and augmentation (Table 21-4). Induction therapy typically includes a calcineurin antagonist (cyclosporine A or tacrolimus) and an antiproliferative agent (mycophenolate mofetil/mycophenolate sodium, or azathioprine) as a loading dose preoperatively. Intra- and perioperatively, high-dose intravenous corticosteroids (methylprednisolone) are given, with many programs also using antilymphocyte globulins or monoclonal antibodies directed against interleukin-2 receptor (e.g., daclizumab or basiliximab). Maintenance immunosuppression is progressively introduced in the hours post-transplant. This is typically a three-drug regimen using a calcineurin antagonist (cyclosporine A or tacrolimus), an antiproliferative agent (mycophenolate mofetil/mycophenolate sodium, or azathioprine) and a corticosteroid (methylprednisolone, prednisolone, or prednisone) in a slowly reducing dose. Tacrolimus, mycophenolate mofetil, and prednisolone are the most common agents for maintenance of immunosuppression in pediatrics.[35] The more important side effects are associated with the calcineurin antagonist, and in the intensive care setting include progressive renal impairment, abnormalities of liver function tests, and neurologic complications—includ-

Table 21-4
Three Phases of Lung Transplant Immunosuppression

Induction	***Typical***	***Alternative***
	Premedication Single oral dose cyclosporine A or tacrolimus Single oral dose azathioprine/ mycophenolate High dose methylprednisolone (IV) IL2 receptor antagonist (IV)	Antilymphocyte globulin (IV) (e.g., ALG, ATGAM,OKT3)
Maintenance	***Typical***	***Alternative***
	Cyclosporine A or tacrolimus (IV then oral) AND Azathioprine or mycophenolate (IV then oral) AND (Methyl)prednisolone or prednisone (IV then oral)	Rapamycin or everolimus (oral) Cyclophosphamide or methotrexate (oral)
Augmentation	***Typical***	***Alternative***
	Methylprednisolone (IV) ALG, ATGAM,OKT3 (IV) Plus Optimize/augment baseline	Total lymphoid irradiation (TLI)

ing seizures[54] and also the rare, but occasionally rapidly fatal, progressive multifocal leukoencephalopathy.[55]

Decisions need to be made early regarding the use of antimicrobial prophylaxis. These will include antibacterial agents that will be targeted by an understanding of recipient infections pre-transplant, donor-acquired infections, and also potentially hospital-acquired organisms. Antiviral agents will be used extensively to prevent primary infection or reactivation of herpes viruses, particularly CMV/EBV. Pediatric lung transplantation is associated with higher rates of primary CMV mismatch[56] as well as high rates of Epstein-Barr–related lymphoproliferative disease.[57,58] Thus an aggressive approach to DNA virus prophylaxis is undertaken.

The requirement for prolonged ventilation in the ICU is usually associated with substantial worsening of early survival—typically because of the subsequent development of gram-negative or nosocomial ventilator-associated infection in the allograft.

Most patients, however, have good early graft function and can typically be extubated within 24 to 48 hours after transplantation. At the time of extubation, good pain relief is essential. The use of epidural analgesia has dramatically improved pain control without the substantial side effects of high-dose narcotics. Although nonsteroidal anti-inflammatories would be a useful adjunct to the pain relief regimen, these are generally contraindicated because of their substantial synergistic effect with calcineurin antagonists causing deterioration in renal function.

EARLY POSTOPERATIVE RECOVERY

Once extubated and clinically stable, patients can be moved to the general ward. Progressively, the arterial line, intercostal catheters, pulmonary artery catheter, and central venous line can be removed depending on clinical need. Typically, the epidural catheter is left in situ until 5 to 7 days post-transplant—at which time a combination of oral analgesia and intravenous narcotic including patient-controlled analgesia (PCA), can be effectively substituted. Early mobilization at this stage is encouraged within the limitations of the intercostal catheters. Patients would typically be capable of sitting on the side of the bed and transferring to a bedside chair. Progressively with removal of catheters and drain tubes further mobilization can be effected. Patients are encouraged to deep breathe and cough regularly. The denervated airways of a lung transplant recipient render the patient often unaware of accumulation of secretions in the transplanted lung. With the removal of the epidural catheter, the urinary catheter can then typically be removed.

Within the first postoperative week, the objective is typically to reach target therapeutic blood levels for the calcineurin antagonist immunosuppressive agent. Regular monitoring of bloods is often required. This has conventionally been based on predose (C_0) levels; however, recently a strategy to monitor levels 2 hours (C_2) post-dose has been adopted by some programs. This single measure best reflects the area under the curve in formal pharmacokinetic studies,[59,60] although it is less reliable in recipients with cystic fibrosis. Young patients often have intravenous access devices available (including Infusaports) which may facilitate both intravenous infusion and venesection. Early consideration of implanting a device capable of both infusion and regular venesection (e.g., a Hickman-type catheter) should be undertaken to prevent venous access being an impediment to ongoing management.

Rehabilitation

Rehabilitation of the patient should commence as soon as is practical. Severe lung disease is associated with marked structural alteration in skeletal muscle.[61-63] These changes are exacerbated by high-dose corticosteroids and the effects of calcineurin antagonist on skeletal muscle mitochondrial function.[64,65] To prevent further deterioration in functional capacity, weight bearing and ambulation is undertaken as soon as possible. The ultimate objective of this phase of therapy is to have a patient and family fully conversant with the requirements for continued rehabilitation and the drug regimen required in the long term as well as the monitoring requirements.

ONGOING MONITORING

Once discharged from hospital, patients are typically continued in supervised rehabilitation for a further 6 to 8 weeks. Regular visits and regular monitoring of their immunosuppression is required. Monitoring of the allograft through regular lung function tests and infrequent but regular bronchoscopy (with lavage and/or transbronchial biopsy) forms an integral part of patient follow-up in most transplant centers. By 3 months, most patients have improved to the point that they are capable of returning to normal activities.

OUTCOME

Survival

There is often a perception that survival in pediatric lung transplantation is inferior to that of adult lung transplantation. The International Society for Heart and Lung Transplant—United Network of Organ Sharing (ISHLT/UNOS) registry provides regular reports (regularly updated on www.ishlt.org) on the outcome for heart/lung transplantation, bilateral lung transplantation, and single lung transplantation in adults and pediatric patients.[35,66] For heart/lung transplantation, the 1-year survival is 64% in pediatric patients and 62% in adults, with a 5-year survival of 39% in pediatric patients and 43% in adults. Bilateral lung transplantation has a 77% 1-year survival in pediatric patients and 76% 1-year survival in adults, with 5-year survival of 47% and 52%, respectively. Survival in single lung transplant is inferior in pediatric patients, with a 54% 1-year survival compared to 76% 1-year survival in adults and 5-year survival of 27% in pediatric patients and 45% in adults. These poor results in single lung transplantation in pediatric patients are responsible for a substantial reduction over the years in the number of single lung transplants performed in this population.

However, it is difficult to accurately compare the figures because the mix of transplant indications is different when comparing adults and pediatric patients. From the ISHLT/UNOS registry a comparison between adult CF bilateral lung transplant recipients and pediatric bilateral lung transplant recipients (all indications, but largely CF) shows poorer survival in the pediatric group (Fig. 21-3).

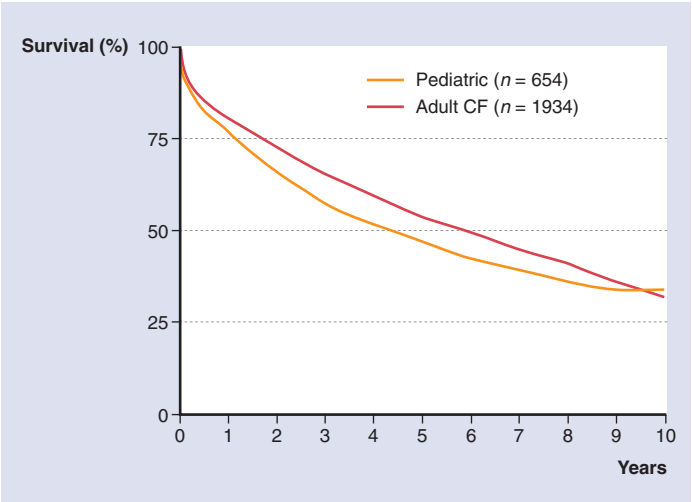

Figure 21-3 Survival following bilateral lung transplantation comparing adult cystic fibrosis (CF) bilateral recipients to all pediatric bilateral lung transplant recipients (72% of whom had cystic fibrosis). The survival is similar in both groups. Data derived from ISHLT/UNOS registry data at www.ishlt.com/, accessed December 2005.

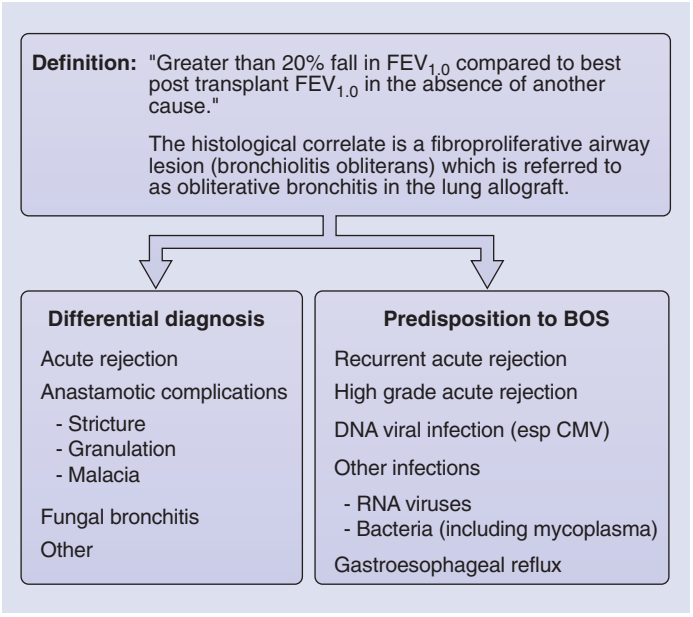

Figure 21-4 Definition, predisposing factors, and important differential diagnoses for bronchiolitis obliterans syndrome (BOS).

Comprehensive 5-year data for live donor lobar transplantation are not available at present. In pediatric patients Starnes and colleagues reported[67] 85% 1-year and 77% 2-year survival for live donor lobar transplantation. Date and colleagues reported a very impressive 100% survival in 30 patients with 1 to 66 months of follow-up following live donor lobar transplantation.[68]

Lung Function

Lung function tests have been used extensively to monitor graft function following lung transplantation. Deterioration in vital capacity or FEV_1 greater than 10% is used as a marker of significant complication[69] which requires detailed evaluation. A 20% fall in FEV_1 from best post-transplant in the absence of a clear cause is used to define established bronchiolitis obliterans syndrome (BOS)[70]—although this is graded BOS 1 to BOS 3 based on the magnitude of FEV_1 fall. More recently patients with >10% fall in FEV_1 without other identifiable cause are designated as "potential" BOS (BOS-op) to reflect the need for careful evaluation earlier in the evolution of BOS.

Patients with heart/lung transplantation and bilateral lung transplantation typically have a persistent mild restrictive ventilatory defect following lung transplantation. Interestingly, this can continue to slowly improve up to 18 months post-transplant.[71,72]

Diffusing capacity is also slightly reduced, even when corrected for the reduced lung volume and the slightly low hemoglobin seen after transplant.[71,72] Live donor lobar transplantation also results in a mild restrictive ventilatory defect and a slightly reduced diffusing capacity.[73] The development of airflow obstruction in patients with heart/lung or bilateral lung transplantation suggests significant pathology. Once bronchial anastomotic complications have been excluded, then other causes including acute rejection, infection, and BOS need to be seriously considered (Fig. 21-4).

Lung function tests following single lung transplantation are persistently abnormal in most circumstances. Patients with obstructive lung disease who have a single lung transplant have a persistent obstructive ventilatory defect, and those patients with restrictive ventilatory defects have persistent restrictive ventilatory defects following lung transplantation.[72] Diffusing capacity is inevitably reduced. Baseline spirometry is clearly important to discern early complications.

Pediatric transplantation also raises the specter of the capacity of lung to expand and fill the growing chest cavity. Initial animal studies have indicated that cut-down adult lungs transplanted into younger (smaller) recipients still have the capacity to expand but with an increase in alveolar size (not number). Conversely, transplanted immature lobes are capable of increasing numbers of functional lung units.[74] Although theoretically transplantation of immature lungs may have greater growth potential, this does not appear to be a practically significant issue.[75-77]

Functional Outcome from Lung Transplantation

Despite near normal lung function, lung transplant recipients still have quite substantial reduction in maximum exercise capacity when tested objectively. A peak oxygen consumption of 50% to 60% of predicted is typical, irrespective of pre-transplant diagnosis and transplant type.[71,72,78-83] The cardiac response in heart/lung transplant recipients is abnormal,[84] showing a blunted (denervated) response. Patients who have received single lung transplantation often approach ventilatory limitation and show desaturation at exercise termination.[85] Most patients, however, appear to have peripheral limitation to exercise. They show an early lactate threshold, but generally normal cardiac response to exercise.[80,86] The dominant problem, however, appears to be structural changes in exercising muscle with a reduction in muscle mass and a reduction in type 1 (oxidative) muscle fiber type propor-

tion.[86] Abnormalities of oxidative metabolism,[86] as well as ion channel abnormalities,[63] have now been reported in the lung transplant recipient. These changes are probably in part reflective of severe deconditioning in the pre-transplant period, as well as reflecting postoperative factors such as major surgery, sepsis, and drugs, particularly corticosteroids and calcineurin antagonists.

Despite this, at least 90% of pediatric[35] survivors of lung transplantation report no significant limitation in their activities up to 5 years post-transplant. In practice, recipients can be advised that they can do most tasks without limitation, although it is unlikely that they would perform well in endurance tasks at a high level.

COMPLICATIONS

Causes of Death

The most common cause of early deaths (less than 90 days) include sepsis and primary graft dysfunction. Acute rejection as a cause of early death is very unusual in adults, accounting for 1.5% to 2.5% of deaths in the first year post-lung transplant.[66] The situation in pediatric lung transplantation appears similar with 1.7% to 3.4% of deaths attributed to acute rejection.[35] These data should be interpreted cautiously, as typically patients who have poor early graft function have a prolonged and complicated intensive care stay. These are frequently recorded as death caused by graft failure (37% of deaths in the first 30 days in the ISHLT/UNOS registry report of pediatric lung transplantation). Often poor early graft function leads to prolonged mechanical ventilation and ultimately ventilator-associated infection due to nosocomial pathogens, which may be recorded in the registry as the cause of death. Severe early graft dysfunction is often associated with an inability to support life with conventional mechanical ventilation. Transplant centers often use high frequency ventilation and even extracorporeal membrane oxygenation (ECMO), with increasingly successful outcomes in patients who just a decade ago were unsalvageable post-transplant.[87] The ability to utilize independent lung ventilation has also proved to be potentially lifesaving. Beyond 1 year after transplant, bronchiolitis obliterans (34% of deaths) and infection (20%) are the most common causes of death in pediatric lung transplant recipients.[35]

Acute Rejection

Acute rejection can occur at any time following lung transplantation, and is diagnosed in approximately 50% of recipients within the first 3 months following transplantation. The one exception is that children in the first year of life have a significantly lower incidence and severity of acute rejection.[88] Surprisingly, despite a typically closer HLA match, living donor lobar transplant recipients have a similar incidence of acute rejection to those receiving cadaveric organs.[67] The ISHLT has developed a standard grading system for acute rejection as seen on transbronchial or open lung biopsy.[89] Grade A0 is normal appearance, grade A1 is designated minimal acute rejection. A mononuclear infiltrate may be seen around some vessels, but it is less than five cells deep. Mild acute rejection grade A2 is seen where pulmonary arteries and arterioles are surrounded with a mononuclear cell depth of more than 5 cells. Grade A3, or moderate acute rejection, is defined as extension of the inflammatory process into the pulmonary interstitium; often there are features of endothelial proliferation secondary to the lymphocytic infiltrate (endotheliitis). Severe acute rejection has features of less severe grades of rejection, but there is also evidence of diffuse alveolar damage, and this is defined as grade A4 rejection.

Many centers now perform routine surveillance bronchoscopy with biopsy, and asymptomatic rejection is not uncommon. Both a high-grade rejection[70] and recurrent low-grade rejection[90,91] are important to detect, as they appear to be risk factors for subsequent development of BOS. Typically, patients are not symptomatic unless they have high grade rejection (A3 or A4), which is often associated with pulmonary infiltrate on chest radiographs. Monitoring of lung function is normally employed and a reduction in FEV_1 or vital capacity of 10% should lead to further evaluation, including bronchoscopy and transbronchial biopsy to assess for developing acute rejection or infection.

Although the standard for detecting acute rejection and other post-transplant complications is open (or thoracoscopic) lung biopsy, these are not feasible for routine monitoring of transplant recipients. Transbronchial biopsy has, therefore, been extensively utilized. Multiple transbronchial biopsies are required to have a high sensitivity for A2 rejection (18 biopsies for 95% sensitivity).[92] In practical terms five or six 1 mm diameter transbronchial biopsies are recommended, but this probably has a sensitivity of between 85% and 90% in the diagnosis of acute rejection. Other forms of rejection have been reported. Immediate rejection owing to preformed antibodies (hyperacute rejection) has been very rarely reported.[93] The presence of a pulmonary infiltrate and bronchiolitis obliterans organizing pneumonia (BOOP) on biopsy[94] has been reported as a subacute form of rejection often requiring augmented corticosteroids for several months. BOOP is often seen as a complication of pulmonary infections,[95] but may also be part of the allo-response.

Chronic rejection is most commonly seen in the form of BOS and this is discussed in a separate section, but forms of chronic rejection including chronic vascular rejection and progressive restriction due to fibrosis are occasionally reported.

In all patients in whom rejection has occurred, particularly if repeated or severe, careful evaluation of compliance with the immunosuppression regimen is urgently needed. Compliance is one of the major issues in the management of pediatric lung transplant recipients, and a sudden development of rejection should always alert the clinician to the possibility of sudden cessation of immunosuppression.

Infectious Complications

Infections are a frequent problem in the lung allograft. The lung allograft is unique in that it is not completely revascularized (generally there is no attempt to re-anastomose the bronchial circulation), and it is the only transplanted organ directly communicating with the external environment—leading to the need to clear airborne pathogens to prevent overgrowth and overt infection.

Thus pulmonary infections represent the major infection burden following lung transplantation. Both donor-acquired and recipient-acquired organisms need to be considered. Causative organisms include community-acquired pathogens, nosocomial (hospital-acquired) pathogens, and pathogens seen in the immunocompromised host. Impaired mucociliary clearance related to the bronchial or tracheal anastomosis is a significant risk factor. If a more serious ischemic injury to the bronchial anastomosis has occurred, then sputum retention with the development of frank pneumonia is not an infrequent complication. Allograft injury or small airway injuries as seen in the bronchiolitis obliterans syndrome are also major predisposing factors to persistent and/or recurrent infection in the allograft. The use of indwelling intravenous cannulas is associated with a high incidence of line-related sepsis.

A pulmonary infiltrate with or without other features of sepsis (fever and leukocytosis) is a common clinical scenario following lung transplantation. Chest radiographs and CT scan appearances may give some information as to the differential diagnosis (e.g., a nodular infiltrate as opposed to a diffuse infiltrate), but are rarely diagnostic. The choice of antimicrobial agents will depend on which organisms are known to be present, and also organisms that are likely to be present in the individual patient circumstance. Clearly, a patient presenting in extremis requires cover for all reasonable possibilities, whereas patients presenting early on in the natural history of their infection may be given more focused antibiotic therapy and monitored carefully for response. The organism known to colonize the patient is not necessarily the pathogen at that presentation. Some patients also have polymicrobial infections requiring often complex antibiotic combinations. Notwithstanding this, patients presenting from the community are more commonly infected with community-acquired pathogens compared to more exotic opportunistic pathogens. Indeed, in the age of antibiotic prophylaxis for *Pneumocystis jiroveci*, this important opportunistic pathogen in the T cell immunosuppressed host is almost never seen. In patients presenting abruptly unwell, or those failing to respond to more simple therapy, urgent bronchoscopic sampling, with bronchoalveolar lavage and/or transbronchial biopsy, may be required. Full blood examination, renal function, drug levels, and liver function studies will guide as to the likelihood of infection with an opportunistic pathogen as well as the most appropriate antibiotic treatment. Peripheral blood should be sent for serologic examination when appropriate and cultured for relevant viruses. Diagnostic molecular assays such as polymerase chain reaction (PCR) can be used to detect CMV.

PERIOPERATIVE PNEUMONIA

This is a frequent complication of lung transplantation and may start within hours of the procedure with the patient intubated and ventilated in the intensive care. Known and potential donor pathogens, colonizing organisms in the recipient, prevalent nosocomial pathogens, as well as community-acquired pathogens all need to be adequately covered with antimicrobial agents. Generally, methicillin-resistant *Staphylococcus aureus* (MRSA) and gram-negatives such as *Pseudomonas aeruginosa* and *Stenotrophomonas maltophilia*, as well as other prevalent ICU pathogens, need to be considered at this stage. Opportunistic pathogens are rarely problematic in the first 4 weeks post–lung transplant. Occasionally fungi such as *Aspergillus* can colonize the allograft early, particularly in the absence of an established prophylaxis regimen. Prior to healing of the anastomosis, the organisms can potentially pass through the anastomosis into the mediastinum, and severe systemic infection can occur even without the patient being neutropenic.

Pneumonia Manifesting from the Community

For reasons discussed earlier, pneumonia is a frequent manifestation in the lung-transplant recipient. Pneumococcal pneumonia is prevalent; however, antibiotic choice needs to take into account recent hospital contact as well as known colonizing pathogens.

NONPULMONARY INFECTIONS

Infections in nonpulmonary sites are commonly line related[96] but otherwise related to unusual or opportunistic pathogens. These may include atypical presentations of mycobacterial infections including cutaneous nodules. Gastrointestinal infections with *Giardia* and systemic infections with *Cryptococcus* species are also regularly seen. In pediatric recipients, the high likelihood of a primary mismatch with respect to Epstein-Barr virus (donor positive, recipient negative) can be associated with the development of lymphoproliferative disease or B cell lymphoma.[97] Although these most often manifest within the lung allograft, extrathoracic sites include gastric and small bowel lymphoma. Primary infection with cytomegalovirus may be associated with viremia, pneumonitis, bone marrow suppression, or gastrointestinal manifestations (gastritis or colitis).[56]

Bronchiolitis Obliterans Syndrome

Bronchiolitis obliterans is defined as irreversible loss of lung function with a reduction in FEV_1 of 20% below best post-transplant reading in the absence of known cause. In general, the BOS criteria[70] can be used in children who can perform pulmonary function tests reproducibly (i.e., greater that 5 years of age). However, in defining functional decline, a decrease in percent predicted rather that a change in absolute value should be used to allow for the expected increase with the child's growth.[70] In small children, lung function testing by other methods, most commonly the rapid compression technique, has been used in an attempt to diagnose peripheral airflow obstruction.[98,99]

Pathologically, this is a fibroproliferative condition of small airways, the histologic lesion being bronchiolitis obliterans, which in the transplant setting is called obliterative bronchiolitis. It is not feasible to perform open-lung biopsy on all patients with deteriorating lung function on a repeated basis. For this reason, transbronchial biopsy is used as the primary histologic evaluation of the transplanted lung. This modality lacks sensitivity in the diagnosis of obliterative bronchiolitis and therefore BOS has been used to define what has generally been regarded as a form of chronic rejection. BOS is particularly prevalent in pediatric transplantation in the first 2 years following transplant (Fig. 21-5), where rates exceed that seen in adults—although after the first 2 years new cases seem to occur at about the same rate as in adults.[100] The exception may be in children younger than 3 years of age, in whom the

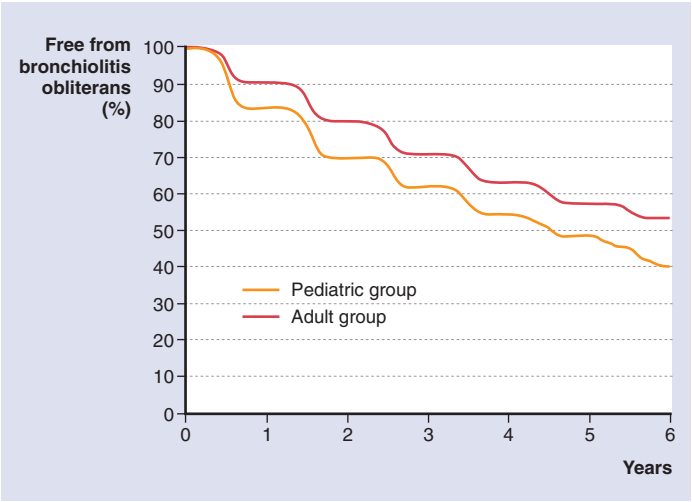

Figure 21-5 Survival curves showing freedom from bronchiolitis obliterans syndrome in adults compared to pediatric lung transplant recipients. Initially higher rates of BOS in the first 2 years post-transplant are evident in the pediatric group (yellow) as compared to adults (red line). Data derived from ISHLT/UNOS registry data at www.ishlt.com/ accessed December 2005.

incidence of BOS may be lower.[70,101] Nevertheless, by 5 years in the ISHLT/UNOS registry 50% of pediatric patients and 40% of adult patients will have BOS.[35,102]

Our understanding of the etiology of BOS has evolved dramatically over the last decade. Initially this was thought to be a manifestation of alloimmunity. The landmark review paper by Estenne and colleagues highlights a number of potential etiologic factors that may be important in the development of bronchiolitis obliterans.[70] Classic alloimmunity remains the leading risk factor and, as noted previously, high-grade acute rejection and/or recurrent low-grade acute rejection are risk factors. Indeed, although the incidence of acute rejection appears similar in pediatric living-related lobar transplants and cadaveric transplants, the better HLA matching seen in the former appears to confer a lower BOS incidence.[67,103]

CMV pneumonitis has been an established risk factor for the development of bronchiolitis obliterans[70,101] and more recently, the presence of this DNA virus, independent of a clinical syndrome, has also been found to be a risk factor.[104] Patients often report a respiratory tract infection prior to BOS developing and it is recognized that community-acquired bacterial[105] and viral infections are associated with the development of BOS.[106] Recently, macrolide antibiotics including azithromycin have been shown to significantly reverse airflow obstruction in patients with established BOS.[107-111] Although this may be due to their antimicrobial action (recurrent bacterial pulmonary infection is a common accompaniment of BOS), it is also possible that by damping down the intensity of the innate immune response, progression is halted and lung function may even improve.

Also of considerable interest is the potential role of gastroesophageal reflux with or without aspiration in the development of BOS,[112-114] including detrimental effects of bile reflux.[115] Some investigators have proposed very early intervention with antireflux surgery[116-119] to halt progression of or to prevent the development of airflow obstruction.

Table 21-5
Potential Treatment for BOS in Relation to Potential Etiology

Recurrent acute rejection/ severe acute rejection	Increase baseline immunosuppression Augmentation Careful monitoring/biopsies
DNA viral infections	Monitoring of viral DNA load (preemptive) antiviral therapy Assess intensity of immunosuppression
RNA viral infections	? Specific antiviral (ribavirin)
Bacterial infection	Targeted antibiotics Anti-inflammatory antibiotics (e.g., azithromycin/clarithromycin
Gastroesophageal reflux	Conservative antireflux measures (not simply antacid therapy) Antireflux surgery

BOS, bronchiolitis obliterans syndrome.

The differential diagnosis of BOS includes acute rejection, fungal bronchitis, and anastomotic complications—as well as other treatable infections. For this reason, careful evaluation including bronchoscopy, bronchoalveolar lavage, and/or biopsy is important is the attempt to exclude these important treatable causes (Table 21-5).

PSYCHOSOCIAL ISSUES

Generally patients are considered for lung transplantation when their anticipated survival is less than 2 years. In the pretransplant era, palliative care supporting both patient and extended family was the focus of the therapeutic team. In many ways, transplantation has complicated this. Patients often hold out in the hope that a suitable donor will become available, well beyond the point that previously they would have accepted palliative care with a focus on symptomatic relief. Patients almost inevitably are in progressive decline once listed for lung transplantation. Deaths on the waiting list are frequent.[39,120,121] Regular review of the patient and family on the waiting list reinforces the transplant unit's determination to offer transplantation. It also allows an assessment as to the urgency of transplantation and perhaps the desirability of using marginal or nontraditional donors for lung transplantation. The transplantation often occurs in a different hospital than the hospital that provided care for many years of the chronic respiratory illness. The ability of the patient and, particularly, the family to become familiar with the transplant hospital becomes important.

Psychosocial evaluation of the child and family is a key part of transplant assessment. Children usually have different priorities than their parents and complying with a complex drug regimen (particularly medications that have substantial toxicities) requires continued sustained effort. Even in seemingly compliant children with well-motivated families, sudden deterioration in graft function may reflect a discontinuation of antirejection medication. This is a frequent occurrence and although it is important not to directly blame anyone, a high index of suspicion for poor compliance must remain in all transplant recipients, especially in children.

The aim of transplantation is to return the recipient to a normal quality of life. On the waiting list for transplantation it is essential to attempt to maintain children whenever possible in educational programs and continuing social contact

with their peers. After transplantation, there is normally a 3-month period of intensive rehabilitation, but after this time it would be realistic for most recipients to return to full-time education.

Patients may prove unsuitable for lung transplantation. This issue requires very careful counseling and support because transplantation often represents the last available option for the potential recipient. Notwithstanding this, some patients have poor chance of success and the most likely outcome is that transplantation will extend their suffering, not improve their quality of life, which is its objective.

CONCLUSION

Lung transplantation has now become standard therapy for patients with severe end-stage lung disease and pulmonary vascular disease. Donor shortages, however, mean that only a small proportion of patients who may benefit will ultimately be offered transplantation. Transplantation in the pediatric age group is complicated by potential growth issues in the recipient, psychosocial issues including poor compliance with complex drug regimens, as well as a high likelihood of primary infection with DNA viruses such as cytomegalovirus and Epstein-Barr virus. Lung transplantation is still far from being a perfect solution; however, in highly selected individuals it can lead to substantially increased survival and improved quality of life.

CHAPTER 22 Home Ventilation and Respiratory Support

Stephen M. Stick, Andrew Wilson, and Howard B. Panitch

TEACHING POINTS

- The goals of home mechanical ventilation are to extend life, enhance its quality, and to reduce morbidity in a cost-effective way.
- Children managed at home requiring home ventilation or positive pressure support are best managed by a multidisciplinary team.
- The decision to ventilate or provide positive pressure support for a child at home will depend on locally available resources, access to appropriate technology, and the attitudes of physicians, caregivers, patients, and other health care staff.
- An appropriate care-plan must be developed with the patient and caregivers before discharge from hospital and should include an assessment of locally available health care resources; access to working utilities and telephone service; access to emergency and respite care; and technological support.
- A wide variety of machines that support ventilation is available. The type of machine and settings should be tailored to the patient's characteristics, goals of ventilation, and the experience of the center managing the child. Flow-generators used for noninvasive positive pressure (NIPP) support might not be suitable for home ventilation in some children.
- Regular follow-up including the assessment of adequacy of ventilation during sleep improves outcomes for children managed at home with ventilatory and positive pressure support.
- Outcomes of children receiving home mechanical ventilatory support are generally good. Mortality typically is most dependent on the prognosis of the underlying disease for which ventilation is being used.
- Quality of life for the patient receiving home mechanical ventilation is also generally good, but this may be at the expense of the family's quality of life.
- Home mechanical ventilation remains an extraordinary undertaking on the part of family caregivers, and must be supported by the medical team and appropriately resourced.

Home mechanical ventilation (HMV) is a treatment option that is becoming increasingly available and one that is being chosen by families with increasing frequency as an alternative to prolonged hospitalization and institutional care. Despite the rapid uptake of this technology, there are relatively few data in children that describe outcomes, and the complex psychosocial, community, and ethical issues associated with HMV are only beginning to be explored in attempts to aid, what can be, difficult clinical decision making. There are few published guidelines concerning the selection of patients for and initiation of HMV. In 1990, the American Thoracic Society (ATS) published Home Mechanical Ventilation in Children, a statement that has not been updated despite dramatic changes in technology and the number of children being treated.[1] In this chapter we will discuss the currently available technology, patient demographics and selection, initiation of HMV, treatment outcomes, patient monitoring, and some of the issues that affect clinical decisions.

ETHICAL CONSIDERATIONS

The goals of home mechanical ventilation in children include extending duration of life and enhancing its quality. Additionally, the use of home mechanical ventilation should reduce morbidity, improve the child's physiologic function, help to achieve normal growth and development whenever possible, and also reduce overall health care costs.[2] The ethical and moral issues surrounding long-term mechanical ventilation are complex. We can only point the reader to relevant reviews and highlight some of the general considerations that can guide good clinical practice. A useful starting point is to have a methodologic framework to help analyze specific situations to arrive at a morally justifiable end point that allows for intercultural and cross-cultural differences and lacks bias. Such a framework based on principles of respect for autonomy (the obligation to respect the decision making capacities of autonomous persons); nonmaleficence (the obligation to avoid causing harm); beneficence (obligations to provide benefits and to balance benefits against risks), and justice (obligations of fairness in the distribution of benefits and risks) has recently been reviewed.[3] Nonetheless, a recent publication notes that for families, when deciding what is right or wrong for their ventilator-dependent children, choices that have life or death implications can be perceived as virtual choices and thus somewhat removed from reality.[4]

For most clinicians the most challenging patients are those with severe neuromuscular weakness such as spinal muscular atrophy (SMA) and Duchenne muscular dystrophy (DMD). Most clinicians would agree that decisions should be reached mutually by the family/patient and medical team and should

favor the child's best interests. The ramifications of that decision need to be viewed from the perspective of the affected individual, the family, and society as a whole. Some of the ethical issues that affect the decision to commence HMV in patients with neuromuscular diseases have been systematically reviewed.[5] Simmonds emphasizes the need for full disclosure of information if a truly informed decision is to be made. The review of the relevant literature by Simmonds revealed that HMV can prolong life, is associated with acceptable quality of life for patients and families, and that in general decisions regarding the initiation of HMV are influenced by local resources, cultural and religious factors, and physician attitudes. Clearly, these factors will have a marked influence on practices in different centers and this makes general management guidelines difficult to develop. A recent Canadian survey showed that 25% of physicians did not offer long-term mechanical ventilation to patients with DMD, most commonly because of the physicians' perception of poor patient quality of life.[6] However, clinicians have a responsibility to help patients and families arrive at ethically and morally justifiable decisions regarding treatment. In our experience, such negotiated care plans are best developed electively, not at times of acute medical crisis and with patients and families having options supported by available evidence presented in an unbiased, nonjudgmental way. In cases where a negotiated care plan cannot be agreed on, further independent medical opinion might be required and in some cases legal intervention is needed to facilitate an appropriate outcome that is underpinned by the principles of autonomy, nonmaleficence, beneficence, and justice.

TECHNOLOGY

The 1990 ATS statement dealt almost exclusively with children ventilated at home via tracheostomy. At that time, the ventilators that were suitable for home use were either simple portable machines that delivered volume-controlled mandatory breaths without continuous flow, or stationary pressure-controlled hospital ventilators that required a separate air compressor to run. Currently available ventilators have benefited from advances in computer-controlled flow and pressure generators, miniaturization, battery design and control algorithms. Furthermore, the advent of noninvasive positive pressure ventilation (NIPPV) via mask (nasal or oronasal) has revolutionized the management of children with a wide range of disorders from neuromuscular disease to obstructive sleep apnea and hypoventilation. However, a note of caution with regard to flow generators designed primarily for use to treat obstructive sleep apnea and that deliver user-defined inspiratory and expiratory pressures with a varying degree of sophistication with regard to modes of control. These machines are not primarily designed for use as home ventilators and their limitations include low maximum back-up rates, rudimentary trigger algorithms, high flows, and inability to accurately set or determine F_{IO_2}. Most flow generators do not have built-in alarms that are sufficiently sophisticated for patients who are ventilator dependent.

PATIENT DEMOGRAPHICS

The prevalence of home mechanical ventilation in Europe in 2001 was estimated at 6.6 users per 100,000 population.[7] The vast majority of these patients were receiving ventilation noninvasively. In 1993, Downes and Pilmer estimated that 4000, or 1.5/100,000 children in the United States were chronically ventilator dependent.[8] Although there are no recent prevalence figures for the pediatric population, it is clear that home ventilation is becoming increasingly common. There have been a number of reports from individual centers[9-15] describing the use of home ventilation in children. There is considerable information about the diagnostic groups into which children receiving home ventilation fall. The underlying diseases can be classified in four main groups: disorders of the respiratory pump (including neuromuscular diseases, diseases of the chest wall and spinal cord injury); obstructive diseases of the airways (including those associated with craniofacial anomalies); parenchymal lung diseases (particularly cystic fibrosis and bronchopulmonary dysplasia); and disorders of the control of respiration (notably congenital central hypoventilation syndrome). In the above series, neuromuscular diseases are the largest single group, accounting for between 28% and 51% of cases. Although parenchymal lung disease is a common indication for home ventilation in adults, accounting for 34% of cases in Europe,[7] this is a much less common underlying disorder in children.

COMMENCING HOME VENTILATION

Generally, children are commenced on home ventilation by one of two pathways. First, mechanical ventilation may be started as a result of an acute illness in which the child is unable to be successfully weaned from ventilation. Alternatively, a decision may be made in a child with chronic respiratory failure to electively commence ventilation. There are no published consensus statements regarding the elective initiation of home ventilation. In general, but not exclusively, mechanical ventilation via tracheostomy is commenced following an acute illness, whereas noninvasive ventilation (NIV) can be commenced either acutely or electively. Even in conditions such as neuromuscular disease, where there is clearly an opportunity to introduce home ventilation electively, these opportunities are often missed. In one series of 73 children and young adults with neuromuscular disease requiring home ventilation, 79% had commenced ventilation acutely following an episode of acute respiratory failure related to a pneumonia.[16] The authors identified nearly 200 missed opportunities to discuss elective initiation of mechanical ventilation during office visits, previous hospitalizations, or after polysomnography. This is despite excellent evidence that nocturnal hypoventilation precedes daytime respiratory failure in neuromuscular disease and that institution of nocturnal ventilation can prevent or ameliorate daytime respiratory failure.[17,18]

In most cases noninvasive ventilation would be the treatment of choice for children requiring long-term ventilation; however, there are certain circumstances in which NIV is contraindicated or in which ventilation via a tracheostomy would be preferred. Ventilation via tracheostomy should be considered if ventilation is required for more than 16 hours per day because of the difficulty in maintaining mask ventilation for this period of time and the level of respiratory insufficiency that this amount of support indicates. Application of NIV is also more difficult in infants because of the limited

number of well-fitting interfaces available, especially in places where custom mask fabrication is not employed. With current technology NIV is also difficult when supplemental oxygen is required. As oxygen must be added to either the ventilator circuit or the mask, it is difficult or impossible to monitor F_{IO_2}. Because flows generated by the ventilator are high, there is a marked dilution of the supplemental oxygen, necessitating high oxygen flows to significantly increase F_{IO_2}. Higher flows of supplemental oxygen bled into the system will also contribute to patient-ventilator dyssynchrony, especially in small children. Here, the additional flow of supplemental oxygen can mask the change in circuit flow generated during a spontaneous inspiration, which is used as a trigger signal for pressure support, assist control, or synchronized intermittent mandatory ventilation. From a practical viewpoint, it is inappropriate to consider home ventilation in a child who requires an F_{IO_2} of greater than 0.4 because of the limitations in supplying such high amounts of oxygen in a home setting. Furthermore, consideration should be given to pulse oximetry for children receiving NIV who have a requirement for supplemental oxygen oximetry—given the uncertainties inherent in oxygen delivery in this situation.

Initial Titration of Ventilation

Patients ventilated via tracheostomy are usually stabilized in the intensive care unit either during an acute episode of respiratory failure or following an elective tracheostomy. In either case, the ventilatory requirements can be relatively easily assessed because of the stable patient interface and the use of versatile ventilators with a range of modes that further facilitate stabilization.

Often, children who receive chronic ventilatory support via tracheostomy for airway or parenchymal lung disease are provided with a minimum back-up mandatory rate, and pressure support ventilation is used to support a portion or all of each spontaneous breath. Because the pressure-supported breath is triggered (initiated) by patient effort and also cycled (terminated) by the physiologic characteristics of the patient's lungs, it is a more natural and therefore often a more comfortable supported breath for the patient than is a mandatory breath that is cycled based on characteristics set by the physician or therapist. In this scheme of synchronized intermittent mandatory ventilation with pressure support (SIMV+PSV), the SIMV breaths can be set to deliver volumes slightly higher than the patient's usual tidal volume breaths, and so act as periodic sigh breaths.

There are several other strategies for determining ventilator settings, and these are based on the equipment available, the underlying disease being treated, and the goals that ventilatory support is intended to achieve. For instance, if a home ventilator that provides pressure support is not available, and one of the goals is to enhance the patient's growth by reducing the caloric expenditure of breathing, the operator might choose to use a relatively high (12 to 15 mL/kg) tidal volume and moderate mandatory breath rate to provide ventilation adequate enough to reduce the child's spontaneous efforts.[19] Patients with neuromuscular disease who often have no underlying parenchymal lung disease should not require supplemental oxygen. They should be given a minute ventilation high enough to avoid hypoventilation and its attendant hypoxemia. Often, these patients can be supported in Assist/Control mode with a minimum set rate that can be superseded by the patient, while still receiving full support during each additional breath. Patients who receive mechanical ventilatory support by a mouthpiece (sip or sip and puff ventilation) can receive breaths in either pressure- or volume-control mode. If used in the volume-control mode, however, the patient can be taught to breath stack and use the ventilator to assist with cough, thereby enhancing autonomy.

However, for patients requiring noninvasive ventilation by nasal or oronasal mask, the situation is more complex. For example, the patient interface is less stable and prone to leaks and the flow generators commonly used for inspiratory and expiratory support ventilation are relatively unsophisticated.

The nature of noninvasive ventilation is such that it is most usually used either during sleep for treatment of chronic sleep-disordered breathing or for short periods during acute illnesses. For patients requiring long-term NIV, the establishment of ventilation is best done in hospital with careful attention paid to mask fitting and titration of ventilatory variables. Initially a crude titration can be performed at the bedside—but a formal titration polysomnogram should be performed at discharge or alternatively, soon after discharge, for stable patients with straightforward ventilation requirements. Recent evidence supports regular six to twelve monthly titration polysomnograms for most patients requiring long-term NIV,[20] and more frequent assessment in patients with evolving conditions, complex respiratory diseases, or difficult interface issues. Prior to titration, care should have been previously taken to fit an appropriate and comfortable mask and then a time is chosen for titration when the child is likely to sleep. A typical example of a formal polysomnogram titration algorithm for hypoventilation that is used in our laboratory is shown in Figure 22-1. Some institutions use a split-night polysomnogram to diagnose the extent of any sleep disordered breathing and establish NIV (Fig. 22-2). The success of this approach will depend on the nature of the breathing disorder, compliance of the child, and expertise available during the study. Approximate bedside titration during the initial establishment of NIV can be effectively achieved using the algorithm in Figure 22-1 prior to a formal polysomnogram.

During titration the commonest problems encountered are air leaks (either from around the mask or through the mouth) and failure to synchronize the ventilator with the child's spontaneous breathing pattern. Spending time choosing an appropriate mask and having a range of masks available can help solve problems with leaks due to a poorly fitting mask. Occasionally, it is necessary to use a custom-made mask, particularly for children with unusual facies and craniofacial abnormalities. In order to reduce leakage of air through the mouth, it is important to ensure that the nose is clear, thus reducing the likelihood of oral breathing. Sometimes changing a mask and headgear to allow for a different sleep-ing posture can help and in young children a pacifier can also reduce airflow through the mouth. However, for some children the use of a chin-strap to elevate the mandible in order to close the mouth is unavoidable.

Air leak is an important cause of failure to synchronize the ventilator with the patient's spontaneous breathing pattern

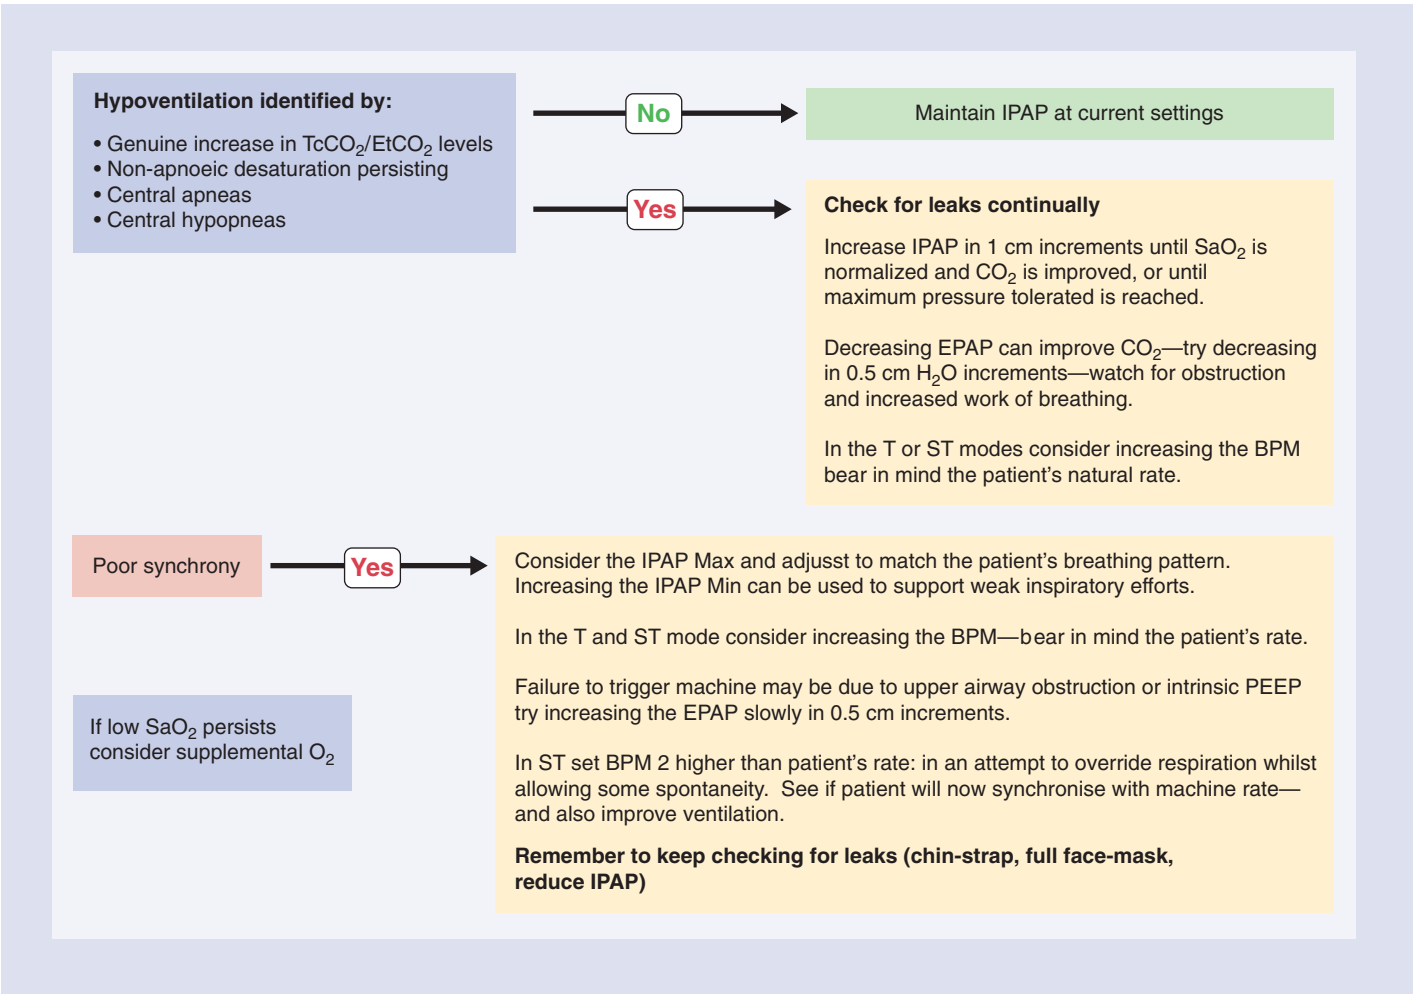

Figure 22-1 Titration algorithm for determining ventilator settings for hypoventilation treated with noninvasive mask ventilation.

and should always be checked first in patients that are difficult to ventilate. Other causes include inappropriate ventilator settings, failure to trigger because of airway obstruction or intrinsic positive end-expiratory pressure—these factors should be methodically assessed using the steps suggested in Figure 22-1.

Equipment Requirements

VENTILATORS

Mechanical ventilatory support can be provided by positive- or negative-pressure body ventilators, and by devices that deliver positive pressure to the airway opening noninvasively via nasal, oronasal, or oral interfaces, or invasively by a tracheostomy tube. Newer positive pressure ventilators suitable for home use also have the capability to provide continuous flow and pressure support ventilation. Portable systems are now available that can be used in volume- or pressure-targeted modes. Bi-level pressure generators deliver pressure pre-set ventilation and continuous flow for noninvasive ventilation, but they are not considered portable and at present, most do not have intrinsic alarm systems. Traditionally, ventilators designed for invasive use have included a greater range of monitoring and alarms and have been equipped with internal batteries. Increasingly, these features are being incorporated in ventilators designed for noninvasive use. There is an ever-enlarging range of devices marketed for the provision of home ventilation. Detailed description of individual machines is inappropriate here, and such a description would soon be obsolete. A description of the more commonly used machines has been produced recently.[21]

There is no single ventilator that is suitable for use in all home-ventilated children. A ventilator should be selected that best suits the needs of the child. Consideration should be given to whether the ventilator is designed for invasive or noninvasive use. In general, machines designed for noninvasive use should not be used via tracheostomy. When invasive ventilation is used, particularly when the child is ventilated for a significant period during the day, portability is a major issue. A ventilator that is of a sufficiently small size (for example to fit beneath a pram or stroller) and has a long battery life is necessary. Other desirable attributes for a pediatric ventilator include a selection of ventilator modes, adjustable trigger, capability to deliver raised FIO_2, and low dead space.

There are significant differences in the consistency of performance of commercially available devices.[22-25] Inconsistencies can be the result of mode of ventilation or ventilator design,[22] and can be exacerbated by extreme patient loads (high resistance, low compliance) imposed on them. Each

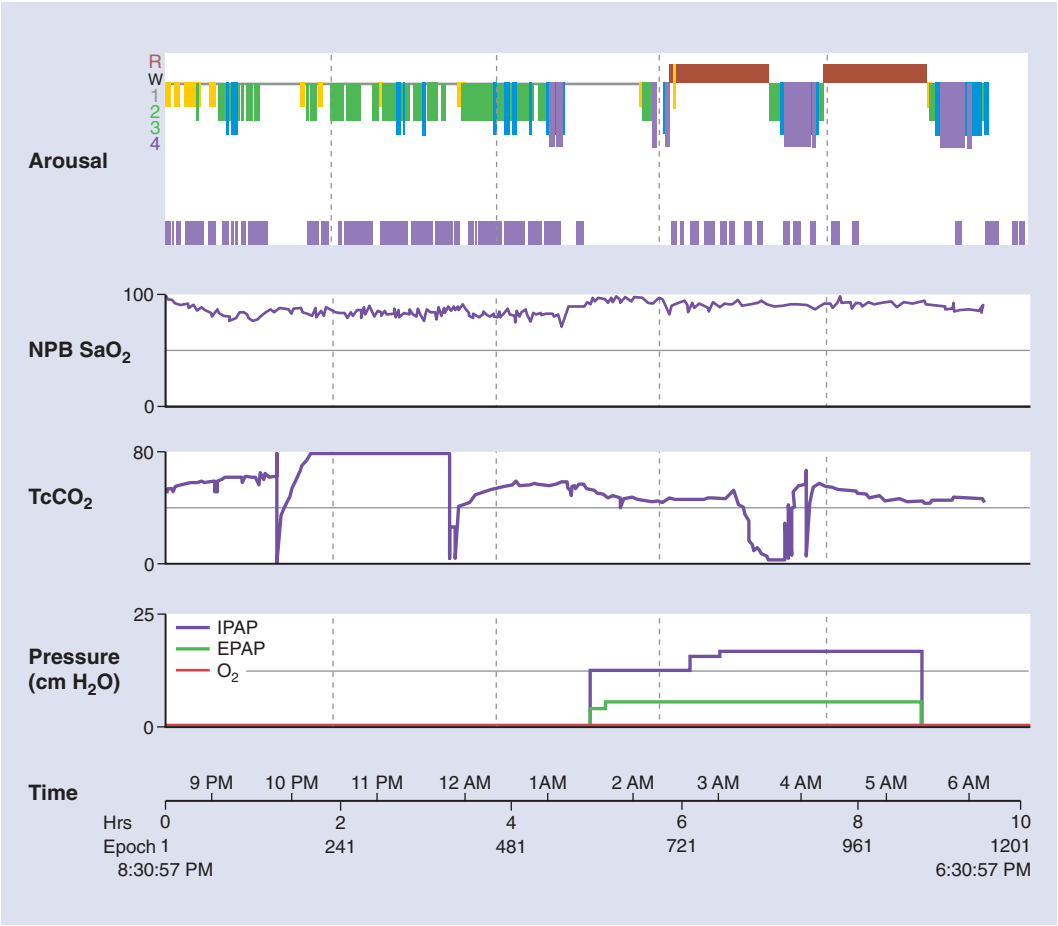

Figure 22-2 A split-night sleep study performed in a 16-year-old boy with Duchenne muscular dystrophy. In the first part of the night he is spontaneously breathing in room air; noninvasive ventilation (NIV) via nasal mask is commenced just before 2 AM. In the first part of the night, there is severe sleep fragmentation, oxygen desaturation, and hypercarbia. Once NIV is commenced, both oxygenation and ventilation improve as does sleep quality. Particular note is made of the phenomenon of rapid eye movement (REM) rebound where an increased percentage of time is spent in REM sleep once adequate ventilation is restored.

company creates its own method for turning on its machine and adjusting ventilator settings and alarms in a way that is often not intuitive—even to health care professionals.[26] Because there is no standardization of ventilator design, consideration of user friendliness must be made not only for families, but also for the center to which the child will be admitted for planned or emergency care. For this reason, many home ventilation programs limit the variety of devices used in their population, to reduce iatrogenic complications when children require rehospitalization.

The equipment needs of children supported at home with mechanical ventilation have been previously described,[27,28] and will vary depending on the interface used (noninvasive versus tracheostomy), number of hours per day the child requires support, and the distance the child resides from the health care facility or home equipment provider. Children who cannot sustain adequate ventilation without mechanical support for >4 hours or who live more than 1 hour from the health care facility or durable medical equipment (DME) provider require a second complete ventilator and circuit as back-up.[27-30]

ALARMS AND MONITORING

Although patients selected for home ventilation are, by definition, clinically stable, their dependence on technology leaves them vulnerable if this technology fails. It is, therefore, important to consider potential problems that the child may encounter and plan for these accordingly. Whereas some children will cope if deprived of their ventilatory support, others are dependent on such support and are at risk of mortality in this situation. A child who has electively commenced ventilatory support via nasal mask for nocturnal respiratory failure has very different requirements from those of a child with a high spinal cord injury who is continuously ventilated via tracheostomy.

Ventilator alarms, both internal and external, are particularly important for the patient who is dependent on ventilation. Positive pressure ventilators made for home use have intrinsic high- and low-pressure alarms. These are critical for detecting possible tube obstruction, inadvertent ventilator circuit disconnection, or accidental tracheostomy decannulation. Importantly, the use of small tracheostomy tubes with inside diameters <4.5 mm can provide enough resistance at

the end of the ventilator circuit to cause low inspiratory pressure alarms to fail to sound in the event of an accidental decannulation.[31] Thus, in smaller children, additional types of monitors are used to identify emergency situations.

External monitors such as oximeters may be indicated in some circumstances, but should not be used as de facto ventilator alarms. Rather than providing each patient with all possible alarms and monitors, it is appropriate to consider each child, the problems that may be encountered, and the child's likely response to each situation. In fact, the use of other types of monitors beyond those associated with the mechanical ventilators is a subject of controversy. Some authors advocate for the use of impedance cardiorespiratory (apnea) monitors,[27,32] whereas others think they are redundant and unnecessary.[33] Such monitors, however, will not alarm in the event of an obstructed tracheostomy tube or displaced nasal mask until hypoxemia has occurred long enough to cause bradycardia. Similarly, some groups feel that continuous monitoring of oxyhemoglobin saturation by pulse oximetry or of carbon dioxide levels by capnography have little or no place in home care.[32,33] Others rely heavily on oximetry both for weaning supplemental oxygen and also as an earlier warning to detect life-threatening events.[34] In one study, a reduction in the incidence of death or hypoxic brain damage related to airway accidents was reduced by the use of pulse oximetry in the home.[8] Oximetry can be used not only as a supplemental alarm for potential airway obstruction, but also as a tool for weaning ventilator support. It is also an early warning for the detection of an acute lower respiratory illness that may require an increase in ventilatory support. Hypoxemia as detected by pulse oximetry is also a sign that more aggressive airway clearance and possible escalation of other therapies are required for children with neuromuscular weakness who are not hypoxemic at baseline and who normally have no underlying parenchymal lung disease.[35] Similarly, intermittent capnography can be used during and after weaning trials to detect changes in adequacy of ventilation. Continuous capnography is typically not indicated for home care of ventilator-dependent children.

In general, potential risks for each patient should be considered prior to discharge, and a risk management strategy devised.[36] In summary, the provision of further home monitoring, such as pulse oximetry and capnography, should be considered on a case-by-case basis. Although pulse oximetry may be useful for assessment purposes, particularly in a child with a supplemental oxygen requirement, it is seldom indicated continuously. Again it should be stressed that an oximeter should not be used as a surrogate for an appropriate ventilator alarm. It should not be the aim of the home ventilation program to provide an intensive care unit in the home; furthermore, the provision of unnecessary monitoring devices has the potential to increase rather than decrease anxiety in caregivers and to add to the overall burden of care.

HUMIDIFICATION AND AIRWAY CLEARANCE

Children with tracheostomies (especially infants) receiving continuous mechanical ventilation require heated humidifiers (active humidifiers) to prevent drying of secretions.[29,37] Heat moisture exchangers (HMEs, passive humidifiers) can be used for short periods of time, but are not reliable for long-term use, especially in infants and small children.[33] Those patients best suited for HME use produce minimal secretions.[38] They are useful for transport, and enhance portability of patients by reducing the amount of equipment needed. Hygroscopic HMEs provide a higher output of humidity than hydrophobic HMEs.[37,38] Care must be taken to avoid excessively increasing dead space and resistance, by using an HME appropriately sized for the patient. The special equipment, supplies, and training required for care of children with tracheostomies has been detailed in a recent statement of the ATS.[38] Both stationary and portable suction equipment should be available for children with artificial airways so that they are not confined to home. Children with impaired cough require either equipment to aid with airway clearance (e.g., a mechanical in-exsufflator), or the family must be taught methods of manual airway clearance.[39]

Humidification may also be desirable for patients supported by noninvasive ventilation. This is especially true if the patient's climate is already dry, during winter months, or for those using lip seal or mouthpiece (sip) ventilation.[29] Both hot and cold passover humidifiers increase the humidity of delivered gas, although hot passover systems are more effective than cold in improving humidification of inspired air and reducing respiratory water loss with nasal continuous position airway pressure.[40]

MASKS AND INTERFACES

The most important consideration when establishing a child on noninvasive ventilation is the provision of an appropriate facial appliance. An increasing range of products are commercially available; in addition the use of custom-made masks has been described.[15]

The three most commonly used appliances are (1) nasal mask, (2) oronasal mask, and (3) nasal pillows. Where NIV is commenced electively, the child is often sent home for a period to become familiar with the mask. For young children, this is particularly important. In some situations incorporation of the mask into play, including the parent, or a doll or stuffed toy wearing the mask may help to reduce the child's anxiety. Because there are potential short- and long-term consequences from the use of a facial appliance for NIV, it may be useful to fit more than one device to assist in preventing and managing these problems. When a child is not tolerating NIV, the appropriateness and fit of the facial appliance is the first factor to be considered. An appropriately fitting interface is necessary not only for the child's comfort, but also to ensure that leak is minimized. Minimization of leak is particularly important in children with neuromuscular disease to ensure patient triggering, synchrony, and hence adequacy of ventilation.

Discharging a Child on Home Ventilation

Much of this discussion will focus on the process for discharging a child on invasive ventilation via tracheostomy. The principles are, however, applicable to the child on noninvasive ventilation. It is first useful to consider the barriers that may exist to discharging the child. When a child has been identified as being suitable for home ventilation, a formal discharge planning process must begin. By means of this process, potential barriers to discharge can be addressed, and transition to home care can occur as safely and promptly as possible.

Regardless of the underlying cause for respiratory failure, medical stability must be demonstrated before the child is deemed fit for discharge to home.[29] Clinically, the child should be free from frequent infection, have adequate stamina for periods of play or therapies, and ideally demonstrate a positive trend on the growth curve. From a physiologic standpoint, the child must have a stable airway (natural or artificial), and should not require excessive support. In this regard, general guidelines include the need for supplemental oxygen that does not exceed an FIO_2 of 0.4, and for children with underlying lung disease, a $PaCO_2$ less than 50 torr on current support. Those with neuromuscular disease should have a normal $PaCO_2$. Importantly, there should be a period of 1 to 4 weeks before discharge—during which time no changes are made to the medical regimen—to ensure that the patient is in fact stable on the proposed home regimen.

The family must demonstrate both willingness and an ability to learn all the care that is necessary to maintain the child safely at home. Children who have tracheostomies require two adults to learn care because many aspects related to tracheostomy care require the involvement of two people. In general, having two adults learn care is desirable even for children with natural airways, in the event that one adult becomes ill or is unavailable. These adults need not necessarily be the child's biological parents. Children from single-parent homes have successfully and safely been discharged on mechanical ventilator support, with another family member, a neighbor, or friend acting as the back-up caregiver. Depending on funding sources and limitations, the family may be responsible for, or at least included in the process of, selecting home care nursing and durable medical equipment companies.

The home must have adequate space to permit all of the necessary equipment as well as health care personnel that will be required for safe care of the patient. There must be adequate heat, electricity, and running water. Most importantly, there must be telephone access so that the family or home care nurse or therapist can contact appropriate medical personnel in the event of an emergency. For children who also require the assistance of a wheelchair, the home may have to be adapted to provide adequate access and egress. If the child lives a substantial distance from the discharging institution, a local emergency room and ambulance service must be identified in case of emergency to stabilize the patient before subsequent transfer.

Although home care of ventilator-assisted children substantially reduces the cost of their care,[41] it is still expensive. Thus, funding of nursing salaries, durable medical equipment rental or purchase, and purchase of disposable supplies must be guaranteed. Local resources need to be clearly identified and appropriate funding arrangements defined and implemented before discharge from hospital. Some costs of care that are typically covered during a hospital stay often subsequently become out-of-pocket expenses for the family. These would include purchase of prescription medications and special formulas. Additionally, utility bills and telephone charges should be expected to increase.

Finally, for long-term home mechanical ventilation to be successful, a multidisciplinary team of health care professionals must be available for periodic reevaluation and immediate feedback and support. Professional services represented on the team include case management and coordination, primary medical care, subspecialty medical care, home nursing services, home respiratory care, social work intervention, nutrition counseling, and input from speech, occupational, physical and developmental therapists.[13,28,29,42-45] Case managers coordinate care and services to maximize the potential of the child by overseeing the distribution of adequate and appropriate services while simultaneously containing costs. Absence of a case manager was identified as one risk factor predictive of increased stress among family members of ventilator-assisted children cared for at home.[46]

Once a child is medically stable and ready to go home on ventilatory support, there are many factors that can conspire to delay discharge. Delay in discharge is particularly apparent for those children requiring invasive ventilation via tracheostomy—indeed the delay in discharge in this situation was reported in one study to average 513 days!.[47] A number of publications have specifically addressed the barriers to discharging a child on home ventilation.[48,49] A formal discharge planning process is necessary to address these barriers and prevent delays in discharge. The most important elements of this process are the identification of a discharge planning team and a discharge planning coordinator. The coordinator needs to ensure that the team meets regularly and that progress toward discharge continues. Particular issues that the team needs to address include equipment requirements and funding sources, the identification and training of caregivers, appropriateness of housing and required modifications, community services, respite arrangements, and multidisciplinary follow-up. It is important that parents be involved at all stages and be able to actively participate in the discharge planning process. It is equally important, however, that the parents not bear inappropriate responsibility for arranging their own child's discharge.

OUTCOMES

Although the long-term outcome of a child on home ventilatory support is clearly dependent on the underlying medical condition, in general the outlook for these children is surprisingly good. When assessing the outcome of home ventilation, however, it is important to consider not only mortality and morbidity, but also quality of life and perhaps most importantly the impact of home ventilation on the child and the family. In addition, there are potential complications of home ventilation that warrant further discussion.

Mortality and Morbidity

Although the primary aim of home ventilation is to improve quality of life for children with respiratory failure, survival obviously remains a very important outcome variable when assessing the success of this intervention. Because NIV is a relatively new modality, there are much more data regarding the mortality of children invasively ventilated via tracheostomy. Prolonged survival of these children is well documented, and survival rates are probably improving. Frates in 1985[50] reported a 5-year survival of 65%; more recently survival rates of up to 71% at 10 years have been reported.[10,51,52] It is important to note that in most cases mortality relates to progression of the underlying condition, and that death from

ventilator or other equipment failure is uncommon. In fact, the greatest predictor of long-term survival in children with chronic respiratory failure is the prognosis of the underlying condition.[53]

Some causes of mortality, however, are directly related to tracheostomy tube obstruction, ventilator circuit disconnection, or inadvertent tracheal decannulation. Downes and Pilmer found that the incidence of life-threatening airway accidents was 2.3/10,000 patient-days in the home compared with 0.9/10,000 patient-days in the hospital.[8] Among a group of 101 infants with chronic respiratory failure cared for over 18 years, 20 died while still being mechanically ventilated and another 10 died after having been weaned.[27] Six of the deaths were caused by airway-related accidents, but only one of these occurred while the child was still in the hospital. Of the five deaths occurring at home, three were in children who had weaned from mechanical ventilation but remained tracheostomy-dependent because of subglottic stenosis. Two other children sustained severe hypoxic encephalopathy resulting from airway-related accidents.

In Frates' retrospective review of 54 patients cared for at home over 20 years, nine patients were weaned from ventilatory support, but 17 died.[50] Of those, four deaths were ventilator-related. Three children died as a result of unwitnessed ventilator disconnections. In each case, the low-pressure alarms failed to sound because the end of the circuit was obstructed by the patient's soft tissues. A fourth child died in a tank ventilator (iron lung) as a result of an overnight power failure. The authors speculated that at least three and perhaps seven deaths might have been avoided if the child had been monitored either visually or electronically. Of 22 children followed in a Canadian home ventilation program, 14 (64%) had neurologic disorders, whereas eight (36%) had primary pulmonary disorders.[45] Seven patients died, three in the neurologic group and four in the pulmonary group. No death was the cause of equipment malfunction, disconnection, or obstruction. One child died of acute bacterial tracheitis, and another died shortly after he presented in septic shock. All other deaths were related to progression of the underlying disease.

Many would expect that a child discharged on tracheostomy ventilation is likely to require frequent rehospitalization. This is actually not the case—these children have been reported to average less than one hospitalization per patient per year.[51] Some children will improve at home, and will be able to cease ventilation or be weaned to noninvasive ventilation. Such outcomes also appear to be related to the child's underlying disease. Infants and young children with parenchymal lung disease, such as bronchopulmonary dysplasia or airway anomalies such as tracheomalacia, have a high likelihood of discontinuing ventilator support. Of 27 children discharged to home successfully on ventilator support from one program, 15 were able to come off all ventilation successfully.[49] Of these, 12 had a combination of chronic lung disease and an upper airway abnormality. In another series, 8 of 12 ventilator-dependent children with chronic lung disease or congenital anomalies were able to be weaned completely from ventilator dependence, and there were no deaths in those groups.[54] In contrast, only 1 of 16 children with neuromuscular disease or central nervous system disorder was able to wean from ventilator support, but five died. Overall up to 40% of children discharged on home ventilation will eventually be able to be decannulated.[49,54]

As mentioned earlier, there are limited data on the long-term survival of children receiving noninvasive ventilation at home. NIV has been reported to significantly reduce morbidity in children with respiratory failure. After commencing NIV, children with neuromuscular diseases have reduced hospitalizations, and reduced days spent in intensive care units.[55] As well as correcting nocturnal respiratory failure and improving sleep parameters, NIV also has been shown to improve daytime respiratory function, and to delay the onset of daytime respiratory failure.[17,18]

Complications

VENTILATOR FAILURE

Failure of the ventilator, or of the power supply, is a particular concern for those children who are dependent on ventilatory support, that is, those who are at risk of mortality without such support. Thankfully, such equipment failure is relatively uncommon, with one incident expected per patient every 1.25 years.[30] Importantly adverse events and hospitalizations are very unlikely to occur as a result of these failures. The provision of appropriate power and ventilator alarms, and back-up power supply has been discussed; these measures minimize patient risk in the event of equipment or power failure. Perhaps the most reassuring evidence of the impact of ventilator failure comes from the Hanshin-Awaji earthquake in Japan.[56] Nineteen children of home ventilation were affected by this disaster, which interrupted water, gas, and electricity supplies. All of these children survived the disaster. By anticipating potential equipment and power problems, potentially catastrophic events can be overcome.

TRACHEOSTOMY-RELATED COMPLICATIONS

Detailed discussion of the risks and complications of tracheostomy is beyond the scope of this chapter. Complications are discussed in detail in the ATS consensus statement on the care of a child with a chronic tracheostomy.[57] Because the tracheostomy is the interface between the child and the ventilator, decannulation and blockage are particularly relevant to children on home ventilation. Again, provision of appropriate ventilator alarms is necessary to minimize these risks. Care should be taken in children with small, uncuffed tracheostomy tubes because standard low-pressure alarm settings may be insufficient to detect accidental decannulation.[31]

The issue of lower airway colonization and infection with microorganisms secondary to tracheostomy is of particular relevance to children receiving home ventilation. Colonization of the lower airways with potentially pathogenic organisms is almost inevitable in these children.[58] Fortunately, symptomatic infection is less common. Despite best attention to hygiene and airway toilet, however, lower respiratory tract infection remains a significant risk.

MASK-RELATED COMPLICATIONS

Local complications such as pressure sores are common, particularly over the nasal bridge, or, depending on the mask, over the forehead. These can be prevented or treated. Appropriate mask selection and education about mask fitting, par-

ticularly avoiding over-tightening, are paramount. If necessary, local skin dressings can be used. On occasion, an alternative mask may be provided to rotate potential pressure sites. Of more concern, there are increasing reports of midface hypoplasia in children receiving long-term NIV by nasal mask.[59,60] Prolonged daily use, commencement of NIV before 8 years of age, and facial muscle weakness have been identified as risk factors for this problem.[60,61] The optimal methods for prevention and management of facial growth complications of NIV are yet to be determined; however, regular evaluation of maxillary growth is recommended, particularly in the presence of the risk factors just described.

Quality of Life

When using physiologic indicators to gauge the impact of long-term mechanical ventilation, it is clear that mechanical ventilation is beneficial. The use of positive pressure ventilation is associated with fewer hospitalizations, better sleep quality, and improved daytime function in patients with neuromuscular disease.[55,62] Daytime ventilation also improves in those subjects with diurnal hypoventilation who begin nocturnal ventilation.[63] When examining more global issues, quality of life of children who receive chronic mechanical ventilatory support at home is at least as good as that of children with other chronic diseases.[63] Older ventilator-dependent patients, including those with progressive neuromuscular weakness, are reported to have a positive outlook regarding their quality of life and look to the future with regard to life plans.[6,64,65] However, a recent study suggested that adolescent ventilator-dependent children may be less satisfied with their daily activities than are younger ventilator-dependent children, and overall satisfaction correlated with a greater degree of activity.[66] The amount of support patients receive through skilled professionals or trained caregivers and assistive technologies has also been found to relate directly to a better quality of life.[67]

The practice of caring for a ventilator-dependent patient at home is stressful for families, and that stress increases with the duration of home mechanical ventilation.[64,68] Caring for a ventilator-dependent child also has adverse impacts on the health of the caregivers, including interrupted sleep, and limited time for the caregiver to pursue health-promoting activities.[69] Mental health of caregivers is more likely to be adversely affected than physical health.[70] Although family quality of life may suffer, parents typically express a preference to have their child at home instead of in a hospital.[4,71] Children, when given the opportunity, express the same desire to be at home.[72] Some factors that have been associated with greater caregiver stress include limited financial resources, absence of a nurse case manager and fewer services provided at the time of discharge, and an unstable family environment.[4,46]

It is important to stress that the child and the family's assessment of the child's quality of life may well be very different from what is perceived by medical staff. Indeed, health care practitioners are likely to assess a child's quality of life as markedly lower than the child's caregivers.[73]

CONCLUSION

Home mechanical ventilation of infants, children, and adolescents has become a widely accepted treatment option for many who survive but do not completely recover from acute life-threatening illnesses or those who have diseases that result in chronic respiratory failure. Significant advances have been made over the last half century, and particularly over the last 20 years, in the equipment used to support these children, in monitoring capabilities, and in our understanding of the underlying processes that lead to pediatric respiratory failure. Challenges remain, however, and include ways to provide this resource-intensive care in the most cost-effective way, how best to support families so as to avoid caregiver fatigue/burnout and disruption of the family structure, and how to resolve ethical dilemmas associated with conditions for which this type of care is considered futile by some. For those adolescents with chronic conditions that result in permanent respiratory compromise, programs for transition to adult care will have to be created, as will social programs to guarantee access to public transportation, housing, and employment opportunities.

CHAPTER 23 Lung Trauma: Near-Drowning and Toxin Inhalation

Robert Henning

TEACHING POINTS

- In a burned child, intubate early if there are any signs of airway obstruction.
- Consider carbon monoxide and cyanide poisoning in any closed space fire.
- In burn inhalation or near-drowning, consider early bronchoscopy for diagnosis, removal of casts, or if lobar or segmental atelectasis is present.
- Use microbiologic surveillance only if there are new or increasing signs of sepsis.
- In blast injury, the principal lung problems are alveolar edema and air embolism.
- In any traumatic or inhalation injury to the lung, avoid corticosteroids and prophylactic antibiotics.
- Use the lowest ventilator pressures and tidal volumes that are compatible with acceptable gas exchange.
- In toxic chemical injury, remove from exposure, decontaminate, support breathing and oxygenation, and consider antidotes—repeated as often as needed.
- In suspected hydrocarbon inhalation, avoid induced vomiting, nasogastric lavage, and milk gavage.

SMOKE INHALATION: RESPIRATORY BURN INJURY

Burns are a leading cause of accidental death in children in the Western world.[1-3] In 2004 in the United States, fire caused the death of 3900 people and 18,000 were significantly injured.[4] Male gender, low socioeconomic status, and membership in a minority racial group increase the risk of death or injury from burns in children.[5] Burn injuries in house fires are more likely to cause death than were burns in other situations, especially in children under age 5, principally because inhalation injury is more common in house fires[5] and because young children lack the experience and strength to escape. Smoke inhalation is responsible for twice as many deaths as skin burns.[6] Inhalation injury increases burn mortality by 20% in large (>80% body surface area [BSA]) burns, 4-fold in medium (20% to 80% BSA) burns and 20-fold in smaller (<20% BSA) burns.[5]

Causes of Lung Injury

HEAT

Inhalation of hot dry gas (at up to 1000° C within a burning building)[7] injures the mucosa of the mouth, nose, pharynx, and larynx, but subglottic injury is limited to the upper third of the trachea because the inhaled gas has a low specific heat and the large heat-exchanging surfaces of the nose, mouth, and pharynx cool the gas before it reaches the mid-trachea. Flame burns from an explosion may cause severe mucosal injury to the upper trachea but do not burn small airways or lung parenchyma. Steam, which has a high specific heat, causes severe injury to the whole tracheobronchial tree and can injure alveoli. Scalds (e.g., in a toddler who swallows hot coffee) usually injure the mouth, pharynx, and larynx, but hot inhaled liquid can also injure the trachea, especially the subglottic region, and occasionally more distal parts of the bronchial tree[8] (for causes of lung injury, see Box 23-1).

CHEMICAL INJURY

Smoke consists of carbon particles suspended in a mixture of toxic gases. The particles, 5 μm to 5 mm in diameter, are coated with toxic products of burning or pyrolysis (heat-induced, nonoxidative decomposition of organic materials) (Table 23-1).[9-11] The high specific heat of the particles causes further heat injury to the mucosa of large and small airways. The particles also combine with sloughed cells, mucus, denatured protein, and edema fluid to obstruct airways and fill alveoli.

The gaseous and particle-coating toxins may be water soluble (e.g., NH_3, HCl, ketones) or water insoluble (e.g., phosgene, nitrogen oxides). Other constituents of smoke include systemic toxins such as carbon monoxide (CO), cyanide, antimony, cadmium, chlorobenzene, and propionitrile.[7,12] The water-soluble irritants cause coughing and increased ventilation, which exposes bronchioles and alveoli to the other toxins and promotes the entry of carbon particles into small airways. Alveolar ventilation increases on initial exposure to smoke and then decreases due to central nervous system depression.[7]

PULMONARY EFFECTS OF A SKIN BURN

Cutaneous burns cause acute lung injury (ALI: see Chapter 19), with impaired gas exchange, reduced lung compliance, and diffuse pulmonary infiltrates on the chest radiograph in the absence of inhalation injury. Massive chest wall edema and eschar formation cause severe restriction of tidal volume in the hours after a circumferential burn to the thorax, requiring urgent escharotomy to relieve the restriction and permit adequate ventilation.

BOX 23-1 Causes of Respiratory System Injury in the Burned Child

- Smoke gases
- Toxin-coated carbon particles
- Hypoxia
- Carbon monoxide
- Cyanide
- Skin burn: systemic inflammatory response syndrome and chest wall edema

Pathology of Inhalation Injury[13]

AIRWAY EPITHELIAL INJURY

Flame injury to the oropharynx causes severe edema of supraglottic structures: massive swelling of the epiglottis, aryepiglottic folds, and ventricular folds develops over the first 1 to 4 hours postinjury, causing severe supraglottic airway obstruction and making visualization of the larynx extremely difficult.[14] The absence of supraglottic edema does not rule out significant injury to small airways, alveoli, or capillary endothelium, however. Soot is visible in the trachea in up to 30% of patients with clinical evidence of burn inhalation injury,[14] and up to 85% have erythema or edema of the tracheal mucosa.[15]

Heat and toxic chemicals (see Table 23-1) cause mucosal cells to separate rapidly from the basement membrane.[16] In moderate to severe injury, live mucosal cells may only be found in crypts and mucosal folds.[17] Necrosis of mucosal cells and inhibition of ciliary action in surviving cells by smoke chemicals such as aldehydes mean loss of ciliary activity, which leads to the blockage of airways by debris, causing atelectasis and secondary infection. A pseudomembrane consisting of sloughed cells, together with mucus from stimulated mucous glands, proteinaceous exudate, and carbon particles,[18] accumulates in alveoli and small and large airways.

Bacterial colonization of the airway is detectable by 72 hours.[19] Deeper injury to the basement membrane and submucosa permits the entry of bacteria into the interstitial tissues of the lung and into blood. In the longer term, it causes fibrous scarring with narrowing of large airways, especially at the tip of an endotracheal tube.

Water enters damaged type I pneumocytes, causing them to become rounded and bulge into the alveolar lumen, and to produce intercellular gaps, through which interstitial edema fluid enters the alveolus. Necrosis of type I pneumocytes leaves a bare alveolar basement membrane. By 7 days postinjury, this is gradually covered by proliferating type II pneumocytes.

HEALING

Airway healing occurs through the proliferation of surviving mucous gland cells or metaplasia of epithelial cells.[18] If the lung's reticulin fiber framework remains intact, normal lung architecture can be restored, but fibroblast proliferation and formation of mature collagen distort or obliterate alveoli and narrow the lumens of small bronchi and bronchioles. Complete healing takes up to 4 weeks in moderately severe injury.

SURFACTANT

Smoke inhalation and steam injury of the lung reduce surfactant activity, trebling the minimum surface tension, and abolishing the normal hysteresis of the surface tension–surface area curve.[20]

BRONCHIAL BLOOD FLOW

Bronchial blood flow rapidly rises 8- to 20-fold after inhalation injury.[10] As well as increasing the delivery of activated polymorphonuclear leukocytes to lung tissue, where they mediate tissue injury, this increased blood flow promotes fluid accumulation in the lung by increasing the capillary surface area available for fluid filtration and increasing downstream intracapillary pressures (see Pulmonary Edema). The

Table 23-1
Chemical Constituents of Smoke

Constituent	Source	Role	Effects
Acetic acid	Petroleum products, wood, paper, cotton	Irritant	Cough, bronchospasm, laryngospasm, mucosal injury
Acrolein	Wood, paper, cotton, acrylics, petroleum	Irritant	Cough, bronchospasm, damages cilia and macrophages
Formaldehyde	Wood, paper, cotton, melamine, wallpaper	Denatures protein	Mucosal and alveolar injury; pulmonary edema
HCl	PVC	Irritant	Cough, bronchospasm, pulmonary edema. Damages cilia and macrophages.
NH_3	Wool, nylon, melamine	Irritant	Cough, bronchospasm, laryngospasm, mucosal cell necrosis Airway and alveolar edema.
Nitrogen oxides	Wallpaper, nitrocellulose	Denatures protein	Cell necrosis in alveoli and bronchioles. Pulmonary edema and BOOP
Phosgene	PVC	Denatures protein	Cell necrosis in alveoli and bronchioles. Pulmonary edema and BOOP
Carbon monoxide	Most organic materials	Asphyxiant	Systemic anoxia: brain and heart failure
Cyanide	Nylon, polyurethane, carpets, upholstery	Asphyxiant	Systemic failure of electron transport: brain and heart failure

BOOP, bronchiolitis obliterans organizing pneumonia; PVC, polyvinyl chloride.

mechanism of these changes is not yet certain, but inducible nitric oxide synthetase (iNOS) and sensory nerve–mediated release of substance P and calcitonin gene–related peptide may have roles.[10,21]

PULMONARY EDEMA

Alveolar and interstitial lung edema develops rapidly after a skin burn, even in the absence of inhalation injury. In addition, about 4 hours after inhalation injury, extravascular lung water and lung lymph flow increase markedly.[16] Proteinaceous fluid accumulates in alveolar septa, interstitial extravascular spaces, and bronchial submucosa, where it contributes to the marked small airway obstruction seen in burn inhalation injury. Edema fluid also fills alveoli, contributing to intrapulmonary shunting and increasing lung elastance.

Raised pulmonary and bronchial capillary pressures and transiently (lasting 48 hours) increased capillary permeability are responsible for the accumulation of fluid in the lung.[22] Several mechanisms underlie the increase in capillary permeability, including release of proteases and active oxygen species by activated neutrophils and upregulation of iNOS by polyADP-ribose polymerase (PARP) in damaged pulmonary epithelial cells. Inhibition of each of these pathways and neutrophil depletion reduce lung water and reduce the deterioration in gas exchange in animal models of inhalation injury.[21,23]

Carbon Monoxide

CO produced by partial combustion of a variety of organic materials (see Table 23-1) impairs oxygen transport by displacing oxygen from hemoglobin, for which its affinity is 250 times that of oxygen. CO shifts the oxyhemoglobin dissociation curve to the left, impeding the release of oxygen to the tissues, so that the total effect on tissue oxygenation is much worse than that of hypoxia alone.

At a P_{CO_2} of 0.16 mm Hg, 75% of hemoglobin is combined with CO, so that an FICO less than 0.1% can sequester much of the circulating hemoglobin.[24] When carboxyhemoglobin (COHb) is present, a pulse oximeter overestimates the true oxygen content of blood and may read 96% saturation, when COHb is 44% of total hemoglobin (i.e., when *available* hemoglobin is only 56% of total hemoglobin).[25]

The main intracellular effects of CO are as follows:

1. Inhibition of cytochromes, especially cytochrome *c* oxidase, leading to cellular energy failure, especially in brain, liver, kidneys, and myocardium[26]
2. Increasing the amount of free NO radical, which combines with superoxide anion to form peroxynitrite, leading to widespread endothelial injury, especially in the brain and lungs[24]

Myocardial injury reduces the cardiac output, and the consequent reduction in oxygen delivery exacerbates the energy failure, especially in central nervous system neurons. About 14% of survivors of significant CO poisoning develop acute neurological abnormalities (disorientation, excitement, lethargy, and coma), of whom some have permanent residual neurological deficits. COHb levels of 30% to 40% cause headache, nausea, confusion and syncope, and levels of 50% to 60% cause coma.

Cyanide

Cyanide is produced by the combustion of nitrogen-containing materials such as nylon and silk and polymers such as melamine and polyurethane.[27] Cyanide reversibly inhibits cytochrome oxidase, causing failure of mitochondrial energy metabolism and a metabolic acidosis, only a small proportion of which is due to excess lactate production.

Inhaled CN^- concentrations greater than 100 ppm cause death within 60 minutes, and 180 ppm causes death within 10 minutes.[28] Symptoms occur minutes to hours into moderate exposure to CN^-. Delayed toxicity (onset of symptoms hours after removal from CN^-) does not occur.

Central nervous system dysfunction due to cyanide varies from anxiety, lethargy, and confusion to coma, convulsions, and brain death.[28] Low concentrations of cyanide at brief exposure cause tachypnea (due to metabolic acidosis), which increases the entry of other toxins into the lungs, whereas central nervous system depression in prolonged exposure leads to hypoventilation and apnea. Myocardial toxicity causes tachycardia and hypertension early, followed by myocardial depression, hypotension, and reduced cardiac output, which further exacerbates the failure of intracellular oxidation and energy supply.

Diagnosis

In fire victims, inhalation injury is likely to be present in those with facial burns, conjunctivitis, or rhinorrhea and in those rescued from fire in a closed space (e.g., a house or an automobile fire). Dyspnea, cough, stridor, wheeze, and a hoarse voice are rarely present on arrival at the hospital but may develop later, and children almost never expectorate soot-laden sputum. Inhalation injury is a little more likely with larger than with smaller BSA burns.[29]

A history of inhalation of hot steam or of an infant who swallows hot liquids should lead to suspicion of an upper airway injury, with close observation for signs of stridor or upper airway obstruction, and investigation (see later) if necessary.

The principal issues to be considered at presentation in a child who has one or more of these risk factors are those that require early intervention:

1. Is upper airway obstruction present now, or is it likely to develop in the next few hours to the point that airway protection will become necessary?

Facial burns and a history of flame or hot steam exposure (or hot liquid ingestion in an infant) mean the child is at risk of supraglottic and subglottic swelling and obstruction. The presence of stridor with or without chest wall indrawing, a barking cough, a hoarse or muffled voice, or drooling or inability to swallow means that upper airway obstruction is present *now* and is likely to progress rapidly unless the airway is protected by insertion of an endotracheal tube. The stridor is usually low pitched and may be inspiratory or expiratory or both. Frequent observation to detect these signs is the most reliable method of functional assessment of the airway.

If the clinical signs are inconclusive, awake fiberoptic laryngoscopy following topical anesthesia of the nasopharynx

with lidocaine spray may give useful information about injury to the supraglottic tissues and the need to protect the airway by tracheal intubation.[30] Reduction of supraglottic swelling seen at laryngoscopy is a useful guide to the timing of extubation.[31]

Flexible bronchoscopy via an endotracheal tube may be used to diagnose airway injury and to assess its extent. Many pediatric burn units recommend bronchoscopy of all children with suspected inhalation injury on the day of admission.[32,33] Follow-up bronchoscopy over the next 72 hours is used to detect airway narrowing and the presence of airway casts. Recurrent airway obstruction by casts may require repeated bronchoscopy over the first 2 to 3 days. Large casts, however, may require rigid bronchoscopy for their removal.

After extubation, bronchoscopy may be used routinely to detect ulceration and swelling at the level of the vocal cords (especially the anterior commissure and interarytenoid area), at the cricoid cartilage, and at the endotracheal tube tip, to which burned children are especially prone.[34] Bronchoscopy is not a sensitive predictor of parenchymal lung injury.[15]

Spirometry and meaningful flow-volume curves are generally impossible to achieve in children younger than 6 years, especially in the presence of facial burns, pain, distress, and depressed conscious state. In teenagers with inhalation injury, FEV_1 and the FEV_1/VC ratio decrease in the first 6 hours after injury due to swelling of the mucosa in the large and small intrathoracic airways.[31,35]

2. Will this child develop respiratory failure in the next 6 to 12 hours?

The key to diagnosis of incipient respiratory failure is repeated clinical examination by an experienced observer. Dyspnea, tachypnea (especially if increasing), wheezing, crackles on auscultation, and hypoxemia are late signs of injury to the parenchyma and airways and imply the need for close monitoring and for immediate consideration of examination and protection of the airway and support of breathing.[36]

Cyanosis may be difficult to detect in the presence of skin burns, especially burns of the face or oropharynx. Pulse oximetry is unreliable when skin blood flow is reduced by hypovolemia, or when the tissues are edematous. Arterial blood gas analysis is then required to assess gas exchange. In most children with inhalation injury, $PaCO_2$ is normal or low. $PaCO_2$ may be raised by impaired respiratory drive due to head injury, hypoxic brain injury, cyanide or CO poisoning, or opiate drugs. Hypercarbia may also be caused by severe upper or lower airway obstruction or by splinting of the chest wall by edema, eschar formation, or pain.

Clinical signs of lung injury may fluctuate: dyspnea and cough may disappear when the child is removed from the smoky atmosphere but may return in 6 to 12 hours, as inflammation of the lung parenchyma increases. Wheezing due to airway mucosal edema, mucus production, and separation of sloughed mucosa in large and small airways may appear a few hours after injury and may suddenly increase due to movement of airway casts, requiring urgent bronchoscopy for cast removal. Gas trapping with chest hyperinflation, pulsus paradoxus, and occasionally pneumothorax may become more severe over the next 96 hours.

Chest auscultation is difficult over extensive skin burns, but areas of reduced air entry and focal or diffuse wheezes and crackles may be detectable. In small infants, there may be few signs other than hyperinflation, wheezing, poor air entry, tachypnea, and sometimes apnea.

Most wheezing after inhalation injury is due to mucosal edema, increased mucus production, and cast formation in the large and small intrathoracic airways; smooth muscle contraction is less often a significant factor. In children with reactive airways, irritant components of smoke such as NH_3, chlorine, and acrolein may provoke wheezing by stimulating type C sensory nerves within the respiratory tract mucosa. These sensory nerve fibers then release neuropeptides such as substance P and neurokinins A and B, which increase mucus production and vascular permeability, cause bronchoconstriction, and may activate mast cells.[37]

3. Is CO or cyanide poisoning present?

The most reliable indicators of CO and cyanide intoxication are a history of fire in a closed space, unconsciousness (even brief), confusion, convulsions, cyanosis (much more common than cherry-red mucous membranes in CO poisoning), pulmonary edema, or hypotension. Children are symptomatic (syncope or lethargy) at lower levels of COHb (e.g., 25%) than are adults.[38] Kussmaul breathing due to metabolic acidosis and red venous blood (due to impaired oxygen extraction) may be present in cyanide poisoning.

In any child suspected of suffering smoke inhalation, the child should breathe, or be ventilated with, 100% oxygen and blood samples should be taken for measurement of COHb and plasma cyanide. A high COHb may indicate the need for further normobaric or hyperbaric oxygen therapy, but the history of the fire conditions and repeated assessment of mental function are better guides to therapy when the COHb on presentation is low, as COHb depends on the time elapsed since exposure and the FIO_2 breathed in the meantime.[31,39]

The result of plasma cyanide measurement often arrives too late for timely administration of an antidote. In a child with a history of smoke exposure, metabolic acidosis, and physical signs of cyanide toxicity, administration of nitrites and sodium thiosulfate is justified if the COHb is high (>25%), as CO and cyanide intoxication often occur together.[31,40,41]

Radiological Investigation (Box 23-2)

The initial chest radiograph on presentation to hospital is an insensitive predictor of the development of parenchymal lung disease, as changes are present in only 50% of patients who later develop the condition.[32,42]

Some patients (up to 38%) in whom significant inhalation injury is suspected on clinical grounds never develop radiological changes attributable to the smoke injury. In patients who develop such changes, the great majority do so in the first 24 hours, and the remainder by 48 hours (Fig. 23-1A). Radiological changes appearing after 48 hours are generally associated with positive cultures of tracheal mucus and are more typical of bronchopneumonia or of fluid overload.[43]

If gas exchange deteriorates and dyspnea and the respiratory rate increase, a plain chest radiograph may reveal a pneumothorax, a collapsed lung or lobe, pulmonary edema,

BOX 23-2 Plain Chest Radiographic Signs of Burn Inhalation Injury

Atelectasis
Local (especially perihilar) or generalized alveolar opacity
Interstitial opacity
Regional or generalized overinflation due to gas trapping
Perivascular haziness
Peribronchial cuffing

From Whitelock-Jones L, Bass DH, Millar AJ, et al: Inhalation burns in children. Pediatr Surg Int 15:50-55, 1999; Wittram C, Kenny JB: The admission chest radiograph after acute inhalation injury and burns. Br J Radiol 67:751-754, 1994; and Teixidor HS, Rubin E, Novick GS, et al: Smoke inhalation: radiologic manifestations. Radiology 149:383-387, 1983.

an endotracheal tube displaced downward into a bronchus, pneumonic consolidation, or a pleural effusion.

Thoracic computed tomography (CT) scans may reveal more detail of the extent of atelectasis or consolidation (see Fig. 23-1B) and of associated injuries such as blunt trauma or blast injury of the lung (see later) than is seen on plain chest radiographs. CT scans have been used to grade the severity of lung damage in animal models of inhalation injury,[44] but for treatment and prognosis, the important indicators of injury severity are the functional variables of gas exchange and lung mechanics.

Management of Inhalation Injury (Box 23-3)

All patients should be given high flow oxygen (>10 L/min) by mask, and the stomach should be decompressed by a nasogastric tube because acute gastric dilation with its attendant risks of regurgitation-aspiration and impairment of venous return and of diaphragmatic movement is very common in children with skin burns and inhalation injury.

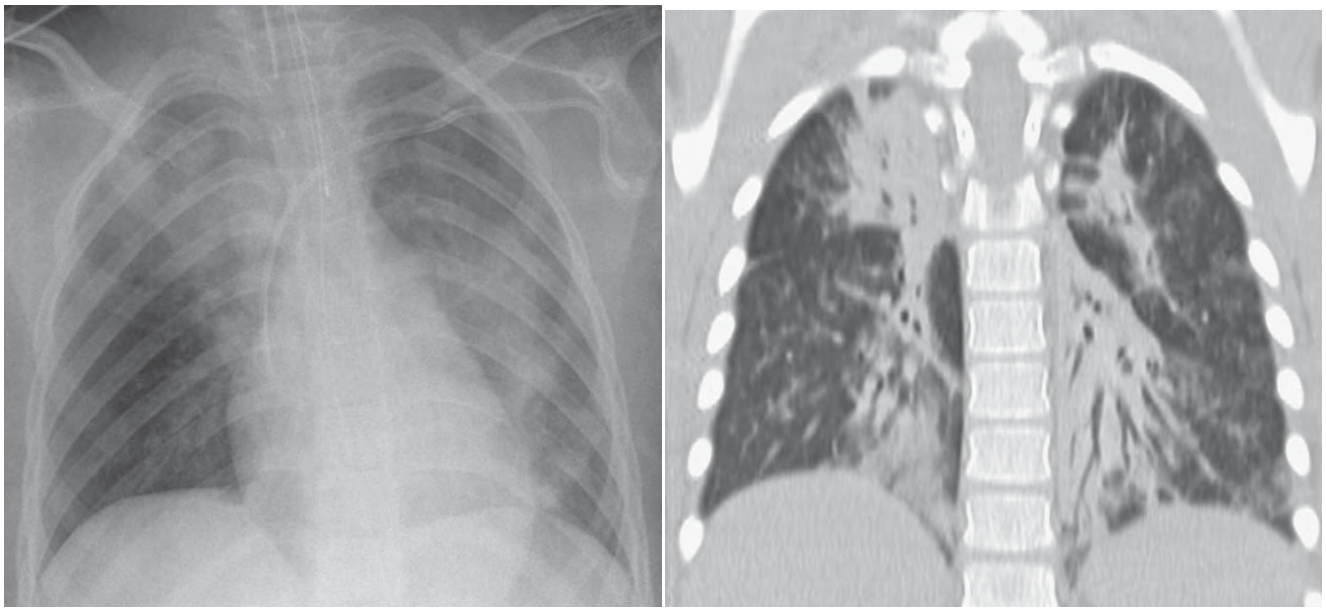
AIRWAY

If significant airway obstruction appears early after the injury, the child's trachea should be intubated immediately, because mucosal swelling and airway obstruction are likely to increase over the next 2 to 3 days. It is safer to intubate early rather than later, when mucosal edema in the mouth and pharynx and swelling of the tongue and its supporting structures make it much more difficult to visualize the larynx, identify landmarks, and enter the trachea. Inhalation anesthesia is used for tracheal intubation, as for any patient with upper airway obstruction.

Endotracheal tube fixation and patency are critically important in these patients because re-insertion of a dislodged or blocked endotracheal tube may become impossible when edema is at its maximum, and emergency tracheostomy may be extremely difficult and dangerous in the presence of neck burns. Nasotracheal tubes are more readily secured than are orotracheal tubes in small children, provided that there is no contraindication such as fractured skull base or severe coagulopathy. Adequate humidification, frequent tracheal suction, and close nursing observation are essential to the successful management of a child with inhalation injury of the airway.

BOX 23-3 Priorities in Acute Management

Maintain an adequate airway, breathing, and circulation
Establish venous access
Exclude carbon monoxide and cyanide poisoning



A B

Figure 23-1 **A,** Chest radiograph of a 3-year-old girl, 36 hours after burn inhalation injury, showing confluent airspace opacities in the right upper and left lower lobes, with loss of lung volume in the right upper lobe and some peribronchial cuffing. **B,** Coronal cut of a chest CT scan 1 month after inhalation injury (same patient), showing multiple areas of consolidation with patches of ground glass appearance.

If airway obstruction is minimal, the child should be observed very closely in a well-lit ward, with the diagnostic measures already discussed. There is no benefit from mist tents or steroids.[45] Although nebulized epinephrine may reduce the severity of large and small airways obstruction caused by edema, its use may not benefit the patient if it merely postpones tracheal intubation to a time when it becomes difficult or dangerous.

If tracheal intubation is impossible, or the laryngeal inlet cannot be seen, the safest options are (1) passage of an orotracheal tube over a fiberoptic laryngoscope and (2) needle or surgical cricothyroidotomy in a child older than 12 years and needle cricothyroidotomy in a child younger than 12 years.[45] Elective tracheostomy is rarely required, as even children who require tracheal intubation for 4 or more weeks can be safely managed with translaryngeal intubation, given meticulous attention to airway care and sedation.[46]

GAS EXCHANGE

Hypoxemia and the ($P_{AO_2} - P_{aO_2}$) difference increase progressively in the first 72 hours after inhalation injury. All patients should be given the highest available concentration of oxygen (by mask or endotracheal tube) if there is any suspicion of CO (see later) inhalation. If the P_{aO_2} deteriorates despite O_2 by mask, the child requires tracheal intubation and continuous positive airway pressure (CPAP) or intermittent positive pressure ventilation (IPPV) with positive end-expiratory pressure (PEEP) (see Chapter 19).

After 18 hours, any beneficial effect of a high partial pressure of inspired oxygen (P_{IO_2}) is outweighed by the risk of pulmonary oxygen toxicity, so every effort should be made to keep the F_{IO_2} below 0.5. This may involve permitting a P_{AO_2} of 45 to 50 mm Hg and using high levels of PEEP or high-frequency ventilation (Box 23-4).

The basic management of impaired gas exchange in inhalation injury is that of ALI (see Chapter 19). Institution of CPAP or IPPV/PEEP before hypoxemia develops will provide better long-term survival than if it is started after hypoxemia appears.[47] Noninvasive CPAP or bilevel positive airway pressure (BiPAP) delivered via face mask (see Chapter 19) can avoid tracheal intubation and its complications in many cases[48] but should be used only when airway injury has been excluded and the child is conscious and cooperative.[49] It is feasible even in the presence of facial burns[48] but may be more useful in older children and teenagers than in preschool children and infants, who have smaller faces (to which mask adjustment is more difficult) and are more irritable. Noninvasive ventilation requires close monitoring, lest the signs that bronchoscopy or intubation/ventilation are needed urgently be missed.

High-frequency oscillation with or without prone positioning (see Chapter 19) may be used when adequate oxygenation cannot be achieved by conventional ventilation without the use of excessive airway pressures.[33,50,51] Several centers have reported the use of ECMO with intact survival in children with burn inhalation injury.[52,53] Atelectasis, sputum retention, and airway casts may contribute to hypoxemia. Maintenance of gas exchange requires adequate humidification of inspired gas, regular tracheal suction, and, if necessary, bronchoscopic removal of casts. A pneumothorax caused by airway obstruction and consequent gas leak may lead to sudden hypoxia and hypotension and require urgent tube thoracostomy. Escharotomy of the chest wall is often needed to correct the restrictive lung defect and hypoventilation caused by circumferential chest burns.[45]

Bronchodilator drugs such as β_2-sympathomimetics do not improve the P_{AO_2}, P_{aO_2}, or lung mechanics when most wheezing is due to narrowing of large airways or the presence of airway casts or mucus plugs (and may increase the $P_{AO_2} - P_{aO_2}$ gradient by impairing focal hypoxic pulmonary vasoconstriction), but a therapeutic trial of nebulized albuterol is sometimes worthwhile. The use of corticosteroids for wheezing is justifiable only in patients who are known asthmatics or in patients dependent on exogenous steroids.[45] Their use in other children who wheeze after burn inhalation injury increases the risks of sepsis and gastric hemorrhage without demonstrable benefit.

SEPSIS

Secondary bronchopneumonia occurs in 30% to 50% of children with inhalation injury,[32,54,55] most commonly in the first 7 days and is a major cause of early and late (more than 3 weeks postburn) death. The principal risk factor for lung infection in children with inhalation injury is tracheal intubation, which bypasses the barriers to infection of the normal respiratory system and allows colonization of the airways by bacteria from the patient's own mouth, skin, and bowel.[11]

Routine bacteriological surveillance of tracheal aspirate and blood is likely to reveal tracheal colonization and transient bacteremias, respectively, neither of which requires antibiotic treatment. Cultures should be taken only when there is clinical suspicion of pneumonia (new fever, deteriorating gas exchange, new alveolar opacities on chest radiograph, rising white blood cell count with increasing immature neutrophils). In these circumstances, cultures of blood and bronchoscopic or blind bronchoalveolar lavage tracheal aspirate should be taken. Antibiotic therapy should cover *Staphylococcus aureus*, *Enterococcus* spp., and gram-negative bacilli including *Pseudomonas* spp.

Prophylactic antibiotics do not reduce the incidence or severity of pneumonia in children with inhalation injuries, but do increase the risk of colonization with antibiotic-resistant bacteria.[56] The evidence that drugs that suppress gastric acid secretion (e.g., ranitidine or proton pump inhibitors) are more likely to predispose a burned patient to gram-negative pneumonia than gastroprotective agents such as sucralfate is conflicting.[57,58] Experimental and nonhelpful trentments for

inhalation injuries are listed in Box 23-5[59-61] and Box 23-6, respectively.

CARBON MONOXIDE AND CYANIDE

Any child who was unconscious at the fire scene or was rescued from inside a burning house or automobile may have sustained CO or cyanide poisoning and should receive high-flow oxygen by mask. The trachea of a child who has been unconscious should be intubated to allow 100% oxygen to be delivered.

The rate of COHb dissociation is proportional to the PaO_2,[62] so the use of hyperbaric oxygen (HBO_2) should be considered in any child whose COHb concentration is greater than 30% at hospital admission. The use of HBO_2 therapy remains controversial.[24] Of the six randomized trials that have assessed the outcome of its use, four found no benefit, whereas two found some benefit. All trials were flawed, and meta-analysis of the trials did not demonstrate a benefit.[63] Nevertheless, a number of nonrandomized trials and case series have found an unexpectedly good outcome in CO-poisoned patients after HBO_2 therapy, and its use is recommended in many centers,[24] provided that adequate staff expertise and facilities are available for safe transport of the child and care within the hyperbaric chamber.

Testing of blood for plasma cyanide is time consuming, so a decision to treat presumed cyanide toxicity is made on clinical grounds. Any child found unconscious or convulsing after inhalation injury and any child with severe CO poisoning should be treated for cyanide toxicity (Box 23-7).

BOX 23-7 Treatment of Cyanide Toxicity

Amyl nitrite: Inhale vapor from one amyl nitrite pearl for half of each minute until IV sodium nitrite infusion started.
Sodium nitrite 3% solution: infuse 0.33 mL/kg (maximum 10 mL) over 2 to 5 minutes
Then:
Sodium thiosulfate 25% solution: infuse 1.65 mL/kg (maximum 50 mL) over 5-10 minutes

Complications of Burn Inhalation Injury

Early complications include atelectasis, lung infection (discussed earlier) and barotrauma. Gas trapping due to obstruction of small and large airways by edema, slough, and carbon particles leads to air leakage from alveoli or from damaged airways. Pneumothorax, pneumomediastinum, pneumoperitoneum, and subcutaneous emphysema are especially common in patients mechanically ventilated with tidal volumes greater than 10 mL/kg but can occur with lower tidal volumes and even following coughing in nonventilated patients.[11]

Late complications include injury to the larynx and upper trachea and to small airways and lung parenchyma. Laryngeal injury by heat and smoke toxins may be exacerbated by tracheal intubation, leading to laryngeal scarring. Subglottic injury is generally found at the level of the tip of the tracheal tube or at the level of its cuff, especially when high cuff pressures are used. To avoid these injuries, the use of low cuff pressures, low ventilator airway pressures, and possibly early (within 10 days postinjury) tracheostomy should be considered.[64]

Some degree of small airways obstruction and increased airway reactivity occur commonly after inhalation injury[65,66] and may persist for 6 months or longer. In children, a combined restrictive and obstructive pattern may be found.[67] Bronchiectasis, bronchial stenosis, and bronchiolitis obliterans with progressive respiratory failure have also been reported following inhalation injury (see Box 23-8 for specific teaching points).

DROWNING

Drowning is a leading cause of death in Western countries. In the United States, approximately 850 children drown each year (1.4 : 100,000), of whom 60% are aged less than 4 years, while another 4500 sustain nonfatal immersion.[68] Boys are 4 times more likely to drown than are girls.[69] *Drowning* implies death within 24 hours after immersion, and *near-drowning* is an immersion injury with survival for at least 24 hours (Table 23-2).

Drowning causes a hypoxic-ischemic insult to the whole body. The main determinant of outcome is the severity of the hypoxic-ischemic brain injury. The lung itself suffers a hypoxic insult, as well as a direct injury from aspiration of water,

BOX 23-8 Burn Inhalation Teaching Points

- Intubate early if there are any signs of airway obstruction.
- Provide adequate humidification and tracheal tube suction.
- Early bronchoscopy is used for diagnosis and removal of casts.
- Consider noninvasive CPAP or BiPAP.
- Provide lung-protective ventilation strategy.
- Provide a trial of bronchodilator drugs for wheezing.
- Culture blood and tracheal mucus if clinical signs of sepsis are present.

Table 23-2

debris, dissolved toxins, microorganisms. and gastric contents. Pulmonary edema due to impaired performance of the asphyxiated myocardium and secondary septicemia further reduce lung function in near-drowned children.

Although it is often stated that 10% to 15% of drowned people do not inhale water, the evidence for this statement is in doubt, and many of these "dry-drowning" victims appear to have sustained a cardiac arrest before immersion.[70] A large study found the incidence of "dry drowning" to be less than 2%.[71] Most survivors of near-drowning have aspirated 22 mL/kg or less.[72] Gastric distention due to swallowed water leads to vomiting during resuscitation in at least half of child survivors, and aspirated gastric contents are found at autopsy in 70% of drowning victims[73] (Fig. 23-2).

Small or large bronchi may be obstructed by particles of sand,[74] mud, undigested food, or plant or animal debris, leading to atelectasis soon after rescue and to secondary infection of the obstructed lobe or segment (Table 23-3).

Table 23-3
Injurious Components of the Immersing Medium

Component	Effect
Water	Inflammation, edema, and surfactant depletion
Osmolality	Cell swelling (fresh water) or shrinkage (seawater)

Suspended solids: sand,[74] clay, and mud	Airways obstruction and secondary infection
Phytoplankton and zooplankton	Airways obstruction; secondary inflammation and infection
Vegetable matter	Airways obstruction; secondary infection
Microorganisms	Pneumonia

Pulmonary Effects of Water Aspiration

Aspiration of sterile isotonic saline causes peribronchial and perivascular edema, thickening of alveolar septa, dilation of alveolar capillaries, and vesiculation of capillary endothelial cells and type I pneumocytes. Associated with these changes, static lung compliance decreases progressively over 3 or more hours postinsult. At 24 hours later, static compliance is still 50% of preinsult values, and focal areas of pneumonitis are present, with a peribronchial and perivascular infiltrate, mainly of mononuclear cells. Areas of atelectasis alternate with areas of hyperexpansion.[75] Removal, inactivation, and impaired production of surfactant, as well as capillary congestion and increased interstitial fluid, contribute to the reduction of static lung compliance.

Tonicity of the Aspirated Fluid

These changes are most severe when distilled water is aspirated but are almost as severe when 3% saline (similar to seawater) is aspirated.[76] Inhalation of fresh water leads to water movement into cells, and dilution of extracellular and intracellular fluid electrolyte concentrations, while inhaled seawater increases electrolyte concentrations and leads to exit of water from cells. In practice, in most cases, these electrolyte changes are very minor because of the small volume of water aspirated. The severity of pulmonary edema in survivors of freshwater drowning is very similar to that in salt water near-drowning.[77]

Injury to alveolar cells impairs surfactant production, obstructs air entry into alveoli, and impedes alveolocapillary gas diffusion. Injury to airway mucosal cells leads to increased mucus production and airway obstruction by swelling and sloughed cells and predisposes to gas trapping and to secondary infection. Acute respiratory distress syndrome (ARDS) develops within 1 to 48 hours in about 40% of survivors of near-drowning, because of a combination of direct lung injury (including a hypoxic-ischemic injury to the lung); the global hypoxic-ischemic injury, including that to the bowel; sepsis, and the host inflammatory response (see Chapter 36).

Hypoxic-ischemic injury to the myocardium impairs systolic and diastolic function, causing pulmonary congestion and edema, which exacerbates the defects in gas exchange and lung mechanics of the acute lung injury. A generalized increase in capillary permeability often follows a global hypoxic-ischemic injury, leading to pleural effusions, ascites, and edema of the lungs and chest wall. This further reduces respiratory system compliance, leading to hypoventilation, atelectasis, and impaired gas exchange.

Secondary Infection

Although lung infection complicates only a minority of near-drownings, it can be a severe, life-threatening complication. It appears more commonly in immersion in water polluted with microorganisms (e.g., sewers, drains, spas), in warm-water immersion, and when there is aspiration of gastric contents[78] or persistent atelectasis. The use of mild hypothermia for 12 to 24 hours to improve the neurological outcome in patients who have sustained a cardiac arrest does not appear to increase the risk of developing pneumonia[79,80] (Table 23-4).

Many of these pneumonias are associated with bacteremia and with a high case-fatality rate.[78]

Table 23-4

Southeast Asian pools	*Burkholderia pseudomallei*

Assessment of the Near-Drowning Victim

On arrival at hospital, the airway is cleared and secured, adequate ventilation and oxygenation are achieved, independent circulation is established, and a nasogastric tube is passed. It is useful to know the duration of immersion, the nature of the immersing medium (fresh or salt water, muddy, polluted), and whether the child is known to have vomited.

Examination should address the patency of large and small airways, respiratory effort, and the adequacy of the child's breathing and gas exchange. Wheezing or asymmetry of air entry may suggest bronchial obstruction with foreign bodies. Tachypnea, expiratory grunt, alar flaring, tracheal tug, and soft tissue in-drawing are often present at the time of first assessment, and widespread crackles are commonly found on auscultation. In nonventilated children, these signs increase in prominence over the next 4 to 6 hours.

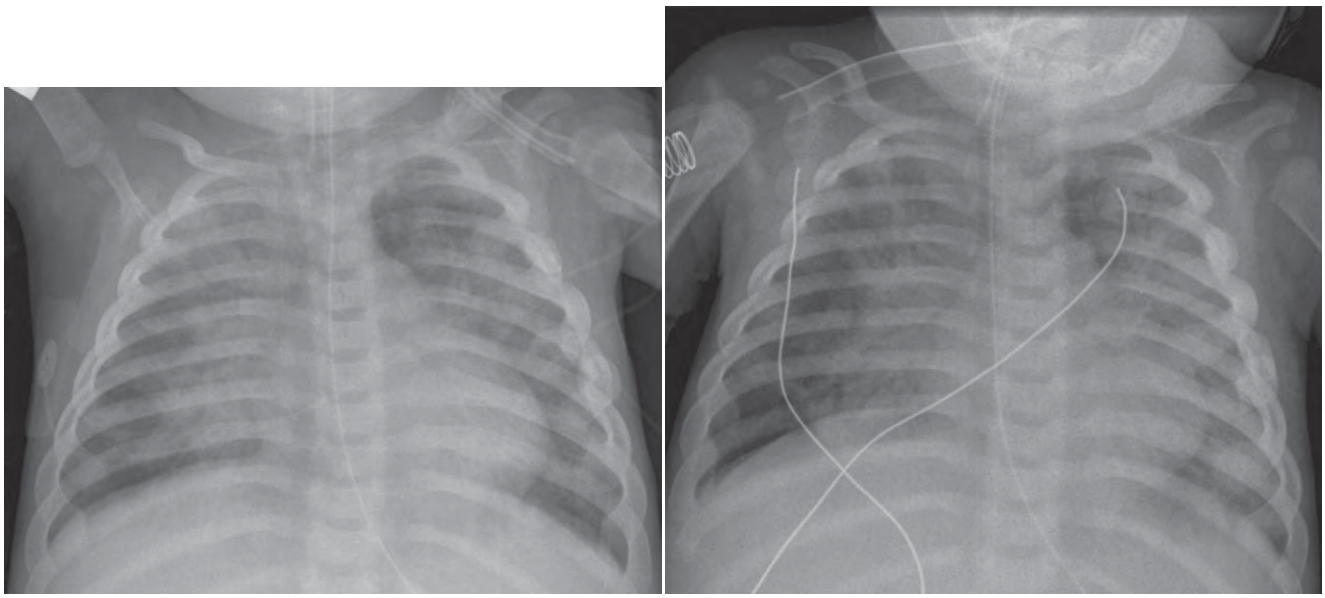
Initial assessment should include pulse oximetry and frequent arterial blood gas analysis, with calculation of the $P_{AO_2} - P_{aO_2}$. Gas exchange and lung mechanics often deteriorate over the first 12 hours in hospital, requiring increasing levels of respiratory support. A chest radiograph frequently shows patchy alveolar infiltrates (Fig. 23-3) and may show areas of atelectasis, gas trapping, or barotrauma due to obstruction of airways by foreign bodies. If the history suggests the possibility of large particle aspiration or if lobar or segmental atelectasis is present, fiberoptic bronchoscopy may be performed through the endotracheal tube. Rigid bronchoscopy may be needed for large particles.

After prolonged immersion (longer than 5 minutes) or if there is a history of asystolic cardiac arrest, or persistent hypotension, or if inotropic drugs are required, repeated echocardiographic examination is useful to monitor impaired myocardial performance as a contributor to respiratory dysfunction.

The total and differential white cell counts can indicate the development of infection in near-drowned children,[81] although the white cell count is commonly raised for 2 to 3 days (and the child may be febrile) after a global hypoxic-ischemic insult, even in the absence of sepsis.[78] Transient leukopenia due to hypoxic bone marrow depression, followed by leukocytosis with many immature neutrophils, often follows prolonged cardiac arrest. Bacteriological surveillance should include blood cultures and bronchoalveolar lavage if there are clinical or laboratory signs of sepsis. Organisms grown from cultures of tracheal mucus of near-drowned children may be upper airway contaminants, airway colonizers, or pathogens, so diagnosis of pneumonia in these circumstances depends on finding a positive blood or tracheal culture in the presence of new clinical signs of pneumonia, a secondary rise (or fall) in leukocyte count, and new radiographic changes.[78]

Management (Table 23-5)

The child's airway, breathing, and circulation are assessed and secured during primary resuscitation. The trachea should be intubated if the airway is obstructed, if the child's airway protective reflexes are inadequate, if ventilation will be required for more than a few minutes, or if the child's



A B

Figure 23-3 **A,** Chest radiograph of a 13-month-old, 2 hours after fresh water immersion, showing extensive, mainly perihilar, airspace opacities. **B,** Chest radiograph of the same patient, 24 hours later, showing some clearing of the pulmonary edema.

consciousness is impaired. All other near-drowned children should receive high-flow oxygen by mask.

In the presence of encephalopathy, the SaO_2 should be maintained greater than 96% (PaO_2 greater than 80 mm Hg) and the child should be mechanically ventilated to achieve a $PaCO_2$ of 35 to 40 mm Hg for optimal brain protection. In the absence of encephalopathy, SaO_2 should be maintained at greater than 90% (PaO_2 greater than 60 mm Hg). If this cannot be achieved by mask delivery of oxygen, CPAP 5 to 15 cm H_2O or bilevel positive airway pressure (BiPAP) may be delivered by face mask or nasal prongs. If these measures fail to maintain adequate gas exchange, the child requires tracheal intubation and mechanical ventilation. Prone positioning, high-frequency oscillation ventilation, and occasionally extracorporeal membrane oxygenation (ECMO) have been used, with a successful outcome in near-drowned children.

Table 23-5
Controversial Treatment Measures in Near-Drowned Children

Treatment Goal	Treatment Measure	Evidence of Efficacy
Maintain gas exchange	Open lung strategy: high PEEP and low tidal volume	Controlled trials suggest benefit[82]
	Prone positioning	Case reports suggest benefit[83]
	High frequency oscillatory ventilation	Case reports suggest benefit[84]
	ECMO	Case reports suggest benefit[85-87]
	Inhaled nitric oxide	Case reports suggest benefit
	Surfactant	Case reports suggest benefit[88]
Reduce lung inflammation	Pentoxifylline	Animal studies suggest benefit[89]
	Steroids	Reviews of evidence found little evidence of benefit from steroids[78,90]
Prevention of pneumonia	Prophylactic antibiotics	Not recommended. Case series did not show benefit[91,92]

Patients are usually hypovolemic from capillary leak of fluid after a significant near-drowning event.[77,93] Central venous pressure monitoring, fluid replacement, and inotropic drugs are more appropriate than diuretics, despite the presence of pulmonary edema.

Therapeutic bronchoscopy is often useful to remove obstructive debris when there is lobar or segmental atelectasis. Prophylactic antibiotics do not reduce mortality or the risk of pneumonia and should not be used. Although some recommend the use of frequent sputum cultures to direct antimicrobial therapy, the presence of colonizing organisms and upper airway contaminants makes interpretation of such cultures difficult. An alternative approach is to perform cultures only when there is new or increasing evidence of sepsis. Empirical treatment with an extended spectrum β-lactam/β-lactamase inhibitor with or without an aminoglycoside covers most bacterial causes of pneumonia in near-drowned children.[78]

Outcome

Mortality among patients who reach hospital after a near-drowning event is 10% to 20%.[93-95] Most deaths are due to neurological injury: Mortality due to acute lung injury or pneumonia occurs in 1% to 3% of patients.[93,94] About 70% of patients with cough and chest crackles develop pulmonary edema, and 15% develop pneumonia.[94]

In survivors, transient restrictive lung defects (lasting up to 4 months), and long-lasting small airways obstruction and bronchial hyperreactivity have been described[96,97] (see Box 23-9 for specific teaching points).

BOX 23-9 Drowning Teaching Points

- Early bronchoscopy is used if lobar or segmental atelectasis is present.
- Use microbiologic surveillance only if there are new or increasing signs of sepsis.

TRAUMATIC LUNG INJURY

Trauma is the principal cause of death in children in the United States. Chest trauma is second to brain trauma as a cause of death.[98] Thoracic injury is present in 5% of admissions to a pediatric major trauma center.[99] About 30% of these have an isolated chest injury,[99,100] with mortality about 5%.[99] When combined with a head injury, mortality increases to 35%.[99]

The most common intrathoracic injury is lung contusion or laceration in 50% of chest-injured children. Only 25% have rib fractures. Smaller numbers have injury to the trachea or major bronchi. From 60% to 90% of chest injuries in children are nonpenetrating (mainly to passengers or pedestrians in automobile accidents or due to falls or nonaccidental injury). The remainder are penetrating (gunshot or stabbing).[99,101,102]

Mechanism of Injury

When struck by an object (e.g., the ground or part of a motor vehicle) or a blast pressure wave, the body wall deforms. Its viscoelastic properties mean that high-velocity impacts transmit more energy to chest viscera than does lower-velocity deformation of the same or greater depth.[103] Fast impacts such as blast produce high-amplitude pressure waves in tissues: these travel at or above the velocity of sound. Slower impacts (e.g., deceleration of a moving body) cause low-velocity shear waves, which severely distort tissues and organs. This causes collision of viscera with rigid structures; stretching and tearing tissue components (e.g., bronchi and blood vessels) at points of attachment, and acceleration of tissues of different densities (e.g., alveoli and blood vessels) at different rates, causing asynchronous motion and tearing.[104]

Although rib fractures (including fractures at two sites on the same rib, producing a flail segment) may uncommonly be found in children, a more common finding is severe injuries to thoracic viscera without rib fracture,[102] as the child's less-calcified ribs can flex markedly without breaking.

Lung Contusion

Widespread disruption of alveoli and alveolar capillaries underlying the area of impact (or in the opposite lung, because of contrecoup injury) causes extravasation of blood into alveoli, small airways and interstitial spaces in the lung, obstructing air entry to injured and noninjured parts of the lung, and providing a substrate for secondary infection. Intrapulmonary shunt and ventilation-perfusion mismatch increase, leading to hypoxemia.[105] Extravasated blood, the consequent inflammatory response, and reduced surfactant production increase lung water and lung elastance, leading to increased work of breathing and hypercarbia.[106] Increased mucus production exacerbates the obstruction of large and medium-sized airways caused by the presence of blood.

Following the interstitial hemorrhage, inflammatory edema and cellular infiltrate accumulate over 48 hours[106,107]; the contusion heals over 7 to 10 days with little pulmonary scarring.[107]

At presentation to hospital, there may be few clinical signs apart from mild tachypnea and desaturation. These may become more severe over the next few hours, requiring CPAP or mechanical ventilation to maintain adequate gas exchange. Air entry may be reduced, and dullness to percussion and inspiratory crackles appear. Patchy alveolar opacity appears on plain chest radiographs in the first 6 hours and becomes more dense over the next 12 hours. On CT scan, the contused area is usually a subpleural crescent of consolidation in the posterior part of the lung. It often extends across the boundaries of lung segments and lobes[108] (Fig. 23-4).

The most common differential diagnosis is fat embolism, especially in older children and teenagers with long bone fractures. The most useful differentiating features are the presence of overlying skin injury and the localized nature of the lung contusion compared with widespread, late-appearing (24 to 48 hours postinjury) radiological opacities in fat embolus. Less reliable indicators are the presence of skin petechiae, encephalopathy, and urinary fat globules in the fat embolism syndrome.

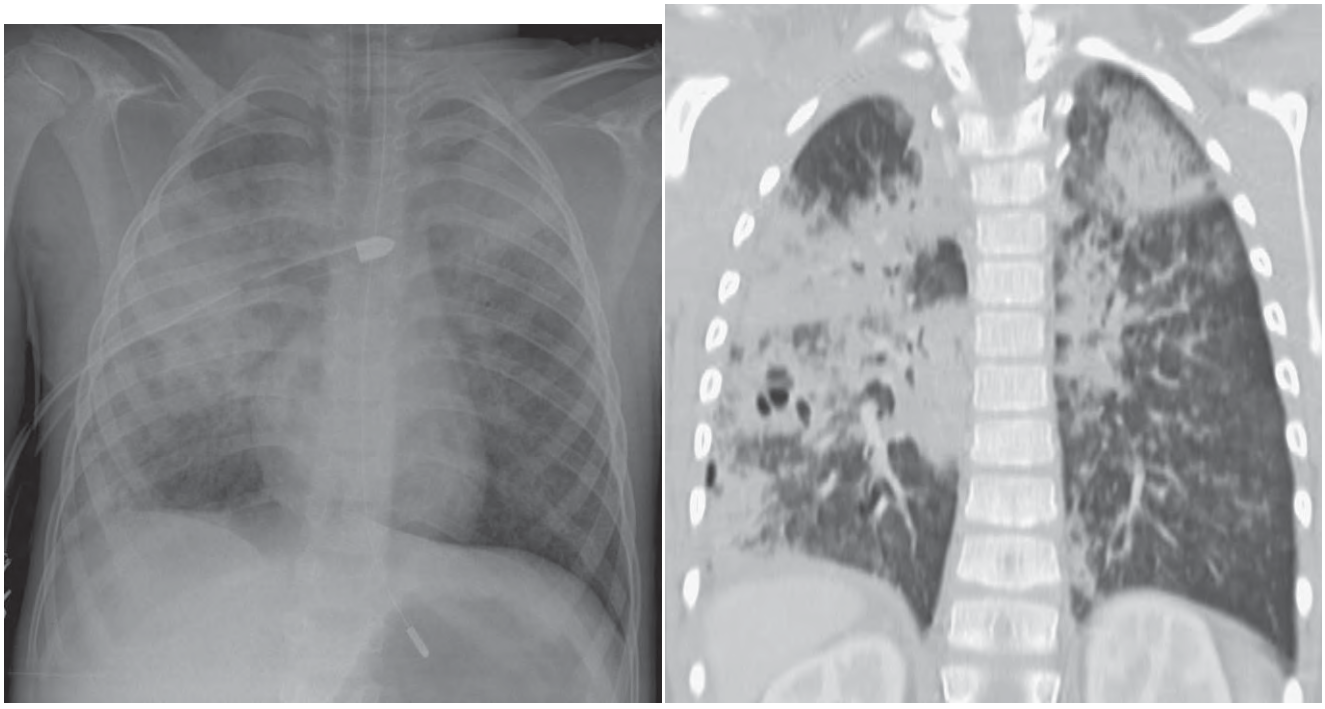
Management of lung contusion is supportive. Blood gases should be maintained in the normal range by mechanical ventilation only if required for optimum management of associated injuries (especially head injury and hemorrhagic shock). Otherwise, more conservative management goals (e.g., PaO_2 greater than 50 mm Hg and pH greater than 7.25) may be used. There is no convincing evidence to support the use of steroids or prophylactic antibiotics in lung contusion.[104]

In contrast to adults, 70% of whom have residual restrictive lung defects after sustaining lung contusion,[109] most children recover without residual abnormalities of lung function.[110]

Lung Laceration

The lung surface can be lacerated by the ends of fractured ribs or, in the absence of rib fracture, by extreme deformation of a child's flexible rib cage. Hemothorax, pneumothorax, and hemopneumothorax are often found in association with tears of the lung surface. They may uncommonly be associated with injuries to major bronchi and other mediastinal structures. A small pneumothorax found on plain chest radiograph or CT scan should be observed clinically and on follow-up radiographs but does not require drainage, even in children on mechanical ventilation,[111] unless it expands significantly or interferes with gas exchange or with venous return. Larger pneumothoraces and hemothoraces require tube thoracostomy[98] (preceded, in the case of a tension pneumothorax, by needle thoracostomy). Rarely, a large laceration causes a severe air leak and requires surgical repair, preceded by bronchoscopy to exclude tracheobronchial injury.[98]

Lung deformation and tearing can also lead to the formation of cavities within the lung that may become filled with blood (intrapulmonary hematoma) or with air (traumatic



A B

Figure 23-4 **A,** Chest radiograph of an 8-year-old, 1 hour after being run over by an automobile, showing extensive confluent airspace opacities in the periphery of both lungs, with a residual right-sided hemothorax. **B,** Coronal cut of a CT scan from the same patient, 4 hours after injury, showing widespread, mainly subpleural opacities, with some cystic areas in the right upper lobe and the apical segment of the right lower lobe.

pneumatocele). The hematoma, a rounded opacity that may contain an air pocket, appears on chest radiographs only when the surrounding area of contusion begins to fade. It generally resolves over 1 to 2 months without specific treatment.[112]

Traumatic pseudocysts may be asymptomatic or may be associated with dyspnea, cough, and hypoxemia. They appear on plain erect chest radiographs after 5 to 6 days as a round or oval air-filled cavity that may have a fluid level but may not be apparent on supine films.[113] They do not require drainage or other specific treatment unless they become infected, bleed or expand progressively, or rupture into the pleural cavity.

Tracheobronchial Injuries

Tears in the airway occur anywhere from the glottis and extrathoracic trachea (causing severe subcutaneous emphysema) to the major bronchi, where they cause pneumothorax, bronchopleural fistula, and mediastinal and subcutaneous emphysema, as well as airway obstruction and collapse of a lobe or lung. The usual cause is anteroposterior crush injury of the larynx, trachea, or chest wall or a blow-out injury by severe chest and lung compression with a closed glottis.[98] Investigation requires bronchoscopy. Small tears may be managed conservatively, but larger tears require surgical repair (see Box 23-10 for specific teaching points).

BOX 23-10 Traumatic Lung Injury Teaching Points

- Low-velocity trauma causes lung laceration and subpleural consolidation.
- Avoid corticosteroids and prophylactic antibiotics.

BLAST INJURY

Accidental blast injuries are less common in childhood than in young adults, but landmine- or terrorism-related blast injuries in children are becoming increasingly common.[114-116]

Detonation involves very rapid expansion of gases, which produces a wave of high pressure traveling faster than the speed of sound, followed by a wave of low pressure, then a longer-lasting blast wind that is strong enough to throw the human body and other objects about, causing severe injury. Blast in enclosed spaces (e.g., buses, trains, or buildings) is even more damaging, as reflection of shock waves produces very high pressure summation waves. This explains the much higher mortality rate and frequency of lung injury in closed-space explosions compared with open-air explosions.[117]

In addition to the tissue disruption caused by differential acceleration of structures of different densities,[118] shock waves due to blast cause "spalling" (shearing or bursting) at gas–liquid interfaces such as alveoli, which disrupts alveoli and alveolar capillaries. They also cause implosion due to rebound overexpansion of gas-containing spaces after the pressure wave passes.[104] Widespread damage to alveoli and alveolar capillaries leads to hemorrhage into alveoli and airways, to rapid accumulation of edema fluid in alveoli and pulmonary interstitial tissues, and to the entry of air into pulmonary vessels, with consequent systemic air embolism. Air emboli to cerebral or coronary vessels can lead to sudden

BOX 23-11 Blast Injury Teaching Points

- The principal lung problems are alveolar edema and air embolism.
- Drain any hemothorax or pneumothorax.
- Use the lowest ventilator pressures compatible with acceptable gas exchange.

death in minutes. Widespread air or fibrin emboli cause long-lasting injury to tissues and organs, including the spinal cord.[118,119]

Blast injury to the lung is very often associated with other primary injuries, including burns, traumatic amputations, and injuries to the head, abdomen, eyes, and tympanic membranes and to penetrating shrapnel injuries.[117,118,120] Patients present with dyspnea, hypoxemia, cough, chest pain, and hemoptysis. Bloodstained froth is found in tracheal or gastric aspirates. There may be signs of air emboli to brain, heart, and other organs. Most patients have alveolar infiltrates on chest radiograph, usually bilateral and perihilar, but sometimes diffuse. Pneumothorax and pneumomediastinum may also be present.[120]

Management is supportive: hemothoraces and significant pneumothoraces should be drained. The prone position or affected lung downward is used to limit the entry of air into the left ventricle.[121] All patients should receive the highest practicable concentration of oxygen by mask, or (unless basal skull fracture is suspected) by mask CPAP. Severe type II respiratory failure or severe hemoptysis requires tracheal intubation and mechanical ventilation using permissive hypercapnia and, if necessary, PEEP at 10 cm H_2O.[120] The lowest peak airway pressure that achieves acceptable PaO_2 (50 mm Hg) and pH of 7.2 is used, as high peak airway pressures increase the risk of systemic air embolism.[118] Occasionally, high-frequency oscillation or jet ventilation may be needed.[122] Hyperbaric oxygen treatment has been used to treat systemic air emboli.

Although almost all patients with pulmonary blast injury develop signs within 1 hour, it is prudent to observe blast victims without such signs, and with a normal chest radiograph and blood gases, for at least 6 hours.[121] Patients with moderate or severe injury may develop ALI and multiorgan failure, while those with milder injury begin to improve within 24 hours of injury.[122] Many survivors have complete asymptomatic recovery, while a few have a residual restrictive defect[120] (see Box 23-11 for specific teaching points).

BIOLOGICAL WARFARE AGENTS AND THE CHILD'S RESPIRATORY SYSTEM

Biological warfare is the intentional release of infective organisms or their toxic products for the purpose of killing or harming enemy military personnel or populations. In the case of biological terrorism, the target is the civilian population, and the aim is to disrupt the society by overwhelming its medical and social resources and undermining the confidence of the civilian population in the infrastructure and institutions of the society. In warfare, biological weapons are more likely to be used as strategic weapons (against populations) than as tactical weapons against troops, because their onset of effect is too slow for tactical use.[123] Therefore, either in warfare or in terrorist attacks, children are likely to be affected (Box 23-12).

BOX 23-12 Characteristics of an Effective Biological Warfare Agent

Cheap and easy to produce
Easy to deliver in an effective form (e.g., 1- to 6-μm aerosol particles)
Easy to disseminate (e.g., as aerosol rather than diluted in a water supply)
Easy to conceal and transport
Short incubation period causes mass casualties simultaneously for maximum psychological effect
Lethal effect
Highly contagious
Difficult to treat
Its name causes fear in the population (e.g., "plague" or "anthrax")

From Weinstein RS, Alibek K: Biological and Chemical Terrorism: A Guide for Healthcare Providers and First Responders. New York, Thieme, 2003.

The U.S. Centers for Disease Control and Prevention (CDC) classifies possible biological warfare agents as class A (easily disseminated or person-person transmission; high mortality; requiring intensive public health intervention and preparedness; likely to cause panic: e.g., plague, anthrax; smallpox, viral hemorrhagic fevers; botulism; tularemia); class B (moderately easily disseminated; moderate morbidity but low mortality: e.g., brucellosis; Q fever; ricin; T-2 mycotoxins) or class C (pathogens that are available and could be readily produced and engineered as bioweapons: e.g., hantaviruses; yellow fever; tick-borne encephalitis).[123] Box 23-13[125] lists reasons for the vulnerability of children to biological agents.

Adequate treatment of several of these diseases depends on early diagnosis and treatment in the incubation period or at the first manifestations: Box 23-14[126] lists possible indicators of the presence of a biological attack (Tables 23-6 and 23-7).

BOX 23-13 Vulnerability of Children to Biological and Chemical Warfare Agents

Inexperience and small size make avoidance and escape difficult.
Inability to communicate symptoms impedes timely diagnosis and treatment.
Some vaccines (e.g., plague and anthrax) are not licensed for children.
There is a reluctance to use drugs such as doxycycline and fluoroquinolones in children.

From Cieslak TJ, Henretig FM: Bioterrorism. Pediatr Ann 32:154-165, 2003.

BOX 23-14 Indicators of a Biological Attack

- Appearance of an uncommon disease (e.g., inhalational anthrax)
- Clusters of patients with an uncommon disease in a nonendemic area
- Unusual route of infection or time of year for that disease
- Unusual patient age, clinical presentation, or severity of a known disease
- Increased mortality in birds or animals
- Unusual variant of microorganism, including antibiotic sensitivity pattern
- Claim of attack by a terrorist group

From Khardori N: Bioterrorism and bioterrorism preparedness: Historical perspective and overview. Infect Dis Clin North Am 20:179-211, 2006.

Individual Diseases

ANTHRAX

Organism

Bacillus anthracis

Weapon

Aerosolized 1- to 2-μm endospores

Disease

Inhalational anthrax

Mortality

Fifty kilograms of anthrax spores spread upwind of a city of 500,000 is estimated to cause illness in 250,000 people and kill 100,000.[127]

Presentation

Fever, rigors, dry cough. After 2 to 3 days, sudden severe dyspnea, fever, profuse sweating, and shock appear. Severe mediastinal lymphadenopathy may cause stridor and superior vena caval obstruction with head and neck edema; 50% have hemorrhagic meningitis. Rapidly increasing respiratory failure and shock lead to death within 36 hours.[128]

Diagnosis

Depends on awareness and suspicion. The chest radiograph shows a wide mediastinum with pleural effusions and alveolar infiltrates. These changes and the hilar adenopathy are even more evident on CT scan and are the most sensitive and specific features that differentiate inhalational anthrax from community-acquired pneumonia or influenza-like illness. Other differentiating features are nausea, vomiting, temperature above 100.4° F, altered mental status, and cold mottled, cyanotic, or sweaty skin.[129] Blood culture is positive if taken before antibiotics are given.[128] Enzyme-linked immunosorbent assay or polymerase chain reaction testing of blood, cerebrospinal fluid, or tracheal aspirate may confirm the diagnosis.[130]

Treatment

In children, combination therapy with ciprofloxacin 10 to 15 mg/kg (maximum 400 mg) IV every 12 hours or doxycycline 2.2 mg/kg (maximum 100 mg) IV every 12 hours, *plus* amoxicillin 50 mg/kg IV every 6 hours is recommended.[130,131]

Table 23-6
Biological Warfare Agents That Cause Fever Plus an Acute Respiratory Illness (Cough, Dyspnea, and Cyanosis)

Disease or Agent	Delivery	Person-Person Transmission	Incubation Period
Inhalational anthrax	Spores/aerosol/food	No	1-5 days
Blastomycosis	Spores/aerosol	No	30-45 days
Hantavirus	Aerosol/food/water	No	1-5 weeks
Legionnaires' disease	Aerosol	No	2-10 days
Leptospirosis	Aerosol	Rare	3-30 days
Melioidosis	Aerosol/soil/water	Yes	2-400 days
Pneumonic plague	Aerosol or fleas	Yes	1-6 days
Psittacosis	Aerosol	Rare	5-15 days
Q fever	Aerosol/food/water	No	2-14 days
Pneumonic tularemia	Aerosol/ticks/food/water	No	3-14 days

From Weinstein RS, Alibek K: Biological and Chemical Terrorism: A Guide for Healthcare Providers and First Responders. New York, Thieme, 2003.

Table 23-7
Agents Causing Respiratory Failure but with a Nonrespiratory Presentation or Site of Action

Disease or Agent	Delivery	Person-Person Transmission	Incubation Period
Botulism	Aerosol/food/water	No	18-36 hr
Tricothecene (T-2) mycotoxins	Aerosol/droplets/skin absorption	Via skin contact with a victim	Minutes to hours
Tetrodotoxin	Aerosol/food/water	No	10 min to 3 hr
Saxitoxin	Aerosol/food/water	No	30 min to 10 hr
Lassa fever	Aerosol	Yes	5-14 days

Patients given antibiotics earlier than the median 4.7 days from symptom onset had a 40% mortality rate, compared with 75% mortality for those treated later than 4.7 days.[132]

Prophylaxis
Ciprofloxacin 10 to 15 mg/kg (maximum 500 mg) orally every 12 hours or doxycycline 2.5 mg/kg (maximum 100 mg) orally every 12 hours. The cell-free $Al(OH)_3$-adsorbed vaccine AVA effectively prevents inhalational anthrax when combined with post-exposure antibiotics, but requires a series of six inoculations over 18 months and is available only to individuals at high risk of exposure.[130]

BLASTOMYCOSIS[124]

Organism
Blastomyces dermatitidis

Weapon
Aerosolized spores

Disease
Sixty percent of cases develop pneumonia.

Mortality
Five percent

Presentation
Fever, rigors, cough, myalgia, arthralgia; 60% develop a productive cough, hemoptysis, pleuritic chest pain, and dyspnea. Chest radiograph may show hilar lymphadenopathy, alveolar infiltrates, nodules, and cavitation.

Diagnosis
Depends on suspicion plus culture and staining of yeast-like organisms in tracheal aspirate, bronchoalveolar lavage fluid, or lung biopsy specimens

Treatment
Treatment of pneumonia: Amphotericin B 0.3 to 0.6 mg/kg IV daily until stable, then itraconazole 4 mg/kg daily orally for 6 months; 10% to 14% relapse; review every 3 to 6 months for 2 years

HANTAVIRUS[133]

Organism
Members of the genus *Hantavirus* (especially Sin Nombre virus)

Weapon
Aerosol of virus or of infected rodent excreta

Disease
Hantavirus pulmonary syndrome

Mortality
Forty percent

Presentation
Three to 5 days of mild febrile illness: fever, rigors, myalgia, malaise, headache, nausea, diarrhea, followed by sudden onset of severe pulmonary edema due to increased capillary permeability. Tachypnea, hypoxemia, and dyspnea usually require mechanical ventilation. Severe cases have marked myocardial depression, with hypotension, metabolic acidosis, exacerbation of pulmonary edema, and tachyarrhythmias. In survivors, heart function returns to normal over 1 week, but many have residual small airways obstruction.

Diagnosis
Based on clinical suspicion plus sudden onset of pulmonary edema, with thrombocytopenia, hemoconcentration and left shift of polymorphs, together with rising titres of Hantavirus-specific IgM and IgG

Treatment
Supportive: Mechanical ventilation for respiratory failure, and management of circulatory failure using close hemodynamic monitoring, inotropic drugs, and antiarrhythmic agents as required

LEGIONNAIRES' DISEASE (see Chapter 35)

Organism
Legionella pneumophila

Weapon
Aerosolized droplets

Disease
Legionnaires' disease

Mortality
Five percent to 15%

Presentation, Treatment, and Outcome
See Chapter 35.

MELIOIDOSIS[124,134]

Organism
Burkholderia pseudomallei

Weapon
Aerosolized droplets

Disease
Acute pulmonary melioidosis

Mortality
After a bioterrorist attack, not known

Presentation
Sudden onset of high fever, rigors, headache, myalgia, cough, and chest pain. This may progress to pneumonia with lung abscesses, which may become chronic.

Diagnosis
Clinical suspicion plus chest radiographic appearance of pneumonia, miliary nodules, or lung abscess. The organism may be cultured from blood, urine, tracheal aspirate or needle aspirate of abscesses, or from skin lesions.

Treatment
Ceftazidime 50 mg/kg IV every 6 hours plus amikacin 15 to 20 mg/kg IV daily plus sulfisoxazole 75 mg/kg (maximum 4 g) stat, then 35 mg/kg (maximum 1.5 g) orally every 6 hours for 4 weeks[134]

PNEUMONIC PLAGUE

Organism
Yersinia pestis

Weapon
Aerosol of organisms or release of infected fleas

Disease
Pneumonic plague, which can develop primarily from inhalation of an aerosol or may develop from progression of bubonic plague caused by the bite of an infected flea

Mortality
Almost invariably fatal if antibiotic treatment is started more than 24 hours after onset of symptoms.[135] Fifty kilograms of dried organism released 2 km upwind of a population center of 500,000 has been estimated to cause 100,000 casualties, of whom 55,000 will die.[123] Pneumonic plague is extremely contagious via droplet spread.[124]

Presentation
Pneumonic plague: Sudden onset of fever, rigors, headache, myalgia, and malaise. Buboes are absent. Chest pain, dyspnea, and productive cough follow rapidly. Sputum (in adolescents and older children) is mucoid or frothy and blood-streaked. Respiratory failure ensues early, followed by circulatory collapse, disseminated intravascular coagulation, and multiorgan failure. Chest radiograph shows patchy atelectasis or segmental consolidation, which spreads rapidly

Diagnosis
Depends on recognition of profuse gram-negative or bipolar stained bacilli in blood or sputum, especially if the laboratory is aware of the possibility of plague[123,131]

Treatment
For 10 days: Streptomycin 15 mg/kg (maximum 1 g) IM every 12 hours or gentamicin 6 mg/kg IV daily or doxycycline (>8 years old) 2.2 mg/kg IV every 12 hours. *Exposure prophylaxis (for 7 days):* Ciprofloxacin 15 mg/kg every 12 hours by mouth

PSITTACOSIS (see Chapter 41)

Organism
Chlamydia psittaci

Weapon
Aerosol of organisms

Disease, Presentation, Clinical Course, and Treatment
See Chapter 41.

Mortality
Approximately 20% (possibly greater in a bioterrorism attack due to the high initial organism load)[124]

Q FEVER (see Chapter 35)

Organism
Coxiella burnetii

Weapon
Aerosol of organisms

Disease, Presentation, Clinical Course, and Treatment
See Chapter 35.

Mortality
Uncommon

TULAREMIA (see Chapter 35)

Organism
Francisella tularensis

Weapon
Aerosol of the organism

Disease
Pneumonic tularemia

Presentation, Clinical Course, and Treatment
See Chapter 35.

Mortality
From 35% to 45% if untreated; 5% to 9% if diagnosed and treated early[136,137]

BOTULISM

Agent
Toxin of *Clostridium botulinum*

Weapon
Aerosol or contamination of food or water

Disease
Descending paralysis, including paralysis of respiratory and bulbar muscles, leading to respiratory failure, which may last weeks to months

Lethality
LD_{50} of 1 ng/kg

Treatment
Horse serum antitoxin is most effective if given within 24 hours of the onset of symptoms.[138] Therapy is supportive and includes prolonged (weeks) mechanical ventilation.

SAXITOXIN (PARALYTIC SHELLFISH POISONING)[124,139]

Agent
Toxin produced by various marine microalgal dinoflagellate species, including *Alexandrium* spp., *Pyrodinium* spp., and *Gymnodinium* spp.

Weapon
Aerosol or contamination of food or water

Disease
Numbness and paraesthesiae of the face and limbs, rapidly progressive ascending paralysis, including paralysis of respiratory and bulbar muscles, leading to respiratory failure. Hypersalivation and sweating. Cardiac failure and arrhythmias and hypotension in severe cases. Muscle power returns in 3 to 4 days.

Treatment
Supportive: Mechanical ventilation if needed, plus support of cardiac failure and cardiac arrhythmias

TETRODOTOXIN[124,139]

Agent

Toxin of several marine species, including toadfish, puffer fish, blue-ringed octopus, xanthid and horseshoe crabs, and some newt, frog, and worm species

Weapon

Aerosol or contamination of food or water

Disease

Facial numbness and paresthesia, progressive ascending paralysis, including paralysis of respiratory and bulbar muscles, leading to respiratory failure. In severe cases, there may be hypotension or hypertension, cardiac arrhythmias, and seizures

Lethality

Up to 50% in severe cases, even with intensive supportive treatment

Treatment

Supportive care of airway, breathing, and circulatory abnormalities

TRICOTHECENE MYCOTOXINS[124,140]

Agent

Mycotoxins, including T-2, produced by various fungal species of the genus *Fusarium*

Weapon

Aerosol is inhaled or absorbed through intact skin

Disease

Rapid onset of skin and eye redness, burning and ulceration; epistaxis, wheeze, dyspnea, cough, and pulmonary hemorrhage with hemoptysis

Treatment

Supportive: Intravenous fluids, analgesia, and mechanical ventilation if necessary. Decontamination of skin by irrigation may prevent person-to-person transmission.

LASSA FEVER[124,141-143]

Agent

Several members of the Arenavirus family, including the Lassa, Junin, Machupo, and Sabia viruses, cause similar syndromes of viral hemorrhagic fever.

Weapon

Aerosol of the virus or contamination of surfaces, food, or water

Disease

High fever, rigors, sore throat, myalgia, and diarrhea. Endothelial damage and increased vascular permeability lead to a widespread petechial rash, mucosal bleeding, shock, and pulmonary edema. Facial and laryngeal edema and pleural effusions are seen in severe cases.

Lethality

From 1% to 2% overall and 15% to 20% in hospitalized patients

Diagnosis

Lymphopenia and thrombocytopenia peak at 10 days. Enzyme-linked immunosorbent assay or reverse transcription–polymerase chain reaction testing of blood, throat swabs, or urine identifies the virus.

Prophylaxis

Ribavirin 7.5 mg/kg twice daily for 8 days is suggested for high-risk contacts, but its efficacy is unproved. Several vaccines are undergoing testing in animals.[143]

Treatment

Ribavirin 30 mg/kg IV once, then 15 mg/kg IV every 6 hours for 4 days, followed by 7.5 mg/kg IV every 8 hours for 6 days. Respiratory and circulatory support may require mechanical ventilation, replacement of fluid losses, and inotropic drugs (see Box 23-15 for specific teaching points).

CHEMICAL WARFARE AGENTS AND THE RESPIRATORY SYSTEM

Chemical warfare agents are substances that can be released deliberately with the aim of causing death and disability. They may be used against a body of troops or against a population with the aim of causing fear and disruption of the function of the society. Chemical agents may be military agents such as the nerve gases, sulfur mustard, or CS gas or may be industrial chemicals such as chlorine, ammonia, methylisocyanate, or phosgene, which are stored in bulk close to population centers and can be released by military or terrorist action. Box 23-16 lists likely chemical terronism agents.

Military agents are expensive and generally difficult to clandestinely produce, store, transport, and release, whereas very large quantities of industrial chemicals can be released by a terrorist-detonated explosion at a storage facility or in a bulk-transport vehicle. The use of either type of agent causes fear, anxiety and very large numbers of mildly affected casualties, which, in turn, threatens disruption of the society's health care resources.[144]

Chlorine, phosgene, cyanide, and sulfur mustard were used in World War I. The nerve gases were developed in the 1930s to 1950s but not deployed on a large scale until the Iran-Iraq war in the 1980s. The terrorist organization Aum Shinrikyo released sarin gas on two occasions: in 1994, Sarin was released upwind of an apartment block, killing 7 and injuring 500. In 1995, sarin was released in several Tokyo subway trains, killing 12 and injuring 3800.[145]

Accidental release of a mixture of gases including cyanides and methylisocyanate in Bhopal, India, in 1984 killed at least 3000 people and injured at least another 80,000.[144]

BOX 23-15 Biological Warfare Agents Teaching Point

- Children are vulnerable because small size and inexperience increase exposure.

BOX 23-16 Chemical Warfare Agents

Military Agents	Others
Nerve gases	*Cyanides*
Tabun	*Riot control agents*
Sarin	CN (mace)
Soman	CS
VX	DS
Vesicants	Bromobenzyl cyanide
Mustard	Capsaicin (pepper spray)
Nitrogen mustard	*Respiratory agents*
Sulfur mustard	Ammonia
Lewisite	Chlorine
Phosgene oxine	Phosgene

Chemical agents can injure many levels of the respiratory system. Those that cause seizures or coma (e.g., nerve agents, cyanides, H_2S) impair respiratory drive and airway protective reflexes, while nerve agents also cause flaccid paralysis of all skeletal muscles including the diaphragm and intercostal muscles. Vesicant agents and irritants such as NH_3 and Cl_2 cause mucosal swelling and necrosis from the mouth and larynx to the respiratory bronchioles, as well as causing alveolar injury and flooding. Nerve agents and irritants also cause small and large airway obstruction due to bronchorrhea. Cyanides impair cellular utilization of oxygen.

Children are more vulnerable than adults to agents that form dense vapors lying close to the ground (chlorine and sarin).[146] They are also more vulnerable than adults to the epileptogenic effects of nerve gases.[147]

Individual Agents

NERVE AGENTS

These organophosphate compounds inhibit acetylcholinesterase, which is the enzyme that degrades acetylcholine at muscarinic (postganglionic parasympathetic and central nervous system) and nicotinic (autonomic ganglia and skeletal neuromuscular junction) sites. Enzyme inhibition causes acetylcholine to accumulate, resulting in overexcitation at these sites. Volatile agents such as sarin, tabun, and soman form vapors and may be inhaled. Less volatile agents such as VX are 10 times as potent and form droplets that are absorbed through the skin. Binding between agent and enzyme is initially reversible (e.g., by oxime compounds such as pralidoxime), but "aging" by dealkylation irreversibly inactivates the enzyme, such that oxime antidotes are ineffective. Restoration of normal function then depends on the synthesis of fresh acetylcholinesterase. Aging takes place over minutes (soman) to days (VX).[148]

RESPIRATORY EFFECTS OF NERVE AGENTS

- Increase in airway secretions: profuse bronchorrhea and sialorrhea causing widespread airways obstruction
- Bronchoconstriction
- Fasciculation, weakness, and flaccid paralysis of skeletal muscles including respiratory and bulbar muscles.
- Seizures, coma, and central apnea
- Death is usually due to obstruction of large and small airways by mucus.[148]

Diagnosis

There may be a history of exposure or a cluster of patients presenting with similar signs of dyspnea, wheezing, profuse nasal, oral and respiratory secretions, meiosis, lacrimation, sweating, diarrhea, involuntary urination, muscle fasciculation and paralysis, seizures, and coma.

Treatment

- Atropine 0.04 mg/kg (2 to 6 mg in adults) IM or IV, repeated every 2 to 5 minutes as needed to control secretions, dyspnea, and wheezing
- Diazepam 0.2 mg/kg IV repeated as needed for seizures
- Pralidoxime 20 mg/kg, repeated every 2 to 5 minutes as needed to control symptoms
- Tracheal intubation, suction, and mechanical ventilation
- Consider inhaled salbutamol.
- Intravenous fluids
- Remove the patient's clothing into sealed plastic bags. Decontaminate the skin using soap and water or sodium hypochlorite, 1 part in 9 parts of water.

VESICANT AGENTS (BLISTER AGENTS)

These are alkylating agents (the mustards) or arsenicals (Lewisite) that cause widespread cellular necrosis and basement membrane degeneration in skin and respiratory epithelium within 2 to 12 hours of exposure.[149] Although most of these agents have low volatility, respiratory injury due to inhalation of vapor is more likely when they are used in warm environments or when the more volatile Lewisite is combined with sulfur mustard.

The mustards cause blistering and epithelial necrosis of the mouth, nose, pharynx, larynx, and upper airways. These are associated with a burning sensation in the mouth and nose, epistaxis, dry cough, laryngospasm, and wheezing. In severe exposures, and especially with Lewisite and phosgene oxime, pulmonary edema and necrotizing bronchiolitis may appear and pseudomembrane formation obstructs large airways.

Early death is uncommon and is usually caused by airways obstruction or pulmonary edema. More commonly, death occurs 5 to 10 days after exposure, due to ALI or secondary pneumonia, to which leukopenia caused by bone marrow suppression make the victim more vulnerable.[124,149,150]

Management

- Rapid (minutes) decontamination: remove clothing; adsorb the agent with powders such as charcoal, flour, powdered soap or earth, then rinse with water.
- Administer oxygen by mask.
- Consider early intubation, tracheal toilet, humidification, and bronchoscopy to remove pseudomembranes.

- Consider the use of bronchodilators.
- In the presence of pancytopenia, consider the use of granulocyte colony stimulating factor (GCSF) and of cotrimoxazole (the latter as prophylaxis against *Pneumocystis jiroveci*).

RESPIRATORY AGENTS (Box 23-17)

Chlorine (see later regarding chemical and particulate injury), ammonia, and phosgene are stored and transported in bulk in populated areas, and mass release of these agents by terrorist action against storage or transport containers is the most likely source of intentional inhalational exposure.

On contact with water within the airway, phosgene hydrolyses to form HCl, chlorine forms HCl, HOCl, and free oxygen radicals, and ammonia forms the highly alkaline NH_4OH. Each causes cell membrane damage and denaturation of cytoplasmic proteins.

Phosgene, which is less irritant and therefore less likely to evoke airway protective reflexes, penetrates more deeply into the respiratory tree, mainly affecting bronchioles and alveoli, where it causes pulmonary edema and bronchiolitis obliterans. Chlorine and ammonia, being highly irritative, cause cough, laryngospasm, and bronchoconstriction, but with greater exposure (e.g., in a small child who is unable to escape the low-lying cloud of denser-than-air chlorine), alveolar injury with pulmonary edema appears in 2 to 4 hours.[151] With all of these agents, the greater the inhaled dose, the earlier do the symptoms appear.

Treatment[151]

- Removal from exposure
- In the case of Cl_2 and NH_3, copious irrigation of skin, eyes, and mucous membranes
- Close observation for signs of desaturation or respiratory distress
- Supportive respiratory care
  - Oxygen by mask
  - Consider the use of bronchodilators with or without steroids for severe wheezing
  - Consider noninvasive CPAP or BiPAP for severe wheezing or pulmonary edema.
  - Intubation and mechanical ventilation with high PEEP if needed for pulmonary edema.
  - Consider the use of nebulized lidocaine 1% for pain and severe coughing.
  - Consider flexible bronchoscopy to locate and remove pseudomembranes if wheezing is persistent and unresponsive to bronchodilators.

BOX 23-17 Examples of Industrial Chemicals Capable of Causing Lung Injury

Anhydrous ammonia
Sulfur dioxide
Hydrogen chloride
Hydrogen fluoride
Phosgene
Nitrogen oxides
Chloropicrin
Perfluoroisobutylene (PFIB)
Benzene
Methylisocyanate

RIOT CONTROL AGENTS (see Box 23-16)

Children may be exposed accidentally or as hostages, or by terrorist action. The agents can be dispersed as powders, droplets, or vapor from cannisters, projectiles, or via the air conditioning system of public buildings. The effects of these agents are of relatively short duration (minutes to 2 to 4 hours after removal from exposure).

Respiratory effects are mainly confined to the upper airways (cough; burning sensation in the throat; laryngospasm) but bronchospasm is sometimes seen, and noncardiogenic pulmonary edema may rarely occur when the agents are used in confined spaces, or when exposure is prolonged (e.g., the victim is unconscious or is too young and inexperienced to escape).[152]

Treatment[152]

- Remove from exposure.
- Decontaminate skin by irrigation with water plus soap or a very dilute solution of $NaHCO_3$.
- Administer oxygen by mask.
- Support oxygenation and ventilation by noninvasive CPAP or BiPAP if necessary.
- Victims of severe exposure may require mechanical ventilation with PEEP.
- There are no specific antidotes for these agents.

INCAPACITATING AGENTS

Analogues of fentanyl and benzodiazepines with a very short time of onset and duration of action have been used against groups of people, notably in the Moscow theatre siege. The principal respiratory effects of such agents are central respiratory depression or apnea, and upper airway obstruction due to unconsciousness. Severe exposure is most likely when the agents are used in a confined space (e.g., via the ventilation system of a building), and its outcome is severe hypoxic injury to the brain and heart, leading to death.

Treatment

- Remove from exposure.
- Provide conventional management of the unconscious patient with attention to airway maintenance and to the adequacy of breathing.
- Mechanical ventilation via endotracheal tube may be required.
- Specific antidotes to opioids (e.g., naloxone) or to benzodiazepines (e.g., flumazenil) may have to be given repeatedly or by infusion until full consciousness and adequate spontaneous ventilation return and remain stable.[152,153]

CHEMICAL AND PARTICULATE LUNG INJURY

Major lung injury resulting from the inhalation of noxious gases, chemicals, and particulates is less common in children than in adults, in whom chemical pneumonitis is most commonly associated with industrial accidents. The most common causative agents are hydrogen sulfide, phosgene,[154] sulfur dioxide,[155] nitrogen oxides,[156] cadmium, nickel, and other metal fumes,[157] although damage to the respiratory system can be caused by a very wide range of industrial and domestic chemicals.[158] The epidemiology of inhalation in children predominantly reflects the availability of noxious substances within the home. Pulmonary injury in children has been reported after the inhalation of chlorine, talcum powder, detergent powders, and mercury and the aspiration of activated charcoal. Children with asthma are particularly susceptible to respiratory irritants; chlorine, NH_3, nitrogen dioxide, and sulfur dioxide have been reported as precipitants of airway obstruction.

Chlorine

Chlorine is an irritant gas that can damage the tracheobronchial tree and lung parenchyma. Its use in households as a component of cleaning agents and swimming pool disinfectant[159,160] means that it is frequently encountered by children. Pulmonary toxicity from chlorine inhalation has been reported in children of all ages.[161-163] Voluntary chlorine inhalation has been reported in adolescents.[161,164]

DISEASE MECHANISMS

Chlorine gas is more dense than air and dissipates slowly, leading to prolonged exposure. Chlorine is estimated to be 20 times more toxic as an oxidizing agent and irritant than HCl. It is irritating to the eyes and skin and causes bronchoconstriction, airway inflammation, and alveolar injury. Inhalation of 40 to 60 ppm can produce pneumonitis and pulmonary edema. Cellular toxicity results from the reaction of molecular chlorine with water, forming reactive oxygen species plus HCl and HOCl, which cause denaturation of proteins and cell necrosis. Because the formation of toxic products requires water, damage is most severe in tissues with a high water content, such as the mucosa of the conjunctival sac and the respiratory tract. Pathological examination of the lungs of patients who have died after chlorine gas exposure shows denudation of alveolar and bronchial epithelium, alveolar edema, hyaline membrane formation, and pulmonary intravascular thrombi.[165]

CLINICAL PRESENTATION

Symptoms begin within minutes of exposure to more than 5 ppm. They include irritation of the eye, nose, and upper respiratory tract. Wheezing develops early. Paroxysmal cough, dyspnea, lacrimation, chest discomfort, mucus production, palpitations, dizziness, headache, and nausea are the major symptoms at presentation.[163,166] Wheeze and tachypnea are early signs. Stridor caused by laryngeal edema may be present. Cough with frothy sputum, cyanosis, and crackles on auscultation usually develop within the first 24 hours after exposure[159] and indicate severe lung injury with pulmonary edema. The onset of pulmonary edema may be rapid. Respiratory alkalosis is most common in mild exposure, but persistent hyperchloremic metabolic acidosis may occur.[159,163,167] The presence of hypercarbia or hypoxemia with an increased $P_{AO_2} - P_{aO_2}$ indicates severe respiratory involvement. A depressed conscious state, most probably caused by hypoxemia, has been reported in severely affected children.[159] Spirometry in the acute stages shows an obstructive pattern with a fall in the FEV_1 and the FEV_1/VC ratio[166,168] Reduction of the functional residual capacity indicates pulmonary edema.[169,170] Lung compliance is reduced, and there is intrapulmonary right-to-left shunting. The chest radiograph may be normal at presentation or may show evidence of airflow obstruction with hyperinflation or pulmonary edema with interstitial markings and perihilar alveolar opacities. Ventricular arrhythmias[161] and poor tissue perfusion requiring the infusion of plasma expanders[159] have been reported.

MANAGEMENT

- Most cases require only supplemental oxygen.
- Consider β_2 sympathomimetics and corticosteroids for wheezing.
- Consider noninvasive CPAP or BiPAP.
- Provide tracheal intubation if needed for upper airway obstruction.
- Intubation plus mechanical ventilation with high PEEP may be needed for severe respiratory failure.
- Consider the use of HFOV and ECMO.
- Restrict fluid intake to 70% maintenance to limit lung water accumulation.
- Monitor arterial blood gases and cutaneous oximetry.
- Avoid prophylactic antibiotics
- Experimental: nebulized $NaHCO_3$ to prevent pulmonary edema[171]
- If hypoxemia resulting from pulmonary edema persists despite oxygen therapy, CPAP (delivered by mask, nasopharyngeal catheter, or endotracheal tube) or IPPV with PEEP may be needed. PEEP may not be advantageous if the predominant pulmonary abnormality is airflow obstruction and air trapping resulting from bronchospasm, rather than pulmonary edema, although a trial of CPAP or IPPV with PEEP is justified if gas exchange is deteriorating despite conservative therapy. Patients with airflow obstruction may generate their own "auto-PEEP," and this may be an indication for positive-pressure support. Tracheal intubation and assisted ventilation are required when hypoxemic or hypercapnic respiratory failure, a depressed conscious state, or severe upper airway obstruction occurs. Serial blood gases and continuous cutaneous oximetry should be used in all children with respiratory signs. Observation for 24 hours is indicated for all children who have had significant exposure.

PULMONARY SEQUELAE

Several studies have documented persistent obstructive pulmonary abnormalities in adults after acute chlorine exposure.[166,168] Some 2 weeks after minimally symptomatic exposure, 18 adults had diminished FEV_1 and a maximum mid-expiratory flow rate. Those with the greatest reduction from predicted values were those with the most severe symptoms after exposure and those with a past medical history of

smoking or asthma.[166] Airway reactivity may persist for many years after exposure.[168,172] It is not known whether preexisting bronchial hyperreactivity accounts for the apparently high prevalence of persistent airflow obstruction after chlorine exposure. Residual volume may be reduced for years after exposure, possibly due to peribronchial fibrosis.[168] Recurrent episodes of wheezing and cough, with airflow obstruction that was responsive to bronchodilators and that resolved over 2 years, have been reported in a child exposed to chlorine.[163] Children who have significant exposure to chlorine require follow-up for the assessment of pulmonary function and treatment if symptomatic airflow obstruction develops.

Ammonia

Liquid NH_3 is a component of household cleaning products, but exposure to NH_3 gas with inhalational injury is rare in childhood. NH_3 is highly water soluble and in aqueous solution forms strongly alkaline NH_4OH. Exposure to high concentrations of NH_3 causes liquefactive necrosis of the mucous membranes and submucosal tissues of the upper respiratory tract. This leads to laryngeal edema and inflammation, mucous hypersecretion, mucosal sloughing, tracheitis, and bronchoconstriction. Pulmonary edema may result from massive exposure or may develop after the relief of upper airway obstruction.

Severe lacrimation, pharyngeal irritation, cough, and stridor may develop within minutes of exposure. Upper airway obstruction may be severe and require endotracheal intubation. Treatment is supportive and is similar to that for chlorine inhalation. Bronchodilators are indicated for airflow obstruction. Corticosteroids have not been shown to be of definite benefit but probably should be given for symptomatic upper airway obstruction. Nebulized epinephrine may reduce laryngeal edema and maintain a patent airway without tracheal intubation. Although most patients recover, long-term pulmonary function abnormalities and bronchiectasis have been found in adults after acute NH_3 gas inhalation.[173,174]

Alkaline Laundry Detergents

Via a mechanism similar to that of NH_3, sodium carbonate–containing laundry detergents have caused upper respiratory tract obstruction.[175] Children drool and experience stridor 1 to 5 hours after ingestion of the powder. Most vomit after ingestion. One child reported to have inhaled detergent developed symptoms immediately. At endoscopy, there was edema of the pharynx, epiglottis, and larynx. Tracheal intubation may be required for airway management.[175] Caustic burns may be associated with corneal injury.

Talcum Powder

Talc inhalation is a common problem that affects primarily infants up to the age of 2 years. Exposure occurs most commonly at times of diaper changes. Some reports have suggested that the similar appearance of baby powder containers to nursing bottles is an etiological factor.[176] Aspiration of talc has caused severe respiratory distress and death in young children.[177,178] The mortality rate may be up to 20% in cases severe enough to require assisted ventilation.[178]

DISEASE MECHANISMS

Talc is a powder of hydrous magnesium silicate ($Mg_3Si_4O_{10}H_{20}$). It consists of a layer of magnesium hydroxide between two silica sheets that slide past each other, giving the slippery feel. The mean particle size is less than 5 mm. Inhaled talc causes airway obstruction, drying of the respiratory mucosa, impairment of the ciliary clearing mechanism, and inflammation.[179] Inflammatory infiltrates in biopsy and autopsy specimens consist of mononuclear and giant cells filled with crystalline doubly refractile bodies.[180] Hyaline membrane formation, obliteration of small bronchi and alveoli, and fibrotic changes are also seen.

Children usually develop cough and respiratory distress immediately after inhalation. Sometimes the onset of symptoms is delayed for several hours.[181] Cardiorespiratory arrest due to obstruction of large airways has been reported after massive aspiration.[178] Many children have minimal or transient symptoms. Wheezes, crackles, and tachypnea are common. A chest radiograph may show hyperinflation with patchy infiltrates. Hypoxemic respiratory failure should be treated like other causes of severe respiratory distress syndrome: with supplemental oxygen, PEEP, fluid restriction, and assisted ventilation (see Chapter 19). Sedation and paralysis may be required. Barotrauma has been reported in talc inhalation.[179] Corticosteroids have been used to modify the inflammatory response. Bronchoalveolar lavage has been used therapeutically to clear debris obstructing large airways, but whether the benefit of this procedure outweighs the risks is unknown.

Complete resolution of pulmonary lesions with normal lung function at follow-up has been reported in survivors even after massive aspiration, although a combined restrictive and obstructive pulmonary function defect may occur.

Activated Charcoal

The use of activated charcoal has become widespread in the treatment of toxic ingestions and overdoses, and there has been substantial morbidity and several reports of deaths resulting from aspiration pneumonia associated with its use. Some clinical aspects of drug intoxication make the nasogastric administration of charcoal particularly hazardous. The patient may have a depressed conscious state or have seizures with poor airway protection or may be combative and uncooperative, resulting in malpositioning or dislodgment of the nasogastric tube. The ingested poison may cause vomiting by a central effect or from gastric irritation, gastric stasis, or intestinal ileus. Gastrointestinal obstruction may be caused by a solid charcoal bolus.[182] Multiple doses of charcoal in patients with impaired bowel motility[183] or even a single dose after the administration of ipecac[184] is likely to be especially dangerous.

DISEASE MECHANISMS

When aspirated, the thick charcoal suspension may cause obstruction of the large[184] and small[185] airways. Gas trapping and barotrauma are common features. Pneumonitis with all the features of ARDS may develop. This may be exacerbated by the aspiration of gastric contents. Autopsy findings have shown lung parenchymal scarring with bronchiectasis, bronchiolectasis, and bronchiolitis obliterans. Large amounts of

residual charcoal are found in the airways and alveoli associated with an inflammatory reaction that includes giant cells,[185] alveolar macrophages, and histiocytes. Regional lymph nodes also show charcoal deposition within histiocytes. Diffuse pulmonary thromboembolism has also been reported.

CLINICAL FEATURES AND MANAGEMENT

Charcoal aspiration produces severe respiratory failure. Tachypnea, dyspnea, wheezing, and cyanosis may increase in severity in the 48 hours after aspiration. Wheezes and crackles are audible widely over the chest, and areas of reduced air entry may be found in the presence of obstruction of the large airways. Radiological findings of lung infiltrates (Fig. 23-5) may underestimate the extent of lung affected. ARDS may develop despite relatively normal early chest radiographs.[186] Bronchoscopy and tracheobronchial toilet may be useful.[184,185] Copious charcoal-laden secretions may be aspirated from the trachea for many days after the inhalation episode. β-Sympathomimetic agonists have been used to treat wheeze after aspiration, but the reversibility of airflow obstruction is probably minimal. After charcoal aspiration, bacterial colonization of endotracheal tube secretions may be associated with systemic evidence of sepsis.[183,185,186] Management should include bacteriological surveillance of blood and tracheal aspirate and appropriate antibiotic treatment if infection is likely.

Activated charcoal should be used very cautiously in childhood ingestions. In many cases of suspected poisoning in children, the lung disease that may be induced by aspiration carries a far higher risk of mortality and morbidity than the ingested poison.

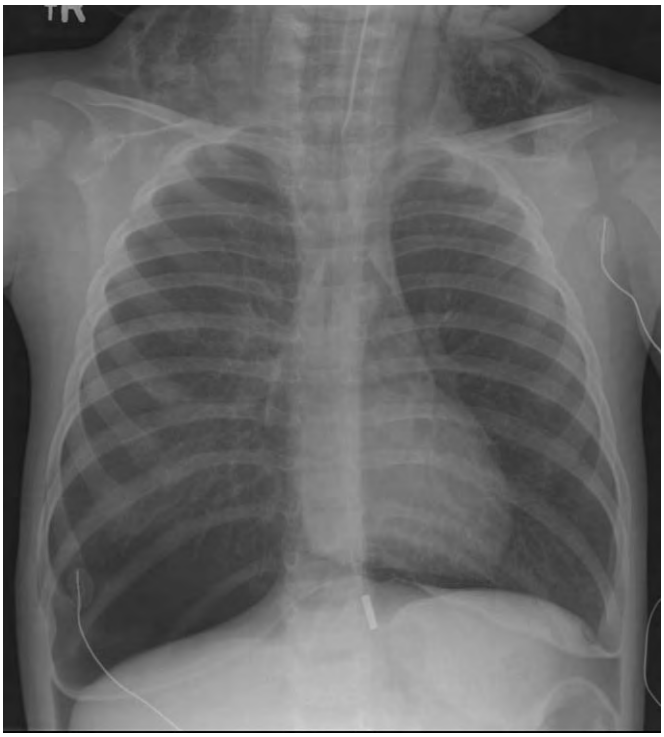


Figure 23-5 Chest radiograph of a 15-month-old, 12 hours after aspiration of activated charcoal, showing gas trapping on the left, with a right-sided pneumothorax, mediastinal gas, and subcutaneous emphysema.

Mercury

Mercury vapor inhalation is a very rare condition in childhood but causes severe acute respiratory distress and is commonly fatal.[187] The heating of mercury has been used to separate gold from gold ore and form a gold-mercury amalgam. Children have developed progressive pulmonary failure within hours of exposure; this failure is clinically and pathologically similar to other causes of ARDS. There is one report of HFOV being successfully used to maintain gas exchange in an infant with this condition.[188]

Hydrogen Sulfide

Hydrogen sulfide (H_2S) is a widely distributed cellular asphyxiant.[189] It is produced by decomposition of organic matter in oxygen-poor environments, such as sewers, farm manure pits (into which children may fall, or around which they may play), as well as in some industrial processes and from volcanic gas vents. Olfactory detection of H_2S fatigues rapidly, increasing the risk of prolonged exposure and severe intoxication.[190]

H_2S impairs oxidative metabolism by inhibiting cytochrome oxidase on the mitochondrial inner membrane. The brain and heart are especially vulnerable to H_2S toxicity, because of their high metabolic activity. At low concentrations (less than 100 ppm), H_2S acts as an irritant, causing cough, dyspnea, and tachypnea. High concentrations (greater than 500 ppm) rapidly cause death due to central nervous system depression and apnea. Pulmonary edema at concentrations of 300 to 500 ppm is caused by asphyxial depression of the myocardium plus direct injury to the alveolar epithelium.[189,190] Survivors of significant exposures show inflammation of large and small airways, with wheezing, atelectasis, and impairment of gas exchange.

DIAGNOSIS

The diagnosis is based on a history of exposure plus signs of central nervous system and myocardial depression, conjunctivitis, cough, wheeze, dyspnea, and clinical and radiological evidence of pulmonary edema.

MANAGEMENT

- Remove immediately from exposure.
- Provide supportive care.
- Administer high concentrations of oxygen by mask.
- Provide tracheal intubation and mechanical ventilation with PEEP for pulmonary edema or hypoxic-ischemic encephalopathy.
- Provide myocardial support with inotropic drugs if necessary (see Box 23-18 for specific teaching points).

BOX 23-18 Chemical Warfare Agents Teaching Points

- Remove the patient from exposure.
- Decontaminate the patient.
- Support breathing and oxygenation.
- Consider antidotes: repeated as often as needed.

LIPOID PNEUMONIA AND HYDROCARBON PNEUMONITIS (Table 23-8)

Accidental Ingestion in the Preschool-Age Child

From 1985 through 1989, 129,024 children younger than 6 years in the United States ingested hydrocarbons; of those, 5 died and 168 suffered major effects. This represents 3.3% of all poison exposures in this age group and 4% of all deaths resulting from poisoning.[191] Hydrocarbon ingestion occurs when the child, often a boy between 12 months and 5 years of age, drinks the liquid from a bottle (frequently a soft drink bottle) stored within reach.

Substance Abuse

The intentional inhalation of volatile organic chemicals for recreational use[192] is mainly a phenomenon of the preteen and early teenage years. In the United States in 2001, the lifetime prevalence of inhalant abuse among eighth-graders (the age at which abuse peaks) was 17%: in 1995, the corresponding figure was 22%.[192]

Although pulmonary injury is not a prominent cause of death among solvent abusers, pulmonary edema (most likely cardiogenic) has been found at postmortem in gasoline sniffers.[193] The toxicity of solvent abuse mainly involves the kidneys, central nervous system, bone marrow, heart, and peripheral nerves. In paint sniffers, nonhydrocarbon components of the paint, such as aluminum and silica, may cause more pulmonary damage than the hydrocarbon components.[194]

Inhalation of solvents by bagging (spraying into a plastic bag and inhaling) is more likely than inhalation by huffing (spraying onto a cloth held to the mouth) to lead to asphyxial injury. Toxic or asphyxial myocardial depression causes pulmonary edema. Toxic or asphyxial injury of the central nervous system impairs the respiratory drive. Loss of consciousness and seizures can lead to upper airway obstruction, vomiting, and aspiration pneumonia (see later).[192]

Expiratory wheezing has been found in adolescents examined within hours of inhaling toluene. A group of 37 chronic glue-sniffers had significantly higher residual volumes than a group of controls of similar age, although the FEV_1 and the FEV_1/VC ratio were not different from those of the controls.

Table 23-8
Epidemiology

Toddlers and preschool-age children	Exploratory ingestion of gasoline, kerosene, turpentine, baby oil, furniture polish, etc.
Teenagers and older children	Solvent abuse: gasoline, xylene, toluene, or paint
Teenagers and older children	Inadvertent aspiration of gasoline or kerosene while siphoning from a tank or container
Infants, children with gastroesophageal reflux, debilitated or developmentally delayed children	Administration of liquid paraffin, olive oil, or fish oil (adult-type lipoid pneumonia)
Unusual aspirations	Lip gloss or petroleum jelly on lips, nose, or face

In lung specimens obtained at autopsy from three chronic glue-sniffers who died of traumatic injuries, there were changes suggesting panacinar emphysema, mononuclear infiltration and thickening of some alveolar septa but thinning and rupture of others, smooth muscle hypertrophy in the terminal bronchioles, widespread mucus plugging, and papillomatous hypertrophy of bronchiolar submucosal tissue.[195]

Adult-Type Lipoid Pneumonia

Adult-type lipoid pneumonia is commonly seen in debilitated, chronically ill adults who have taken oil-containing medications such as mineral oil for constipation or oily nosedrops.[196] In infants or children who are debilitated or who have neuromuscular disease or gastroesophageal reflux, viscous oils, including mineral oil and cod liver oil, may be aspirated silently. Forced oral administration of any oily preparation can lead to aspiration of the oil, sometimes causing the child's death.[197] Silent aspiration of oil-based lip gloss, oily nosedrops and petroleum jelly applied to the face, has also been reported in children.[196,198]

Physical Properties of Hydrocarbons (Box 23-19)

Low-viscosity compounds such as gasoline, turpentine, mineral oil (in furniture polish), petroleum ether, lighter fluid, and toluene are far more toxic than more viscous hydrocarbons such as fuel oil, lubricating oil, mineral oil, and petroleum jelly. Highly volatile components evaporate at room temperature, displacing oxygen from alveoli and causing hypoxemia.[199]

DISEASE MECHANISMS

The earliest histological changes are in the pulmonary vessels, leading to hemorrhage and edema; an inflammatory exudate and signs of bronchial injury appear later[200] (Table 23-9).

In the rabbit, intense alveolar hemorrhage and edema are seen within 15 minutes of kerosene instillation into the trachea. These changes appear in a patchy fashion over both lungs. Later, neutrophils are found in the alveolar fluid.[201] Autopsy examination of the lungs of children who die soon after hydrocarbon aspiration also show vascular congestion, alveolar hemorrhage, and edema with later changes of vascular thromboses, interstitial and alveolar inflammatory exudate, and atelectasis and necrosis of the bronchial, bronchiolar, and alveolar walls.[202] In massive ingestion, these changes may

BOX 23-19 Compounds with Low Viscosity and Surface Tension (e.g., Gasoline, Toluene, Turpentine)

Increase the risk of lung injury and death
Reduce effectiveness of laryngeal reflex
Encourage spreading into small airways
More alveolar damage
More damage to lung capillary endothelium
Reduce surfactant effectiveness: more atelectasis and pulmonary edema

Table 23-9
Pathological Changes after Tracheal Instillation of Kerosene

Time	Change
1 hr	Engorgement of large and medium-sized vessels
4 hr	Engorgement of alveolar capillaries
24 hr	Peribronchial inflammation
	Focal areas of alveolar inflammatory exudate and consolidation
72 hr	Early resolution of alveolar exudate
7 days	Resolution of consolidation
	Persistence of some peribronchial inflammation
14 days	Persistence of vascular engorgement
	Resolution of most alveolar and peribronchial inflammation

extend very rapidly over the whole lung within hours of the event, leaving very little air-containing lung.[201] Later, the alveoli become lined with thick hyaline membranes and contain profuse fibrinous clot with erythrocytes, cellular debris, and macrophages containing small oil droplets. The lining of bronchioles is shed into the lumen.

Areas of hyperinflation and emphysematous bullae visible at autopsy can also be seen on chest radiograph.[203] These may be caused by air trapping because of the ball-valve effect of bronchial mucosal edema and sloughed bronchial mucosa. Large pneumatoceles, mainly involving the lower lobes, have been reported to occur uncommonly in children after kerosene ingestion. These pneumatoceles appear after 6 to 13 days in children aged 1 to 5 years who have persistent respiratory symptoms for up to 10 days. They remain visible on radiographs for 1 to 8 months despite the absence of respiratory symptoms. They appear in consolidated areas of the lung, may be single or multiple, and may contain fluid. Pneumothorax, pneumomediastinum, pneumopericardium, subcutaneous emphysema, and pleural effusions have also been reported in children after hydrocarbon ingestion.[204]

Aspiration of more viscous aliphatic hydrocarbons such as mineral oil causes less acute toxicity, with no evidence of endothelial injury. At first, lipid-filled macrophages occupy the alveoli and interalveolar septa as well as the lymphatic vessels and regional lymph nodes. Later, the macrophages disappear, and foreign body granulomas form with fibrosis and giant cells; extracellular oil droplets may be found.[196] Paraffin granulomas may be found in debilitated patients who aspirate mineral oil or oily nosedrops. These form a mass lesion with indistinct borders, often in the posterior axillary segment of the upper lobe, and disappear slowly when oil ingestion ceases.[205,206]

The intensity of lung tissue reaction to animal and vegetable oils is proportional to the amount of free fatty acid present. Generally, this is greater in animal fats (e.g., cod liver oil) than in vegetable oils. Free fatty acids produce a severe injury with tissue necrosis, hemorrhage, vascular thrombosis, neutrophil infiltration, and later, fibrosis, which may obliterate alveoli and cause thickening of the walls of the small muscular arteries.[196,205]

Bacterial clearance from animal lungs is impaired by hydrocarbon ingestion, and secondary infection with aerobic and anaerobic bacteria may follow hydrocarbon inhalation. However, animal studies and clinical experience in children have not found a major role for bacterial infection in this condition.[202] The routine use of prophylactic antibiotics is not recommended in lipoid pneumonia.[202,207,208] In debilitated patients, active infection with atypical mycobacteria occasionally complicates lipid aspiration.[209,210]

PATHOPHYSIOLOGICAL EFFECTS OF HYDROCARBON ASPIRATION

- Alveolar and interstitial hemorrhage
- Leak of fluid and protein from capillaries into alveoli
- Increased intrapulmonary shunt
- Increased respiratory system elastance and work of breathing
- Inhibition of surfactant production causes atelectasis and small airway closure[211]
- Mucosal injury in bronchioles and small bronchi causes gas trapping[200]
- Residual small airways narrowing; gas trapping and inhomogeneous ventilation 8 to 14 years later in asymptomatic children[212]
- Endothelial injury and perivascular inflammation cause thromboses and pulmonary hypertension[213]
- Volatile vapors displace oxygen, reducing alveolar P_{O_2}.

SIGNS AND SYMPTOMS

Respiratory symptoms occur in 25% to 40% of the preschoolers who ingest low-viscosity hydrocarbons (kerosene, mineral oil). Choking, coughing, and gagging are followed by increasing tachypnea with alar flaring and an expiratory grunt within minutes of ingestion. Fever and intercostal retraction may appear within 30 minutes or may be delayed for 1 to 2 days.[202,203] The fever may be high (41° C), and there is usually tachycardia.[203] Auscultatory signs may be absent, even in patients with cyanosis and severe respiratory distress,[202] or there may be crackles, wheezes, and reduced breath sounds in the lung bases, sometimes associated with dullness to percussion.[207] The odor of kerosene or another hydrocarbon may be detectable on the breath or clothing.

Because many hydrocarbons are central nervous system depressants and gastric mucosal irritants, children seen more than 30 minutes after ingestion may be drowsy or semiconscious. Vomiting with inhalation of gastric contents may contribute to further lung injury. The presence of gross pulmonary edema, especially if associated with cardiomegaly and hepatomegaly, implies massive hydrocarbon aspiration and the combination of direct lung toxicity with myocardial depression.[207]

Respiratory signs may disappear within 24 to 48 hours in mild cases, but when complications such as ARDS, secondary bacterial infection, or pneumatoceles ensue, the child may remain symptomatic for 10 days or more.[203,214] In particular, the fever may persist for up to 3 weeks.[203]

RADIOLOGICAL CHANGES

Radiological abnormalities are seen in 75% of infants who ingest hydrocarbons, but only 25% to 50% of these become symptomatic.[215,216] Although radiological changes may appear within 30 minutes of ingestion,[202] chest radiographs taken in the first 2 hours may be deceptively clear or may show only mild hyperinflation of part or all of the lungs.[203] Most patients

Figure 23-6 Chest radiograph of a 5-year-old, 24 hours after ingestion of kerosene, showing widespread airspace opacities in both lungs with some overinflation.

with hydrocarbon lung injury have radiological signs within 12 hours[202] (Fig. 23-6) Fine, punctate, perihilar densities extend and coalesce, becoming coarse areas of consolidation involving mostly the lower lobes.[201-203] Regions of air trapping may be present in the periphery of the lung, and pneumothorax, pneumomediastinum, or pleural effusion may be seen.

High-resolution CT shows nodular opacities, mainly in the lower lobes, and areas of ground glass opacity, superimposed in some places on thickened septa in a "crazy paving" pattern.[217,218] In most children, the chest radiograph changes disappear within a few days after the respiratory symptoms have resolved. In some cases, radiological signs may persist for months, especially when pneumatoceles or paraffin granulomas are present. Even these eventually disappear completely.[204,206]

INVESTIGATIONS

If there is doubt about the cause of pneumonia from the history, physical examination, and chest radiograph, the presence of fat-laden macrophages in sputum, tracheal aspirate, bronchoalveolar lavage fluid, or an open biopsy specimen from the lung may indicate hydrocarbon inhalation as the cause. This is more likely to be necessary in an older, debilitated child with a swallowing disorder.[219]

MANAGEMENT

Management consists of monitoring for signs of respiratory distress and injury to the heart, brain, liver, and kidneys with supportive treatment as required.

DECONTAMINATION

Induction of vomiting, nasogastric lavage, and mineral or olive oil gavage are contraindicated in any child who has ingested an oil or a hydrocarbon because these procedures are associated with an increased incidence of lipoid pneumonia.[220,221] Even the presence of a cuffed endotracheal tube does not guarantee protection of the lungs from vomited hydrocarbon. The use of activated charcoal is so frequently associated with vomiting that it is not justified in children with hydrocarbon ingestion.

RESPIRATORY MANAGEMENT

Frequent reevaluation of clinical signs, especially in the first 72 hours, and monitoring of respiratory rate, heart rate, and hemoglobin saturation indicate the progress of respiratory failure. Monitoring of arterial blood gases by intra-arterial catheter may be needed in severe cases. The chest radiograph excludes pneumothorax and pneumopericardium in the event of sudden clinical deterioration. Decisions about changes in respiratory care are based on clinical needs rather than on radiographic changes.

Oxygen should be given by mask to any child with respiratory distress, cyanosis, or a low hemoglobin saturation. If the saturation remains below 80% despite the administration of high-flow oxygen by mask and is deteriorating or if the child's respiratory rate is rising rapidly without radiological evidence of pneumothorax, then tracheal intubation and CPAP or mechanical ventilation may be needed. High levels of CPAP, peak airway pressure, and PEEP have a serious risk of pneumothorax, pneumopericardium, or air leak from overinflated areas of the lungs.[212,222] Minimization of this risk requires that airway pressures and tidal volume be no greater than those needed to maintain an arterial pH above 7.1[223] and a PaO_2 above 50 mm Hg. The FIO_2 should be kept below 0.5 if possible. If mechanical ventilation fails to control the respiratory failure, ECMO may be used. Survivors have been reported after the use of ECMO in children with hydrocarbon aspiration.[222]

OTHER MEASURES

Steroids have no place in the treatment of hydrocarbon inhalation; human and animal studies have shown no benefit from their use,[199,208] and the impaired mononuclear cell response in the lung caused by steroids may increase the risk of secondary bacterial pneumonia.[208] The routine use of antibiotics is not justified.[202,208] Rather, clinical monitoring, bacteriological surveillance, and frequent total and differential white blood cell counts should guide antibiotic therapy. Culture of fluid obtained by bronchoscopic or nonbronchoscopic bronchoalveolar lavage via an endotracheal tube may give a more accurate guide to the infecting organism when there is evidence of developing bacterial pneumonia. Wheezing in these children is due to structural damage to the bronchial and bronchiolar walls, and there is no evidence to support the use of bronchodilators.

PROGNOSIS

In the United States in the late 1980s, the mortality rate was 0.01% of children with respiratory symptoms resulting from hydrocarbon ingestion.[191,202] The majority of children deteriorated over the first 24 hours and then improved and became asymptomatic over 3 to 4 days. In more severely affected children, symptoms may persist for 10 days or more,

BOX 23-20 Hydrocarbon Pneumonitis Teaching Points

- The lower the viscosity, the greater is the lung toxicity.
- Most patients with hydrocarbon toxicity develop symptoms within 12 hours.
- Avoid induced vomiting, nasogastric lavage, and milk gavage for hydrocarbon ingestions.
- Avoid corticosteroids and prophylactic antibiotics.

but in other children, the condition may progress to intractable respiratory failure over 2 to 3 days.[222] Some infants have been reported to die after 1 to 2 months of progressive respiratory failure with extensive lung consolidation and recurrent pneumothoraces.[197] Up to 80% of asymptomatic children have residual abnormalities on detailed lung function testing (especially of markers of small airway narrowing) on 8- to 14-year follow-up[212] (see Box 23-20 for specific teaching points).

CHAPTER 24

Foreign Body Aspiration

Cecille G. Sulman, Christopher G. Green, and Lauren D. Holinger

TEACHING POINTS

- Children younger than 3 years are at higher risk for foreign body aspiration.
- History is the key element in diagnosing an airway foreign body.
- A negative chest radiograph does not exclude the diagnosis of an airway foreign body.
- Education and prevention are importing in avoiding airway foreign body.
- Delayed diagnosis increases complications of airway foreign body.

The propensity of small children to place objects into their mouths is well known. Most objects lodge in the esophagus, but many of these objects are aspirated. Foreign body aspiration attracts a great deal of attention, some of it for the novelty of the aspirated items. However, the danger of foreign body aspiration should never be minimized; in 2003, the National Safety Council reported 4300 deaths from choking in the United States.[1] The majority of these fatalities occur soon after aspiration, with the patient never having been seen by a physician. Two thirds of all deaths related to foreign body ingestion occur in the home, and choking is the fourth most common injury leading to death in the home.

In addition to the danger of the aspiration episode itself, foreign body removal, despite technological advances, remains a technically challenging procedure due to the size of the airways in which the foreign bodies are lodged.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

A child's fascination with placing objects in the mouth begins soon after grasping becomes effective. Other contributing factors include improper preparation of food (e.g., pieces being too large, bones not being removed), an immature swallowing mechanism, hasty eating and drinking, playing while eating, talking with food in the oral cavity, small objects being within grasping distance, and improper supervision of small children playing near infants. Older children commonly force objects into their younger siblings' mouths. There is a male preponderance for airway foreign bodies.[2] Only careful supervision can lessen the chance of aspiration.

Organic material is the most frequent foreign body found in the airway. Nuts, seeds and popcorn are commonly encountered, with peanuts being the most common.[3,4] Nuts should not be given to children younger than age 4 years because this group does not have fully developed oral motor control or the molar teeth to chew them. Children who have diminished perception and sensation are at increased risk of aspiration. The American Academy of Pediatrics recommends that certain foods be kept from children less than 4 years of age (Box 24-1).

Unfortunately, many victims of foreign body aspiration never survive the first few minutes. Most often, these incidents involve aspirated food objects. "Round" foods, such as hot dogs, nuts, and grapes, are most likely to cause asphyxiation.[5] Other dangerous factors include a smooth or slippery surface, compressibility, and failure to break apart easily. Dried beans and peas can cause delayed airway obstruction as they swell with the absorption of moisture.

The U.S. Consumer Product Safety Commission requires age-appropriate labeling on toys and products for older children that contain small parts. Toys for children aged 3 years and older should be kept from young children. Small toy parts are often radiolucent, making diagnosis difficult.

Three distinct clinical phases occur after a foreign body is aspirated. The first is immediately after aspiration. There may be coughing, gagging, choking, stridor, and wheezing. A cyanotic episode may occur. Many caregivers seek medical attention for the patient during this phase. After this initial phase is a quiescent period. This asymptomatic period can last from minutes to months depending on the location of the foreign body, the degree of airway obstruction, and the inflammatory reaction to the material aspirated. During this phase, the foreign body can easily change location, with a subsequent change in signs and symptoms. The third phase is a renewed symptomatic period due to complications relating to the presence of a foreign body. During this phase, airway inflammation or infection results in symptoms such as cough, sputum production, fever, wheezing, and rarely, hemoptysis. Clinical manifestations vary based on the object's location.

Foreign bodies occur least frequently in the larynx. Laryngeal foreign bodies may cause complete obstruction resulting in sudden death unless they are dislodged promptly with intervention such as the Heimlich maneuver where appropriate. Partially obstructive objects may cause stridor, hoarseness, aphonia, croup-like cough, odynophagia, hemoptysis, wheezing, and dyspnea. These symptoms may be secondary to the foreign body itself or may result from a residual laryngeal reaction from a foreign body that has migrated to

BOX 24-1 Foods to Avoid in Children Younger Than 4 Years

Hot dogs
Nuts and seeds
Chunks of meat or cheese
Whole grapes
Hard, gooey, or sticky candy
Popcorn
Chunks of peanut butter
Raw vegetables
Raisins
Chewing gum

the trachea. An esophageal foreign body may cause similar symptoms due to inflammation with anterior displacement of the posterior tracheal wall or secretion overflow with resultant laryngeal symptoms.

Tracheal foreign bodies occur rarely. The predominant symptoms are obstruction, stridor, wheeze, and dyspnea. Esclamado and Richardson[6] showed that the incidence of complications in the laryngotracheal foreign body group is at least 4 to 5 times greater than that reported for all aspirated foreign bodies.

Bronchial foreign bodies are the most common, manifesting primarily with symptoms of coughing and wheezing. Hemoptysis and dyspnea may also be present. Foreign bodies in the lower trachea, however, may shift from one bronchus to the other and give rise to a variety of signs and symptoms.

Initially, foreign bodies often cause obstructive emphysema (air trapping); later, atelectasis, pneumonia, and, rarely, lung abscess or empyema occur with bacterial overgrowth. Organic materials are more likely to cause an intense inflammatory reaction with accompanying granulation tissue and purulent mucus[7] (Fig. 24-1). Late manifestations of bronchial foreign body aspiration may be reduced by prior treatment with antibiotics or steroids.

DIAGNOSIS

The initial evaluation of a child with suspected airway foreign body includes three elements: history, physical examination, and radiography. The history is the key element. Children who aspirate foreign objects have a variety of signs and symptoms. The most common include a history of coughing and choking, occurring in up to 91.8% of patients.[8-10] The classic triad of cough, wheeze, and unilaterally reduced breath sounds may be present in half of the patients.[8,9] A history of aspiration may be obtained in the majority of patients with thorough questioning.[2,11] Lack of a clear history or misdiagnosis may delay recognition of a foreign body. Often, a diagnosis of exclusion is made, and patients may see several physicians before the foreign body is identified. Most common misdiagnoses are reactive airway disease, pneumonia, and croup (Box 24-2). Because most aspirated foreign bodies occur in small children, communication after the event is problematic. For example, although the episode may have been witnessed by an older child, that child may not disclose information secondary to fear of repercussion.

BOX 24-2 Differential Diagnosis of Aspirated Foreign Body

Reactive airway disease
Empyema
Pneumonia
Croup
Tracheobronchial tumor
Bronchitis
Tracheomalacia
Psychogenic cough
Bronchomalacia

The physical signs of bronchial foreign bodies vary. Careful auscultation of the chest in a systematic fashion is essential. All lung fields should be assessed for breath sound symmetry (phase, pitch, amplitude, and heterophony) and adventitial breath sounds, particularly wheezing. Asymmetric wheezing is a strong indicator of unilateral bronchial obstruction, although symmetric wheezing may also be present. Depending on the size, shape, and location of the foreign body, breath sounds may vary. Foreign bodies in children have been reported to be located equally in the right bronchus and left bronchus, predominantly in the right bronchus, and even predominantly in the left bronchus.[7,9] This observation may be explained by most children having a fairly symmetric bronchial angle until about 15 years old. Around that age, the aortic knob fully develops, displacing the left main bronchus and creating a more obtuse angle at the carina.[12] Secretions may shift from one location to another, affecting the physical examination. The foreign body may shift position and cause a variation in the aeration distal to the object.

Radiographic studies provide valuable information to the endoscopist. They not only document the presence of a foreign body but also act as an aid in extraction. Studies that are incomplete or are poor in quality may lead to errors or a

delay in diagnosis. Although many foreign bodies are radiolucent, special techniques may help establish a diagnosis.

If a laryngeal or tracheal foreign body is suspected, a lateral neck radiograph may provide useful information. Esclamado and Richardson[6] showed that the neck radiograph is more likely to be abnormal than the chest series with a laryngeal or tracheal foreign body. With high-quality neck radiographs, the caliber of the airway can be clearly seen. When the arms and shoulders are positioned inferiorly and posteriorly, a single lateral radiograph can profile the air column in both the larynx and trachea. However, extreme care must be taken because the patient is at risk for life-threatening airway obstruction.

In cases of suspected foreign body aspiration, a standard chest series should include anteroposterior and lateral end-inspiratory views as well as an end-expiratory radiograph.[13] Radiographs are carefully examined for local atelectasis, local hyperinflation, and visible foreign bodies. Expiratory radiographs delineate postobstructive hyperinflation with air trapping behind the foreign object and subsequent failure of the trapped air to empty on exhalation (Fig. 24-2). This can cause mediastinal shift to the uninvolved side. Unfortunately, expiratory radiographs are often unsuccessful in small children.[9] In these cases, decubitus radiographs or fluoroscopy may provide additional information. Most airway foreign bodies are radiolucent, and some cases present with a bypass valve phenomenon. A normal chest series does not rule out the presence of a foreign body in the airway. The sensitivity of chest radiographs in the evaluation of airway foreign bodies has been reported to be 68% to 76%, with a specificity of 45% to 67%.[14] In various case series, the incidence of a negative chest radiograph in the presence of an airway foreign body has been reported to range from 25.6% to 75%.[2,8] The longer the foreign body has been retained, the more likely is it that there will be findings such as air trapping or consolidation.[9] In the face of a suggestive history, even with negative chest radiographs, bronchoscopy is performed. *History—not radiographs—is the primary determinant of the need for bronchoscopy*.

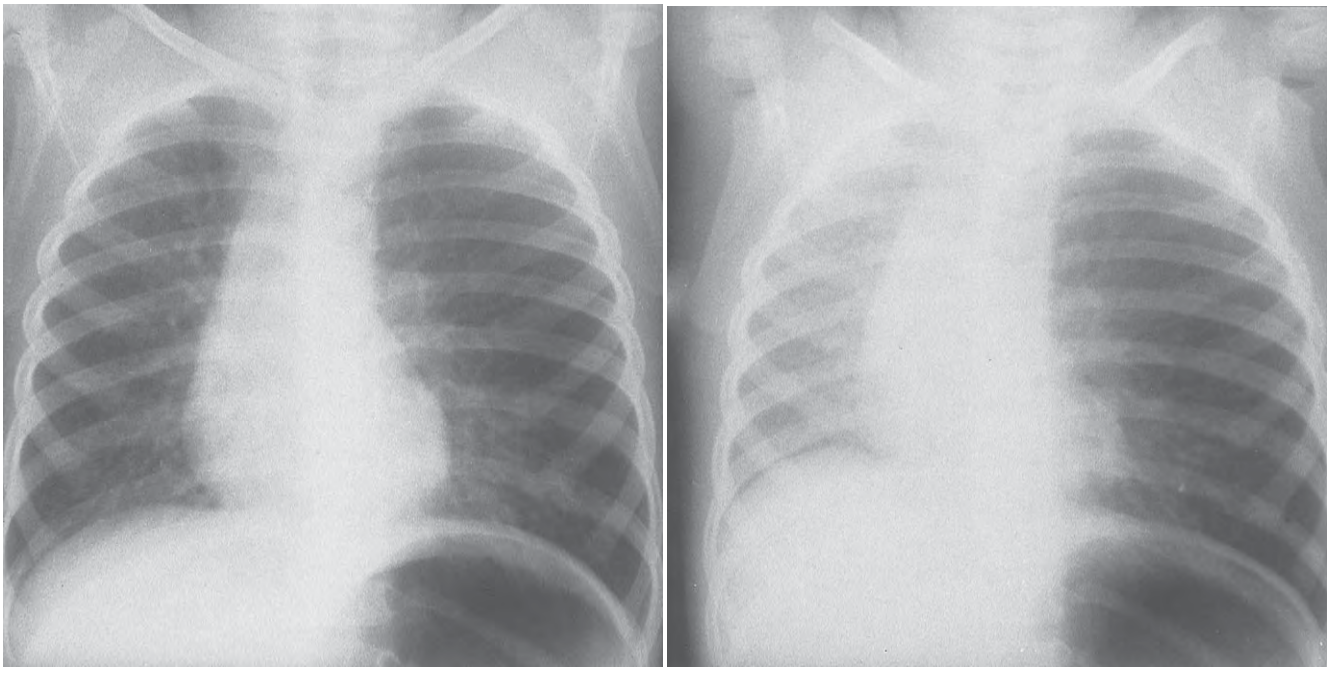
For radiopaque objects lodged far in the lung periphery, simultaneous biplane fluoroscopy is used to visualize the object during extraction. This important technique may serve as a "last chance" to assist removal of a foreign body endoscopically. Thoracotomy is the only alternative if endoscopic efforts fail.

Although computed tomography and magnetic resonance imaging have revolutionized medicine in the last decade, they have little value in the diagnosis and management of foreign body aspiration. Magnetic resonance imaging has been used to diagnose a previously unidentified bronchial foreign body.[15] However, because of the young age of the patients, the time and expense involved, and the need for sedation (or general anesthesia) in a patient with pulmonary compromise, the use of these modalities in foreign body aspiration remains limited.

TREATMENT

Acute Aspiration: Complete Obstruction

In a witnessed foreign body aspiration with acute complete airway obstruction, the Heimlich maneuver is the procedure of choice. Currently, this maneuver is recommended for children older than 1 year of age. For infants younger than 1 year, chest thrusts and back blows in the head down position are recommended.[16] Unlike adults, younger children may not be able to respond to the question traditionally asked of suspected aspiration victims: "Can you speak?" Blind finger



A B

sweeping in the oropharynx is contraindicated in infants because the foreign body may be pushed down and become lodged in the larynx, converting a partial obstruction into a complete one. This maneuver may also force the foreign body into the esophagus, where it may compress the trachea against the upper sternum.

Questionable Foreign Body Aspiration: Flexible Versus Rigid Bronchoscopy

Because the diagnosis of foreign body aspiration is not always obvious, bronchoscopy may initially serve as a diagnostic procedure. In this setting, either flexible or rigid bronchoscopy is indicated. Selection of a particular technique depends on physician expertise and experience in a particular geographic area.

If a foreign body in a child is confirmed by physical examination or radiographic studies or if the endoscopist has a high index of suspicion that a foreign body is present, rigid bronchoscopy is the preferred technique for removal. The same holds true if a foreign body is noted on flexible endoscopic examination.[17] The flexible bronchoscope is not the instrument of choice for bronchial foreign body removal for several reasons: limited suction, lack of ventilatory capability, limited instrumentation, and lack of airway control. A unique indication for flexible bronchoscopy is a nonradiopaque peripheral foreign body that cannot be seen with a rigid bronchoscope. In this situation, inserting a flexible instrument through a rigid bronchoscope may greatly assist in making a diagnosis.

Rigid Bronchoscopy

In general, a suspected airway foreign body should be removed as soon as possible. Haste should not preclude having the necessary equipment and experienced operating room personnel available. If the *optimal infrastructure* is not available, consideration is given to transferring the patient to another facility.

Airway foreign body removal can be a technically demanding exercise. Removal is facilitated by careful preparation. This includes checking equipment for malfunction before the procedure and having backup equipment available. If possible, a duplicate of the aspirated foreign body is obtained. This facilitates scope and forceps selection by allowing practice attempts to grasp the duplicate (Fig. 24-3).

Two methods of extraction through a rigid bronchoscope are available. The first is forceps removal through a distal lighted bronchoscope. This technique offers a large variety of forceps and tactile feedback. The second method is foreign body extraction with an optical forceps system. This system with fiberoptic lighting and telescopic viewing offers an improved "look" at the aspirated object and serves as an excellent teaching tool. The endoscopist should have experience with both.

Regardless of the technique used, difficulties may be encountered in rigid bronchoscopic foreign body extraction. Objects may fragment or be stripped off the forceps in the larynx. A large laryngeal forceps is made available to deal with this possibility. Occasionally, forceps may be unable to grab a particular foreign body. In these cases, a balloon catheter placed distally or a stone basket used to encircle the object may be helpful.[18,19]

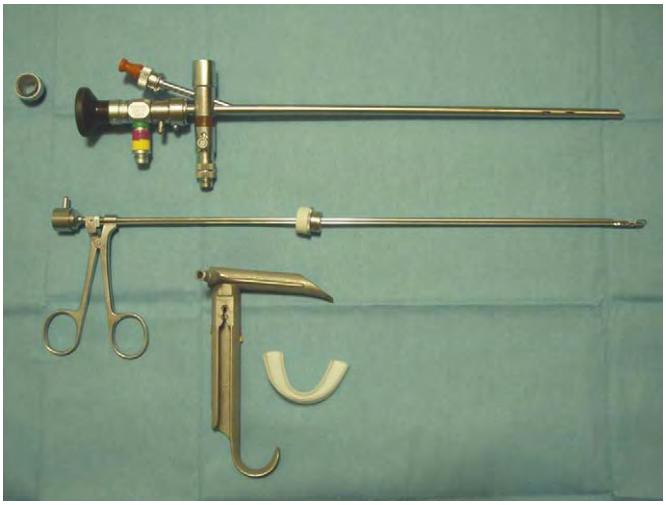

Figure 24-3 Set-up for airway endoscopy and foreign body removal. The instruments depicted include a bronchoscope with a telescope, foreign body grasper, laryngoscope, mouth guard, and glass window.

No more than $1^1/_2$ hours should be spent attempting to remove an aspirated foreign object. Occasionally, edema or bleeding may obscure the endoscopist's view and necessitate stopping a procedure prematurely. In this situation, antibiotics and corticosteroids are administered and the patient brought back to the operating room in 3 to 4 days for another attempt at removal. Rarely, an object may be aspirated that is too large to be removed endoscopically. In this situation, a combined endoscopic and external cervical approach is used.[20] Although this requires a tracheal incision to remove the foreign body, no long-term sequelae should be expected. An endoscopist and two assistants are required to perform this technique successfully.

Most patients who undergo removal of airway foreign bodies have an uneventful postoperative course. For patients who have a long-standing foreign body extracted, productive postoperative coughing may occur as secretions trapped behind the object are released. Hemoptysis from disrupted granulation tissue may also be seen. Antibiotics are not routinely administered after foreign body extraction and postoperative chest radiographs are not routinely ordered. This is obviated by "second-look" bronchoscopy, in which the bronchi are examined immediately after the initial removal to check for remnant material or an additional foreign object.

Alternative Therapies

In the past, methods other than endoscopy have been advocated for the treatment of aspirated foreign bodies. Burrington and Cotton[21] introduced a technique of bronchodilator inhalation followed by postural drainage and percussion. This technique was continued up to 4 days before bronchoscopy. A subsequent report, however, found that this technique had only a 25% success rate compared with an 89% success rate with bronchoscopy.[22] In addition, the authors reported an episode of cardiopulmonary arrest secondary to foreign body migration. Because of the great risk of complications and low success rate, bronchodilation and postural drainage are not recommended.

BOX 24-3 Complications after Airway Foreign Body Removal

- Acute airway obstruction
- Laryngeal lacerations
- Pneumomediastinum
- Bronchial stenosis
- Pneumothorax
- Tracheoesophageal fistula
- Massive hemoptysis
- Distal bronchiectasis
- Laryngeal edema
- Pneumonia
- Abscess
- Parenchyma destruction

Expectant management of aspirated foreign bodies is also not advised. The chance of a complication increases while waiting for an object to be coughed up: The object may migrate, or the inflammatory response becomes more intense. Even in objects thought to be dissolvable, bronchoscopy should be performed. Hard candy, which theoretically should melt away, may cause an intense inflammatory reaction. The hazard of leaving a potential irritant in the airway outweighs the risks of rigid bronchoscopy performed by experienced personnel.

CLINICAL COURSE AND PROGNOSIS

Airway foreign bodies can be removed with a low rate of complications with careful preoperative preparation. Improvements in surgical techniques, instruments, and modern anesthesia have allowed bronchoscopy to be effective in greater than 95% of the patients with a less than 1% complication rate.[12] Although rare, mortality is still a potential complication.[2] A negative bronchoscopic evaluation in 10% to 15% of patients is acceptable to avoid the morbidity of a missed foreign body.[12,23] Potential complications after removal are listed in Box 24-3.

Delay in diagnosis has a marked effect on the rate of complications, probably greater than any other factor.[24] This is not always attributable to caregiver negligence because many patients have been seen previously by a physician. At least 25% of patients who present at least 1 week after aspiration of a foreign body have complications.[2,3] Complications may be as high as 60% in a diagnosis delay greater than 30 days. Bronchiectasis is the most common complication. Lobectomy may be necessary if a chronically retained foreign body causes severe bronchiectasis.[7] Long-term complications have not been associated with inorganic foreign bodies; however, organic foreign bodies have an association with granulation tissue, purulence, and edema.[7] Unfortunately, a low index of suspicion for an airway foreign body can lead to tragedy, as exemplified by two reported cases of death after undiagnosed foreign body aspiration.[25]

Aspiration may be prevented by following guidelines for avoidance of foods or toys that pose a risk for young children. Additionally, children should be monitored during meals and never allowed to run, walk, or lie down with food in their mouths. Clinicians should have a low threshold for bronchoscopy with a suspicious history for foreign body aspiration.

CHAPTER 25

Aspiration Syndromes

John L. Colombo and Heather M. Thomas

TEACHING POINTS

- Aspiration is a common event with a spectrum from normal to subclinical, but disease causing; to massive, leading to acute respiratory failure and death.
- Diagnosis is challenging due to the lack of specific tests able to show cause-effect for aspiration to a clinical syndrome.
- Gastroesophageal reflux is commonly associated with respiratory disease, but aspiration is only one possible mechanism of this association.
- Swallowing is an extremely complex function, and its impairment is consistently reported to be the major cause of recurrent pneumonia in children.
- Both the diagnosis and management of recurrent aspiration and/or gastroesophageal reflux are multifaceted and must be individualized for each patient.

Inhalation of foreign materials into the lungs was noted to be a health hazard by Hippocrates in 400 BC, but it was not until Mendelson's classic description in 1946 that clinicians appeared to recognize the widespread nature and clinical importance of aspiration lung injury.[1] Although much has been learned over the 60 years since Mendelson's description, the diagnosis and treatment, particularly of chronic aspiration, remain a challenge in patients of all ages.

The terms *aspiration pneumonia* and *pneumonitis* are often used as generic descriptions of several clinical syndromes. Clinical findings depend on host factors as well as the quantity and type of material aspirated (Table 25-1). Certainly these processes are not necessarily mutually exclusive, and an individual may suffer from one or more. Aspiration is actually a common event, frequently occurring silently, even in normal individuals, especially during sleep.[2] At the other end of the spectrum is massive aspiration, causing acute respiratory failure. This typically occurs with gastric contents but sometimes from other toxic materials. Gastroesophageal reflux (GER) has increasingly been recognized as having a significant association with many respiratory symptoms and disorders. Other specific types of pulmonary aspiration including foreign bodies, near-drowning, and hydrocarbon aspiration are discussed in other chapters.

It is often not possible to definitively prove that aspiration is the cause of an existing lung disease. Therefore, a large element of clinical judgment is required. The initial step in diagnosis is to recognize both the clinical manifestations of aspiration (see Table 25-1) and conditions that predispose to aspiration (Box 25-1).

ACUTE, LARGE-VOLUME ASPIRATION

Disease Mechanisms

The most common cause of large-volume acute aspiration is aspiration of gastric contents. This can have a broad range of pathological and physiological consequences, depending especially on the pH and volume of the aspirate as well as the amount of particulate material (see Table 25-1). Most information on pathophysiological consequences is necessarily derived from animal studies. Aspiration of large particles can produce acute airway obstruction and severe hypoventilation. Smaller particle or liquid aspirates may induce hypoxemia by a variety of mechanisms, including reflex airway closure, hemorrhagic pneumonitis, destruction and dilution of surfactant with secondary atelectasis, and pulmonary edema from extravasation of intravascular fluids and protein. With acid aspiration, these events are typically more severe and prolonged than with neutral liquids. Mendelson's classic study described an "asthma-like reaction" of obstetric patients who had aspirated large amounts of gastric contents. In subsequent animal studies, he and others showed that large-volume acid aspiration (greater than 1 mL/kg and/or $pH < 2.5$) caused severe hypoxemia. Localized areas of atelectasis may occur within a few minutes after acid aspiration.[3] Other early histological findings include bronchial epithelial degeneration, pulmonary edema and hemorrhage with necrosis of type I alveolar cells followed by acute infiltration of neutrophils and fibrin in alveolar spaces. Over the next 24 to 36 hours a marked increase of neutrophil infiltration results in alveolar consolidation, and mucosal sloughing may be seen in the airways. This correlates with the clinical findings of fever and increased infiltrates on chest radiographs. Hyaline membranes may be seen after 48 hours. Reparative processes, including the regeneration of bronchial epithelium, proliferation of fibroblasts and decreased acute inflammation, begin within 72 hours of an aspiration event. Lungs from animals obtained 2 to 3 weeks after acid aspiration show parenchymal scarring with macrophages, lymphocytes, and hemosiderin, often with bronchiolitis obliterans.[4]

Physiological changes typically occur significantly later, and the inflammatory response is more prolonged with aspiration of small particles than after liquids. Intravascular fluid

Table 25-1
Clinical Findings and Pathophysiologic Events Associated with Aspiration

Syndrome/Clinical Findings	Substances	Major Pathophysiologic Events
Large airway obstruction	Large solids (meat, poultry)	Atelectasis
Atelectasis	Large-bolus liquids or large particles (gastric contents)	Hypoxemia
Asphyxia ("café coronary")		Hypercapnia
Hyperinflation		Bronchitis, bronchiectasis, pneumonia
Pneumothorax		Death
Wheeze, cough		
Apnea or laryngospasm		
Acute chemical injury	Gastric contents (pH<2.5, small particles)	Pulmonary edema
Diffuse infiltrates	Toxic exogenous liquids (hydrocarbons)	Shock
Adult respiratory distress syndrome	Toxic gases	Hypoxemia
Apnea or laryngospasm		Hemorrhagic pneumonia
Tracheobronchitis		Alveolar consolidation with polymorphonuclear neutrophil leukocytes, fibrin
Infectious injury (acute or chronic)	Nasal or oral secretions	Mucosal sloughing
Pneumonia/bronchopneumonia	Gastric contents (hospitalized patients)	Necrotizing pneumonia
Abscess	Exogenous contaminated materials	Alveolar consolidation with polymorphonuclear neutrophil leukocytes, exudate
Empyema or effusion		Bacteria (anaerobic or mixed anaerobic and aerobic), gram-negative bacilli in hospital-acquired abscess
Ventilator-associated pneumonia		
Recurrent chemical injury	Oral, nasal, or gastric contents	
Bronchitis of bronchiolitis		Granulomatous inflammation
Bronchopneumonia or pneumonia		Fibrosis
Atelectasis		Interstitial inflammation
Wheezing, cough		Lipoid pneumonia
Apnea or laryngospasm		Meat or vegetable fibers
Gastroesophageal reflux		Bronchiolitis obliterans

shifts into the lungs occur within minutes after liquid aspiration and usually after 3 to 4 hours with small particles. With aspiration of smaller volumes, of either acid or gastric juices, acute interstitial pneumonia develops followed by chronic airway inflammation, interstitial thickening, granuloma formation, and fibrosis.[5] The critical volume for severe pneumonitis is estimated at 0.8 mL/kg.[6] In animal models, the combination of small particle plus acid aspiration produces greater lung injury, inflammation, and cytokine release, particularly monocyte chemoattractant protein (MCP)-1 and interleukin (IL)-10, than either substance alone.[7]

Although bacterial clearance has been shown to be decreased in animal models, infection does not usually play a primary role in aspiration of gastric contents. However, such aspiration may impair pulmonary defenses, reduce bacterial clearance, and hence predispose to secondary bacterial pneumonia.[8] Infectious complications of aspiration are discussed in the next section.

Clinical Manifestations

Earlier reports of massive aspiration reported mortality as high as 40% to 80%. However, more recent reports involving children and adults indicate mortality rates of 5% or less with no deaths occurring in perioperative aspiration by children in two large series.[9,10] Another large retrospective survey for adults showed no mortality if there was radiographic involvement of three or fewer lobes.[11]

Diagnosis of massive aspiration pneumonia usually involves a witnessed inhalation of vomit or tracheal suctioning of gastric contents, particularly in a patient with artificial airway. In the absence of such events, the diagnosis depends on noting compatible clinical and radiographic findings in a patient at risk for aspiration. Early bronchoscopy has also been reported to be a useful diagnostic adjunct, either in finding gastric contents grossly or microscopically in the tracheobronchial tree or the finding of localized erythema.[12]

Infectious Complications of Aspiration

Although to some the term *aspiration pneumonitis* is synonymous with bacterial pulmonary infection, only about 50% of patients with aspiration of gastric contents develop subsequent pleuropulmonary infections.[13] The risk of infection is increased with conditions listed in Box 25-2. The originating site of bacterial pathogens usually is the oropharynx, but colonizing organisms from the stomach have also been implicated. The bacteriology of aspiration pneumonia is more often determined by the presence or absence of preexisting disease. Detection of superimposed infection can be difficult, and its treatment will depend on the clinical setting.

Disease Mechanisms and Clinical Manifestations

Although most bacterial pneumonias originate from aspiration (usually microscopic) of oral secretions in normal people, this would fall under the category of bacterial pneumonia discussed elsewhere. Early clinical features of large volume aspiration include fever, coughing, wheezing, leukocytosis, and infiltrates seen radiologically. The subsequent development of an infection should be suspected if unexpected deterioration occurs in these findings, particularly after initial

BOX 25-1 Conditions Predisposing to Various Aspiration Syndromes

Anatomical and Mechanical

Nasoenteric tube
Tracheostomy
Endotracheal tube; postextubation
Micrognathia
Macroglossia
Cleft palate
Laryngeal cleft
Tracheoesophageal fistula
Vascular ring
Gastroesophageal reflux
Achalasia (cricopharyngeal)
Gastrointestinal tract obstruction (e.g., esophageal stricture, malrotation)
Collagen vascular disease (scleroderma, dermatomyositis)
Tumors, masses (foreign body, abscess)
Ataxia-telangiectasia

Neuromuscular

Depressed consciousness (e.g., general anesthesia, drug intoxication, head trauma, seizure, central nervous system infection)
Immaturity of swallowing (prematurity)
Cerebral palsy
Hydrocephalus
Increased intracranial pressure
Vocal cord paralysis

Endotracheal intubation
Prone positioning without elevation of head
Use of antacids or acid blockers

improvement. Supporting evidence should be sought with repeat cultures, radiographs, serial white blood cell counts, and inflammatory markers, such as C-reactive protein.

Detection of infectious agents causing aspiration pneumonia depends upon the technique used. Percutaneous transtracheal aspirates have shown a predominance of anaerobic bacteria.[14] Using transtracheal aspiration, Brook and Finegold found anaerobic bacteria in 90% of aspirates. Gram-negative enteric rods were more frequently isolated in children younger than 4 years, and *B. fragilis* was absent in children younger than 2 years. Aerobic and facultative bacteria found included *S. pneumoniae*, group A streptococci, *S. aureus*, *Proteus* spp., *Pseudomonas aeruginosa*, *Klebsiella pneumoniae*, *Escherichia coli*, *Aerobacter* spp., *Haemophilus influenzae*, and others. Investigators in adult patients, using protected specimen brush specimens, have shown mixed results, some indicating high incidence of anaerobic infections[15] and others have found a low incidence.[16] These have primarily studied ventilator-associated pneumonia in adults. Anaerobic organisms predominate in the oropharynx with a ratio between 3 : 1 and 10 : 1. However, *Bacteroides melaninogenicus* and spirochetes are present in fewer numbers in children younger than 13 to 16 years.[17] Organisms obtained from empyema in children, when not excluding those with suspected aspiration, have yielded, in descending order, aerobic bacteria, anaerobic bacteria, followed by mixed aerobic and anaerobic bacteria. Care must be taken to collect and maintain an anaerobic condition to successfully culture for anaerobic organisms.[18]

When aspiration occurs in the hospitalized patient or in a patient receiving broad-spectrum antibiotic therapy, nosocomial and facultative organisms predominate. Most commonly, these include *E. coli*, *Proteus* spp., and *P. aeruginosa*.[19]

Management

Prevention is the mainstay of treatment. Aspiration may be decreased by placing the patient in a semirecumbent position as opposed to supine.[20] Minimizing the amount of subglottic secretions by continuous aspiration decreased the incidence rate of ventilator-associated pneumonia.[21] This is particularly true in the intubated patient receiving enteral feeds. Delivery of continuous feeds to the jejunum as opposed to the stomach may reduce episodes of reflux and aspiration. This fact was supported in a study of 38 critically ill patients randomized to gastric tube feedings or endoscopically placed jejunal tubes. Two patients in the gastric tube–fed group developed nosocomial pneumonia compared with zero in the jejunal tube–fed group.[22] Another study demonstrated a significant reduction in gastroesophageal regurgitation and a trend toward less microaspiration.[23] However, more recent reports have not supported this finding.[24,25] Enteral feeding via the jejunum also decreases gastric distention thereby decreasing respiratory effort. Fasting before procedures requiring anesthesia has long been thought to decrease the incidence of aspiration. Recent evidence suggests that children who are not permitted oral fluids for more than 6 hours preoperatively do not necessarily benefit in terms of intraoperative gastric volume and pH over children permitted clear liquids up to 2 hours before the procedure.[26]

Witnessed aspiration should immediately prompt lateralization of the head and suctioning of the oropharynx. The airway should be secured with an endotracheal tube if the mental status of the patient is compromised or if signs of significant respiratory distress develop. The nasotracheal

intubation route may be superior to the oropharyngeal route in decreasing aspiration in mechanically ventilated children.[27] Supporting ventilation with the use of oxygen, positive expiratory pressure, and/or mechanical ventilation and prevention of further aspiration are critical. Bronchoscopy may be warranted if large particle aspiration is suspected or there is evidence of large airway obstruction. Corticosteroids are controversial in the management of witnessed aspiration and most likely do not add benefit.[28,29]

Patients should be observed closely for the development of aspiration pneumonitis over the next 24 to 48 hours. If the patient has very limited reserve (pulmonary or immunological) or highly infectious aspirate is suspected (see Box 25-2), early empirical antibiotics may be warranted. Otherwise, in the absence of a clinical picture suggestive of pneumonia (fever, leukocytosis, chest radiograph changes, and/or mucopurulent secretions), empirical antibiotic therapy should be withheld to decrease the emergence of resistant organisms. In the presence of signs and symptoms suggestive of a bacterial infection, a culture of the lower respiratory tract, either via bronchoscopy or airway suctioning, should be obtained and appropriate antibiotic therapy should be instituted.[30] Antibiotic choice is based largely on the underlying condition and past medical history of the patient. In the previously healthy individual, in whom anaerobic bacteria are most likely to predominate, initial therapy with penicillin, ampicillin, or clindamycin is recommended. In the treatment of pneumonia in children with underlying chronic lung disease, institutionalized patients, and those having received prior broad-spectrum antibiotic therapy, a second- or third-generation cephalosporin should be considered. In immunocompromised patients, a combination of an aminoglycoside and a synthetic penicillin or cephalosporin such as ceftazidime might be initiated until culture results are available to guide more specific therapy. Culture results should be used to discontinue or narrow antibiotic therapy. Length of antibiotic therapy has not been addressed in a controlled study; however, treatment for 7 to 10 days appears reasonable for patients who respond promptly.

RECURRENT, SMALL-VOLUME ASPIRATION AND GASTROESOPHAGEAL REFLUX (GER)

Introduction

Recurrent, small-volume aspiration, whether it occurs with swallowing or secondary to GER, is commonly encountered in both pediatric and adult medicine. This is often termed "microaspiration" or "silent aspiration." Small-volume aspiration into the lungs is a relatively common event, with normal adults aspirating oropharyngeal secretions during sleep.[2] It is important to remember that aspiration with swallowing and GER, although often found together, may also exist completely independently.

Disease Mechanisms

Often it is difficult to establish a relationship between small-volume aspiration and pulmonary disease. This likely results from a combination of low sensitivity of tests detecting such intermittent aspiration and the low specificity of tests documenting aspiration as the cause of existing disease. It is generally easier to detect GER, and this may be the reason that lung disease is more commonly associated with it. However, direct aspiration with dysfunctional swallowing is a more common cause of recurrent pneumonia than is GER.[31]

Just as aspiration from above can be a normal event, GER also occurs physiologically with an inverse relationship to age in children. However, depending on the criteria used for a diagnosis, 25% to 80% of children with chronic respiratory disease have an *abnormal* degree of GER.[32] Numerous respiratory diseases and symptoms have been associated with GER (Box 25-3). Possible mechanisms to explain this relationship are listed in Box 25-4. Direct aspiration of refluxed material certainly can be expected to cause respiratory symptoms, just as it does by direct aspiration with swallowing. Bronchoalveolar lavage studies have shown airway inflammation and probable gastric contents in children with GER and difficult-to-treat respiratory symptoms.[33] Animal studies have suggested that microaspiration may cause symptoms directly from airway inflammation as well as predisposing to or accentuating airway hyperreactivity.[34,35] The strong association of bottle feeding

BOX 25-3 Disorders Associated With Gastroesophageal Reflux

Asthma
Chronic cough

BOX 25-4 Mechanisms for the Association of GER and Respiratory Disease

GER Causing Respiratory Disease

Aspiration
Direct effect: tracheitis, bronchitis, pneumonia, atelectasis
Reflex from irritation of the trachea or upper airway, laryngospasm, bronchospasm
Indirect effect: Inflammation or another alteration predisposing to airway hyperreactivity
Esophageal: airway reflex without aspiration

Respiratory Disease Causing GER

Diaphragm flattening and changes in abdominopleural pressure gradient
Effects of medication (e.g., theophylline) causing decreased lower esophageal sphincter pressure

in the crib during early life and later wheezing and asthma indicates a possible human clinical correlation.[36]

Reflex bronchoconstriction from esophageal acidification has been demonstrated in both animals[37] and humans.[38] However, 10 mL of acid infused into the cat esophagus produced less than one third of the increase in total lung resistance evoked by 0.05 mL of acid instilled in the trachea. Both reactions appear to be vagally mediated.[37] In a study of nine asthmatic children, four patients with positive Bernstein test (epigastric pain after esophageal acid infusion but not with saline) developed wheezing when 30 mL of 0.1 N hydrochloride was infused into the distal esophagus during sleep, but five patients with negative Bernstein test studied similarly showed no respiratory effect.[38] Esophageal acidification can also increase nonspecific airway hyperreactivity without necessarily causing a change in baseline pulmonary mechanics.[39]

Both central and obstructive or mixed apnea have been associated with GER.[40,41] However, another study did not find apnea related to GER in premature infants.[42] Other GER-associated respiratory disorders are listed in Box 25-3.

Improvement after antireflux therapy is perhaps the strongest evidence establishing GER as a direct cause of respiratory disease. Generally such treatment has been shown to be more effective in reducing cough than asthma symptom scores or improving pulmonary function.[43-45] However, very few of these studies are prospective, controlled trials.[46,47] See later for more about treatment.

It is also possible that respiratory diseases and/or treatment can provoke GER. More negative intrathoracic pressure and increased abdominal pressure induced by coughing may increase the likelihood of reflux. Hyperinflation and diaphragmatic flattening with secondary stretching of the crura can also predispose to reflux. However, no increased reflux was found during provoked bronchospasm in adults with both asthma and GER.[48] Theophylline and caffeine decrease lower esophageal sphincter pressure, thus predisposing to GER.[49] Positional changes associated with postural drainage and chest physiotherapy have been associated with increased likelihood of GER. Although at least one study has shown increased GER in the sitting position,[50] a small but definitive study has shown improved pulmonary outcomes over 5 years when the head-down position is avoided with CF infant physiotherapy.[51]

Diagnosis

Evaluation begins with a detailed history and physical examination. Other causes of similar findings should be considered (Box 25-5). The patient or caregiver should be asked about the timing of symptoms in relation to feedings and position changes, spitting or vomiting, irritability in an infant, epigastric discomfort in an older child, and nocturnal symptoms of coughing or wheezing. It is important to remember that there may be no symptoms with silent aspiration in a child with depressed cough reflex. For a child with a history of frequent recurrent vomiting, a trial of therapy is usually warranted before any further evaluation is performed. Observation of the child during a feeding is an essential element of the exam when the diagnosis of aspiration is being considered. Particular attention should be given to nasopharyngeal reflux, difficulty with sucking or swallowing, and associated coughing or choking. The palate, tongue, and oropharynx should be inspected for gross abnormalities and stimulated to assess the gag reflex. Drooling or excess accumulation of secretions in the mouth suggest dysphagia or esophageal motility disorder. Auscultation may reveal transient wheezes or crackles after feeding, particularly in the dependent lung segments.

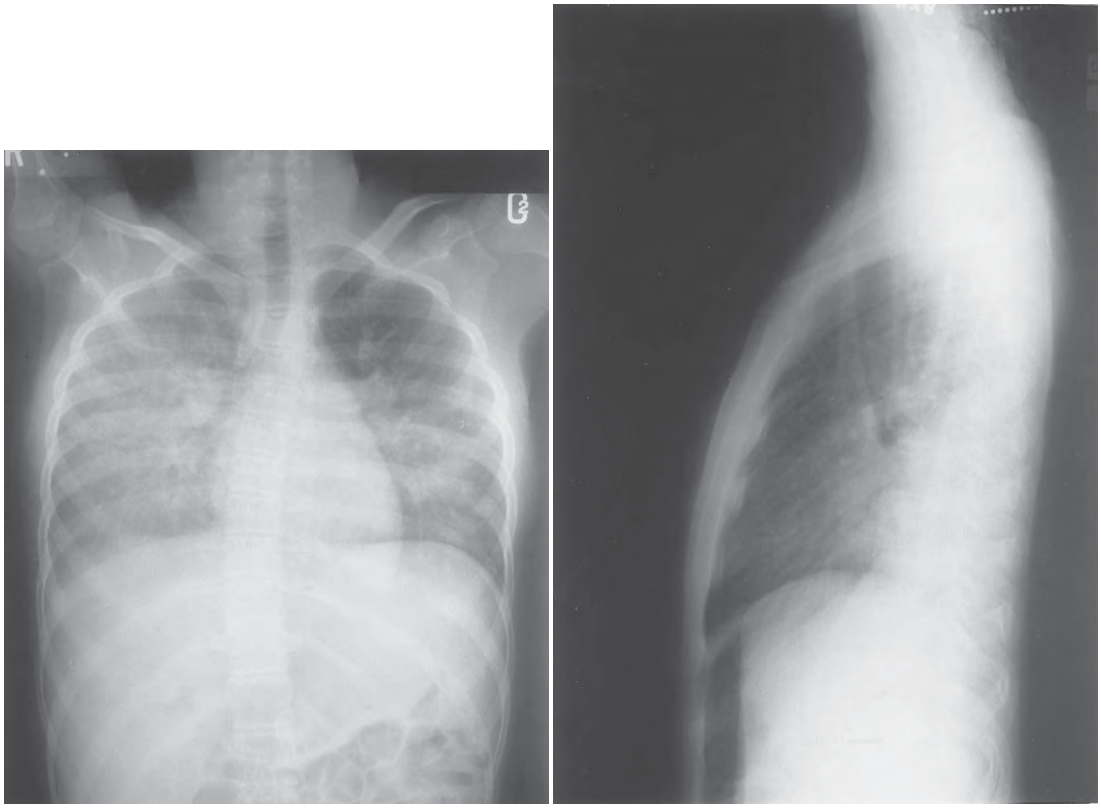
BOX 25-5 Differential Diagnosis of Chronic Recurrent Aspiration

Cystic fibrosis
Interstitial pneumonitis
Asthma
Bronchopulmonary dysplasia
Bronchiectasis
Pulmonary edema
Primary ciliary dyskinesia
Gastroesophageal reflux (without aspiration)
Airway foreign body

A plain chest radiograph is the initial study for a child suspected of having recurrent aspiration. A patient with classic radiographic findings is shown in Figure 25-1. Although segmental or lobar infiltrates localizing to dependent areas may be common, there is a wide variety in radiographic findings. In 22 children with known recurrent aspiration, chest radiograph showed localized infiltrates involving no more than two lobes in 41%, diffuse infiltrates in 27%, and bronchial wall thickening or hyperinflation in 18%. Chest radiograph was normal in 14% of these patients.[52] A computed tomography scan may be helpful in diagnosing lipoid pneumonia (Fig. 25-2), although this would most likely be performed when recurrent aspiration is not highly suspected, and other diagnoses are being explored.

Numerous other tests are available for detecting GER and/aspiration (Table 25-2). A properly performed barium esophagogram may demonstrate reflux into the nasopharynx or direct aspiration into the trachea. It is sometimes difficult to differentiate aspiration through the vocal cords during swallowing from that through a laryngoesophageal cleft. An esophagogram is most useful in detecting anatomic problems, including vascular rings, strictures, hiatal hernias, and tracheoesophageal fistula without atresia (H type). The latter may be difficult to demonstrate. An esophagogram also yields qualitative information on esophageal motility and, when extended, on gastric emptying. A short observation time renders the esophagogram relatively insensitive for detecting aspiration and GER. Because physiological reflux episodes do occur, it can also be nonspecific.[32] However, if repetitive free GER is noted, it is probably unnecessary to do further tests for GER.

A modified barium swallow, using videofluoroscopy imaging, is the most common study for evaluating the swallowing mechanism. Because it uses different textures and quantities of liquid barium or foods laced with barium, it is a sensitive and detailed test for evaluating swallowing, aspiration, and defining food textures and techniques that can be used to reduce aspiration. It has been shown to be much



A B

Figure 25-1 Posteroanterior (**A**) and lateral (**B**) chest radiographs of a 15-year-old patient with mental retardation and recurrent aspiration. The classic findings of dependent area consolidations in the lower lobes and posterior segment right upper lobe are demonstrated.

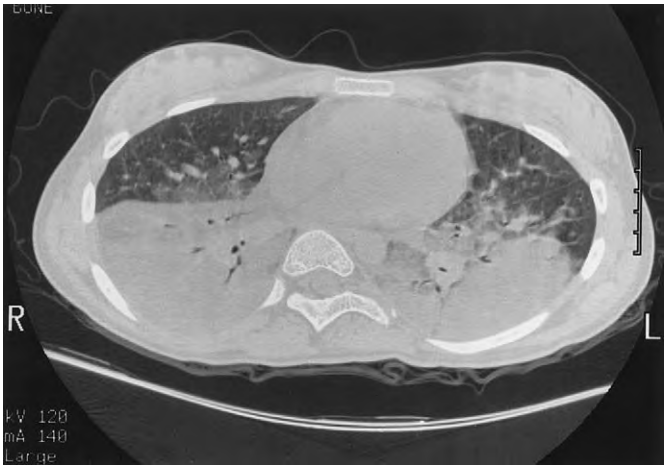


Figure 25-2 Computed tomography scan through the midthorax of the same patient as in Figure 25-1. The density of consolidation measured −35 to −40 Hounsfield units, which is consistent with lipoid pneumonia.

more sensitive than clinical evaluation, particularly for aspiration of solids.[53]

Fiberoptic endoscopic evaluation of swallowing (FEES) is being increasingly used to diagnose dysphagia and aspiration. It is performed with a fiberoptic laryngoscope or bronchoscope passed transnasally with observation of the oral cavity and larynx while the patient is fed small quantities of various textures of liquid or solid foods. Sometimes these are stained with a dye for easier observation. This has been shown to have high correlation with results of modified barium swallow and has the advantage of direct visualization of anatomy by means of fiberoptic laryngoscopy and no radiation. A disadvantage is the invasive nature, which may be less tolerated by some children. However, cooperation with modified barium swallow is also sometimes difficult.[54]

The gastroesophageal scintiscan, also called milk scan, is more physiological and sensitive than the barium esophagogram in detecting GER. Some investigators have found that it can detect aspiration in as many as 25% of children with chronic respiratory symptoms.[55] However, it is generally thought to be less sensitive and specific for a diagnosis of GER than esophageal pH monitoring.[32] Although the scintiscan measures both acid and nonacid reflux, it observes for a much shorter period of time than pH monitoring. It is quite insensitive for the diagnosis of aspiration.[56] Another radioisotope study that has been used for diagnosing aspiration is the "salivagram," which uses a small amount of concentrated marker placed on the tongue or a continuous oral infusion of labeled fluid.[57] This has been proposed to be useful for neurologically impaired children in evaluation for possible laryngotracheal separation.[58]

Monitoring of esophageal pH for 18 to 24 hours is often considered to be the gold standard for detecting significant GER. When performed with high and low esophageal pH probes, both upper and lower esophageal reflux, the duration and frequency of reflux episodes, and nocturnal reflux can be

Table 25-2
Major Diagnostic Tests for Aspiration and Gastroesophageal Reflux (GER)

	Relative Sensitivity
Aspiration	
Modified barium swallow	High
Gastroesophageal scintiscan	Low
Salivagram	Moderate
Bronchial washings for*	High
Lipid-laden macrophage quantitation	
Glucose, lactose	
Pepsin	
Food particles	
Fiberoptic endoscopic evaluation of swallowing (FEES)	High
Dye or other marker studies*	Moderate, low for dye in enteral feeds
GER	
Multichannel intraluminal impedance	High
Esophageal pH monitoring	Moderate-high
Gastroesophageal scintiscan	Moderate
Esophagoscopy, esophageal biopsy	Moderate
Esophageal motility	Low
Barium esophagogram	Low
Empirical trial of therapy	Moderate

*These can also indicate GER in patients with strictly intragastric feedings.

detected. By simultaneously monitoring symptoms or recording polygraph tracings, it sometimes is possible to detect a temporal relationship with esophageal acidification and respiratory abnormalities. The disadvantages include cost (often requiring hospitalization), inability to detect nonacid (e.g., postprandial) reflux, and possible effects of the catheter resting in the nasopharynx and esophagus. It is also important to remember that esophageal pH monitoring may demonstrate a relatively normal amount of GER, which, although not expected to cause esophagitis, may still cause respiratory symptoms or disease.[32]

Impedance monitoring in the pharynx and esophagus is a newer technique for detecting liquid or gas reflux. Unlike pH monitoring, it will detect nonacid reflux. This requires insertion of a probe that measures impedance at various levels along the pharynx and esophagus. There are probes available that monitor impedance and pH simultaneously. Although it has been reported to be more sensitive than pH monitoring, it also misses some episodes of reflux that are detected with pH studies.[59] Esophagoscopy alone is very insensitive for detecting GER; however, when combined with biopsy, it becomes much more useful, with the sensitivity reported as high as 97%.[60]

Tracheobronchial aspirates can be examined for numerous entities to evaluate for aspiration from patients with artificial airway. The most common test is placement of an oral dye and visual examination of tracheal secretions for the presence of staining. Several tests, collectively termed modified Evans blue dye tests, have been used. The sensitivity of these tests greatly depends upon the precise technique used. Impregnating ice chips with Evans blue dye and giving three successive swallows, repeating this on three separate occasions separated by at least 1 hour, followed by suctioning from the tracheostomy, revealed a sensitivity of 82% compared with FEES. For patients receiving mechanical ventilation, the sensitivity was 100%.[61] A more common method is to place four drops of dye on the back of the tongue and follow with tracheal suctioning, observing for stained secretions. The staining of enteral formula to detect aspiration into tracheobronchial secretions has been shown to be insensitive[62] as well as associated with adverse outcomes, including death. For these reasons, this test is not recommended.[63]

Detection of glucose and/or pepsin in tracheal secretions has been studied in mechanically ventilated children. Pepsin appears to be a more specific marker, with glucose concentrations being elevated for reasons other than aspiration.[64]

The finding of lipid in alveolar macrophages has long been associated with lipid aspiration pneumonia.[65] Simply siting lipid-laden macrophages is a nonspecific finding. These cells also occur due to endogenous lipoid pneumonia, particularly with bronchial obstruction, with sepsis, bronchiolitis obliterans, pulmonary hemosiderosis, and in patients receiving intravenous lipid infusions. However, performing semiquantification of these macrophages, and taking into account the reported causes of false positives appears to significantly increase the specificity of this test for children.[66] Lipid-laden macrophages are observed within 6 hours after milk instillation into the rabbit airway. They disappear rapidly, 1 to 2 days after a single milk instillation, and somewhat more slowly after repeated instillations.[67]

Preliminary studies have also proposed examining bronchial washings for several endogenous and exogenous substances including milk antibodies, food fibers, polystyrene microspheres, carbon, and other items. There has been limited experience with these tests in a clinical setting. Further study is required to determine their usefulness.

The diagnosis of recurrent, small-volume aspiration-induced lung injury remains a challenge. Often the best that the clinician can achieve is to demonstrate that aspiration occurs and that existing lung disease is probably caused by aspiration, often by exclusion of other processes.

Management

Chronic aspiration or microaspiration occurs in otherwise normal children as well as children with underlying medical conditions. The extent of therapy should be dictated by the degree of respiratory compromise as well as the underlying condition. The "happy spitter" may require minimal intervention while the neurologically compromised child may require extensive surgical treatment.

Aspiration may occur secondary to material (i.e., saliva, stomach acid) entering the lungs as a result of pharyngeal, laryngeal, or esophageal motor problems. Medical therapy with scopolamine (1.5-mg transdermal patch) or glycopyrrolate (40 to 100 μg/kg/dose three or four times daily) has been shown to be effective in decreasing the amount of saliva.[68] Introducing botulinum toxin A into the salivary glands has been shown to be as effective as scopolamine in decreasing the amount of saliva production.[69] Surgical intervention is an option in children who fail medical management. This includes parotid duct and/or submandibular duct ligation.[70] Children who continue to aspirate and show signs of recurrent pneumonitis may benefit from laryngotracheal separation or isolated tracheostomy. Laryngotracheal separation

(LTS) is a drastic, yet effective, procedure in these children. In one report, 11 children with intractable aspiration pneumonia underwent an LTS procedure and the frequency of suctioning decreased 8-fold, pneumonia was eliminated in 10 patients and all parents rated LTS as excellent or good in terms of its improvement of the quality of life.[71] Because artificial airways can exacerbate aspiration, the benefits should clearly outweigh the risks when isolated tracheostomy is considered for improving airway clearance.

Lifestyle changes form the basis of GER disease (GERD) therapy at all levels of GERD severity. Caregivers should be educated about the importance of small frequent feedings, not jostling the infant after a feeding, preventing air feeding, and holding the infant in a cradled position in order to decrease reflux. Thickening of the formula (1 tablespoon of dry rice cereal per ounce of milk formula) or using a commercially available prethickened formula has benefits for the regurgitating infant, especially the regurgitating infant with poor weight gain.[72,73] Prone positioning during sleep is superior to supine, side, and upright (i.e., sitting in a car seat) positioning in the infant with reflux.[74,75] Risk-to-benefit factors of GERD for sudden infant death syndrome and other issues (e.g., blankets in the bed, second-hand cigarette smoke) should be considered with caregivers before recommending the prone position in the infant with reflux. Consensus from the North American Society for Pediatric Gastroenterology and Nutrition states that prone positioning generally should be avoided due to risks outweighing benefits in children less than 12 months of age.[32] Bottle feeding in the bed or crib before sleep time should be discouraged during the first year of life because the risk of wheezing between the ages of 1 and 5 years increases with this practice.[76] Adolescents and older children with GERD symptoms should avoid caffeine, nicotine, alcohol, and spicy foods that exacerbate symptoms. Weight loss should be encouraged in the overweight child/adolescent.

Pharmacotherapy works mainly by acid suppression or accelerating gastric emptying. Treatment with histamine-2 receptor antagonists such as ranitidine, 2 mg/kg/dose twice daily, reduced by 44% the duration that gastric pH was less than 4, and with three-times-daily dosing, the reduction was 90%.[77] Proton pump inhibitors (PPIs) are generally superior to histamine-2 receptor antagonists.[78,79] Omeprazole and lansoprazole are the PPIs most often used in children. The dosage range for treatment of GERD for omeprazole is 0.3 to 3.5 mg/kg (maximum 80 mg/day), and for lansoprazole, 0.73 to 1.766 mg/kg/day (maximum 30 mg/day).[80] Although the evidence supports the use of cisapride in infants and children with GERD who would benefit from a prokinetic agent, the potential for serious cardiac arrhythmias has limited its use dramatically.[81] Cisapride is not on the market in the United States, nor is it recommended for use in the pediatric population. Most evidence suggests that metoclopramide often contributes more adverse effects than benefits to the treatment of GERD in children.[82,83] If the use of a prokinetic agent is warranted, then erythromycin (1 to 3 mg/kg) in combination with acid suppression could also be considered.[84]

Surgical intervention for GERD is most frequently used for children with neurological impairment. However, underlying lung disease, apparent life-threatening events, and failure to thrive are other common reasons for surgical treatment after failure of medical management in the child with GERD. Nissen fundoplication is the most common procedure performed for the treatment of reflux. The laparoscopic approach has been associated with improved rates of extubation, shorter recovery room stays, shorter durations of chest physiotherapy, fewer intensive care unit admissions, and overall decreased length of stay in neurologically normal and impaired children.[85] In a 2- to 5-year follow-up of a cohort of children who underwent laparascopic fundoplication, 66% of patients reported complete relief and 26% reported considerable improvement of respiratory symptoms.[86] Despite these impressive statistics, the potential complications of this procedure (i.e., gas-bloat syndrome, dumping syndrome, GERD recurrence, dysphagia) must be discussed with families.[87]

Although medical management of the child with GERD is increasing, lifestyle changes should remain an important part of first-line therapy. A search for the underlying cause should always be undertaken. Histamine-2 receptor antagonists remain a reasonable first-line therapy in children with reflux. PPI therapy may be reserved for patients with persistent symptoms, although adult studies have indicated that starting with an empirical PPI trial may be most cost-effective.[88] After failure of medical management, surgical intervention may be appropriate for the child with GERD causing significant respiratory complications. It is important to remember that some children, especially those with profound neurological impairment, may experience recurrent aspiration from the oropharynx in addition to GERD. This is often a reason for "failure" of GERD treatment to reduce pulmonary complications.

PITFALLS AND CONTROVERSIES

- Possibly because of aspiration of oral secretions, tube feeds (even transpyloric) do not necessarily reduce aspiration.
- There is a strong association of gastroesophageal reflux and respiratory disease. Cause-effect relationship remains controversial due to paucity of controlled clinical trials.
- Infectious complications do not occur with approximately 50% of aspiration events. Therefore, antibiotics are not necessarily indicated.
- Adding dye to chronic tube feedings for aspiration detection is insensitive and carries risk of adverse effects.
- Quantity of GER may be "normal" from a gastrointestinal perspective yet cause respiratory disease.
- Thickened feeds reduce vomiting and nonacid GER but do not affect acid GER.
- Most tests for aspiration and GER are helpful when positive but have relatively poor negative predictive value.
- Treatment for GER yields mixed outcomes for respiratory disease, often with improvement in symptoms, but little or no improvement in pulmonary function test results.
- Recent studies in children have not shown increased risk of ventilator-associated pneumonia with use of acid blockers or stress-ulcer prophylaxis.

CHAPTER 26 Respiratory Effects of Anesthesia and Sedation

Daniel J. Weiner, Mark Helfaer, and Julian Lewis Allen

TEACHING POINTS

- Safe anesthesia requires careful preoperative assessment, intraoperative monitoring, and knowledge of airway management.
- Important pharmacologic agents include anticholinergics, neuromuscular blockers, sedatives, parenteral analgesics/anesthetics, and inhalational anesthetics.
- There are important effects of anesthesia on lung mechanics, including decreased lung compliance and lung volume, and as a consequence, increased airway resistance.
- Hypoxic vasoconstriction is blunted by general anesthesia, impairing ventilation/perfusion matching.
- Mucociliary clearance can be negatively impacted by anesthesia. Cough, however, can be induced by anesthetics as well as airway instrumentation.

GENERAL CONSIDERATIONS

Preoperative Assessment

Prior to anesthetizing patients for any procedure in general, and bronchoscopy in particular, a preoperative assessment is necessary. The focus of the preoperative assessment is a review of the history with special focus on medications, allergies, and past experiences with anesthetics. Often, history of bronchospasm, "BPD spells," wheezing, and recent upper respiratory infections will guide the choice of anesthetic agents. Cardiovascular disease can present with airway compression and can complicate bronchoscopic evaluation[1] as well as the anesthetic conduct of the case. Aspiration risk must be assessed and minimized. Fasting guidelines should be reviewed and orders should be written in accordance with best practices; a summary of these recommendations is included in Table 26-1. The use of pharmacologic agents to reduce the risk of pulmonary aspiration should be considered cautiously. Agents such as gastrointestinal stimulants, gastric acid secretion blockers, antacids, or antiemetics may reduce the risk of pulmonary aspiration, but the application of this principle has to be applied on a case-by-case basis.[2] The physical examination should focus on the airway, breathing, and circulation as a priority. The airway should be evaluated for any congenital or acquired pathologies that would make control of the airway a challenge, such as loose teeth, excessive secretions, Pierre Robin sequence, and limitation of jaw opening. Bronchodilator therapy or airway distending pressure may be required for children with asthma or airway collapsibility (e.g., tracheomalacia). Cardiovascular concerns include any right-to-left shunts that would add to pulmonary shunting in contributing to desaturations requiring more liberal uses of oxygen. Right-to-left shunting also dictates meticulous attention to the potential for an embolic stroke from, for instance, air in the intravenous line. Issues of pulmonary hypertension should be clarified preoperatively by history, electrocardiogram, and/or echocardiogram. If pulmonary hypertension is present, strategies to minimize decompensation during the procedure include a greater depth of anesthesia, liberal use of oxygen, and minimizing hypercarbia, hypoxia, and acidosis.

Initiation of Sedation and Anesthesia

Whenever anesthetizing a patient, the operator's first focus is on the ability to establish an airway. The patient's ability to protect the airway depends on the depth of sedation/anesthesia (Table 26-2). Preparations must be made to respond to deeper levels of sedation or anesthesia.

Monitoring

Monitoring must be applied to the patient in accordance with anesthesia standards for monitoring (Table 26-3). Pulse

Table 26-1
Fasting Recommendations to Reduce the Risk of Pulmonary Aspiration

Ingested Material	Minimum Fasting Period
Clear liquids (water and juice without pulp)	2 hr
Breast milk	4 hr
Infant formula	6 hr
Non–human milk	6 hr
Light meal (not fatty foods)	6 hr

Reprinted with permission from Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: Application to healthy patients undergoing elective procedures: A report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. Anesthesiology 90(3):896-905, 1999.

Table 26-2
Continuum of Depth of Sedation: Definition of General Anesthesia and Levels of Sedation/Analgesia (Approved by ASA House of Delegates on October 13, 1999, and Amended on October 27, 2004)

	Minimal Sedation (Anxiolysis)	Moderate Sedation/ Analgesia ("Conscious Sedation")	Deep Sedation/ Analgesia	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful* response to verbal or tactile stimulation	Purposeful* response following repeated or painful stimulation	Unarousable even with painful stimulus
Airway	Unaffected	No intervention required	Intervention may be required	Intervention often required
Spontaneous ventilation	Unaffected	Adequate	May be inadequate	Frequently inadequate
Cardiovascular function	Unaffected	Usually maintained	Usually maintained	May be impaired

Minimal sedation (anxiolysis) is a drug-induced state during which patients respond normally to verbal commands. Although cognitive function and coordination may be impaired, ventilatory and cardiovascular functions are unaffected.
Moderate sedation/analgesia ("conscious sedation") is drug-induced depression of consciousness during which patients respond purposefully* to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway and spontaneous ventilation is adequate. Cardiovascular function is usually maintained.
Deep sedation/analgesia is a drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully* following repeated or painful stimulation. The ability to independently maintain ventilatory function may be impaired. Patients may require assistance in maintaining a patent airway, and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained.
General anesthesia is a drug-induced loss of consciousness during which patients are not arousable, even by painful stimulation. The ability to independently maintain ventilatory function is often impaired. Patients often require assistance in maintaining a patent airway, and positive pressure ventilation may be required because of depressed spontaneous ventilation or drug-induced depression of neuromuscular function. Cardiovascular function may be impaired.
Because sedation is a continuum, it is not always possible to predict how an individual patient will respond. Hence, practitioners intending to produce a given level of sedation should be able to rescue† patients whose level of sedation becomes deeper than initially intended. Individuals administering moderate sedation/analgesia ("conscious sedation") should be able to rescue† patients who enter a state of deep sedation/analgesia, while those administering deep sedation/analgesia should be able to rescue† patients who enter a state of general anesthesia.
* Reflex withdrawal from a painful stimulus is NOT considered a purposeful response.
† Rescue of a patient from a deeper level of sedation than intended is an intervention by a practitioner proficient in airway management and advanced life support. The qualified practitioner corrects adverse physiologic consequences of the deeper-than-intended level of the sedation (such as hypoventilation, hypoxia, and hypotension) and returns the patient to the originally intended level of sedation.

oximetry is the mainstay of monitoring to avoid hypoxemia. Carbon dioxide concentrations are often difficult to measure in the absence of a secure airway, but can be measured during bronchoscopy.[3]

When preparing a patient for a procedure, optimal positioning needs to be ensured.[4-6] Adequate padding for pressure points, avoidance of hyperextension of extremities, and eye protection need to be ensured. There is always a possibility of causing a depth of anesthesia greater than intended. In deeper levels of anesthesia, corneal reflexes are blunted, such that accidental injury to the cornea is a possibility requiring either taping the eyes shut or lubricating the eyes with ointment. In addition, the normal airway reflexes are not present. Anesthetics will depress the innervations of the upper airway muscles, making obstruction more likely due to, for example, loss of genioglossus tone. Side lying may minimize some of this loss of airway tone but often makes the bronchos-copy more difficult. Jaw thrust and shoulder rolls in the supine position can overcome these as well. Early on in the preparation, drying agents are often helpful in optimizing views of the airway structures. Anticholinergics are the most commonly used agents, which can also minimize the bradycardias associated with narcotic coadministration.[7]

To establish an airway, the most useful maneuvers are a jaw thrust or placement of an oral airway or a nasal airway to displace the tongue forward.[8] Failing this, the difficult airway algorithm can be used to direct therapies to assure an airway in a step-by-step fashion (Fig. 26-1).

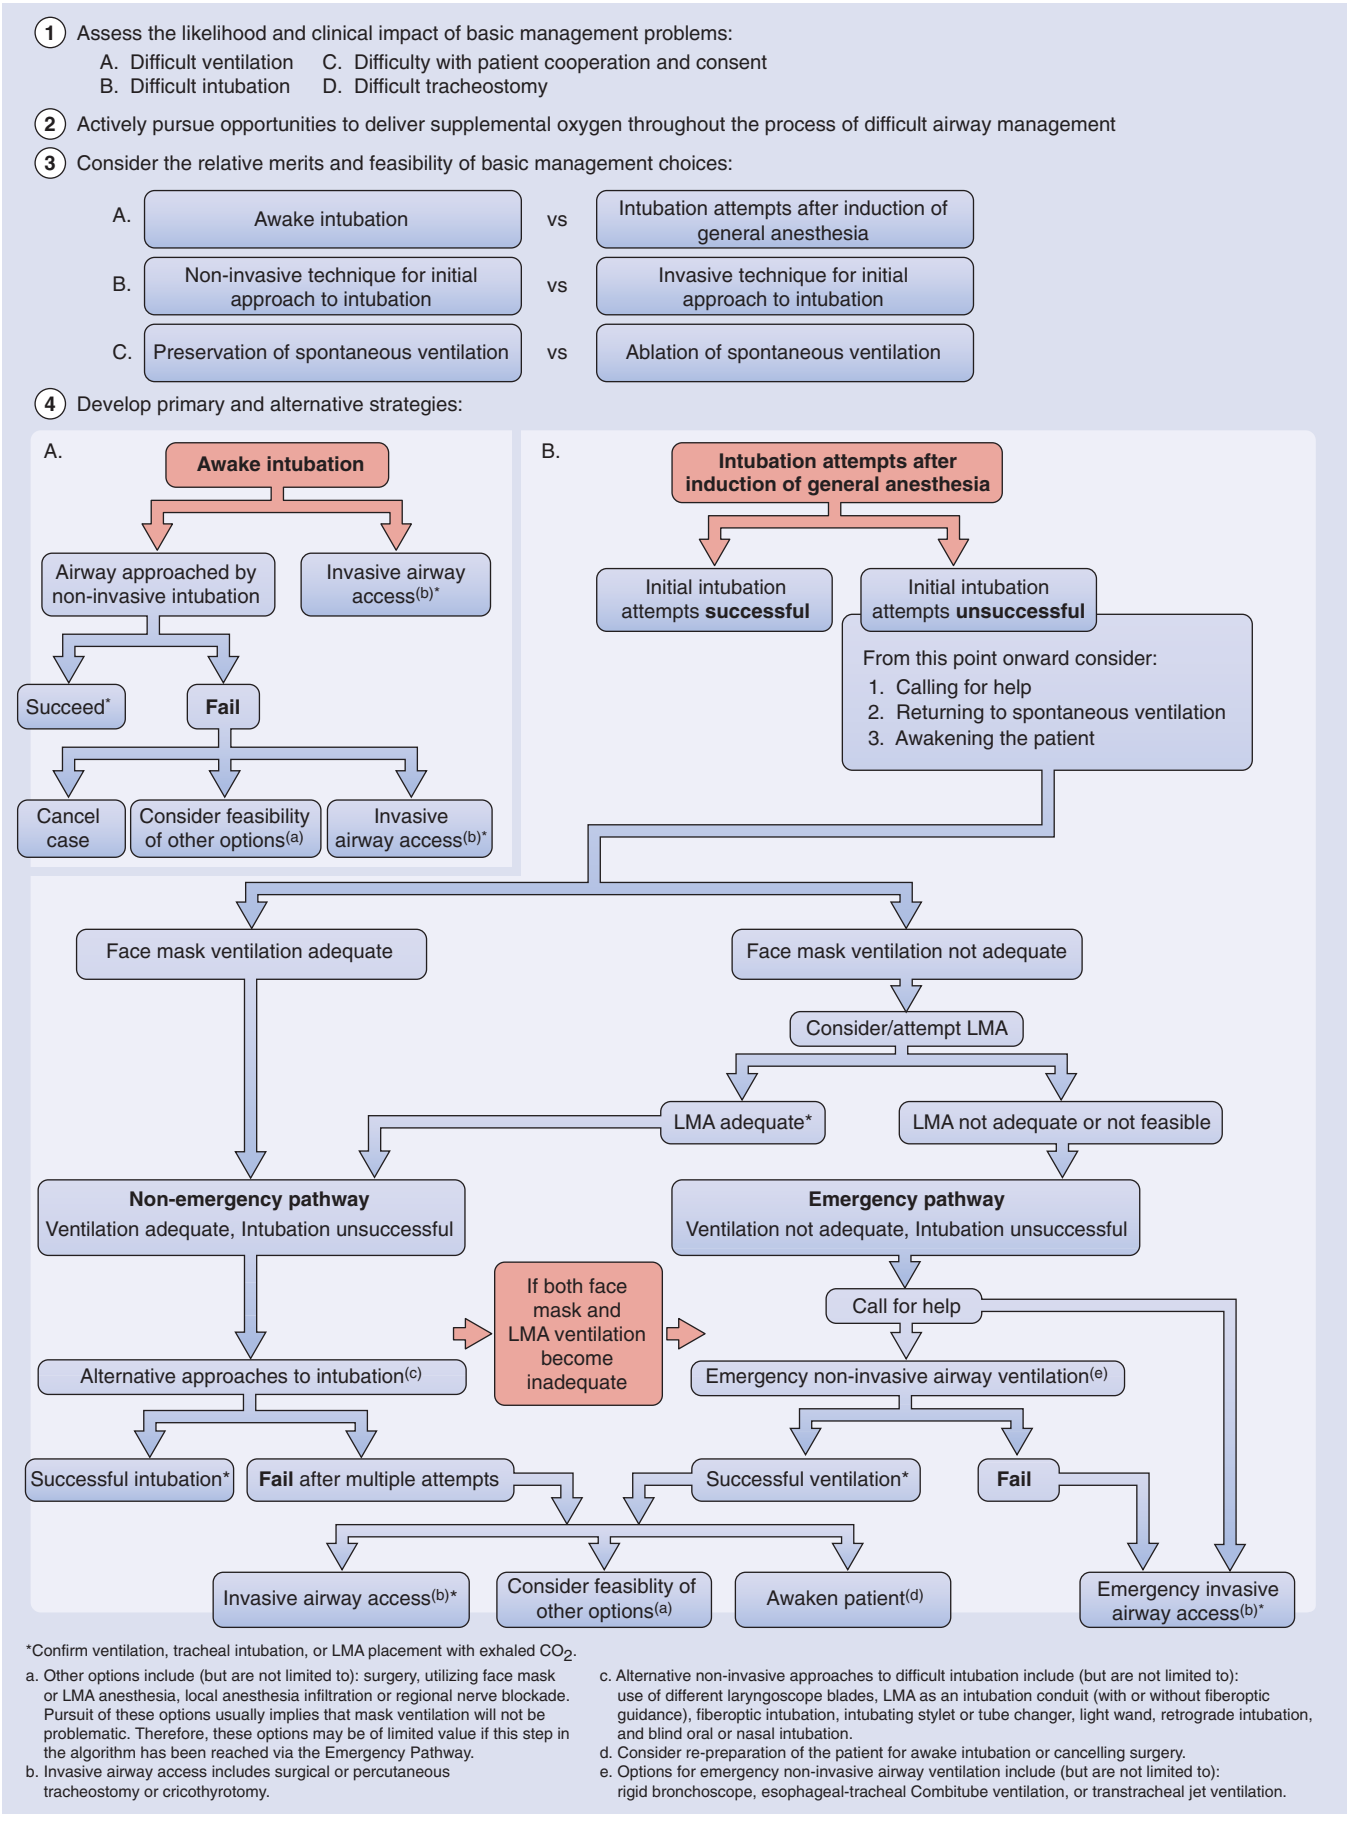
Special Considerations for Airway Procedures

When considering bronchoscopy, decisions of the merits of flexible versus rigid bronchoscopy should be addressed. Retrieval of airway foreign bodies is best addressed by rigid bronchoscopy.[9] The latter most regularly requires neuromuscular blockade, because patient movement when the rigid bronchoscope is in the airway can cause injury. Flexible bronchoscopy is superior for evaluation of more distal airways,

Table 26-3
Standards for Basic Anesthetic Monitoring (Approved by the American Society of Anesthesiologists House of Delegates on October 21, 1986, and Amended on October 25, 2005)

Measure	Monitor
Concentration of inspired oxygen	Oxygen analyzer and low oxygen alarm
Oxygenation	Pulse oximetry
Ventilation	Clinical: chest rise and auscultation. When possible, and always when an endotracheal tube is in place: expired carbon dioxide concentration.
Circulation	EKG, heart rate, and blood pressure at least every 5 mins
Temperature	Thermometer (especially with small infants or neonates)

Data from http://www.asahq.org/publicationsAndServices/standards/02.pdf with permission of the American Society of Anesthesiologists, 520 N. Northwest Highway, Park Ridge, Illinois 60068-2573.



*Confirm ventilation, tracheal intubation, or LMA placement with exhaled CO_2.

a. Other options include (but are not limited to): surgery, utilizing face mask or LMA anesthesia, local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency Pathway.

b. Invasive airway access includes surgical or percutaneous tracheostomy or cricothyrotomy.

c. Alternative non-invasive approaches to difficult intubation include (but are not limited to): use of different laryngoscope blades, LMA as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, retrograde intubation, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or cancelling surgery.

e. Options for emergency non-invasive airway ventilation include (but are not limited to): rigid bronchoscope, esophageal-tracheal Combitube ventilation, or transtracheal jet ventilation.

Figure 26-1 Difficult airway algorithm. A loss of protective airway reflexes and control of breathing necessitates that the practitioner must be in a position to take over these normal physiologic functions, have a step-wise plan if initial efforts are not successful, and outline both procedures and necessary equipment. (Reprinted with permission from Practice Guidelines for Management of the Difficult Airway: An updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway. Anesthesiology 98:1269-1277, 2003. Erratum in: Anesthesiology 101:565, 2004.)

and for obtaining bronchoalveolar lavage for cultures or cytology.

Flexible bronchoscopy is most commonly performed through the nose, but alternative approaches such as through the mouth with or without a laryngeal mask airway can be considered.[10,11] If assessment of glottic or supraglottic function (e.g., of vocal cords) or of dynamic airway collapsibility is required, light sedation is often required. The anesthetic may need to be deepened once supraglottic function is assessed and progression below the vocal cords is required. A greater depth of anesthesia can be accomplished systemically with potent inhaled anesthetics or intravenous anesthetics such as ketamine, propofol, or narcotics. Greater depths of anesthetics will affect airway tone, pulmonary blood flow, and functional residual capacity. The effects of lidocaine are often underestimated; lidocaine can affect upper airway tone and lead to upper airway collapse, mimicking obstructive apnea. Likewise, inhalational anesthetics can cause asynchronous breathing patterns.[12]

Patients with bronchomalacia or laryngomalacia[13] often require more tone to maintain airway patency. In these cases, agents causing muscle relaxation can worsen airway obstruction. Neuromuscular blockade affects only striated, and not smooth, muscle paralysis, so these agents may have a variable effect on the pathology of malacia.

CLASSES OF INHALED AND INTRAVENOUS ANESTHETIC/SEDATING AGENTS

Adjuvant Agents

ANTICHOLINERGIC AGENTS

Anticholinergic agents will block the vagotonic effects such as bradycardia with manipulation of the airway.[7] In addition, these agents will minimize secretions, allowing better views during bronchoscopy. Atropine is the mainstay of this group of agents. An absolute minimum dose (0.15 mg) is usually suggested despite the size and weight of the patient. Smaller doses present problems with measurement, the possibility of inadequate muscarinic blockade, as well as increased risk of tachycardia. Glycopyrrolate as an antimuscarinic agent has the advantage that, as a quaternary ammonium salt, it does not cross the blood-brain barrier and causes less tachycardia. There is very little effect on dead space ventilation with vagal blockade. There are effects of bronchodilation especially in the case of a viral illness causing bronchoconstriction. Blocking the muscarinic 3 receptor may limit bronchospasm, which may optimize ventilation/perfusion ($\dot{V}/\dot{Q}$) matching[14] (Table 26-4).

NEUROMUSCULAR BLOCKADE

Neuromuscular blockade is often used for rigid bronchoscopies, but for flexible bronchoscopy where functional assessment of vocal cord function is desired, paralysis is counterproductive. Recently, there is increasing use of short-acting nondepolarizing agents such as vecuronium or rocuronium. Respiratory mechanics, as expected, are profoundly affected by neuromuscular blockade.[15] Succinylcholine is an agent with fewer indications due to complications, which, although rare, can be life threatening.

LIDOCAINE

Directly anesthetizing the airway provides a systemic anesthetic drug-sparing effect, and for endotracheal intubation this is most commonly provided with intravenous lidocaine. Alternatively, lidocaine can be nebulized[16] and inhaled, allowing anesthesia of the upper airway, glottis, and trachea. In addition, local instillation at the time of the bronchoscopy allows for local anesthesia as well. Caution should be exercised if exceeding 5 mg/kg lidocaine by any of these routes of administration, for systemic absorption is excellent in the airway.[17] Seizures are the most concerning side effect and can be mitigated by other agents such as benzodiazepines. Topical lidocaine, by either nebulization or direct instillation, will affect upper airway muscle tone and can worsen malacia.[18]

Sedative Agents

BENZODIAZEPINES

Anxiolysis is a primary goal of anesthesia. This can be achieved pharmacologically with benzodiazepines. Alternatively, there are psychological adjuvants to minimize anxiety in patients prior to procedures.[19,20] As a goal of anesthetizing children, amnesia is of great importance. Antegrade amnesia is often induced by benzodiazepines. Benzodiazepines can be administered early in the procedure or as a premedication. Midazolam has the advantage that it can be administered by the oral, intramuscular, rectal, intranasal, or intravenous routes. It is short acting and water soluble outside of the body, and it becomes lipid soluble when injected into a nonacidic medium such as the blood. Other benzodiazepines such as diazepam last longer than midazolam and can be administered via the oral or intravenous route. Lorazapam can be given via the intramuscular route, unlike diazepam. Benzodiazepines as a single agent do not substantially affect respiratory function, but when combined with other agents, they can profoundly affect the drive to breathe, including blunted carbon dioxide response as well as hypoxic drive to breathe. Benzodiazepine overdose can be treated with flumazenil, although seizures are a serious side effect. Waiting for spontaneous reversal with time is the most conservative approach to cases of overdosing. Retrograde amnesia cannot be reliably achieved, although scopolamine has been advocated for this. The potent penetration into the brain makes it a less attractive agent as an antisialagogue and cardiac vagolytic. The neurologic effects persist for many hours after the procedure, making the postoperative care challenging.

Chloral hydrate is an agent with a long history of use in children, although there is a paucity of literature supporting its use. It can be administered enterally or rectally. There are very few studies evaluating the utility of choral hydrate for pediatric bronchoscopies, but there are studies evaluating chloral hydrate for other procedural sedations (such as for infant pulmonary function testing). In general, as a single agent, the usefulness is somewhat limited.[21-25]

Dexmedatomidine is a new agent that is a specific α_2-adrenergic agonist and has provided useful sedation in adults. The usefulness in children is being evaluated.[26]

NARCOTICS

Narcotics are the most potent antitussive agents and therefore are quite helpful in airway procedures. In addition, ade-

Table 26-4
Anesthetic, Sedating, and Adjuvant Agents

Class	Agent	Purpose	Route of Administration	Reversal Agent	Cautions	Effect on Pulmonary Vasculature	Effect on Bronchial Tone	Effect on CO_2 Response	Effect on O_2 Response
Anticholinergics	Glycopyrrolate Atropine	Dries secretions Maintains heart rate	IV, IM, PO	Physostigmine	No CNS effects Possible CNS effects		Some bronchodilation	Minimal	Minimal
Narcotics	Fentanyl	Anesthetizes airway	IV, IM, PO, intranasal	Naloxone		Excellent anesthetic for pulmonary hypertension	Minimal	↓ Ventilatory drive	↓ O_2 response
	Morphine Remifentanil		IV, IM, PO, inhaled IV						
	Meperidine		IV, IM, PO		Seizures				
Inhaled anesthetics	Nitrous oxide	Anesthetizes whole body	Inhaled			Minimal		↓ Ventilatory drive	↓ O_2 response
	Halothane				Hypotension Calcium	Vasodilators	Dose-dependent bronchodilation	Increased apneic threshold	Paralyzes HPV
	Sevoflurane				Flush machine; first case Monday AM	Minimal dilation	Dose-dependent bronchodilation		
	Isoflurane						Dose-dependent bronchodilation		
	Desflurane				↑ Bronchospasm, laryngospasm		Dose-dependent bronchodilation		
Other agents	Chloral hydrate		Rectal, enteral			Variable	Variable	Variable	
	Propofol	Anesthetizes whole body	IV		Sulfites in generic, infectious, egg allergy; shake before using	\			
	Ketamine	Anesthetizes airway, preserving cardiovascular function	IV, IM		Sensitizes airway, causes secretions			\	

quate analgesia by a narcotic will facilitate procedures such as bronchoscopy. As a sole agent, it takes very high doses to blunt the responses to airway manipulation, but narcotics are a mainstay of anesthesia for bronchoscopic evaluation. Short-acting agents are optimally used for brief evaluations and prompt recovery.[27] Narcotics will universally decrease apneic threshold, and therefore preparations should be anticipated to control the airway. Many different narcotics, summarized in Table 26-4, can be used.

Anesthetic Agents

PARENTERAL AGENTS

Ketamine is an intravenous agent[28] used for many procedures in children. It is touted to be a safe agent, but when given to very sick patients, the direct negative inotropic effects can cause cardiovascular collapse. Likewise, like all potent intravenous agents, the effects are dose dependent, and large doses of ketamine will cause apnea and can ablate the cough reflex. Emergent delirium is a serious side effect that is seemingly unpredictable. Attempts at preventing this with other agents such as benzodiazepines have met with mixed results without consistent success. Ketamine may also increase airway secretion production and should be combined with an anticholinergic agent.

Propofol, administered intravenously, is becoming increasingly popular for many procedures in adults and children.[27] The amnestic effects are dose dependent and variable, so often a benzodiazepine is coadministered to ensure amnesia. Lidocaine is frequently coadministered to minimize the stinging sensation engendered by direct intravenous administration. Additionally, propofol can produce myotonic activity during administration that can mimic seizures. Continuous propofol infusions in the pediatric intensive care unit are contraindicated due to cases of unexplained metabolic acidosis and death in children. However, short-term use for procedural sedation is a safe practice. The infectious risks of propofol administration must be considered carefully; the solution is a rich medium for growth of bacteria, and there have been cases of serious infectious consequences of propofol prepared in a nonsterile manner. The generic preparation contains sulfites, which can cause allergic responses in sensitized individuals.

Etomidate, also administered intravenously, is sometimes used despite a paucity of pediatric data. Although touted as preserving cardiopulmonary function, potential complications include the drug's proemetic effects as well as effects on steroidogenesis.

INHALATIONAL AGENTS

Inhaled anesthetics are often the ideal agents to use during an airway procedure. Halothane is less commonly used and is being supplanted by newer, safer agents that are far better tolerated, such as sevoflurane.[29] These agents can be used as total anesthetics, providing all the necessary components of hypnosis, sedation, analgesia, bronchodilation, and airway anesthesia.[30] Assurance must be focused on adequate depth of anesthesia. Unfortunately, depth of anesthesia is difficult to assess. Bispectral (BIS) monitoring is sometimes utilized to evaluate the depth of hypnosis in adults, but it has not been consistently validated in children.[31] Manipulation of the airway in an inadequately anesthetized patient (i.e., stage 2 anesthesia) can result in severe laryngospasm, bronchospasm, and decompensation. The inhaled agents also have the advantage of preserving spontaneous ventilation (albeit with a blunted carbon dioxide response to breathing), thus allowing for assessment of vocal cord function. Some agents such as sevoflurane are much better tolerated than are other agents such as desflurane. First cases in the operating room on Monday morning should be preceded by adequate flushing of the machine to avoid toxic byproducts. The improved tolerance to sevoflurane includes lower risks of laryngospasm and bronchospasm during the procedure and on emergence from the procedure (see Table 26-4).

MECHANICS (LUNG, CHEST WALL, AND FUNCTIONAL RESIDUAL CAPACITY)

Total respiratory system compliance (C_{rs}) decreases during anesthesia, although the mechanisms by which this occur are somewhat controversial. One hypothesis is that anesthetics (or mechanical ventilation during anesthesia) might directly alter pulmonary surfactant, although evidence for this is quite limited.[32] Alternatively, C_{rs} might be reduced as a consequence of lowered lung volume (see later) due to airway closure or atelectasis. Although not an effect of anesthesia per se, CO_2 insufflation for laparoscopic procedures is a well-defined cause of decreased lung compliance.[33]

Airway resistance also decreases with inhaled anesthestics; the decrease is thought to be due to direct inhibition of autonomic mediators (e.g., acetylcholine) on airway smooth muscle (ASM) tone.[34] Ketamine may induce bronchodilation via release of cathecholamines and their effects on β_2-adrenergic receptors on ASM or via other mechanisms.[35,36] Airway resistance can also increase as a result of histamine release due to neuromuscular blockade, although this is not always clinically apparent. In one study, rapacuronium decreased forced expiratory flows in children anesthetized with remifentanil and propofol, although total respiratory system resistance increased nonsignificantly.[15] Changes in forced expiratory flow and mechanics with mivacurium were comparatively much smaller. Upper airway resistance increases due to loss of pharyngeal muscle tone, and this is usually managed with use of distending pressure, an artificial airway, or both. A variety of techniques have been used to measure mechanics, including single-breath occlusion techniques[37] and low-frequency forced oscillation.[38]

Anesthetics and muscle relaxation can affect both the chest wall (including the diaphragm) and the lung, such that the elastic recoil of the respiratory system increases, favoring a decrease in lung volume (Fig. 26-2). This mechanism has been well demonstrated in an animal model.[39,40] It is therefore not surprising that resting lung volume (functional residual capacity [FRC]) decreases 15% to 20% during anesthesia with spontaneous breathing. This reduction occurs early during anesthesia, and the degree of reduction is not significantly affected by the use of paralytics. These effects might be particularly important in infants, whose chest wall is highly compliant compared with their lungs (or compared with the chest walls of older children), further reducing elastic recoil pressure and FRC. Indeed, infants actively maintain their lung volume above that which would be passively determined

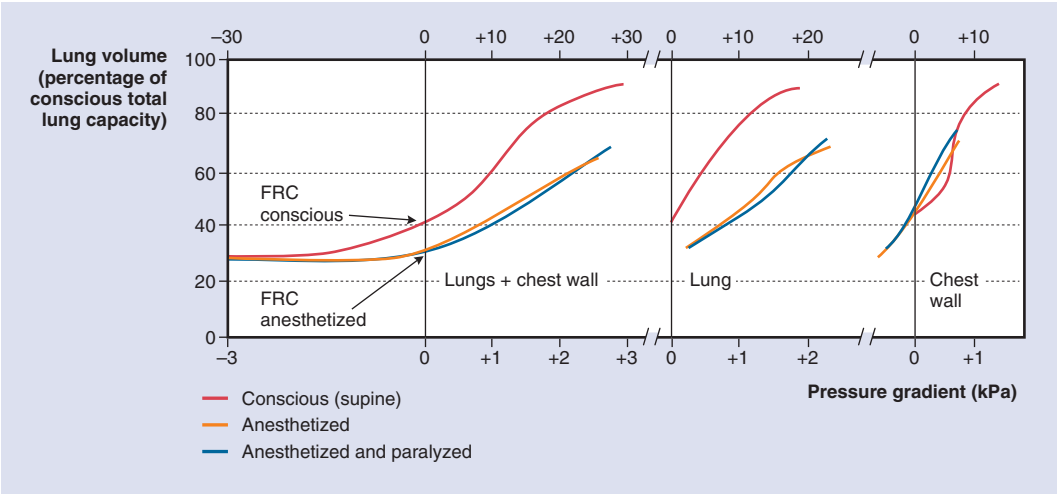


Figure 26-2 Pressure and volume relationships in healthy adults before and after anesthesia (with and without paralysis). The respiratory system (lungs + chest wall) becomes significantly less compliant during anesthesia, without significant differences related to use of paralysis. The majority of these mechanical changes appear to be due to changes in lung, rather than chest wall, compliance. Note that FRC (denoted by the arrows) decreases significantly with anesthesia. (Redrawn with permission from Nunn JF: Nunn's Applied Respiratory Physiology, 4th ed. Stoneham, Mass, Butterworth-Heinemann, 1993.)

by elastic recoil with strategies such as postinspiratory activity of the diaphragm and glottic braking[41,42]; the effectiveness of these strategies are likely attenuated during anesthesia.

These effects can reduce the lung volume to near residual volume, and potentially below the closing capacity, resulting in airway closure and atelectasis. This lowered lung volume reduces lung compliance and increases airway resistance, offsetting the beneficial effects of anesthetics on airway smooth muscle tone. Significant atelectasis increases $\dot{V}/\dot{Q}$ mismatch and intrapulmonary shunt (see later).

VENTILATION AND BRONCHOMOTOR TONE

The reductions in lung and respiratory system compliance and in FRC cause functional reductions in ventilation in patients undergoing anesthesia. Diminished neural drive also reduces minute ventilation and alters the pattern of inspiratory muscle activation between the diaphragm and intercostal muscles. Anesthesia preferentially depresses the intercostal muscles over the diaphragm, leading to an altered pattern of chest wall motion (Fig. 26-3). These changes may or may not be compensated for by the administering anesthetist, who can control the rate and depth of respiration, the PEEP, and the fractional inspired concentration of oxygen.

The presence of an endotracheal tube can promote bronchospasm in some susceptible patients. This complication is more likely in the setting of asthma, but viral upper respiratory tract infections can also predispose to airway hyperreactivity in otherwise healthy children. Although in the past, a recent (in the past 2 to 4 weeks) or current URI usually was viewed as cause for cancellation of anesthesia (usually for 4 to 6 weeks), these guidelines have been somewhat relaxed.[43-45]

Increased airways resistance can also result from upper airway obstruction due to anesthesia-induced loss of upper airway muscle tone, because muscles of the upper airway are the most susceptible respiratory muscles to the depressant

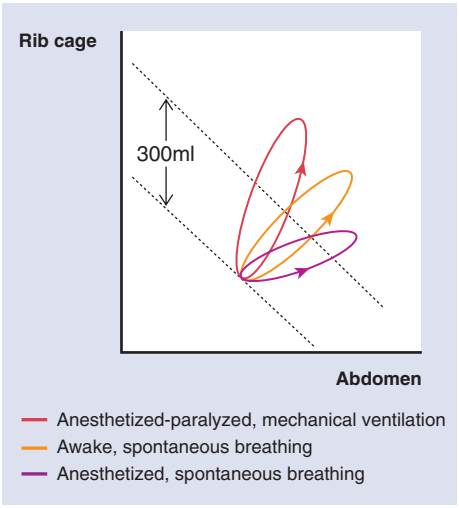

Figure 26-3 Rib cage and abdominal excursions (measured by inductance plethysmography) and their relative contribution to tidal volume change in awake, anesthetized, and paralyzed subjects. Note that the rib cage contribution to ventilation decreases during anesthestized spontaneous breathing, and is increased by mechanical ventilation. (Redrawn with permission from Handbook of Physiology: Section 3. The Respiratory System, Section Editor: Alfred P. Fishman: Volume III: Mechanics of Breathing, edited by Peter T. Macklem and Jere Mead, Part 2. Bethesda, MD, The American Physiological Society, 1986.)

effects of anesthesia. In the absence of an endotracheal tube, use of a laryngeal mask or face mask with an oral airway ameliorates this complication in both infants[46] and young children.[47] Finally, because airway caliber is lung volume dependent, the reduction of FRC due to anesthesia can increase airways resistance. However, most anesthetic gases have bronchodilating effects, and this can counteract the reduction in FRC, leading to little net change in the airways resistance in the spontaneously breathing patient (Fig. 26-4, points B-D). Administration of PEEP can counteract this

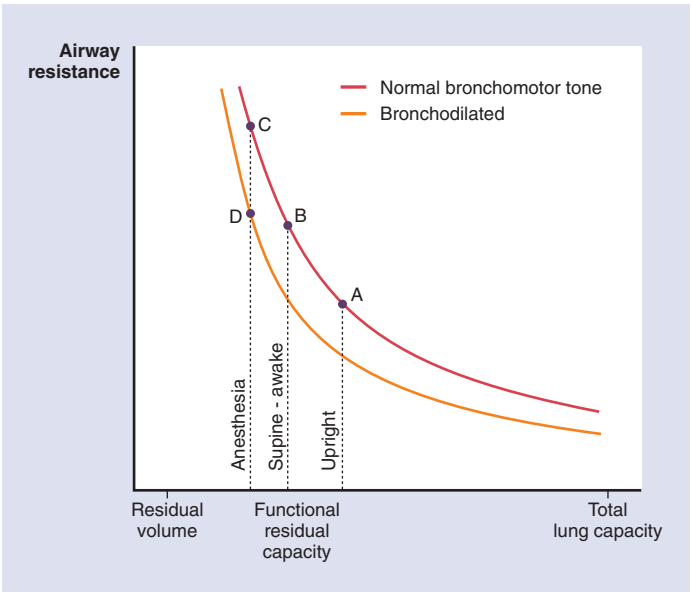

Figure 26-4 Airway resistance as a function of lung volume. Airway resistance rapidly increases as lung volume decreases below functional residual capacity and with reduction of FRC during anesthesia (points B-C). Bronchodilation with inhaled anesthetics offsets the change in resistance due to lowered lung volume (points C-D). (Redrawn with permission from Nunn JF: Nunn's Applied Respiratory Physiology, 4th ed. Stoneham, Mass, Butterworth-Heinemann, 1993.)

increase of lower airways resistance resulting from reduction of FRC, as well as the increase of upper airways resistance resulting from loss of upper airway motor tone. Such PEEP may be intentionally administered, or result from either advertently or inadvertently choosing a respiratory rate and ventilation strategy in which the expiratory time is short relative to the expiratory time constant of the respiratory system.

During anesthesia, ventilation to the dependent regions is markedly diminished, probably due to atelectasis engendered by the low FRC state (Fig. 26-5). Use of computed tomography has clearly demonstrated atelectasis in dependent lung regions.[48] In addition, anesthesia alters the vertical distribution of ventilation along the normal lung, with less prominent differences of ventilation between lower and upper regions seen than in the awake state (Fig. 26-6). Application of PEEP restores much of the normal ventilation gradient by recruiting atelectatic areas and perhaps by overdistending apical lung regions, making them less compliant.[49]

PULMONARY BLOOD FLOW AND PULMONARY VASCULAR RESISTANCE

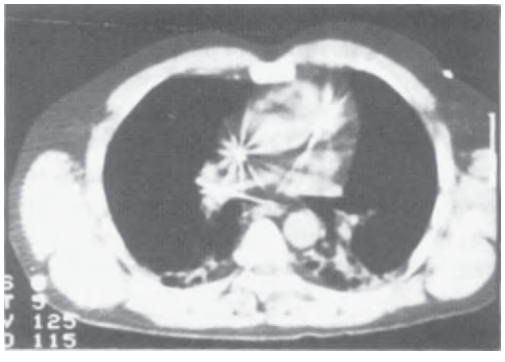
In contrast to the distribution of ventilation, lung perfusion increases from the upper to the more dependent regions of the lung, except at the bottom-most region, in which pulmonary blood flow is also diminished (see Fig. 26-6). The vertical distribution of blood flow is similar to that in the awake state and is related to the hydrostatic gradient.

Hypoxic pulmonary vasoconstriction is diminished by up to 50%, but not abolished, by several inhalational anesthetics; this may not be the case with intravenous anesthetics such as barbiturates. Loss of hypoxic pulmonary vasoconstriction, while somewhat of a protection against rises in pulmonary artery pressure engendered by alveolar hypoxia, leads to regions of low $\dot{V}/\dot{Q}$.

VENTILATION/PERFUSION MATCHING

The multiple inert gas elimination technique has clarified the mechanisms of gas exchange abnormalities that occur during anesthesia. The redistribution of ventilation (and to a lesser extent perfusion) during anesthesia also leads to alterations in $\dot{V}/\dot{Q}$ matching (Fig. 26-7). Greater relative ventilation to the apices leads to increased regional dead space ventilation ($\dot{V}/\dot{Q} > 1$) in a tidal volume–dependent fashion (Fig. 26-8).

Figure 26-5 Three-dimensional reconstruction of chest computed tomography scans of a patient under anesthesia. Note bilateral dependent atelectasis that is less prominent toward the lung apices. (Reprinted with permission from Hedenstierna G: Respiratory Measurement [Principles and Practice Series]. Ames, IA, Blackwell BMJ Books, 1998.)



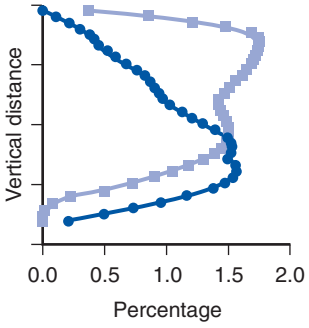


Figure 26-6 Anatomic and physiologic assessment of ventilation/perfusion. The CT scan (*left*) demonstrates dependent atelectasis in this anesthetized patient. Ventilation and perfusion are assessed (at *right*) using SPECT and radioactively labeled albumin. Perfusion (*dark circles*) is highest in the lower regions, while ventilation (*light squares*) is highest in the upper regions and absent in the atelectatic areas at the bottom. (Reprinted with permission from Hedenstierna G: Respiratory Measurement [Principles and Practice Series]. Ames, IA, Blackwell BMJ Books, 1998.)

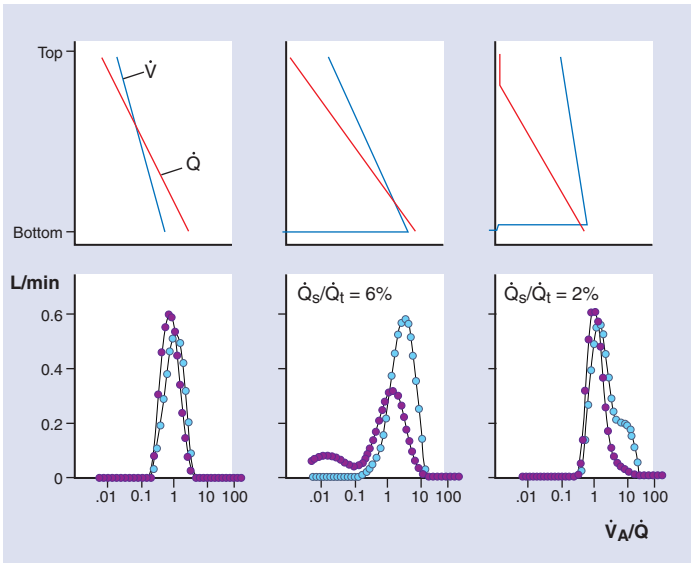

Figure 26-7 Ventilation (*blue circles*)/perfusion (*purple circles*) relationships during anesthesia. $\bar{V}/\dot{Q}$ distributions (as assessed by multiple inert gas technique) are depicted at the *bottom*, and relationships of ventilation and perfusion to lung zones are depicted at the *top*. Note the unimodal distributions of ventilation and perfusion, centered around $\bar{V}/\dot{Q} = 1$ in the awake patient (*left*) and that ventilation and perfusion both increase toward the bases. In the anesthetized patient (*center*), there are increased lung units with very low $\bar{V}/\dot{Q}$ (shunt), which results in oxyhemoglobin desaturation and decreased perfusion to some lung units with preserved ventilation (higher $\bar{V}/\dot{Q}$), which results in hypercarbia. Application of 10 cm H_2O PEEP (*right*) tends to restore normal $\bar{V}/\dot{Q}$ distribution and decrease shunt, although some areas with high $\bar{V}/\dot{Q}$ are receiving increased ventilation. (Reprinted with permission from Hedenstierna G: Respiratory Measurement [Principles and Practice Series]. Ames, IA, Blackwell BMJ Books, 1998.)

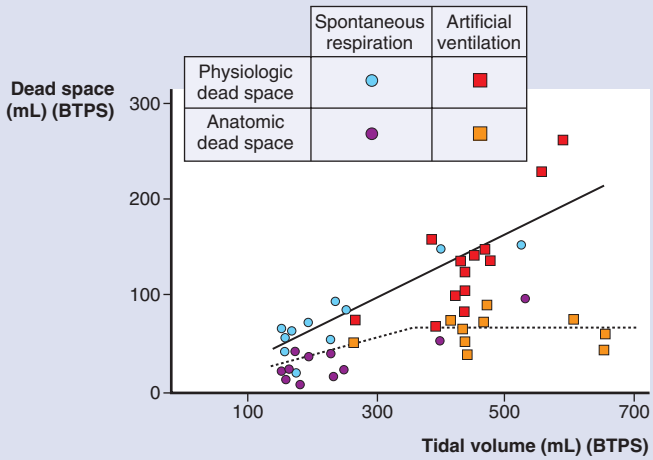

Figure 26-8 Anatomic and physiologic dead space during spontaneous and mechanical ventilation (during anesthesia). Physiologic dead space (anatomic dead space plus alveolar dead space) increases linearly with tidal volume, during both spontaneous and mechanical ventilation, maintaining a constant $\bar{V}_d/\bar{V}_t$. Anatomic dead space remains relatively constant over a range of normal adult tidal volumes but decreases at low tidal volumes (<350 mL). Thus, the increase in physiologic dead space during anesthesia is largely due to increased alveolar dead space. (Redrawn with permission from Nunn JF: Nunn's Applied Respiratory Physiology, ed 4. Stoneham, Mass, Butterworth-Heinemann, 1993.)

Loss of hypoxic pulmonary vasoconstriction results in low $\dot{V}/\dot{Q}$ regions ($\dot{V}/\dot{Q} < 1$), while atelectasis can cause frank shunting ($\dot{V}/\dot{Q} = 0$). Low and zero $\dot{V}/\dot{Q}$ regions widen the A – a gradient for oxygen, while dead space regions increase the dead space to tidal volume ratio, resulting in alveolar hypoventilation and hypercarbia. Application of PEEP can reduce low $\dot{V}/\dot{Q}$ and shunt, thereby reducing the A – a gradient for oxygen.[50,51] Supplemental oxygen increases alveolar P_{O_2} as well. PEEP, however, can increase dead space ventilation (see Figure 26-7, *right*) and must be used judiciously, in order to prevent hypercarbia. The latter can also be diminished by increasing the ventilatory rate.

The addition of pressure support ventilation to end-expiratory pressure further enhances gas exchange in anesthetized children, decreasing end-tidal P_{CO_2}, respiratory rate, work of breathing, and pressure-time product.[52]

Sedation can also cause $\dot{V}/\dot{Q}$ mismatch. Conscious or deep sedation has been associated with oxygen desaturation to less than 90% in 1.7% of children undergoing flexible fiberoptic bronchoscopy. This complication is associated with age less than 2 years, laryngotracheal abnormalities, and deep (compared with conscious) sedation.[53]

CONTROL OF VENTILATION

There are five main determinants that control breathing: carbon dioxide concentrations in the blood and brain, oxygen concentrations, acid-base status in brain, degree of stretch sensed in the lungs, and conscious control (such as anxiety). All anesthetic agents affect each of these, to varying degrees.

One afferent limb of this response is in the central chemoreceptors in the floor of the fourth ventricle. These cells respond to the acidity of the cerebrospinal fluid. The acidity is most affected by carbon dioxide, which diffuses freely from the arterial blood to the cerebrospinal fluid. Other causes of acidity such as ketoacidosis can stimulate this response as well. Another afferent limb is in the carotid and aortic bodies' peripheral chemoreceptors, which respond to the oxygen and, to a lesser extent, carbon dioxide concentrations in arterial blood. The carotid body is located at the division of the common carotid artery into the external and internal carotid arteries. The aortic body is found on the aortic arch and may exert its predominant effects on circulation rather than ventilation. The afferent limb from the carotid body is carried along the glossopharyngeal nerve, and the afferent limb from the aortic body is along the vagus nerve. Virtually all anesthetics affect these physiologic responses. Irritant receptors in the wall of the bronchi cause coughing, breath-holding, and sneezing. These receptors can be anesthetized by local and/or systemic administration of lidocaine. In the elastic tissues of the lung and the chest wall are receptors that respond to stretch. In the absence of adequate stretch such as diminished tidal volumes, these receptors stimulate hyperventilation. These stretch receptors are very difficult to anesthetize, so in the face of restrictive lung disease, hyperventilation is only minimally affected by anesthetic agents. There are also stretch receptors in the blood vessels of the lung, which, when distended, such as in heart failure, stimulate breathing. Narcotics administered by inhalation or systemically can diminish this cause of dyspnea.

Anxiety can lead to hyperventilation, which can disturb the acid-base status of the body as well as the normal control of breathing. The most effective way to pharmacologically treat this is with benzodiazepines.

The efferent limb from the respiratory center passes down the spinal cord to the diaphragm, intercostal muscles, and accessory muscles of inspiration in the neck. The diaphragm is supplied by the phrenic nerve (spinal nerves C3-5) The intercostal muscles are segmentally innervated by intercostal nerves (T1-12) The accessory muscles in the neck are supplied from the cervical plexus.

The effects of the anesthetics on respiratory control are summarized in Table 26-4. The effects of the anesthetics are often synergistic rather than additive, so that a small amount of a potent inhalational anesthetic as well as a narcotic will have a profound effect on carbon dioxide responsivity as well as apneic threshold. Decrease in the apneic threshold results in the initiation of breathing at a higher level of arterial carbon dioxide than is usual (around 40 mm Hg). The ventilatory responses to CO_2 (slope and apneic threshold) both decrease in a dose-dependent manner. It is a common misconception that some agents such as ketamine do not affect carbon dioxide responsivity, apneic threshold, or cardiovascular stability. Although this is true to some degree, ketamine can affect these factors in a dose-dependent manner. Because the doses required to affect these physiologic changes are higher than those with other agents, ketamine is viewed as a safer agent. This agent, as well as propofol and etomodate, must be treated with the same degree of respect as any of the anesthetic agents, for deeper levels of anesthesia can be achieved quickly with escalating doses of any anesthetic. Many anesthetics have an effect on muscle strength independent of the neural control of breathing. Benzodiazepines relax muscles and diminish respiratory muscle strength at the level of the spinal cord.

MUCOCILIARY CLEARANCE

Normal mucociliary clearance is important for local defense of the airways against infection and obstruction by secretions. Mucociliary clearance can be affected by either alteration of ciliary motion or alteration of airway secretions. Inhalation of dry gases (such as could occur during mechanical ventilation in the operating room) can diminish ciliary function but can be reversed with the addition of humidification to the inspired gas. Studies of respiratory secretions obtained from endotracheal tubes during elective surgery demonstrated no abnormalities in mechanical properties (e.g., viscoelasticity, rigidity), suggesting that mucociliary transport is altered via other mechanisms.[54] A cuffed endotracheal tube can cause direct trauma to airway mucosa and its ciliated epithelium, mechanically impairing ciliary clearance. In animal models, several inhaled anesthetics (including halothane and enflurane), as well as some intravenous agents (i.e., thiopental), have been shown to diminish ciliary activity.[55,56] This may be due to decreasing beat frequency or synchronous motion of the cilia. These effects may be prolonged, and should be considered especially important for patients with impaired cough clearance (e.g., neuromuscular weakness) or underlying diseases (cystic fibrosis, ciliary dyskinesia), which could further impair clearance of secretions.

COUGH

The incidence of significant symptomatic cough during general anesthesia is 4% to 6%.[57,58] Coughing can happen at any time during anesthesia and can significantly interfere with operative procedures. However, the most vulnerable periods are during intubation/induction and emergence. Irritation of laryngeal and tracheal receptors is more likely to cause cough than is irritation of bronchial receptors during anesthesia.[59] The depth of anesthesia also plays a role; light anesthesia exaggerates the cough reflex and prolongs it, while the deepest levels of anesthesia suppress the cough reflex (see Table 26-2). Various anesthetic agents have differing potentials for inducing cough; for example, isoflurane is more potent than halothane in precipitating the cough reflex.[60,61]

Various agents have been used to suppress anesthetic-induced cough. Intravenous lidocaine suppresses cough during intubation.[62,63] It was most effective when given at a dose of 2 mg/kg 1 to 5 minutes before intubation.[64] Lidocaine can also be given via endotracheal tube or instilled through the instrument channel of the bronchoscope to effectively suppress cough during anesthesia.[65] Albuterol and atrovent are not as effective.[45]

HEMATOLOGIC/OXYGEN DELIVERY EFFECTS

Some topical/local anesthetics (e.g., lidocaine, prilocaine,[66] benzocaine,[67,68] cetacaine) can oxidize the iron molecule in heme ($Fe^{2+} \rightarrow Fe^{3+}$), producing methemoglobin and reducing oxygen affinity. Congenital enzyme deficiencies (cytochrome b5 deficiency) or hemoglobin variants (e.g., hemoglobin M) can accentuate this potential toxicity. The presence of high concentrations of MetHb can produce erroneous readings with noninvasive pulse oximetry, with SpO_2 values trending toward 85% regardless of the PaO_2 and SaO_2. However, this is not simply an interesting artifact of measurement, as actual oxygen content [CaO_2 (mL/dL) = 1.34 mL of O_2/dL × Hb g/dL × SaO_2%] and delivery (delivery = content × ca rdiac output) will be reduced. Treatment of symptomatic methemoglobinemia involves use of methylene blue to reduce the heme in methemoglobin and avoidance of inciting agents.

CHAPTER 27 Therapy-Induced Pulmonary Disease

Jonathan Steinfeld and Daniel V. Schidlow

TEACHING POINTS

- Therapy-induced pulmonary disease is often a diagnosis of exclusion.
- One therapy may cause several different pathologic patterns.
- Acute and chronic pathology may be present at the same time.
- The entire respiratory system is susceptible to injury.
- Prognosis is extremely variable.

More than 350 pharmacologic agents can cause pulmonary disease.[1] With few exceptions, most reports of therapy-induced pulmonary disease concern adult patients. The incidence of such disease in the pediatric population is very difficult to estimate. Usually the diagnosis is one of exclusion, as there are no specific laboratory tests to corroborate a causative effect for many of these agents. Adding to this uncertainty, the signs and symptoms of therapy-induced pulmonary disease are often similar to the pulmonary complications of an underlying disease. Furthermore, the onset of lung disease may occur long after the administration of the medication has been started or discontinued. Physicians must be aware of the agents that commonly lead to pulmonary disease and constantly be alert for symptoms that can be due to new therapies, which have not been previously described.

This chapter highlights some of the more common therapies that damage the lungs, but it is not comprehensive. Literature and Internet searches are recommended for more complete information. The Website www.pneumotax.com is an excellent resource that may be searched by either medication name or pattern of injury.

PATHOGENESIS

The two main routes for therapies to affect the respiratory system are through either inhalation or systemic circulation. A third, less common route, radiation therapy, directly damages cells.

The vast majority of deleterious inhaled agents are industrial and nontherapeutic. Patients may inhale smoke or other particulate matter that can damage epithelial cells directly or induce bronchospasm.

Medications given systemically, either orally or intravenously, reach the lungs through the bronchial blood supply. Although not harmful in their native states, medications are biotransformed—or activated—in the lungs. This biotransformation has two phases.[2] In phase I, the medication undergoes an oxidative reaction through enzyme systems such as cytochrome P450–dependent mono-oxygenases, flavin-containing mono-oxygenases, or prostaglandin synthase. This metabolite is then conjugated in phase II. Conjugation typically increases excretion by binding a lipid soluble particle to a water-soluble carrier. Damage can occur if the metabolite from phase I is not cleared by phase II or if the phase II metabolite is so toxic that any accumulation leads to cellular injury.

The bioactivated metabolites of certain medications damage cells through oxidative stress. Harmful medications create reactive electrophilic metabolites, which lead to cellular dysfunction or mutations when they bind to essential macromolecules. Other medications produce activated oxygen species, such as superoxide anion, hydrogen peroxide, and hydroxyl radicals. These oxygen free radicals overwhelm native antioxidant defense systems, creating oxidative stress.

PATHOLOGY

The entire respiratory system is susceptible to therapy-induced injury. The airways, alveoli, interstitium, vasculature, and the pleural spaces can all experience damage by medications. It is helpful to classify the different types of histologic damage; however, because the lungs' response to injury is limited, there is significant overlap from even one harmful agent. In fact, acute and chronic injury may be seen in the same biopsy. See Box 27-1 for histologic patterns that have been associated with therapy-induced pulmonary disease.[3] Other manifestations, such as bronchospasm and cough, do not have histologic findings.

CLINICAL MANIFESTATIONS

Despite the lungs' relatively limited pathologic responses, therapy-induced lung disease has many clinical manifestations. Dividing these manifestations anatomically helps to make some sense of this wide spectrum. Therapeutic damage can be classified anatomically: the airways, alveoli, interstitium, vasculature, and pleural spaces. These are not discrete categories, as very frequently there is overlap in damage to several anatomic regions from the same agent.

BOX 27-1 Histologic Patterns Associated with Therapy-Induced Pulmonary Disease

Pulmonary edema
Alveolar hemorrhage
Alveolar proteinosis-like reaction
Diffuse alveolar damage
Organizing pneumonia
Usual interstitial pneumonia–like pattern
Diffuse cellular interstitial infiltrates ± granulomas
Nonspecific interstitial pneumonia
Acute or chronic eosinophilic pneumonia
Small-vessel angiitis
Pulmonary arterial hypertension
Pulmonary veno-occlusive disease

BOX 27-2 Therapies Associated with Airways Disease

Bronchospasm
- Amphotericin B
- Aspirin
- β-Blockers
- Erythromycin
- Methotrexate
- Nitrofurantoin
- NSAIDs

Cough
- ACE inhibitors
- Fentanyl
- Methotrexate
- Nebulized hypertonic saline
- Nebulized medications
- Nitrofurantoin
- Propofol

Bronchiolitis obliterans organizing pneumonia (BOOP) or bronchiolitis obliterans (BO)
- Amiodarone
- Amphotericin B
- Bleomycin
- Carbamazepine
- Interferon α
- Minocycline
- Nitrofurantoin

AIRWAYS

Damage to the airways can lead to bronchospasm, cough, bronchiolitis obliterans organizing pneumonia (BOOP), or bronchiolitis obliterans (BO).[4] Box 27-2 lists therapies that commonly affect the airways.

Bronchospasm can present as cough, wheezing, or simply chest tightness. Children who are able to do pulmonary function testing may show a decreased FEV_1/FVC ratio or FEF_{25-75}. Bronchospasm can be caused by a large list of medications and exposures but is most commonly caused by aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs), or β-blockers.

While aspirin should be avoided in all pediatric patients, there are still many over-the-counter preparations that contain aspirin that parents may be unaware of. Aspirin-induced asthma has been recognized since 1922 and has been estimated to be present in up to 4% of children.[5,6] NSAIDs are a commonly used class of medications that lead to bronchospasm through the same mechanism as aspirin. Both aspirin and NSAIDs inhibit cyclooxygenase, which leads to decreased prostaglandin synthesis and subsequently increases activation of the leukotriene pathways. Leukotrienes are proinflammatory agents that increase mucus secretion, vascular permeability, airway edema, and eosinophil recruitment.[7]

β-Blockers are also rarely used in pediatrics but can lead to exacerbations in children with asthma. Although the exact mechanism is unknown, it follows that because β-agonists relieve bronchospasm in asthmatics, the delivery of a β-blocker will create bronchospasm. β-agonists do not relieve the bronchospasm because the receptors are already blocked; therefore, inhaled anticholinergics are the treatment of choice.

Cough can be caused by airway irritation, stimulation of cough receptors, or an unknown pathophysiology. Nebulized medications, such as hypertonic saline and antibiotics, irritate larger airways—which leads to coughing. This cough is typically self-limited and temporally related to the medication responsible. Reaction to fentanyl is a good example of cough secondary to a pulmonary chemoreflex, as 50% of patients will cough due to stimulation of the J receptors.[4] Angiotensin-converting enzyme inhibitors are notorious for having cough as a side effect, the exact mechanism of which is unknown.

BOOP can be caused by antimicrobials, chemotherapy, cardiac medications, and anti-inflammatories. Currently, more than 20 different medications have been linked to causing BOOP.[8] Drugs that are strongly associated with BOOP include minocycline, nitrofurantoin, bleomycin, amiodarone, carbamazepine, penicillamine, gold therapy, and illicit drug use. Unfortunately, it is often difficult to determine whether BOOP is secondary to the primary disease or the therapy used to treat that disease.

BOOP causes lower airway obstruction because of an intraluminal organized mass. The lumina of the small airways and alveolar spaces are filled with a polypoid endobronchial connective tissue mass.[4] Bronchiolitis obliterans differs from BOOP in that it spares the alveoli. The small bronchi and bronchioles are "obliterated" by fibrous tissue. Patients with either condition may present with such nonspecific symptoms as cough or shortness of breath. Pulmonary function testing shows an obstructive defect with air trapping. Luckily, many of the reported cases of therapy-induced BOOP have improved after cessation of the drug, although some have required glucocorticoids.[8]

Alveoli

Alveolar spaces can be the initial area of therapy-induced lung disease or, more commonly, the end result of interstitial damage. Alveolar damage includes exogenous lipoid pneumonia, radiation pneumonitis, eosinophilic pneumonia, pulmo-

nary edema, and acute respiratory distress (ARDS). Box 27-3 lists therapies that commonly lead to alveolar disease.

Exogenous lipoid pneumonia can be a consequence of a variety of therapies. From mineral oil for constipation to oily nasal drops for nasal congestion, culture-specific therapies may place children at high risk of aspiration.[9] The severity of the pneumonia is dependent on the amount as well as the type of oil aspirated. Animal oil produces an intense inflammatory response, while mineral oil has more of a foreign body–like reaction. Lipid-laden macrophages can be found on bronchoalveolar lavage with Oil-Red-0 or Sudan black stain.

Acute radiation pneumonitis occurs in 5% to 10% of patients who receive radiation therapy to the chest.[10] Lung cancer secondary to metastases is the disease most frequently associated with pneumonitis, but radiation for the treatment of breast cancer, Hodgkin's disease, and non-Hodgkin's lymphoma may damage normal lungs. Pneumocytes, endothelial cells, and the interstitium are the first site of injury. Next, surfactant leaks into the alveolar spaces and interstitial edema develops. In the later stages, the chronic inflammatory response develops into pulmonary fibrosis. Patients may present with dyspnea out of proportion to the area irradiated 4 to 6 weeks after therapy.

Eosinophilic pneumonia, also known as hypersensitivity pneumonitis, occurs when eosinophils migrate and preferentially accumulate in the lung tissue. Eosinophils fight microorganisms by releasing cytotoxic chemicals from their granules. If an eosinophil in the lungs degranulates in response to a drug, then these chemicals will also harm the surrounding lung tissue. Patients may have a cough, dyspnea, or no symptoms at all. Therapy-induced eosinophilic pneumonia may also present with systemic reactions, like a fever or rash. Chest radiographs demonstrate patchy segmental or subsegmental infiltrates that are often migratory. Peripheral blood eosinophils are usually elevated. The ideal test is either bronchoscopy or lung biopsy. However, because the symptoms typically resolve with the removal of the offending agent, invasive studies may not be necessary. In contrast to therapy-induced eosinophilic pneumonia, idiopathic chronic eosinophilic pneumonia typically does not have systemic symptoms and patients improve quickly with corticosteroids.[11]

Therapy-induced pulmonary edema and ARDS are typically caused by idiosyncratic reactions to medications. The pathophysiology behind these reactions is poorly understood, but capillary leak, hypervolemia, and anaphylaxis have all been suggested as possible mechanisms.[12] Pulmonary edema can be caused by a wide variety of therapies. Fewer therapies cause ARDS; these are commonly antineoplastics, immune suppressants, amiodarone, nitrofurantoin, and talc. Symptoms are vague and chest radiographs are nonspecific—except for the notable absence of the cardiomegaly that typically accompanies pulmonary edema.

Interstitium

Therapy-induced interstitial lung disease (ILD) presents in a wide variety of histologic patterns. Damage can manifest as cellular and fibrotic nonspecific interstitial pneumonia, pulmonary infiltrates and eosinophilia, organizing pneumonia, lymphocytic interstitial pneumonia, desquamative interstitial pneumonia, pulmonary granulomatosis–like reaction, and a usual interstitial pneumonia–like pattern.[3] The list of medications that can lead to ILD is extensive and medications frequently cause more than one pattern of histopathologic damage[13] (Box 27-4). The histology is so nonspecific that the mechanism of injury is often unknown.

Bleomycin is an antineoplastic agent used to treat lymphomas and testicular carcinomas whose mechanism of action is to reduce oxygen to free radicals, and it is notorious for its toxic pulmonary effects. Bleomycin has been extensively studied in animals—although rarely in humans.[14] While chemotherapy with bleomycin can induce BO with organizing pneumonia or eosinophilic hypersensitivity, the most common pulmonary manifestation is interstitial pneumonitis leading to pulmonary fibrosis. Depending on the criteria used for diagnosis, bleomycin-induced pneumonitis (BIP) may occur in anywhere from none to 46% of patients.[14] The lungs are particularly susceptible to drug accumulation because pulmonary epithelial cells have lower levels of bleomycin hydrolase.[15] Damage occurs due to a decrease in alveolar type I cells. Alveolar type II cells are vulnerable to bleomycin only during periods of proliferation or differentiation into type I cells. The subsequent loss of type I cells creates interstitial inflammation. Fibroblastic repair and collagen synthesis lead to the deposition of fibrin and collagen in the septal walls.[16]

Vasculature

Damage to the pulmonary vasculature leads to several different types of lung injury. The most common histopathologic pattern is pulmonary capillaritis—which has been reported after diphenylhydantoin, propylthiouracil, and all-*trans* retinoic acid. Neutrophils infiltrate the interstitial spaces leading

Penicillamine
Propylthiouracil
Streptokinase
Surfactant

to edema and neutrophilic fragmentation. The inflammatory response to the damaged neutrophils also destroys the capillary walls, allowing red blood cells and more neutrophils to freely enter the alveolar spaces.[17] While this histologic pattern is similar to the alveolar hemorrhage seen in systemic lupus erythematosus (SLE), it is rare in drug-induced lupus.[18]

Several chemotherapeutic agents have been reported to cause pulmonary veno-occlusive disease through either an immune response or a hypersensitivity reaction. The pulmonary vasculature is occluded by fibrin, creating pulmonary hypertension, signs of left atrial hypertension, and alveolar hemorrhage.[17] Alveolar hemorrhage is also present during the diffuse alveolar damage (DAD) that occurs after chemotherapy and crack cocaine use.

Alveolar hemorrhage may occur without any signs of vasculitis. Anticoagulation therapy leads to alveolar hemorrhage, which is characterized by red blood cells packing into alveolar spaces without any other inflammation or damage.[17] See Box 27-5 for therapies that commonly lead to vasculitis.

Pleural Spaces

Close to 30 different therapies have been reported to cause pleural disease (Box 27-6). Presentations include asymptomatic pleural effusions, pleural fluid eosinophilia, or acute pleuritis. Pleural effusions have been reported with the use of two European β-blockers (practolol and oxyprenolol), methotrexate, and sclerosing agents such as sodium morrhuate and absolute alcohol.[19] Pleural effusions secondary to amiodarone toxicity are rare and almost always associated with parenchymal infiltrates.[20] Pleural effusions with greater than 10% nucleated cells are defined as pleural fluid eosinophilia. Of the eight drugs associated with this eosinophilia, isotretinoin, dantrolene, nitrofurantoin, and valproic acid are frequently used in pediatric patients.

More than 80 medications have been implicated in drug-induced lupus (DIL). Pleural effusions and pleuritis are very common in DIL, with a prevalence ranging from 15% to 60%.[21] Pleural effusions are exudative and usually have normal pH and glucose levels. DIL pleuritis rapidly improves after the discontinuation of therapy and only rarely do prolonged symptoms require treatment with NSAIDs or corticosteroids.[19]

DIAGNOSIS

With the ever-expanding list of medications that can damage the lungs, it is difficult to determine exactly which drug is the culprit. Some medications cause damage immediately, while others may not show clinical signs for years. Often, patients are on multiple medications, and it is not immediately clear which is the offending agent. In addition, there are many disorders, especially rheumatologic diseases, where both the disease and the therapy can lead to pulmonary pathology. To further cloud the issue, some over-the-counter medications can create clinical pictures that mimic primary diseases. The anorectics, for example, are well known to induce pulmonary hypertension. However, because few patients will admit to taking appetite suppressants, they may be misdiagnosed with primary pulmonary hypertension.[22] In an effort to help clinicians, Irey[23] created a list of questions to help guide the evaluation of suspected therapy-induced pulmonary disease (Box 27-7).

BOX 27-7 Evaluation of Suspected Therapy-Induced Pulmonary Disease

Correct identification of the drug in question
  Was the patient taking the drug?
  What dose?
  What duration?
Exclusion of other primary or secondary lung diseases
Temporal eligibility: appropriate latent period (exposure to toxicity)
Remission of symptoms with removal of challenge
Recurrence with rechallenge
Singularity of drug
  Are there multiple medications?
Characteristic pattern of reaction to specific drug
  Previous descriptions
  Quantification of drug levels that confirm abnormal levels
Degree of certainty of drug reaction
  Causative
  Probable
  Possible

From Irey NS: Teaching monograph: Tissue reactions to drugs. Am J Pathol 82:613-647, 1976.

Pulmonary function testing should be attempted in all children capable of proper technique. Lower airways obstruction is an indication of airways disease such as BO. A restrictive defect may be seen in interstitial disease and sometimes with pleural disease. Patients with pneumonitis and interstitial disease will have an increased diffusion capacity for carbon monoxide (DLCO). However, patients with alveolar hemorrhage will have a decreased DLCO due to the red blood cells' affinity for carbon monoxide.

A chest radiograph is a quick, helpful, noninvasive study that guides further diagnostic testing. Findings can include hyperinflation, pleural effusion, nonspecific "ground glass" opacification, an interstitial pattern, or a normal study. High-resolution computed tomography (HRCT) further identifies interstitial disease, pleural thickening, and pneumonia. Combining findings from HRCT with the patient's clinical presentation often provides sufficient information to avoid further diagnostic procedures.[24]

Flexible bronchoscopy and bronchoalveolar lavage (BAL) is more invasive than radiographic studies but is typically well tolerated. Findings such as increased numbers of eosinophils, lymphocytes, and dysplastic type II cells support a diagnosis of eosinophilic pneumonia, hypersensitivity pneumonitis, or chemotherapy lung.[21] Another major role of the BAL is to obtain cultures for viral, bacterial, and fungal pathogens to exclude an infectious etiology. Other helpful findings are cytologic atypia, lymphocytic alveolitis, or an increased eosinophil count. The BAL should also be examined for hemosiderin-laden or lipid-laden macrophages, which can be seen in pulmonary hemorrhage and mineral oil aspiration respectively. In some rare cases—such as in gold therapy—the medication itself is present in alveolar macrophages.[25] The presence of the drug indicates that the patient is taking the medication; however, it does not determine whether or not drug levels are toxic.[3]

Flexible bronchoscopy with a transbronchial biopsy is a minimally invasive procedure, but it is often not very helpful. Specimens are small and obtained blindly, so patchy areas of disease may be missed. If the diagnosis is still in question, then a large sample of lung tissue from an open lung biopsy is more useful. An open, or thoracoscopic, lung biopsy is considered the gold standard for diagnosis because the histologic pattern of the disease process can be clearly identified and tissue can be sent for culture. Physicians, and patients, often prefer not to perform an open lung biopsy due to the high amount of pain and discomfort for a purely diagnostic procedure.

TREATMENT AND PROGNOSIS

The wide variety of therapies that damage the lungs makes it impossible to recommend one therapy for all pathologies. The standard of care has been to remove the harmful agent and minimize the inflammatory reaction that it has created. In some cases, the decision is straightforward. For example, patients who experience pleural fluid eosinophilia secondary to nitrofurantoin can be switched to a different antibiotic. On the other hand, radiation therapy, and subsequent pneumonitis, may be unavoidable for certain types of cancer. When possible, steps should be taken to avoid pulmonary injury—such as minimizing the use of supplemental oxygen for patients receiving bleomycin. After the offending agent has been withdrawn, some pulmonary disease manifestations resolve rapidly while others require treatments such as corticosteroids or NSAIDs for complete resolution.

Prognosis is dependent on which pathologic manifestations have occurred and what therapy is responsible. Some patients may have no residual damage, and others may not live through the initial presentation.

SPECIAL CONSIDERATIONS IN PEDIATRICS

Different diseases, medications, and presentations must be taken into account for children with therapy-induced lung disease. For example, premature infants are often treated with exogenous surfactant, which can lead to pulmonary hemorrhage. In addition, children with encopresis and constipation are often treated with mineral oil despite the fact that they are at risk for aspiration, and subsequent lipoid pneumonia, due to poor swallowing coordination.[9,26]

Conversely, advanced age often places patients at higher risk for pulmonary pathology. Elderly patients are at much greater risk of methotrexate lung disease; patients from 50 to 59 years of age have twice the risk, while patients older than 60 years of age have six times the risk.[27] For bleomycin, patients older than 70 years of age are more susceptible to BIP.[14] One study even found a higher incidence of fatal BIP for each decade over 30 years of age.[28]

Nonspecific presenting symptoms are especially difficult in pediatrics. Very young patients cannot give an accurate history—or even a complete list of symptoms. Wheezing and decreased exercise tolerance can easily be mistaken for new onset asthma. Fortunately, most pediatric patients do not have the long list of medications that adult patients typically have, and if therapy-induced pulmonary disease is suspected the cause may be determined after investigation.

CHAPTER 28 Respiratory Disorders of the Newborn

J. Jane Pillow and Alan H. Jobe

TEACHING POINTS

- Respiratory illness is a major cause of neonatal morbidity and mortality.
- Most neonatal respiratory illness initially manifests with tachypnea, grunting, and cyanosis in the hours after birth.
- Neonatal respiratory distress syndrome, the most common respiratory disease in the newborn period, is due to structural and functional immaturity of the respiratory system and is characterized by surfactant deficiency.
- Exclusion of congenital pneumonia, congenital heart disease, congenital malformations, or significant air leak phenomena such as pneumothorax, are important considerations during initial management of neonatal respiratory distress syndrome.

RESPIRATORY DISTRESS SYNDROME

Respiratory distress syndrome (RDS) is the most common cause of respiratory failure in the preterm infant. Although many disorders can manifest with "respiratory distress" in the neonate, the term RDS is used to characterize the immature lung disease in a preterm infant resulting from insufficient surfactant. RDS is a major cause of morbidity and mortality in premature infants born before week 30 of gestation. The introduction of surfactant treatment has changed the clinical course of this disease and has decreased the morbidity and mortality rates.

Epidemiology, Risk Factors, and Pathogenesis

The incidence of RDS decreases as gestational age increases (Box 28-1). In preterm infants, less than 32 weeks' gestation, the incidence of RDS was reported as 71%.[1] The higher incidence and severity of RDS in male compared to female premature infants is explained by increased circulating androgens in males, which delay lung maturation with decreased surfactant production by type II pneumocytes.[2] Black preterm infants develop RDS less frequently than white infants of similar gestational age, and the condition is less severe.[3] The incidence of RDS is increased with maternal diabetes because high fetal insulin levels decrease lung surfactant and structural maturation.[4,5] Birth by cesarean section prior to onset of labor also increases the incidence of RDS.[6,7] Perinatal asphyxia is associated with increased RDS, probably because of the cardiovascular shock and associated persistent pulmonary hypertension.[8] In contrast, prolonged rupture of membranes[9] and other causes of chronic fetal stress, such as maternal drug abuse and chronic congenital infections, tend to decrease the incidence of RDS.[10] Antenatal administration of corticosteroids[11,12] to the mother also decreases the incidence of RDS. Recent studies suggest that maternal hypertension increases rather than decreases the incidence of hyaline membrane disease (HMD).[13]

The six stages of lung development were reviewed in Chapter 3. A preterm infant can be born during canalicular, saccular, or early alveolar stages of lung development. The gas exchange surface may range, therefore, from primitive airspaces with undifferentiated pneumocytes and no juxtaposition of airway epithelium and capillaries, to a lung that is similar to the relatively mature structural, mechanical, and biochemical functioning lung of the term neonate.

Surfactant

Surfactant appears in the fetal lung at 23 to 24 weeks' gestation, when osmophilic inclusions can be first detected in the type II pneumocytes. However, adequate amounts of surfactant are not secreted until about 35 weeks' gestation normally, when the incidence of RDS markedly decreases. Surfactant reduces surface tension in the alveolar spaces, facilitating lung expansion and preventing alveolar collapse during expiration in the human neonate. Spontaneous or mechanical ventilation of the surfactant-deficient lung causes epithelial injury and pulmonary edema which is prevented with exogenous surfactant treatment.[14,15] Surfactant is composed mainly of phospholipids but also contains proteins. Phosphatidylcholine is the most abundant phospholipid in surfactant, representing 80% of the total mass of lipid components. The major phosphatidylcholine species are essential for the surface tension–lowering properties. The other phospholipids in surfactant are phosphatidylglycerol, phosphatidylinositol, phosphatidylserine, phosphatidylethanolamine, and sphingomyelin. Phospholipids may also impart semipermeability to membrane aquaporins and consequently play a role in fluid clearance.[16] The surfactant proteins A, B, and C constitute 10% of pulmonary surfactant. They contribute to the proper function of surfactant by facilitating the formation of phospholipid films at the air-fluid interface of the alveolus by participating in the recycling of surfactant and functioning as host defense proteins.[17]

After synthesis in the type II pneumocyte, the lipid and protein components form into membrane-limited

BOX 28-1 Risk Factors for Respiratory Distress Syndrome

Increased incidence	Decreased incidence
Low gestation	Prolonged rupture of membranes
Male sex	Chronic congenital infections
White race	Maternal substance abuse
Maternal diabetes	Antenatal corticosteroid exposure
Cesarean section pre-onset of labor	
Perinatal asphyxia	
Maternal hypertension	

organelles—the lamellar bodies, which are intracellular storage pools of surfactant. Secretion of surfactant by exocytosis is promoted by mechanical stretch of the lung and physiologic and pharmacologic agents such as beta-adrenergics and purinergic agonists.[18] Within the alveolar space, lamellar bodies transform into the highly surface active form of tubular myelin (Fig. 28-1).[17,19] Surfactant proteins A and B are critical to the structure and function of tubular myelin.[18] In the newborn lung, surfactant components are efficiently recycled from the airspace to the type II cell for re-secretion.

In the very immature infant, in addition to surfactant deficiency, an excessively compliant chest wall and weakness of the respiratory muscles can contribute to alveolar collapse. This collapse alters the ventilation-perfusion relationship, producing a pulmonary shunt with progressive arterial hypoxemia that can lead to metabolic acidosis. Both hypoxemia and acidosis cause vasoconstriction of the pulmonary vessels and reduce pulmonary blood flow. Pulmonary vascular hypertension may produce right-to-left shunting through both the foramen ovale and the ductus arteriosus, worsening the hypoxemia.

The pulmonary blood flow, which is initially decreased, may subsequently increase because of a reduction in pulmonary vascular resistance and persistence of an open ductus arteriosus. Excessive pulmonary blood flow results in accumulation of fluid and proteins in the interstitial and alveolar spaces. The presence of proteins in the alveolar space promotes surfactant inactivation.[20]

The presence of both intrapulmonary and extrapulmonary shunting explains the characteristic hypoxemia in infants with RDS. Atelectasis (with impaired ventilation in some areas) and an increase in dead space caused by poor perfusion of other portions of the lung can elevate the partial pressure of arterial carbon dioxide ($PaCO_2$) in the more severe cases. The premature infant with RDS responds to the loss in lung volume and increase in $PaCO_2$ by increasing the respiratory rate. Hypoxemia, if severe, leads to progressive acidosis, which might contribute to further pulmonary vasoconstriction. If present, perinatal asphyxia and arterial hypotension worsen the metabolic acidosis (Fig. 28-2).

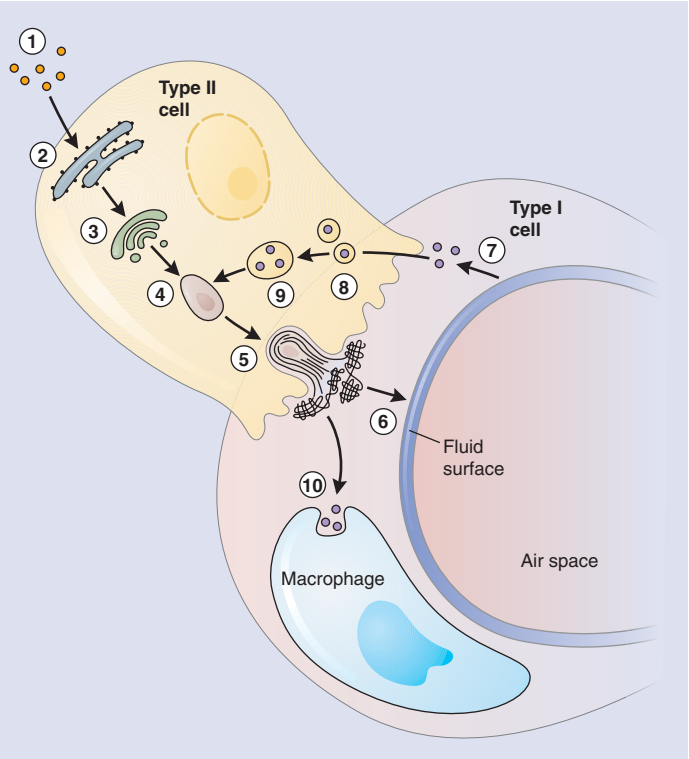

Figure 28-1 Surfactant system. Surfactant is synthesized in the type II pneumocyte from precursors (1) in the endoplasmic reticulum (2) via the Golgi apparatus (3), acquiring the form of lamellar bodies (4). Lamellar bodies are secreted into the alveoli by exocytosis, where they transform into tubular myelin (5) and form a fluid lining of the alveolar airspace (6). Surfactant is then recycled as small vesicles (7) into the type II cell for later re-secretion by using endosomes (8) and multivesicular bodies (9). Some surfactant is also taken up by alveolar macrophages (10). (From Hawgood S, Clements JA: Pulmonary surfactant and its apoproteins. J Clin Invest 86:1-6, 1990.)

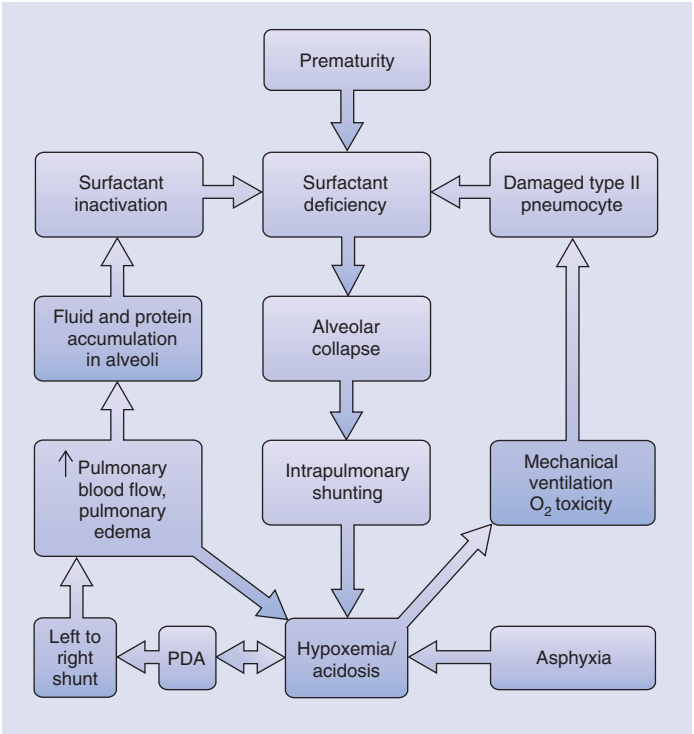

Figure 28-2 Pathophysiology of respiratory distress syndrome. PDA, patent ductus arteriosus.

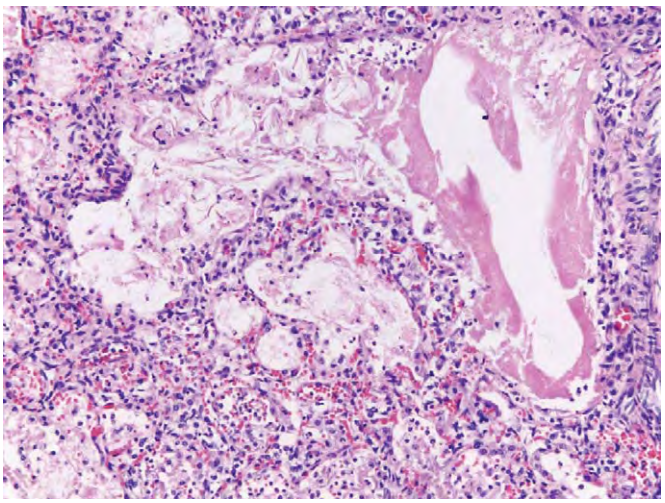

Figure 28-3 Microscopic findings at autopsy in an infant with respiratory distress syndrome (RDS), showing the presence of diffuse alveolar collapse with hyaline membranes lining the few remaining dilated airspaces. Early pneumonic change is also evident.

At autopsy, the lungs appear solid and congested with diffuse atelectasis. Microscopically, hyaline membranes line most of the remaining airspaces (Fig. 28-3). The hyaline membranes are a coagulum of plasma proteins leaked from damaged epithelium. Hyaline membrane disease and associated epithelial necrosis is less severe in autopsy specimens of infants that were treated with exogenous surfactant.[21]

Clinical Features and Diagnosis

The clinical signs of RDS usually appear in the first minutes or hours of life in the affected premature infant (Table 28-1). The signs are characterized by a progressive increase in the respiratory rate as well as subcostal and sternal retractions, grunting, cyanosis, and a bilateral decrease in breath sounds. The chest radiograph shows increased density of both lung fields with reticulogranular (ground glass) appearance, air bronchograms, and elevation of the diaphragm. A marked radiographic improvement can be observed after treatment with exogenous surfactant (Fig. 28-4). The oxygen (O_2) requirement varies depending on the severity of the disease course. Characteristically, arterial blood gas analysis reveals hypoxemia and hypercarbia and, occasionally, a mild metabolic acidosis.

Other causes of respiratory distress in the newborn should be considered in the differential diagnosis. These include pneumonia, congenital heart disease and other congenital anomalies, anemia, polycythemia, and hypothermia.

Without treatment with exogenous surfactant, the severity of the respiratory failure usually increases during the first 2 or 3 days of life. In the absence of complications, the respiratory status subsequently improves, and in infants older than 32 to 33 weeks' gestation, lung function usually normalizes by 1 week of life. In smaller infants, especially those <26 to 28 weeks' gestational age, the clinical course is generally prolonged and is frequently complicated by volutrauma and/or barotrauma from mechanical ventilation, patent ductus arteriosus (PDA), nosocomial infections, and intraventricular hemorrhage. The use of exogenous surfactant has dramati-

cally changed the natural course of the disease by rapidly decreasing the oxygen requirements (supplemental oxygen is not required) and reducing the incidence of gas leaks (see section on surfactant replacement therapy).

Treatment

In addition to the administration of exogenous surfactant, the general management of infants with RDS includes careful stabilization, proper monitoring of cardiopulmonary function, adequate respiratory support, and thermal, metabolic, and nutritional support.

Prevention

Because RDS occurs primarily in the preterm infant, prevention of prematurity is the most effective way to avoid this disease, although this is seldom possible. The widespread use of antenatal glucocorticoids to accelerate fetal lung maturation has reduced the incidence and severity of RDS in recent years.[22,23] A reduction in functional residual capacity (FRC) and a marked decrease in lung compliance are characteristics of RDS.[24] Some alveoli are collapsed because of surfactant deficiency, whereas others are filled with fetal lung or edema fluid, thereby explaining the decrease in FRC. In response to this, the premature infant with RDS frequently develops a grunting respiration that prolongs expiration and protects against further loss in FRC. Lung compliance is markedly reduced to values that are well below 0.5 mL/cm H_2O/kg of body weight,[25] less than half the normal value. Giving continuous positive airway pressure (CPAP) or positive end expiratory pressure (PEEP) can minimize this loss in FRC.

ANTENATAL PREDICTION OF LUNG MATURATION

In 1973, Gluck and Kulovich[10] described the relation of lecithin and sphingomyelin in the amniotic fluid as indicators of fetal lung maturity. This test is possible because the fetal lung secretes fluid and surfactant into and changes the composition of the amniotic fluid. The incidence of RDS is only 0.5% when the lecithin-sphingomyelin ratio is 2 or more, but it is close to 100% when the ratio is lower than 1. Phosphatidylglycerol, which appears in the amniotic fluid at about 36 weeks' gestation, is a further indicator of lung maturity.[26] Newer tests of lung maturity that include lamellar body counts are now available for lung maturity testing.[27,28]

INDUCTION OF FETAL LUNG MATURATION

Many hormones positively or negatively influence lung maturation in experimental systems. Agents that can accelerate lung maturation are corticosteroids, thyroid hormones, epidermal growth factor, and cyclic adenosine monophosphate. These substances may act by stimulating the synthesis of surfactant.[29] Only corticosteroids have been shown to decrease the incidence and severity of RDS consistently in randomized controlled trials.[11,12,30,31] At least two distinct mechanisms promoting lung maturation have been identified: (1) a relatively rapid change (within 15 hours) in lung structure that is associated with improved compliance, increased lung volume, and decreased capillary protein leak; and (2) a slower, increased synthesis and secretion of surfactant by type II cells.[32] The delay between corticosteroid administration and upregulation of surfactant production and secretion limits the effectiveness of corticosteroids administered less than 24 hours before delivery. Although initial trials suggested that the combined antenatal use of corticosteroids with thyrotropin-releasing hormone (TRH) could further reduce the incidence or severity of RDS,[33] subsequent publications did not confirm the beneficial effect of antenatal TRH.[34-36]

RESUSCITATION IN THE DELIVERY ROOM

A skilled neonatal resuscitation team present at the delivery can help to facilitate neonatal adaptation and avoid injury of preterm infants at risk of RDS. Hypothermia should be avoided by keeping the infants in a neutral thermal environment in which O_2 consumption is reduced to a minimum. All infants with RDS should be admitted to a neonatal intensive care setting, where continuous monitoring of heart rate, respiratory rate, blood pressure, arterial blood gases, and metabolic parameters is possible.

OXYGENATION AND VENTILATION

Traditional teaching suggested maintaining a partial pressure of arterial oxygen (Pa_{O_2}) between 50 and 80 mm Hg; differences in the oxygenation-dissociation curve of fetal hemoglobin suggest that Pa_{O_2} at the lower end of this range are more appropriate to avoid oxygen toxicity. A Pa_{O_2} of 41 mm Hg (5.5 kPa) is enough to saturate 90% of fetal hemoglobin at a physiologic pH.[37] Prolonged hyperoxia should be avoided because it is a risk factor for the development of retinopathy of prematurity[38] and bronchopulmonary dysplasia (BPD).[39] Current practice uses oxygen saturation pulse oximetry to continuously monitor oxygen saturations to target saturation levels of 88% to 94% to minimize hyperoxia and to limit the number of blood gas samples needed for patient management. Transcutaneous CO_2 monitors also provide continuous information that is noninvasive and can help detect complications such as pneumothorax or to guide management during intubations or surfactant therapy.

MECHANICAL VENTILATORY SUPPORT

Larger infants with RDS (especially those >1500 g) and with mild to moderate hypoxemia and minimal hypercarbia may need only supplemental oxygen. Infants with RDS with respiratory failure have persistent hypoxemia (Pa_{O_2} < 50 mm Hg), are not responsive to the administration of supplemental oxygen, and usually have respiratory acidosis. In these infants, especially those with no or minimal hypercarbia, the use of CPAP is an effective form of treatment.[40] CPAP increases the FRC and stabilizes the airspaces, preventing their collapse during expiration. CPAP effectively reduces oxygen requirements and the need for mechanical ventilation in larger infants (≥1200 g).[41,42] Although the idea of using CPAP soon after birth, including in the delivery suite, in premature infants at risk for RDS has been effective in clinical series,[43-45] there are currently insufficient data from controlled randomized trials[46,47] to support a clinical benefit for this treatment over routine intubation and treatment with surfactant.[48]

In infants for whom CPAP does not work, particularly very small premature infants or those with hypoventilation and hypercarbia, positive-pressure ventilation is required after endotracheal intubation. A myriad of ventilatory strategies have been used over the last decade reflecting the increas-

ing technical refinement of commercial ventilation and monitoring equipment suitable for use in the very small infant. Whereas pressure-limited, time-cycled ventilators were the previous mainstay of mechanical ventilation for preterm newborn infants, there is increasing evidence that volume-targeted ventilatory modalities provide significant clinical benefit, although this has not yet been demonstrated for the outcomes of BPD or death.[49] Infants extubated to CPAP immediately after exogenous surfactant administration are more likely to remain extubated at the end of the first week of life compared to infants who are initially maintained on mechanical ventilation.[50]

The respiratory failure and hypoxemia in infants with RDS are due mainly to an intrapulmonary shunt caused by perfusion of poorly ventilated airspaces (see Fig. 28-2). Increments in the mean airway pressure are required to achieve alveolar recruitment and to obtain adequate oxygenation. Mean airway pressure is a function of the inspiratory and expiratory time, peak inspiratory pressure, PEEP, and bias flow. The use of short inspiratory times (0.25 to 0.50 second) and high respiratory rates appear to reduce both the incidence of pulmonary gas leak and the mortality rate,[51-55] and are sufficient to achieve adequate gas exchange. The use of PEEP is an effective way of maintaining the FRC, and pressures of 4 to 6 cm H_2O are usually required during the acute phase of RDS. When hypercarbia is present, an increase in the peak inspiratory pressure or a decrease in the PEEP improves the tidal volume and minute ventilation. In addition, the respiratory rate can be increased, but excessive rates must be avoided to prevent gas trapping, especially in infants with increased airway resistance.

Weaning from intermittent positive-pressure ventilation can be a long and difficult process, particularly in infants with very low birth weights. Methylxanthines such as theophylline and caffeine act as respiratory stimulants and can facilitate weaning.[56] The use of nasal CPAP immediately after extubation, particularly in the very small preterm infant, improves the success rate of weaning.[57]

High-frequency ventilation is another therapeutic alternative that has been evaluated in neonates with severe RDS. Despite the theoretical benefit of reduced volutrauma, systematic review of controlled randomized trials using a high-volume strategy have demonstrated only a small reduction in the outcome of BPD or the combined outcome of BPD or death at 36 weeks' PMA. There is no evidence of significant adverse effects of high-frequency ventilation in the preterm infant. Only a few studies have reported long-term outcome to date.[58]

Asynchrony between the ventilator and patient ventilation is a major clinical problem associated with the use of intermittent mandatory ventilation causing impaired gas exchange, increased energy consumption, reduced venous return, and wide fluctuations in blood pressure potentially promoting intraventricular hemorrhages.[59] Assist control ventilation (also known as synchronized intermittent positive pressure ventilation) results in faster weaning than is achieved with synchronized intermittent mandatory ventilation. No advantage of synchronized ventilation over conventional ventilation on the incidence of BPD or death has been shown for the very small premature infant.[60] The promotion of spontaneous breathing in the ventilated preterm infant may be critical to avoidance of ventilator-induced diaphragmatic dysfunction.[61]

SURFACTANT REPLACEMENT THERAPY

Systematic reviews of multiple clinical trials show that the intratracheal administration of exogenous surfactant decreased mortality by up to 40%, and the risk of pneumothorax by between 30% and 65%.[62-64] Surfactant treatments have had no consistent effects on outcomes of chronic lung disease (CLD), patent ductus arteriosus, or intraventricular hemorrhage. The presence of surfactant proteins in the surfactant preparations may aid surfactant adsorption and resist surfactant inactivation. New surfactant preparations are being developed that contain phospholipids with recombinant or analog peptides of the hydrophobic surfactant proteins SP-B and SP-C. Initial clinical studies suggest these new surfactants are similar in terms of efficacy and safety to animal-derived surfactants.[65] The new synthetic surfactants avoid the batch-to-batch variability of natural surfactant protein levels and the hypothetical risk of transmission of unconventional infectious agents from animal-derived products.

For infants judged to be at high risk of developing RDS (less than 28 weeks' gestation or <1 kg),[43,44] very early (delivery room) treatment rather than treatment after the development of RDS can reduce the development of pneumothorax and pulmonary interstitial emphysema as well as decrease mortality.[66] Although the administration of surfactant before the signs of RDS are established might promote more homogeneous distribution throughout the lung, treatment of established RDS avoids unnecessary surfactant treatment and the associated costs for many infants who would never develop RDS. The benefits of very early treatment will be less apparent if infants are treated as soon as RDS is diagnosed, generally at <1 to 2 hours of age.

After its administration, exogenous surfactant rapidly improves arterial oxygenation and the alveolar-arterial oxygen difference, reducing the requirements of ventilatory support (Fig. 28-5). Interpretation of studies investigating changes in the lung mechanics occurring in response to surfactant administration are complicated by differences in management techniques, patient characteristics, surfactant preparations used, and ventilation strategies. A combination of mechanisms appears responsible for improving gas exchange following administration of surfactant, including recruitment of alveolar space, distention of already aerated alveoli, and stabilization of gas exchange units. The increase in lung volume results in improved compliance.[67]

ACID-BASE BALANCE

Metabolic acidosis should be prevented because it increases pulmonary vascular resistance and may impair cardiovascular function. Severe metabolic acidosis in the course of RDS is most commonly a manifestation of perinatal asphyxia, sepsis, intraventricular hemorrhage, or circulatory failure. It is, therefore, essential to promptly investigate and correct the cause.

BLOOD PRESSURE AND FLUID MANAGEMENT

Pulmonary edema can contribute to the pathophysiology of RDS. Infants with RDS tend to have a low urine output during the first 48 hours, followed by a diuretic phase with

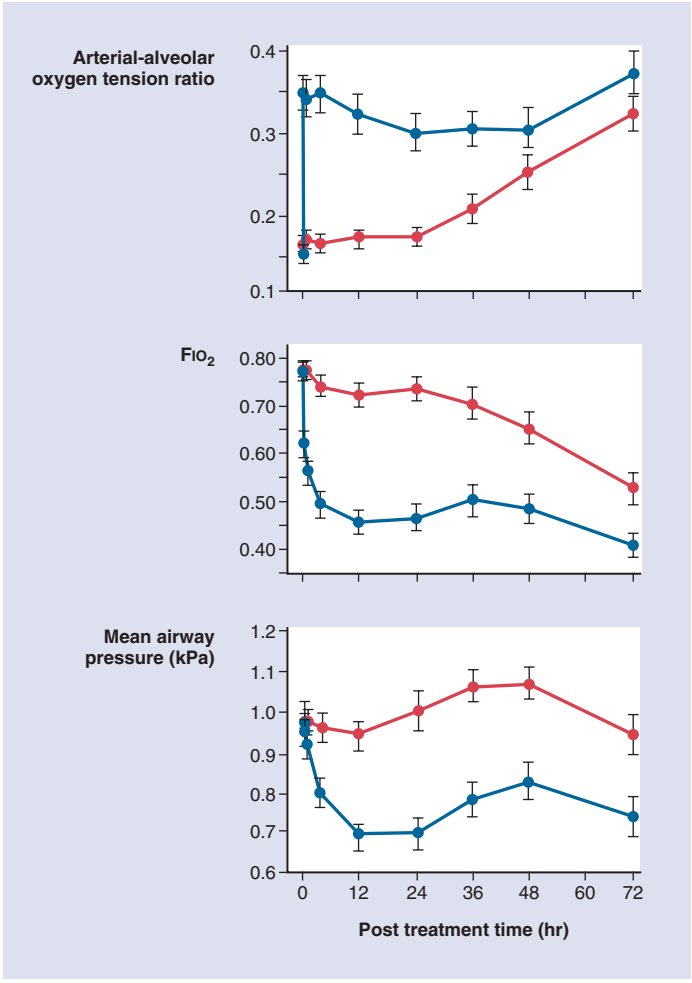

Figure 28-5 Mean values for the arterial-alveolar oxygen tension ratio, fraction of inspired oxygen (FIO_2), and mean airway pressure before and after treatment with exogenous surfactant (*blue circles*) or air placebo (*red circles*) in infants with RDS. (From Horbar JD, Soll RF, Sutherland JM, et al: A multicenter randomized, placebo-controlled trial of surfactant therapy for respiratory distress syndrome. N Engl J Med 320:959-965, 1989.)

weight loss. Fluid overload should be avoided. Fluid intake is usually started at 60 to 80 mL/kg/day and then increased gradually over the next few days, although great individual variations exist. Higher fluid intake may be necessary, especially in the infant with a very low birth weight and high insensible water losses. Fluid intake must be adjusted according to changes in weight, urine output, and serum electrolyte levels. The use of phototherapy, low ambient humidity, and radiant warmers increases fluid requirements. Excessive administration of fluids during the first days may contribute to the development of PDA[68] and BPD.[69] Because spontaneous diuresis has been described before improvement in respiratory status, the use of diuretics during the course of RDS is seldom necessary. Systematic review of diuretic administration in RDS suggests no long-term benefit and the transient improvement in pulmonary function did not outweigh an increased risk for patent ductus arteriosus and for hemodynamic instability.[39]

Careful assessment of systemic blood flow is essential to avoid reduced perfusion of critical organs. It is important to recognize that arterial blood pressure is an unreliable indicator of low systemic blood flow: babies can have low blood flow without hypotension and infants with hypotension may have normal systemic flow.[70] Perinatal asphyxia, sepsis, and hypovolemia are the most common conditions that can produce hypotension and, if suspected, should be treated accordingly. It is important to avoid the excessive use of fluids in an attempt to correct hypotension. Pressor use, such as dopamine, may increase peripheral resistance and further compromise systemic flow despite an apparent increase in arterial blood pressure.[70]

NUTRITION

Adequate nutritional support is essential for these infants; it is achieved during the first days of life by the use of parenteral nutrition. Oral feedings are started as soon as the infant is clinically stable and can begin when the infant is receiving ventilatory support.

ANTIBIOTICS

Neonatal pneumonia, particularly that caused by group B streptococci, should always be considered in the differential diagnosis of RDS, particularly in larger infants with respiratory failure. Conditions that are associated with an increased incidence of infection in the premature infant include: prolonged rupture of membranes, maternal fever during labor, fetal tachycardia, leukocytosis or leukopenia, hypotension, and acidosis. Before findings from blood cultures become available, especially when some of these risk factors are present, the use of penicillin or ampicillin and an aminoglycoside is recommended.

Complications

PATENT DUCTUS ARTERIOSUS

With the survival of smaller infants and the use of exogenous surfactant, early PDA as a complication of RDS has become an increasing problem in the management of the very low birth weight infant during the first days of life. The incidence of PDA in the premature infant with RDS may be as high as 90%,[71] and in two thirds of infants less than 30 weeks of gestational age, the PDA does not close by 5 days of age.[72] Several factors contribute to the slower and less predictable closure of the ductus arteriosus in preterm infants including the following: persistent elevation of the pulmonary vascular resistance due to lung disease, impaired sensitivity of the ductus arteriosus tissue to oxygen, increased circulating prostaglandin E_2, and increased sensitivity of ductal tissue to prostaglandin E_2 and nitric oxide. Sepsis has also been associated with an increased risk of PDA.[73]

A PDA is associated with a left-to-right shunt and increased pulmonary blood flow and pulmonary artery pressure.[74,75] In some studies, increased pulmonary blood flow was associated with reduced lung compliance that improved after PDA ligation,[76,77] although this was an inconsistent finding and not easily reproduced in animal models. Increased pulmonary blood flow can lead to left ventricular failure, hemorrhagic pulmonary edema, and adversely alter oxygenation and lung fluid balance.[78] Leakage of plasma proteins into the alveolar space may inhibit surfactant function.[20] Shear and stretch stress injury resulting from exposure of the lung vasculature

to systemic blood pressure may injure the endothelium, cause profound changes in the pulmonary vascular bed structure and function at the cellular level, and alter regulation of vascular tone and growth.[79]

Physical examination of the infant with symptomatic PDA generally reveals crackles and an active precordium, bounding pulses with a wide pulse pressure, poor peripheral perfusion, and in most but not all cases, a systolic heart murmur best heard below the left clavicle. Radiographically, evidence of pulmonary edema is observed, often in association with cardiomegaly (Fig. 28-6). The presence of a PDA should be confirmed by Doppler echocardiography, and if a clinically significant duct is identified, proper treatment should be promptly initiated. This consists of fluid restriction, adequate respiratory support, and pharmacologic treatment using prostaglandin inhibitors. The systematic review of prophylactic indomethacin treatment for PDA showed an association with a lower incidence of PDA, less subsequent medical treatment of the PDA, and less subsequent PDA ligation, but there were no differences in the incidences of CLD or other morbidities (e.g., necrotizing erterocolitis, feeding intolerance, or retinopathy of prematurity).[80,81] Early targeted treatment of asymptomatic PDA also reduces the incidence of symptomatic PDA on day 3 and may avoid unnecessary treatment of some infants who might never have developed a PDA.[80] Ibuprofen is another prostaglandin inhibitor that has similar efficacy to indomethacin for PDA closure, but is potentially less nephrotoxic (lower serum creatinine values, higher urine output), and has less adverse decrease in organ blood flow and vasoconstrictive adverse effects.[82] If closure of the symptomatic PDA cannot be achieved with medical treatment, surgical ligation should be considered because there may be an increased mortality associated with failed medical closure of the symptomatic PDA. The need for surgical ligation should be weighed against the possible side effects of the surgical procedure, including transport of the infant to an appropriate care facility. The benefit of surgical ligation over nonclosure of the symptomatic persistent PDA has not been subjected to a rigorous, well-designed randomized controlled trial.

HEMORRHAGIC PULMONARY EDEMA

Most cases of pulmonary hemorrhage in the newborn are secondary to severe hemorrhagic pulmonary edema as a complication of RDS and PDA. The incidence of pulmonary hemorrhage in premature infants with RDS is approximately 1%, although at autopsy around 55% will have alveolar hemorrhage.[83] The hemorrhagic fluid in the airspaces most likely represents capillary rupture and interstitial fluid.[84] Histologically, pulmonary hemorrhage can manifest as either interstitial or alveolar hemorrhage[85] (Fig. 28-7).

The associated predisposing factors include perinatal asphyxia, hypothermia, hypoglycemia, congestive heart failure, coagulopathy, pneumonia, severe sepsis, and excessive fluid administration.[86] Pulmonary hemorrhage has also been related to the use of exogenous surfactant,[87] related to increased left-to-right shunt through the ductus arteriosus.[71]

Pulmonary hemorrhage complicating RDS is usually observed in the first 5 to 7 days of life. When it is massive, pulmonary hemorrhage may be catastrophic and rapidly fatal with a sudden deterioration of the respiratory status that is generally associated with bradycardia, metabolic acidosis, and shock. Hemorrhagic fluid is seen coming from the nose and the mouth or through the endotracheal tube. The chest radiograph commonly shows a diffuse opacification of both lung fields.

The immediate management of pulmonary hemorrhage consists mainly of providing adequate ventilatory support. Increasing PEEP reduces the left-to-right ductal flow[77] and may prevent alveolar and small airway closure and severe pulmonary edema. Fluid restriction is indicated when the hemorrhage is due to left ventricular failure. If the cause of pulmonary edema and hemorrhage is a PDA, the PDA should be treated promptly, as should any other underlying cause. Although pulmonary hemorrhage is potentially a complication of surfactant therapy, surfactant treatment posthemorrhage may improve outcome by counteracting the inhibition of natural surfactant by hemoglobin and red blood cell lipids.[88]

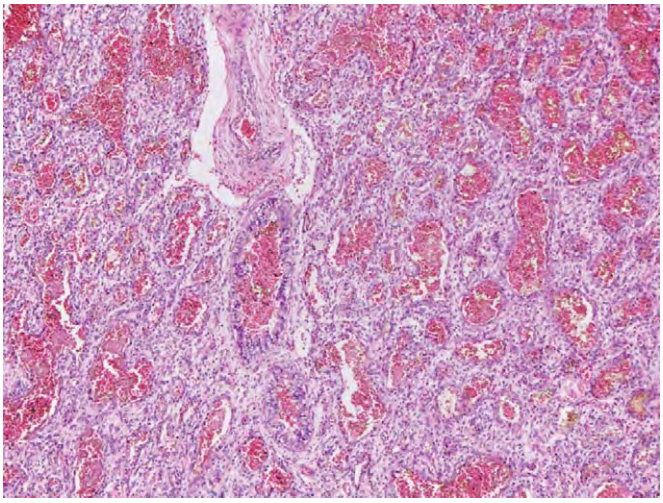

Figure 28-7 Microscopic findings in an infant with pulmonary hemorrhage complicating respiratory distress syndrome. Abundant red blood cells are seen in the pulmonary interstitium and inside the airspaces. Some hyaline membrane formation is also evident.

TRANSIENT TACHYPNEA OF THE NEWBORN

Also known as wet lung syndrome or RDS type II, transient tachypnea of the newborn (TTN) was first described by Avery and colleagues in 1966.[89] The original description was based on a group of predominantly full-term newborns who presented with tachypnea soon after birth and had similar radiographic findings with a benign clinical course. This transient respiratory symptomatology was attributed to a delayed resorption of alveolar fluid, which reduced lung compliance and caused a mild impairment in gas exchange.

Epidemiology, Risk Factors, and Pathogenesis

Transient tachypnea of the newborn affects 1% to 2% of all newborns,[90] primarily full-term infants. Several perinatal risk factors, including elective cesarean section,[91] excessive administration of fluids to the mother during labor,[92] male gender, and macrosomia, have been linked to the development of TTN.[90] Meta-analysis of clinical trials does not currently support a role for delayed clamping of the umbilical cord in TTN.[93]

The removal of fetal lung liquid from the lung at birth is an essential step for newborn adaptation to extrauterine life. The clearance of such liquid has been attributed at least in part to the mechanical compression of the chest at birth.[94] More importantly, there is an antenatal reduction in fetal lung liquid[95] that results from a shift of fluid from the lung lumen into the interstitium.[96] The initiation and process of labor is an important factor in this antenatal redistribution and absorption of lung liquid,[97] explaining, in part, the higher incidence of TTN observed after elective cesarean section.[98,99]

The secretion of fetal lung liquid is decreased or stops during labor. Fetal epinephrine levels increase and activate β-adrenoreceptors, which increase Na^+ transport and fluid resorption. The absorption of fetal lung fluid can be blocked by the administration of amiloride—an Na^+ channel antagonist.[100] Other hormones, including thyroxine and glucocorticoids, also upregulate Na^+ channel-mediated fluid absorption. Additionally, arginine vasopressin, somatostatin, dopamine, and serotonin rise during labor in a similar fashion to epinephrine and are candidates as regulatory hormones for lung fluid resorption. Male sex[101] and maternal history of asthma are associ-ated with the development of TTN.[102] Genetic predisposition to β-adrenergic hyporesponsiveness is proposed as a mechanism to the association between TTN and maternal asthma.[103]

With aeration of the lungs at birth, the fetal lung fluid absorbed across the pulmonary epithelium initially accumulates in the interstitial fluid of ventilated regions of the lung, particularly around the perivascular spaces. Lung fluid is slowly resorbed from the interstitium over a 2 to 6 hour period via vascular and lymphatic systems. The lymphatic system accounts for around 11% of fluid resorption of animals in labor,[96] and up to 50% of fluid resorption for animals not in labor. Any condition that increases hydrostatic pressure in the pulmonary vasculature can interfere with the appropriate resorption of fluid into the pulmonary circulation. Increased hydrostatic pressure can explain the higher incidence of TTN observed after excessive administration of fluids to the mother. Mild left ventricular dysfunction has also been described in infants with TTN.[104] An excessive amount of liquid in the lung may explain lower neonatal thoracic gas volumes after cesarean section compared to vaginal delivery. Infants born via cesarean section take up to 48 hours to establish their full lung volume.[105]

Clinical Features and Diagnosis

Transient tachypnea of the newborn usually manifests in the first few hours of life (see Table 28-1) with tachypnea. The respiratory rate commonly fluctuates between 80 and 120 breaths/minute. Retractions, nasal flaring, grunting, and cyanosis can also be present. Classically, TTN affects full-term infants, particularly those who are large for gestational age, although it can affect larger premature infants. Most such infants have a perinatal history with risk factors for the development of TTN, such as elective cesarean section or excessive administration of fluids to the mother. In addition to respiratory distress, these newborns may have a barrel chest and coarse breath sounds. The results of arterial blood gas analysis may be normal, although they frequently show a mild to moderate degree of hypoxemia. These patients usually require less than 40% oxygen to maintain adequate arterial oxygenation. Occasionally, hypoxemia is accompanied by mild hypercarbia, but both conditions tend to be transient and disappear within the first 24 to 48 hours.

The chest radiograph is characteristic. There are prominent, usually ill-defined central markings which suggest vascular engorgement, branching out from the hila.[89] The interlobar fissures may appear prominent, and small pleural effusions can be seen. The cardiac silhouette is usually enlarged (Fig. 28-8). All these findings are transient and disappear in 48 to 72 hours.

Probably the most challenging step in establishing the diagnosis is ruling out other pathologic conditions with similar clinical presentations. Because TTN occurs predominantly in full-term newborns, it is very important to rule out pneumo-

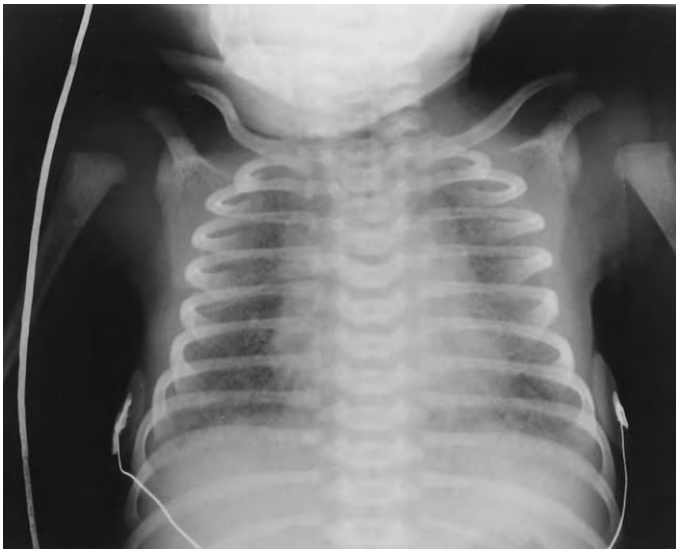

Figure 28-8 Radiographic findings in an infant with transient tachypnea of the newborn (TTN). Increased bilateral markings with prominent interlobar fissures and small pleural effusions can be observed. The heart appears slightly enlarged.

nia, especially that caused by group B streptococci. In infants with pneumonia, the perinatal history may be consistent with that of infection, such as maternal fever or prolonged rupture of membranes. Such infants also frequently have other clinical signs of infection, such as arterial hypotension, temperature instability, leukocytosis, and leukopenia. Other important differential diagnoses to be considered are meconium aspiration syndrome (MAS), RDS (particularly in the large premature infant), congenital heart disease and other congenital anomalies, and pulmonary gas leaks. The clinical course of infants with TTN is benign. The tachypnea and the radiographic abnormalities usually resolve in 24 to 72 hours.

Treatment, Clinical Course, and Prognosis

Because of the benign course of TTN, treatment consists mostly of proper stabilization, adequate monitoring, and careful evaluation to rule out other, more serious conditions. Oxygen should be provided as necessary to maintain normal oxygenation, and generally, mechanical ventilation is not required. Fluid restriction is indicated until the symptoms resolve; oral feedings can be started as soon as the infant is able to tolerate them. Diuretics do not affect the clinical course of the disease.[106,107] The use of antibiotics is indicated in cases in which the diagnosis of neonatal pneumonia is suspected and until the cultures and the clinical evaluation of the infant permit the clinician to rule out this diagnosis.

NEONATAL PNEUMONIA

Because of its grave prognosis, neonatal pneumonia should always be considered in the differential diagnosis in newborns with respiratory distress. The lung is one of the most frequent organs involved in early onset neonatal sepsis. Pneumonia in the newborn period can be acquired during intrauterine life, at the time of delivery, or after birth. Although the most common etiology is bacterial infection, it can be caused by different microorganisms, including viruses and fungi.

Epidemiology, Risk Factors, and Pathogenesis

Infection as a primary cause of death accounts for up to 50% of neonatal autopsies. More than 80% of infants that die from infection in the first 48 hours of life are associated with a pneumonia.[108] In infants who survive, the incidence is difficult to establish because of the frequent inability to make a definitive diagnosis. In a study comparing clinician- and pathologist-stated causes of death, the diagnosis most frequently omitted by clinicians was pneumonia (26.5% of cases).[109] The radiographic incidence of pneumonia was 4% among term infants born to mothers with documented amnionitis.[110] In a prospective study of 19,596 newborns, the incidence of early onset pneumonia was 1.79 per 1000 live births.[111] A higher incidence has been described in black infants[112] and in infants born to low-income families.[113] The agents and mechanisms of pulmonary infection differ depending on the type of neonatal pneumonia.

TRANSPLACENTALLY ACQUIRED PNEUMONIA

Transplacentally acquired pneumonia is a relatively rare event and includes those pneumonias caused by rubella virus, cytomegalovirus, *Treponema pallidum*, and occasionally *Listeria monocytogenes*. Many of these infants are stillborn or die in the first days of life. A hematogenous spread to the fetus from a mother with sepsis or bacteremia is the mechanism of infection in transplacentally acquired pneumonia. A classic example is pneumonia alba, a severe consolidated pneumonia caused by congenital syphilis.

PNEUMONIA ACQUIRED FROM COLONIZATION OF THE AMNIOTIC FLUID

Classically, the responsible microorganism infects the infant via an ascending route from the vaginal canal, usually producing chorioamnionitis, especially after a prolonged rupture of membranes during labor. The infection may also be acquired without evidence of chorioamnionitis during the passage through the birth canal.

In this type of infection, group B streptococci are responsible for the majority of cases of neonatal pneumonia and sepsis in the United States and Europe,[111,114,115] whereas *Escherichia coli* is the main responsible organism in developing countries.[109] The rate of maternal vaginal colonization with group B streptococci at the time of delivery is approximately 20%, and early onset group B streptococcal disease affects 1.8 per 1000 live newborns.[116] Mothers of affected infants usually have complications such as preterm delivery, prolonged labor, prolonged rupture of membranes, and intrapartum fever. In early onset disease, the infants have symptoms at or shortly after delivery, which suggests that most of these infections begin in utero.[116]

Other microorganisms included in this group are *Klebsiella* species, *Haemophilus influenzae*, *Enterobacter* species, *Listeria monocytogenes*, *Chlamydia trachomatis*, *Ureaplasma urealyticum*, *Candida* species, and herpes simplex virus. When neonatal pneumonia is associated with chorioamnionitis in the mother, aspiration of infected amniotic fluid is probably the main mechanism of infection. This is suggested by the presence of amniotic debris and maternal leukocytes in the histologic examination of the lungs.[117] However, chorioamnionitis per se is not always associated with pneumonia, and other factors, such as fetal asphyxia, seem to play an important role. If present, asphyxia can trigger gasping respiratory movements in the fetus that can cause the aspiration of contaminated amniotic fluid.

Any obstetric factors that predispose to chorioamnionitis can also favor the development of neonatal infection. In the case of group B streptococci, the rate of symptomatic early onset disease with pneumonia is considerably increased if there is premature onset of labor,[118] prolonged rupture of membranes, prolonged labor, or maternal postpartum bacteremia.[119]

When the infant acquires the infection during passage through the vaginal canal, the aspiration of infected materials is the route of infection. In these infants the histologic presentation is similar to that in older children and adults (i.e., bronchopneumonia with evidence of bronchitis and bronchiolitis, pleuritis, alveolar hemorrhage, and occasionally pulmonary necrosis with the presence of bacteria). In group B streptococcal pneumonia, hyaline membranes, similar to those observed in RDS, can be found in sections of the lungs.[120] The cytopathic effects of herpes simplex virus can be observed in the lungs of infants with pneumonia caused by herpes infection.

PNEUMONIA ACQUIRED AFTER BIRTH

In infants who remain hospitalized after birth, particularly if the lungs require mechanical ventilation, infection may be transmitted from contaminated personnel or equipment. *Staphylococcus aureus;* coagulase-negative staphylococci; *Pseudomonas*, *Proteus*, *Serratia*, *Enterobacter*, and *Candida* organisms; and respiratory syncytial virus are among the most frequent pathogens that cause nosocomial pneumonia in these high-risk infants. If the patient has been discharged home, viral pneumonias such as those produced by respiratory syncytial virus or adenovirus may occur during the first month of life. C. *trachomatis*, although acquired at birth, usually manifests later, producing afebrile pneumonia during the first 3 months of life.[121]

In nosocomial pneumonia, several mechanisms of infection can be implicated, including contact with contaminated personnel, inhalation of infected aerosols in the nursery, use of contaminated respiratory equipment, and hematogenous dissemination from bacteremia or a distant source. The histologic presentation varies depending on the etiologic agent. *S. aureus* and *Klebsiella pneumoniae* may produce extensive tissue damage with microabscesses, empyema, and pneumatoceles.[122] *E. coli*, a necrotizing agent, may also produce pneumatoceles.[123] In pneumonia caused by C*andida* species, yeasts and pseudohyphae can be observed on postmortem examination of lung tissue. Cytomegalovirus may also cause neonatal pneumonia. Cytomegalic inclusion bodies are evident on microscopy of lung tissue (Fig. 28-9).

Clinical Presentation and Diagnosis

Transplacentally acquired pneumonia is usually symptomatic shortly after birth (see Table 28-1). There may be a history of antenatal complications such as intrauterine growth restriction or fetal distress during labor. Respiration is likely to be depressed at birth, so these infants require resuscitation and, frequently, mechanical ventilation. Besides the classic signs of respiratory distress with retractions, grunting, tachypnea, and cyanosis, these infants commonly have other signs of congenital infection, such as low birth weight, hepatosplenomegaly, petechiae, and neurologic abnormalities. Total immunoglobulin M blood levels are usually elevated, and serologic tests for specific etiologic agents should be performed when congenital infection is suspected.

When pneumonia has been acquired from contaminated amniotic fluid or in the birth canal, the infant may not be affected in the first hours after birth, so a high index of suspicion should be maintained in every newborn with risk factors for neonatal infection. Neonatal pneumonia can manifest with overt or subtle clinical signs. Classic signs are those related to the respiratory system, such as respiratory distress, cyanosis, and crackles found during the physical examination. Perhaps more important are nonspecific signs, the most common being apnea, lethargy, hypotension, tachycardia or bradycardia, poor peripheral perfusion, and temperature instability. These clinical manifestations usually appear during the first 24 hours of life but sometimes are present at birth. In premature infants who have respiratory distress and a chest radiograph suggestive of RDS, pneumonia cannot be excluded. For this reason, appropriate cultures should be performed and antibiotic therapy started in any patient who is suspected of having RDS and who has perinatal risk factors and clinical or laboratory signs suggestive of infection.

The chest radiograph in infants with pneumonia may be quite variable but most commonly shows bilateral diffuse densities or may have a granular appearance, like that of RDS, especially in the case of group B streptococcal pneumonia (Fig. 28-10). Radiographic changes may be present at birth or rapidly progress in severity during the first hours of life, sometimes to a complete opacification of both lungs.

The white blood cell count can reveal leukopenia or leukocytosis, frequently with a leftward shift in the differential count. A positive urine latex agglutination assay for group B streptococci can point the clinician to the diagnosis, but there

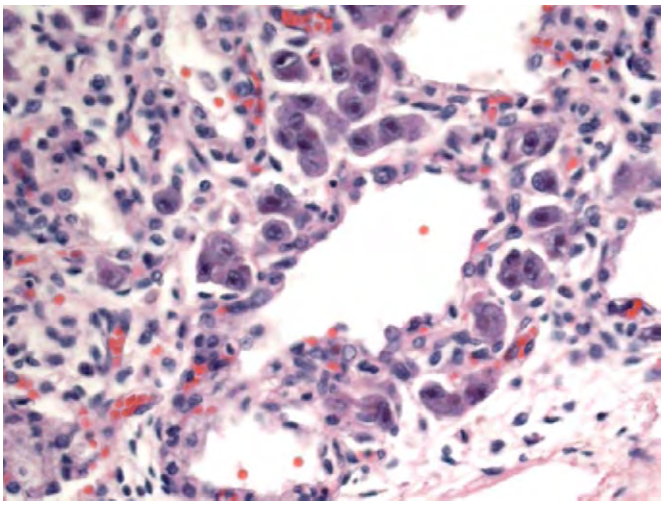

Figure 28-9 Neonatal pneumonia caused by *Cytomegalovirus* organisms. Cytomegalic inclusion bodies are evident.

Figure 28-10 Chest radiograph of an infant with group B streptococcal pneumonia. Note the bilateral diffuse densities that are similar to those observed in infants with respiratory distress syndrome (RDS).

is a high incidence of false-positive and false-negative results. Blood should always be drawn for culture, and when the results are positive, they confirm the diagnosis, but negative results do not rule out the possibility of pneumonia. In one review of early onset neonatal pneumonia, the findings from blood cultures showed the presence of organisms in only 46% of 35 cases.[111]

The presence of white blood cells and bacteria in Gram stain of early tracheal aspirates suggests pneumonia, and the bacteria grown in these aspirates correlates well with those found in simultaneously performed blood cultures.[124,125] However, in the case of nosocomial pneumonia, findings from tracheal aspirates may not be helpful in making the diagnosis. In neonates whose lungs are chronically ventilated, positive findings from tracheal aspirates occurred with equal frequency among infants suspected of having pneumonia and in the control group.[126] If a pleural effusion is present, bacteriologic studies of pleural fluid can also be diagnostic.

Any infant developing a nosocomial infection should be suspected of having pneumonia. This is particularly true for low birth weight infants who deteriorate while requiring mechanical ventilation. Increased requirements of oxygen and ventilatory support, any signs of systemic infection, a change in the characteristics of the tracheal secretions, the colonization of tracheal secretions with an unusual microorganism, and a worsening of the chest radiograph are the most common signs of nosocomial pneumonia. A high index of suspicion should be maintained in these infants because some of the most frequent nosocomial infections, such as those caused by C*andida* organisms or coagulase-negative staphylococci, usually have a subacute presentation with vague symptoms.[127,128] If nosocomial pneumonia is suspected, a complete blood count and appropriate cultures from blood, trachea, urine and, if possible, cerebrospinal fluid should be obtained before treatment is initiated.

Treatment

The goal of treatment should be to achieve adequate antibiotic coverage while providing good supportive care. Proper stabilization of the infant, adequate oxygenation and ventilation, hemodynamic status, temperature control, and fluid management are essential for the recovery of the patient. Careful respiratory management best prevents complications such as pulmonary hypertension, gas leaks, and CLD.

The choice of antibiotics frequently has to be made before cultures are available and is based mainly on the age of the infant and the presence of risk factors for a certain etiologic agent. During the first 5 to 7 days of life, the use of ampicillin and an aminoglycoside provides adequate coverage for group B streptococci, *L. monocytogenes*, and the most frequent, gram-negative bacteria. If late onset pneumonia is suspected and the etiology is unknown, coverage for *Staphylococcus* organisms is necessary, as is the use of aminoglycosides or broad-spectrum cephalosporins for gram-negative bacteria. If C*andida* pneumonia is strongly suspected, the use of amphotericin is indicated. Herpes simplex pneumonia should be considered, especially in the infant who becomes ill 5 to 7 days after birth and has risk factors or other manifestations of herpetic infection. Acyclovir is the treatment of choice for this infection. After the initial treatment, the antibiotics can be changed according to the results of the cultures or the clinical course of the disease. Antibiotics are usually continued for 10 to 14 days. The use of granulocyte transfusions or intravenous immunoglobulin for the treatment of neonatal infections is still controversial.

Complications

Pulmonary hypertension can complicate the course of neonatal pneumonia.[129] In group B streptococcal infection, exposure of type III antigen to blood components within the vascular space can promote the adherence of neutrophils to the endothelial cells.[130] These neutrophils can liberate inflammatory mediators, vasoactive substances such as thromboxane, and leukotrienes, that constrict the pulmonary blood vessels.[131-133]

Septic shock is another frequent complication and is often the cause of death in these infants. Pulmonary interstitial emphysema (PIE) and other types of gas leaks can develop at any time of the clinical course, particularly when mechanical ventilation is required. Pulmonary hemorrhage secondary to vascular damage and pulmonary hypertension can also complicate the evolution of neonatal pneumonia.[84] Neonatal pneumonia caused by *U. urealyticum* has been related to the development of CLD in the premature infant.[134-136]

Clinical Course and Prognosis

The overall mortality rate for early onset neonatal pneumonia has been estimated to be around 29% but is much lower in late-onset pneumonia.[111] Infants who die of early onset pneumonia are more likely to be premature and have a rapid clinical deterioration and a radiographic picture resembling severe RDS.[111] In infants who survive, the severe lung injury related to the inflammatory process plus the damage produced by prolonged mechanical ventilation and oxygen toxicity places them at high risk for developing CLD.

MECONIUM ASPIRATION SYNDROME

Meconium aspiration syndrome (MAS) is a consequence of aspiration of meconium occurring before, during, or immediately after delivery and is one of the most common causes of respiratory failure in infants born at term or after term. The presence of meconium in the amniotic fluid is extremely uncommon in preterm deliveries.[137] The almost exclusive occurrence of asphyxia due to meconium aspiration in the term and post-term infant is probably a developmental phenomenon related to levels of motilin, a substance that stimulates peristalsis. Although the incidence of meconium-stained amniotic fluid has remained stable at approximately 12% of all deliveries, meconium is present below the vocal cords in less than one half of such infants, when the airway is visualized immediately after birth.[138-140] Over the last 2 decades, the incidence of MAS per se has decreased from 5% to 1.5% of infants born at greater than 37 weeks' gestation with meconium-stained liquor,[141] due to reduction in the incidence of post-term deliveries. The risk and the severity are considerably increased when the meconium is thick or particulate.[138,142,143] Some infants born through meconium-stained fluid develop respiratory illness even when no meconium is visualized below the vocal cords at birth, indicating aspiration occurred in utero.

Epidemiology, Risk Factors, and Pathogenesis

Although there is net movement of fluid out of the lung during normal fetal breathing activity, meconium can be aspirated into the distal airways before birth because it is occasionally found in the lungs of stillborn infants.[144,145] The passage of meconium into the amniotic fluid is frequently associated with some degree of fetal distress, but it may also occur in normal or breech deliveries without evidence of asphyxia.[140,143,146,147] In cases of asphyxia, it results from increased intestinal motility produced by the hypoxic stress. The hypoxia and acidosis induce deep fetal respiratory efforts that increase the likelihood of aspiration of meconium-contaminated fluid into the lower airways. Meconium may also be aspirated in the perinatal period (Fig. 28-11).

A number of different damaging effects of meconium on the airways and lung tissue contribute to respiratory disease caused by meconium aspiration.[148] When thick particulate meconium is aspirated into the small airways, the airways become partially obstructed, resulting in gas trapping and overinflation distal to the obstruction. Alveolar gas distal to the completely obstructed small airways is reabsorbed, and the alveoli collapse, increasing the intrapulmonary shunting and arterial hypoxemia. High oxygen concentrations increase the likelihood of collapse distal to obstructed airways. Chemical pneumonitis arising from the interaction of the meconium with the respiratory tissue develops between 24 to 48 hours after meconium inhalation and is accompanied by a marked inflammatory reaction and development of capillary leakage, reducing the diffusing capacity and contributing to hypoxemia.[149] The presence of meconium in the lung results in an increase in pulmonary artery pressure[150] which can be further exacerbated by the presence of hypoxia and acidemia. The inflammatory response to intrapulmonary meconium may exaggerate any vasoconstriction, while chronic hypoxia may result in remodeling of the pulmonary vasculature. The presence of the organic matter in the lung predisposes the infant to pulmonary infection despite the initial sterile nature of the inhaled material. Meconium inhibits surfactant function, further promoting the development of atelectasis.

Clinical Presentation and Diagnosis

Infants who aspirate meconium are born mostly at or after term (see Table 28-1) and frequently have a history of fetal distress, low Apgar scores, and meconium-stained amniotic fluid.[137,142] Their skin, nails, and umbilical cords are also meconium stained. They have signs of respiratory distress shortly after birth, with tachypnea, intercostal retractions, and cyanosis, if not given supplemental oxygen. The chest appears overdistended and is frequently barrel shaped with a protruding sternum. The breath sounds are usually obscured by coarse bronchial sounds, and prolonged expiration indicates small airway obstruction. The chest radiograph shows patchy areas of increased density in both lungs, alternating with hyperlucent areas (Fig. 28-12). The diaphragm is occasionally depressed.[151,152]

Arterial blood gas analysis during the first hour of life may show metabolic acidosis reflecting perinatal asphyxia. The arterial oxygen tension is always lower than normal unless the infant is given supplemental oxygen. The severity of the hypoxemia depends on the degree of the pulmonary damage, and the hypoxemia is aggravated by pulmonary hypertension, which may result in right-to-left shunting through the foramen ovale and ductus arteriosus. The $PaCO_2$ is commonly elevated and in the more severe situations may require the use of mechanical ventilation to correct the alveolar hypoventilation and respiratory acidosis.[153]

Infants with severe MAS have frequent, potentially life-threatening complications including air leak syndromes, persistent pulmonary hypertension of the newborn (PPHN), and

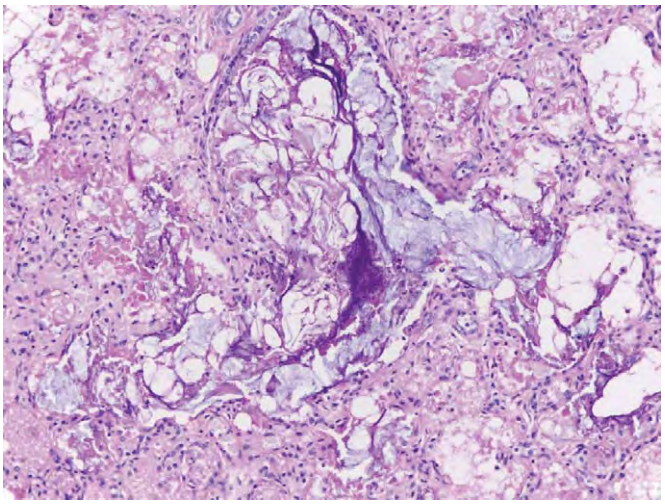

Figure 28-11 Microscopic picture of lung tissue from an infant who died from meconium aspiration syndrome (MAS): An alcian blue/PAS diastase stain has been used. The lungs show patchy aeration. The pulmonary vasculature appears thick walled. Occasional groups of aspirated squamous cells are seen. Mucin stain (*blue*) shows mucus consistent with meconium. There are some areas of congestion and focal areas of hemorrhage. PAS, periodic acid–Schiff.

secondary bacterial infection. Pneumomediastinum and/or pneumothorax occur in 10% to 15% of infants with MAS who require mechanical ventilation,[143] secondary to small airway obstruction that leads to gas trapping and uneven distribution of inspired gas. The high transpulmonary pressure generated by the infant or required on the mechanical ventilator to achieve adequate ventilation increases the risk. Parenchymal inflammation and damage caused by the meconium may also increase the potential for alveolar rupture. No data on secondary bacterial infection complicating MAS are available in infants, but in experimental animals, meconium enhances bacterial growth in the lung.[142] Because of similarities in the clinical and radiographic manifestations of aspiration of meconium and bacterial pneumonia, it is not always easy to diagnose a superimposed bacterial infection during the acute phase of MAS, necessitating a high index of suspicion. Infants who become infected in utero have a higher incidence of perinatal asphyxia and meconium aspiration.[140]

Although the clinical course is difficult to predict, infants who have large amounts of thick meconium in the trachea and grossly abnormal chest radiographs generally have a more severe subsequent disease course.[152] The clinical course is also influenced by the occurrence of complications, such as PPHN, infection, and pneumothorax, which delay recovery. Although mild cases may require only oxygen supplementation for a few hours or days, infants with severe respiratory failure require mechanical ventilation for several days or even weeks and have a high mortality rate. In a series of infants with MAS, approximately 30% required mechanical ventilation; the overall mortality rate was 4.2%.[143]

Neonates with severe MAS have a marked reduction in dynamic lung compliance.[154] This can be secondary to the changes in lung elasticity caused by the inflammatory reaction produced by the meconium, to inactivation of alveolar surfactant, and to the significant increase in airway resistance or overinflation found in most of these infants.[155,156] Minute ventilation is usually increased because of increased respiratory rate, but increased dead space ventilation reduces alveolar ventilation, leading to carbon dioxide retention.[157,158]

Treatment

PREVENTION

The prevention of MAS must start before birth by taking all the necessary precautions to reduce the risk of fetal distress and avoidance of post-term delivery. Correction of possible cord compression secondary to oligohydramnios and dilution of meconium by the use of intrapartum saline amnioinfusion has been proposed as a means of preventing MAS. Although a meta-analysis of amnioinfusion for prevention of MAS in 2002 noted an overall reduction in MAS and cesarean section, the trials included had small sample sizes and poorly defined outcome measures.[159] More recently, a large multicenter trial with 1998 study subjects found that amnioinfusion did not reduce the risk of moderate or severe meconium aspiration syndrome, perinatal death, or other major maternal or neonatal disorders.[160] The benefits of amnioinfusion may be restricted to settings where routine intrapartum fetal heart-rate monitoring and neonatal resuscitation are not available.[161]

RESUSCITATION

The previous practice of aspiration of meconium from the upper airway at birth has been questioned, with recent studies suggesting that suction of any infant with meconium-stained amniotic fluid on the perineum does not prevent MAS and has no clinical benefit.[162] Meta-analysis of four randomized controlled trials did not demonstrate a benefit for routine endotracheal intubation and suctioning in vigorous term babies born via meconium-stained fluid.[163] Currently, intubation and suctioning of meconium from the airways is recommended only in the unresponsive infant; however, suctioning should cease and resuscitative measures should be commenced immediately if bradycardia becomes evident.

Subsequent Clinical Management

In infants with evidence of respiratory failure, an arterial blood gas analysis and a chest radiograph should be obtained as soon as possible. The inspired oxygen concentration must be adjusted to maintain the PaO_2 above 70 mm Hg or the oxygen saturation above 90%. Some degree of metabolic acidosis is frequently observed as a result of perinatal asphyxia. If persistent, this must be corrected to decrease the risk of pulmonary hypertension. In infants who remain hypoxemic despite the use of high inspired oxygen concentrations or in infants in whom the $PaCO_2$ rapidly rises above 50 to 60 mm Hg, it is necessary to use mechanical ventilation. Because of the reduced lung compliance and increased airway resistance, these infants often require high peak inspiratory pressures. Because most of these infants are active and restless, it is often necessary to use sedation, at least during the first 24 to 48 hours of mechanical ventilation, until the infant is stable and the peak airway pressure of the ventilator can be reduced.[164]

In infants with severe respiratory failure who do not respond to conventional mechanical ventilation, the use of high-frequency ventilation using jet ventilators or oscillators can improve gas exchange and arterial blood gas levels.[165] This is usually indicated when the patient develops pulmonary hypertension with extrapulmonary right-to-left shunting and severe hypoxemia. Inhaled nitric oxide has also been found to provide clinical benefit in the situation of refractory hypoxia. Meconium aspiration can inactivate alveolar surfactant and bolus exogenous surfactant reduces the severity of respiratory disease and decreases the number of infants requiring extracorporeal membrane oxygenation (ECMO).[150] More recently, studies have shown that therapeutic surfactant lung lavage results in better gas exchange and/or pulmonary mechanics than either no lavage[166-168] or bolus surfactant therapy,[167] and that lavage removes considerable amounts of meconium from the lung.[167-170] The practicality and safety of the widespread clinical application of this approach has not been demonstrated.

The risk of bacterial infection is increased in infants with MAS, but the clinical diagnosis of a superimposed infection is difficult. When bacterial pneumonia is suspected because of fever, an abnormal white blood cell count, or deterioration in respiratory function and the appearance on radiograph, blood and tracheal cultures should be obtained and antibiotic therapy should be initiated. There is no clear evidence to justify the use of prophylactic antibiotics in meconium aspira-

tion, but some clinicians elect to administer antibiotics until the acute respiratory failure subsides.

The severity of the respiratory failure should not cause the physician to overlook other complications that frequently occur because of perinatal asphyxia. Central nervous system, cardiovascular, renal, and metabolic function should be monitored closely, and any alteration must be promptly corrected.

Clinical Course and Prognosis

Although most infants with MAS survive without sequelae, long-term follow-up studies have revealed an increased prevalence of hyperreactive airway disease, similar to that found in premature infants with CLD.[171,172]

PERSISTENT PULMONARY HYPERTENSION OF THE NEWBORN

This disorder was originally described by Siassi and coworkers[173] in a group of infants without significant lung disease. Today, PPHN in newborn infants is most often secondary to other pulmonary pathologic conditions such as MAS, sepsis and pneumonia, hypoplastic lung, and alveolar capillary dysplasia. PPHN may also occur after antenatal maternal administration of prostaglandin inhibitors in association with congenital heart disease that blocks pulmonary venous outflow and may be iatrogenic secondary to overventilation.

Epidemiology, Risk Factors, and Pathogenesis

In the normal neonate, pulmonary vascular resistance decreases rapidly after birth in response to an increase in lung volume, oxygen tension, and concentration of vascular dilating prostaglandins.[174,175] This reduction in pulmonary vascular resistance produces a fall in the pulmonary artery and right ventricular pressures that results in the cessation of right-to-left shunting through the foramen ovale and the ductus arteriosus. This normal process can be altered in response to hypoxia, acidosis, infection, or pulmonary hypoplasia and a decreased vascular cross-sectional area. Under such conditions, the pulmonary artery pressure remains elevated to values that may surpass systemic blood pressure, maintaining the right-to-left shunting predominantly through the foramen ovale and, to a lesser extent, also the ductus arteriosus.[176] This causes severe arterial hypoxemia that is relatively unresponsive to increased concentrations of inspired oxygen. The elevated pressure in the right ventricle frequently produces tricuspid regurgitation that increases the likelihood of shunting at the atrial level. Tricuspid regurgitation may be aggravated by the papillary muscle necrosis in the tricuspid valve that occurs in some infants with severe perinatal asphyxia.[177]

The magnitude of the right-to-left shunt in infants with PPHN is determined by the pressure gradient between the two circulations. Therefore, systemic hypotension secondary to sepsis or asphyxia increases the severity of the shunting and the hypoxemia.[178]

Postmortem examination of the pulmonary circulation in a group of infants who died of PPHN demonstrated an increase in vascular smooth muscle and extension into the peripheral vascular bed; thus these infants had an antenatal insult that altered the pulmonary vasculature, which prevented normal adaptation after birth.[179,180] Impaired vascular epidermal growth factor (VEGF) signaling has been implicated in the vascular remodeling process.[181] Other factors that may predispose an infant to PPHN are antenatal exposure to prostaglandin inhibitory drugs[182,183] and polycythemia.[184] Increased concentrations in serum or tracheobronchial secretions of a number of prostanoids[185] and inflammatory mediators such as endothelin-1,[186] leukotrienes (LTC4 and LTD4),[187] thromboxane, and platelet-activating factor have been described in infants with PPHN. All these substances are potent vasoconstrictors and may play a role in the pathogenesis of PPHN.[185,188]

Clinical Presentation and Diagnosis

PPHN occurs only occasionally in preterm infants or in neonates with no lung disease. Most infants with PPHN are born at term and have evidence of perinatal asphyxia and meconium aspiration or neonatal infection (see Table 28-1). In some instances, the infant is hypoxemic from birth, but more often there is a period of adequate oxygenation that may last for minutes or a few hours. During the first few hours after birth, there is a progressive deterioration in arterial oxygen tension that may be accompanied by an increase in carbon dioxide tension. The progressive hypoxemia becomes unresponsive to further increases in inspired oxygen concentration and frequently is disproportionate to the degree of pulmonary involvement. In most cases, large fluctuations in the PaO_2 also occur spontaneously or in response to physical stimulation and activity of the infant. A difference between preductal and postductal oxygenation suggests the presence of a right-to-left ductal shunt. The echocardiographic demonstration of high pulmonary artery pressure, tricuspid regurgitation, and shunting through the foramen ovale and ductus arteriosus confirms the diagnosis of PPHN.[189]

Treatment

The management of PPHN is one of the most difficult challenges in neonatal intensive care. Prevention and correction of predisposing factors such as perinatal asphyxia, sepsis, and polycythemia should be the first steps, including dilutional exchange transfusion, if necessary. Avoidance of unnecessary handling is critical, as this may trigger sudden and severe hypoxia. Correction of hypoxemia and acidosis, both potent pulmonary vasoconstrictors, should also be pursued aggressively. A small degree of metabolic and respiratory alkalemia can result in a marked reduction in shunting and an improvement in oxygenation.[190,191] The arterial oxygen tension must be maintained around 80 to 100 mm Hg (10.5 to 13 kPa) to prevent hypoxemia during spontaneous fluctuations in oxygenation. Moderate hyperventilation to achieve eucapnia, and at most mild hypercapnea and a pH > 7.30 are appropriate. Although hyperventilation to achieve a pH of 7.55 to 7.6 improves PaO_2, it is no longer recommended because of the potential adverse effects resulting from reduced cerebral blood flow,[192-195] potential for gas trapping that in turn impedes venous return and pulmonary blood flow,[196] and the lung injury from the mechanical ventilation. In the more

severe cases of secondary PPHN, the use of high-frequency ventilation can markedly improve carbon dioxide elimination and oxygenation.[193,197]

Cardiovascular support also plays an important role in the management of infants with PPHN. Medications such as dopamine, isoproterenol, and dobutamine are frequently used to increase arterial blood pressure and improve cardiac output.[190,198] Calcium infusion can improve myocardial function in the presence of low plasma ionized calcium levels.[199] Sedation and muscle relaxation are also used in infants whose spontaneous activity interferes with mechanical ventilation, resulting in deterioration of gas exchange.[164] A number of vasodilators have been used in PPHN, but none has been shown to alter the final outcome.[200] The major limitation with medications such as α-adrenergic blockers, calcium channel blockers, and prostacyclin is their lack of specificity as they induce systemic hypotension. Prostaglandin D_2, a selective pulmonary vasodilator in fetal animals, was used in a group of infants with PPHN, but the results were disappointing.[201]

The introduction of inhaled nitric oxide, a potent vasodilator rapidly inactivated in the blood, represented a major advance in the treatment of PPHN[202-204] as oxygenation improves without causing systemic hypotension. Because nitric oxide is a gas that is delivered into the airways, it reaches the better ventilated portions of the lung, preventing the ventilation-perfusion mismatch that can occur when vasodilators are administered systemically. The administration of inhaled nitric oxide (iNO) to infants with PPHN results in a rapid improvement in oxygenation in more than one half of patients and reduces the need for extracorporeal membrane oxygenation.[205-207] More than 30% of infants with PPHN do not respond to iNO, however, and there are problems associated with prolonged administration of and weaning from iNO.[208] More recently, phosphodiesterase (PDE) inhibitors, particularly PDE5 inhibitors such as sildenafil, have shown promise as selective pulmonary vasodilators. Pulmonary vascular smooth muscle cells have very high concentrations of PDE5 receptors.[209] Inhibition of such receptors causes cGMP to accumulate, causing hyperpolarization of the smooth muscle cells and subsequent vasodilation.[210]

Infants who do not respond to management can be treated with extracorporeal membrane oxygenation.[211-213] The survival rate with this mode of therapy in most centers is better than 90%, but because of the possible complications and long-term sequelae, this procedure is still used only as a last resort.[214-216]

Clinical Course and Prognosis

The outcome of neonates with PPHN depends on the underlying condition, the severity of the disease course, and the effectiveness of management. Although most infants survive, many require ventilatory support for long periods, and a few have central nervous system sequelae related to episodes of severe hypoxia and the hypocapnia induced by hyperventilation.[195,217] Some infants develop CLD because of pulmonary damage produced by infection or the aspiration of meconium or because of the mechanical ventilation required to maintain adequate gas exchange.

PULMONARY GAS LEAKS

Lung rupture and gas leak are major complications in infants with respiratory failure, especially in those who need assisted ventilation (see Table 28-1). Rupture of the terminal airways leads to the accumulation of extra-alveolar gas, pulmonary interstitial emphysema, pneumomediastinum, pneumothorax, subcutaneous emphysema, or gas embolization of the lymphatic system and pulmonary and systemic circulations.

PULMONARY INTERSTITIAL EMPHYSEMA (PIE)

PIE is the most common form of barotrauma associated with mechanical ventilation and usually observed as a complication of RDS, although it also occurs in association with aspiration syndromes and sepsis. Although normally confined to intubated subjects, PIE has been described in an infant who received only nasal CPAP,[218] and more rarely, in spontaneously breathing, nonventilated subjects.[219] PIE is important because of the significant pathophysiologic alterations it causes and because it commonly progresses to more severe forms of extra-alveolar gas leak (Fig. 28-13).

Epidemiology, Risk Factors, and Pathogenesis

The incidence of PIE in infants with very low birth weights was reported to be 32%.[220] A significant reduction in the incidence of PIE, as low as 7%, has been reported with surfactant treatment for infants with RDS.[221,222] In patients requiring conventional mechanical ventilation, the use of high rates and short inspiratory times appears to reduce the incidence of gas leak, including PIE.[54,60] In theory, ventilatory modalities such as pressure support ventilation that avoid

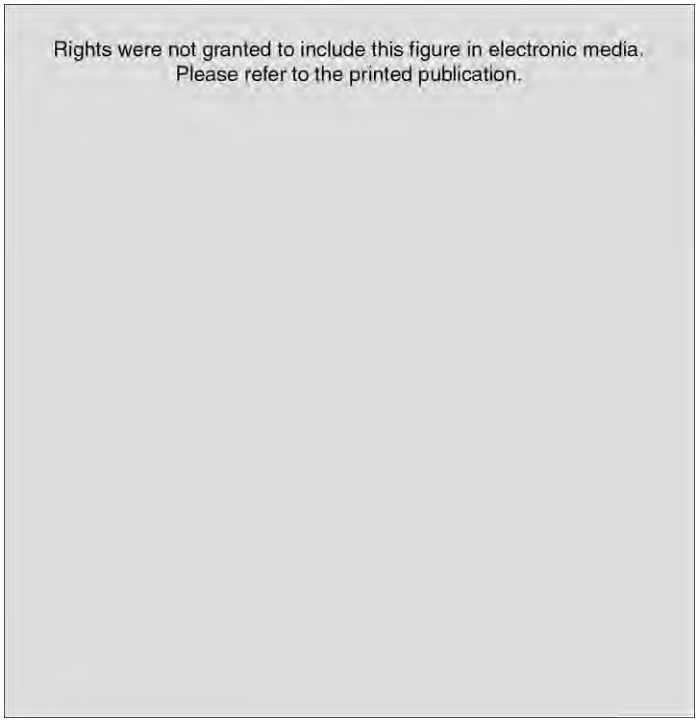

Figure 28-13 Progression of pulmonary gas leak. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 151.)

active expiration should reduce the incidence of PIE and other air leak phenomena, but evidence is not yet available.

PIE is caused by a dissection of gas from the base of ruptured overdistended terminal airways or alveoli into the pulmonary interstitium. Rupture occurs at the alveolar-capillary junction when shear forces exceed a critical threshold. The amount of interstitial gas is variable. PIE can occur spontaneously in infants with parenchymal lung disease but more frequently occurs as a complication of mechanical ventilation. Neonatal alveoli are less able to compensate for excessive pressure and volume than alveoli in mature lungs. In the adult, interalveolar pores (pores of Kohn) act as relief valves that allow higher intra-alveolar pressures to equilibrate with adjacent alveoli when intra-alveolar pressure is nonuniform. These communicating pores are decreased in number and size in the newborn. Nonuniform transmission of pressure to alveoli during mechanical ventilation means that the newborn is more likely to develop alveolar rupture. The presence of meconium, blood, or other particulate matter that exacerbates uneven aeration also exacerbates this tendency. Experimental work using rabbits suggests that the absolute amount of intrapulmonary pressure generated and mechanical stress resulting from overdistention of alveoli, or of alveolar ducts adjacent to atelectatic alveoli, is directly responsible for the development of PIE.[223] Once rupture occurs, gas enters the adjacent interstitial tissue, where it can dissect along the perivascular (particularly pulmonary venous) sheaths to the hilum of the lung. When the volume of gas in the interstitium is large enough, the resulting perivascular pressure can obstruct the pulmonary circulation.

Diagnosis

The development of mild PIE is rarely associated with demonstrable changes in cardiorespiratory function. When PIE is severe and diffuse, deterioration of the respiratory status occurs with hypoxemia and hypercarbia caused by compression of the pulmonary vasculature by trapped gas. The chest radiograph confirms the diagnosis: The lungs have a fine, bubbly appearance, sometimes with larger lucent areas (Fig. 28-14). In a small, preterm infant with diffuse PIE, transillumination of the chest may be indistinguishable from a large pneumothorax.

Treatment

Management consists primarily of preventing progression to other forms of gas leak by using the lowest effective airway pressures and short inspiratory times in the ventilator. Randomized clinical trials comparing conventional mechanical ventilation with high-frequency ventilation have either failed to show a reduction in the incidence of PIE with high-frequency ventilation,[224-226] or demonstrated effective treatment of PIE[227] and could also reduce the incidence of PIE in infants with severe RDS.[228]

For unilateral PIE, selective intubation of the main stem bronchus on the unaffected side[229] or positioning of the infant with the involved side down[230] may be beneficial. In the case of severe PIE, especially when it has progressed to the formation of large cysts, surgical resection of the affected lobe should be considered.[231]

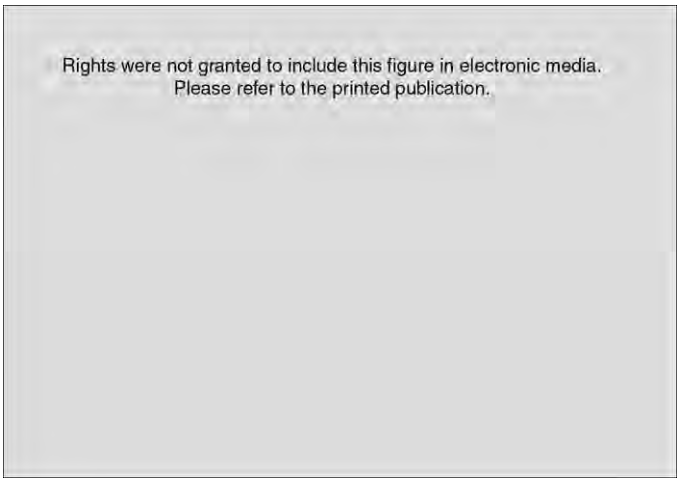

Figure 28-14 Pulmonary interstitial emphysema (PIE). Fine, bubbly appearance of the lungs in an infant with severe respiratory distress syndrome (RDS). (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 154.)

PNEUMOMEDIASTINUM

Pneumomediastinum, a collection of gas within the pleural boundaries of the mediastinum, can occur spontaneously or as a complication of mechanical ventilation.

Epidemiology, Risk Factors, and Pathogenesis

Gas enters the mediastinum after moving along the vascular sheaths toward the lung hilum and then ruptures through the pleura into the mediastinal area. Another cause of pneumomediastinum is traumatic perforation of the pharynx or esophagus.[232] The incidence in well newborns is about 2%[233] but is significantly higher in infants with pulmonary pathologic conditions.[234]

Diagnosis

Pneumomediastinum is symptomatic only if the collection of gas is under sufficient pressure to compress adjacent structures such as the heart or blood vessels, producing cardiorespiratory decompensation. The diagnosis is made radiographically by radiolucency adjacent to the heart border and retrosternal hyperlucency on lateral view.

Treatment

There is no specific treatment for pneumomediastinum.

PNEUMOTHORAX

Pneumothorax is the accumulation of gas in the pleural space between the parietal and visceral pleura. When the pressure of this gas is greater than the atmospheric pressure, the pneumothorax is "under tension." Although pneumothorax can occur spontaneously, it is one of the most common manifestations of pulmonary barotrauma in neonates requiring mechanical ventilation.

Epidemiology, Risk Factors, and Pathogenesis

The incidence of spontaneous, asymptomatic pneumothorax in the newborn has been reported to be 1%.[233] This condition is more frequent in infants with specific lung pathologic conditions that require mechanical ventilation. Before the introduction of surfactant, the incidence of pneumothorax in patients with RDS treated with CPAP alone was close to 20%.[235] In infants with RDS who required mechanical ventilation but did not receive surfactant, the incidence of pneumothorax was 18% when a rate of 60 breaths/minute and a short inspiratory time were used, but the incidence was significantly higher (33%) in infants treated with a slow respiratory rate and longer inspiratory time.[53] The use of high-frequency ventilation in infants with RDS has not affected the incidence of pneumothorax.[225,236]

The introduction of surfactant treatments for the management of infants with RDS has produced a dramatic reduction in the incidence of pneumothorax to a rate as low as 3% to 10%.[221,237,238] Early administration of surfactant seems to be important in reducing the incidence of pneumothorax. When early administration of surfactant was compared with treatment of established RDS in infants of less than 30 weeks' gestation, the incidence of pneumothorax was 7% in the early treatment group compared with 18% in the infants treated several hours after birth.[239,240]

Pneumothorax in the neonate is produced most often by mediastinal gas rupturing through the mediastinal pleura into the pleural space. A large pneumothorax can decrease cardiac output and can increase pulmonary vascular resistance. As the pneumothorax increases in size, compensatory mechanisms can no longer prevent decreases in cardiac output and systemic blood pressure. The increased intrathoracic pressure decreases venous return to the heart and can cause a cardiac tamponade. The accompanying lung collapse also increases pulmonary vascular resistance and contributes to the decrease in cardiac output. Increasing amounts of pleural gas result in a decrease in tidal volume that can initially be compensated for by an increase in respiratory rate—but if severe, it leads to decreased minute ventilation and hypercarbia. As lung volume is decreased and some areas are collapsed, there is an increased ventilation-perfusion mismatch, resulting in an intrapulmonary shunt and hypoxemia.

Intracranial pressure usually increases as a result of an increase in arterial blood pressure, obstruction of venous return, and increased cerebral blood flow. In the premature infant, these factors can increase the risk of intraventricular hemorrhage.[241]

Diagnosis

Clinically, the signs of pneumothorax in the neonate are variable. Although most spontaneously occurring pneumothoraces are asymptomatic, a diagnosis of pneumothorax needs to be considered when significant clinical deterioration occurs in association with lung disease or mechanical ventilation.

Spontaneously breathing infants who develop large pneumothoraces demonstrate the classic signs of respiratory failure, including cyanosis, grunting, intercostal and substernal retractions, tachypnea, and nasal flaring. These signs are sometimes difficult to evaluate in infants whose lungs are ventilated and in whom the only obvious sign of pneumothorax may be abrupt deterioration of the arterial blood gas levels. On physical examination, a pneumothorax is suggested by asymmetrical chest expansion, downward displacement of the liver, and decreased heart and breath sounds on the side of the pneumothorax. The latter sign is particularly unreliable in the small premature infant whose breath sounds are easily heard uniformly all over the chest. A pneumothorax is frequently followed by an increase in respiratory rate, heart rate, and arterial blood pressure.[242] A tension pneumothorax may be associated with shift in the heart sounds to the contralateral side and significant, and often dramatic changes in the vital signs.

The chest radiograph is the best method of confirming the diagnosis. If the radiograph is taken with the infant in a supine position with an anteroposterior view, the pneumothorax can be seen as a crescent-shaped lucency along the lateral aspect of the thorax (Fig. 28-15) without lung markings extending into the lucent area. Care must be taken not to confuse a skinfold or blanket with this type of appearance. These artefacts can frequently be recognized because they extend below the diaphragm. If the lungs do not collapse because of poor compliance or if the accumulation of extrapulmonary gas is anterior, the crescent-shaped lucency may not be present, and the only suggestion of a pneumothorax is a generalized decreased density on the side of the extrapulmonary gas. A medial pneumothorax appears as a lucency just to the right or left of the heart borders. In these cases, the presence of a pneumothorax can be ascertained by obtaining a "cross-table" lateral film. This method should be reserved for the infant who is too unstable to rotate to the decubitus position because

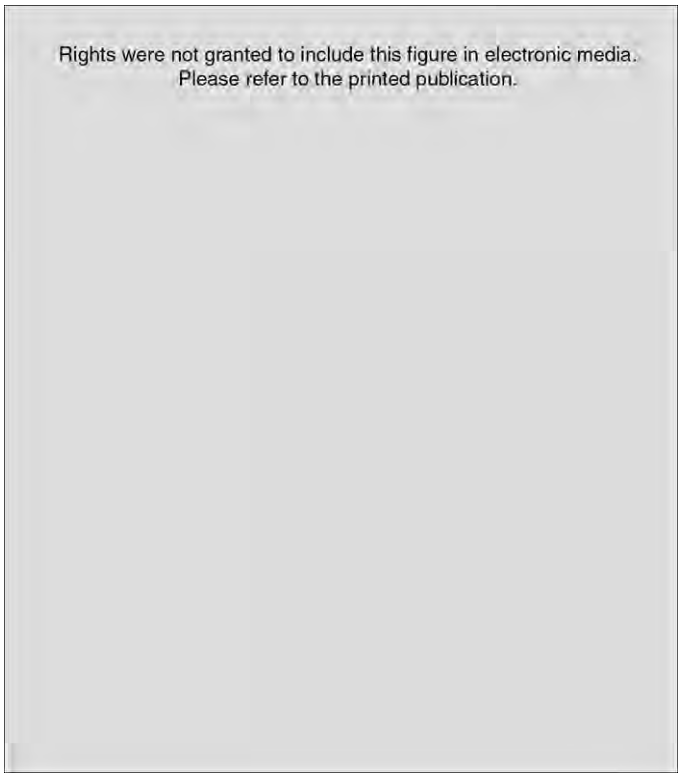

Figure 28-15 Pneumothorax. Chest radiograph shows small crescent-shaped lucency on the left at the level of the apex. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 156.)

the anterior lucency may be difficult to distinguish from a pneumomediastinum.

The presence of a tension pneumothorax is recognized because the mediastinum is shifted to the opposite side, the intercostal spaces are widened, and the diaphragm is flattened on the ipsilateral side (Fig. 28-16). If bilateral tension pneumothoraces occur simultaneously, there may be no shift of the mediastinum, but the bilaterally increased pressure compresses the heart, resulting in a smaller cardiac silhouette. A noncompliant lung in an infant with RDS may not completely collapse, even with a tension pneumothorax. Transillumination of the chest with a fiberoptic light source is a very useful adjunct for diagnosing pneumothorax,[243] particularly in small premature infants in whom physical examination is unreliable. The thin chest wall of such infants allows for a demonstration of the "halo" of light that indicates extrapulmonary gas. Transillumination of the chest in larger infants with thicker chest walls occasionally gives false-negative results. Thus, a radiographic examination should not be omitted because of a negative transillumination. Treatment should not be delayed for radiographic confirmation in the presence of significant clinical deterioration if a diagnosis of pneumothorax is suspected and supported by transillumination.

Treatment

When the diagnosis of pneumothorax is suspected, the plan for treatment is based on the following considerations: the size of the pneumothorax, the extent of the infant's respiratory deterioration, and the need for positive-pressure ventilation. A pneumothorax diagnosed in an infant with no symptoms does not require specific therapy, but the infant should be observed closely for possible signs of respiratory decompensation.

If the pneumothorax is associated with cardiorespiratory symptoms, immediate treatment is indicated. Evacuation can be accomplished by needle aspiration or by thoracostomy with chest tube insertion. The administration of 100% oxygen can accelerate the reabsorption of gas. This is because breathing 100% oxygen will "wash out" nitrogen from the body, including the tissues surrounding the pneumothorax. This increases the nitrogen gradient, facilitating faster absorption of the nitrogen from the gas collection into the bloodstream. Because of the risk of retinopathy of prematurity, this method should not be used in preterm infants less than 34 weeks postmenstrual age. Needle aspiration is indicated only as a temporizing measure in an infant who has a tension pneumothorax or who requires positive-pressure ventilation. In these cases, the immediate placement of a chest tube is indicated. The thoracostomy tube should then be attached to an underwater seal so that air will not be drawn into the pleural space. If the volume of the pneumothorax is relatively small, the negative pressure maintained by the underwater seal is sufficient to evacuate the extrapulmonary gas. However, if there is a large volume of gas or if there is a continuous gas leak, negative pressure (15 to 20 cm H_2O) should be applied to the system to ensure complete evacuation. When there is no further drainage, the negative pressure can be discontinued, and if no re-accumulation occurs, the chest tube can be clamped and removed in 24 hours.

Figure 28-16 Left tension pneumothorax. Tension is indicated by the contralateral shift of the mediastinum, small heart size, and depressed left diaphragm. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 162.)

Clinical Course and Prognosis

Pneumothorax is a potentially fatal complication, but if diagnosed and treated promptly, it may have only minimal consequences. The keys to preventing a poor outcome are a high index of suspicion in infants at risk and the proper equipment and personnel for effectively diagnosing and treating the disorder.

PNEUMOPERICARDIUM

Although the pericardial sac is not in direct communication with the pleural space, extrapulmonary gas can collect in the pericardium. Pneumopericardium is an uncommon form of gas leak.

Pathogenesis

The mechanism of gas entry seems to be directly from the pulmonary interstitial air, traveling along the great vessels into the pericardial sac.[244] The physiologic effects of a pneumopericardium are essentially those of cardiac tamponade. Increased pressure around the heart interferes with diastolic filling, resulting in increased central venous pressure and decreased cardiac output. This produces arterial hypotension with a narrow pulse pressure.

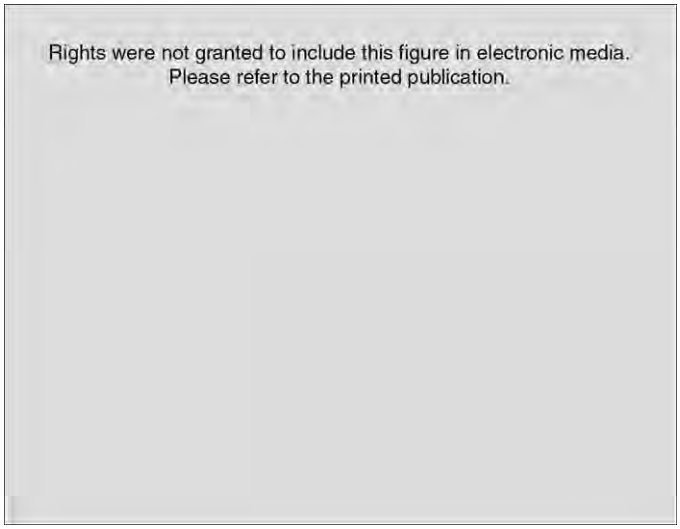

Figure 28-17 Pneumopericardium. The heart is clearly outlined by a collection of gas in the pericardium. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 163.)

Figure 28-18 Pneumoperitoneum. The wall of the stomach is distinct, indicating the presence of an abnormal collection of gas within the peritoneal cavity surrounding the stomach. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 164.)

Diagnosis

The clinical signs of pneumopericardium in the neonate are variable, and most are nonspecific. A small pneumopericardium may develop without any significant change in the infant's cardiorespiratory status—being noticed only incidentally on the chest radiograph. When gas is accumulated under tension, an increase in respiratory distress and hypoxemia is observed, and heart sounds become distant with a decrease in arterial and pulse pressure. An increase in the central venous pressure may also be noticed. Pneumopericardium is rarely isolated because it is most commonly associated with other forms of gas leak.

The diagnosis of pneumopericardium must be suspected in any infant in whom there is an acute clinical deterioration while on mechanical ventilation. A decrease in both pulse pressure and mean arterial blood pressure should alert the clinician to this diagnosis. The chest radiograph confirms the diagnosis by showing a gas lucency surrounding the heart on the anteroposterior and lateral films (Fig. 28-17).

Treatment

When a pneumopericardium is symptomatic, immediate drainage is imperative. Decompression can be accomplished by needle aspiration, but continuous drainage via placement of a pericardial catheter is necessary in most cases to prevent re-accumulation of gas. Without treatment, the mortality rate approaches 70%, and even with pericardiocentesis, the mortality rate remains high (20% to 60%).[245]

PNEUMOPERITONEUM

Free gas in the peritoneal cavity, generally considered evidence of bowel perforation, is recognized as a possible complication of ventilator therapy and not necessarily the result of a perforated viscus. In infants ventilated for RDS, the reported incidence was 1.7% before the introduction of surfactant.[246]

Pathogenesis

Although the diaphragm separates the thorax from the peritoneal cavity, there are potential pathways through which gas can cross from one cavity to the other. Free gas in the mediastinum or pleural space can dissect caudally along the perivascular and periesophageal tissue sheaths into the retroperitoneal space and thence into the peritoneum.

Diagnosis

The signs of pneumoperitoneum secondary to pulmonary gas leak are nonspecific. Commonly, there is abdominal distention, which may be severe enough to compromise ventilation by elevating the diaphragm. The clinical setting in which pneumoperitoneum occurs is characteristic: The infant is receiving high ventilatory pressures and usually has evidence of intrathoracic gas leak before the discovery of intraperitoneal free gas. The development of pneumoperitoneum is not usually associated with clinical deterioration unless the volume of gas is massive enough to compromise ventilation. The diagnosis is confirmed radiographically (Fig. 28-18). Unfortunately, no specific radiographic signs accurately define the presence or absence of visceral perforation.

Treatment

Pneumoperitoneum secondary to pulmonary gas leak usually requires no specific treatment. Rather, attention should be directed at preventing or decompressing the intrathoracic gas collection that leads to the pneumoperitoneum. Once gas is present in the peritoneum, no treatment is necessary unless a perforated viscus is suspected or unless there is significant tension that can be relieved by needle aspiration.

GAS EMBOLISM

Intravascular gas embolism is the rarest but most catastrophic consequence of acute pulmonary barotrauma. Gregory and Tooley[247] first reported a case of gas embolism in a newborn who had RDS and who was receiving positive-pressure ventilation.

Pathogenesis

Gas embolism is thought to result from alveolar-capillary fistulas. In spontaneously breathing infants, the pressure in the pulmonary capillary bed is greater than that in the alveolus. However, with the application of positive airway pressure, this gradient is reversed, favoring the movement of gas from the alveolus into the vascular space. Once in the vascular space, the gas can travel to all parts of the body, including the cerebral and cardiac circulations, leading to rapid death from vascular obstruction.

Clinical Features and Diagnosis

Most of the cases reported are of premature infants receiving relatively high airway pressures. Characteristically, these infants have radiographic evidence of other forms of gas leak before the development of gas embolism. Clinically, they have acute cardiovascular deterioration with development of pallor or cyanosis, bradycardia, and hypotension. Often, the diagnosis is made when gas bubbles are withdrawn from an artery or a venous catheter during the clinical deterioration. The diagnosis is confirmed radiographically with demonstration of gas shadows within the heart chambers and vascular tree (Fig. 28-19).

Treatment, Clinical Course, and Prognosis

Massive gas embolism is invariably fatal; hence, treatment must be viewed as preventive: The lowest possible ventilatory pressures should be used to prevent alveolar rupture and gas leak.

WILSON-MIKITY SYNDROME

Wilson-Mikity syndrome was first described in 1960 and is characterized by late-onset progressive respiratory distress in small preterm infants. In contrast to CLD, it manifests in infants without severe initial respiratory distress syndrome.[248,249] The respiratory symptoms usually begin between 1 and 4 weeks of age and last several weeks or months, after which most infants recover gradually. Radiographically, the lungs have a cyst-like appearance with diffuse streaks of increased density resembling the changes observed in infants with CLD. On histologic examination, the lungs show areas of hyperinflation alternating with areas of collapse and septal thickening, but in contrast with infants with CLD, these infants do not show significant changes in the airway epithelium. The etiology and pathogenesis of Wilson-Mikity syndrome are not known, but congenital infections have been mentioned as possible causes. This condition is seldom diagnosed today in spite of the fact that the survival rate of very small infants has increased.

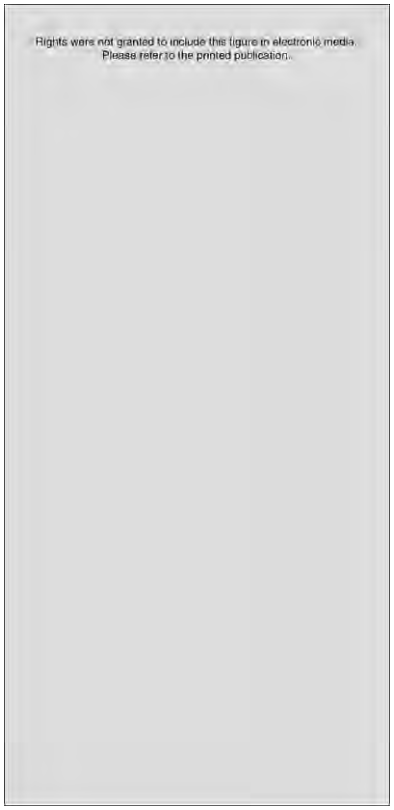

Figure 28-19 Gas embolization. Postmortem radiograph of a premature infant who died suddenly while requiring high ventilatory pressures. Gas can be seen within the heart and in some intra-abdominal veins. (From Bancalari E, Goldman SL. In Milunsky A, Friedman EA, Gluck L [eds]: Advances in Perinatal Medicine. New York, Plenum, 1989, p 129.)

CURRENT MAJOR CONTROVERSIES AND CHALLENGES IN CLINICAL MANAGEMENT OF NEONATAL ACUTE RESPIRATORY DISEASE

- Role of oxygen in initial resuscitation and its contribution to subsequent CLD
- Noninvasive versus invasive mechanical ventilatory support for the extremely preterm infant with RDS
- Pros and cons of new ventilatory modalities and strategies including pressure-support ventilation, proportional assist ventilation, and volume- versus pressure-limited mechanical support
- Pros and cons of inhaled nitric oxide, postnatal corticosteroids, adjuvant vitamin therapy, and new anti-inflammatory agents on the development of the structurally and functionally immature lung and other body organs
- Routine suction of the pharynx and trachea in the infant born through meconium-stained fluid

CHAPTER 29 Chronic Respiratory Complications of Prematurity

Sailesh Kotecha

TEACHING POINTS

- Chronic lung disease (CLD) is a common disease of preterm infants.
- Lung growth abnormalities are important in development of CLD
- Risk factors for CLD include extreme prematurity, male sex, white race, surfactant deficiency, oxygen toxicity, barotrauma, chorioamnionitis, sepsis, patent ductus arteriosus, and fluid overload.
- The mainstay of treatment for CLD is oxygen, but the ideal oxygen saturation is unknown.
- Drug management of CLD is empirical.
- Long-term respiratory outcome, especially in surfactant-treated infants, remains unclear.

CHRONIC LUNG DISEASE: BACKGROUND

Terminology

The term *chronic lung disease* (CLD), used to describe the aftermath of prematurity and its treatment on the respiratory system, is deliberately vague. It implies a wide spectrum of disorders affecting the upper and lower respiratory tract—the result of the complex interaction of antenatal and postnatal factors. Although the use of the term *disease* may seem to indicate the possibility of a clear all-or-none definition, CLD encompasses a range of clinical, physiologic, pathologic, and developmental problems that extends from marginally significant at one extreme to fatal at the other. The vagueness of the term hides the ignorance of many aspects of the pulmonary outcomes of prematurity.

Unlike the well-defined condition *bronchopulmonary dysplasia* (BPD),[1] CLD can be defined a number of ways to suit particular purposes. It is worth exploring the history of the ideas of the respiratory consequences of prematurity to draw attention to the themes that permeate this chapter.[2]

CLD has risen in importance since the advent of effective care for preterm babies. Until the 1960s and the introduction of mechanical ventilation, the survival of infants of very low birth weight (VLBW) was rare. (A VLBW infant weighs less than 1500 g at birth.) No chronic disease was therefore possible. When Northway and colleagues[1] described the chronic clinical and radiologic features of CLD in the preterm survivors of mechanical ventilation and high inspired oxygen therapy, defining bronchopulmonary dysplasia, they created a series of controversies that continue today. The most vehement arguments raged over the importance of barotrauma and oxygen toxicity as causes of lung injury in the neonate. The ignorance of the mechanisms and consequences of CLD has moved to a more sophisticated level because the multiple, interacting causes exert effects that vary in both their pathophysiologic basis and clinical features throughout infancy, childhood, and adolescence.

To some extent, the definitions of CLD reflect the applications of the term (Table 29-1). It has become clear that BPD (chronic oxygen dependency with certain characteristic radiologic features at 28 days of age) has become a less useful term because of the survival of infants at ever-lower gestational ages. Nevertheless, the term *bronchopulmonary dysplasia* or *"new" bronchopulmonary dysplasia* is used more frequently in North America to signify the changing pattern of the disease from both a clinical and pathologic perspective. Most infants who weigh less than 1000 g at birth are still oxygen dependent after 4 weeks. Thus, the continually varying level of risk of an adverse long-term outcome for VLBW infants is still defined according to a single criterion: the need for oxygen therapy.[3] The suggestion of Shennan and coworkers[3] that 36 weeks of gestational age represents the best compromise seems realistic. This cutoff point may vary with local need, secular trends, and changes in the epidemiology of CLD.

Comparisons between units are difficult not only because of differing local practices but also different definitions. A consensus regarding definition would permit comparisons between centers and with historic data. At a recent workshop sponsored by the National Institute of Child Health and Human Development, it was proposed that babies should be considered to have CLD if they had been oxygen dependent for at least 28 days and then be classified as suffering from mild, moderate, or severe BPD according to their respiratory support requirements at a later date.[4]

Diagnostic Overlap

Chronic lung disease includes not only BPD but also several purely neonatal disorders such as Wilson-Mikity syndrome (Table 29-2). Clinically and radiologically, this disorder is very similar to classic BPD (Northway type IV), except for a lack

Table 29-1
Definitions of Chronic Lung Disease

Application	Definition
Recognition of Clinical Abnormality	
Individuals	Definition based on the presence or quantification of clinical features such as hospital readmission or abnormal lung function in infancy
Groups	Statistical definition based on the quantification of excess morbidity
Risk Prediction for Clinical Intervention	Criteria dependent on the risk of possible interventions (e.g., the need for a fraction of inspired oxygen at 40% at 4 weeks would justify low-risk intervention; the prediction of intermittent positive-pressure ventilation at term might justify a very risky procedure)
Audit	
Clinical efficacy	All-or-none definitions such as bronchopulmonary dysplasia (BPD), which may be useful
Financial cost of care	Statistical definition based on excess respiratory morbidity (e.g., excess "bed days" as a result of all respiratory causes in premature infants)
Long-Term Health Care Planning	Definitions according to risk of need for long-term management, such as need for domiciliary oxygen therapy
Death Certification	Histopathologic criteria

Table 29-2
Clinical Disorders That Are within the Spectrum of Chronic Lung Disease (CLD) or That Contribute to Morbidity

Disorders	Comment
Neonatal disorders	
Developmental abnormalities	Pulmonary hypoplasia, intrauterine infection
BPD	
Type I	Small "gray" lungs on chest radiograph
Type II	Classic Northway type IV
Wilson-Mikity syndrome	Similarity to type II BPD, without preceding RDS
Chronic pulmonary insufficiency of prematurity	Similarity to type I BPD, without preceding RDS
Recurrent pulmonary aspiration	Gastroesophageal reflux, which often accompanies CLD
Disorders of Later Infancy in Which Morbidity Rate May Be Greater in Preterm Infants	
Wheezing disorders	Excess lower respiratory tract morbidity, which is seen in infants born prematurely and can be considered epidemiologically as a form of CLD
Defects of host defense	Very rare incidence, apart from cystic fibrosis
Developmental anomalies	Excess incidence of congenital heart disease in infants with CLD

BPD, bronchopulmonary dysplasia; RDS, respiratory distress syndrome.

of mechanical ventilation in its early postnatal course. Some pathologists deny any specific histologic features. Within the restricted category of BPD, at least two types are recognized: type 1 with "gray" lungs on chest radiographs and type 2 with classic radiologic changes.[5] There are other clinical distinguishing features (see Table 29-2). The role of developmental lung disorders such as pulmonary hypoplasia and of common clinical problems such as gastroesophageal reflux (GER) with aspiration is clearly complex. Such problems often contribute to CLD, but unless they are strikingly obvious, they do not usually warrant an independent diagnostic label. Recognizing their contribution may be important in understanding the etiology of CLD, its management, and its prognosis.

Diagnostic overlap is even more of a problem in later infancy, when infants of preterm birth tend to have greater morbidity in a range of clinical situations (see Table 29-2). For instance, because at least 30% to 60% of preschool children suffer from recurrent lower respiratory illness, mostly with wheezing,[6-8] the symptom is common in children born prematurely. Preterm infants are, in fact, at increased risk,[9-12] but it would be fruitless to try to define a level of morbidity that distinguishes "ordinary" wheezing lower respiratory illness from CLD. In clinical practice and increasingly in clinical epidemiology, a problem-oriented approach is more useful than one based on categorical diagnostic labels. The same argument applies to the other disorders in Table 29-2. This chapter uses the term *chronic lung disease* to encompass both a range of well-characterized syndromes and an overall increase in respiratory tract morbidity in infancy and later life.

EPIDEMIOLOGY, PATHOLOGY, RISK FACTORS, PATHOGENESIS

Epidemiology

The prevalence of CLD varies widely. Crude figures, even when adjusted for birth weight, are difficult to interpret and, hence, are of only limited value except as starting points for further exploration. Inaccuracy of terminology and diagnostic overlap produce so much "noise" that signals relating to important risk factors are difficult to discern. In the well-known eight-center, comparative study of VLBW infants in the United States,[13] strict diagnostic criteria were applied. Even so, major differences in the prevalence of CLD were observed that were not explained by different mortality rates within the institutions or by differences in birth weight, race, or gender. The authors speculated that the differences in 28-day oxygen requirements, which varied between 21% and 42%, might be accounted for by early postnatal management practices. At the center with the lowest incidence, nasal continuous positive airway pressure was instituted early for all symptomatic infants, and mechanical ventilation (without muscle paralysis) was commenced only when the partial pressure of carbon dioxide (P_{CO_2}) had risen to 60 mm Hg. Local variations in management may, therefore, have influenced the long-term outcome.

In another large, multicenter study in the United States, the incidence of CLD varied from 3% to 33% of all preterm infants and up to 50% of those who had respiratory distress syndrome (RDS).[14] By taking a complete, clearly defined VLBW population, Kraybill and associates[15] eliminated selection and diagnostic bias but came to the conclusion that although most of the variation between centers was due to differences in birth weight, about one third was due to other

BOX 29-1 Factors Determining the Prevalence and Variations in Diagnostic Criteria of Chronic Lung Disease

Population base of community
- Social factors
- Environmental factors
- Age and health structure of community
- Ethnic mix of population

Referral patterns of neonatal unit
- Obstetric population (high or low risk)
- Obstetric practices
- Postnatal referrals from units with less expertise

Morbidity of patients
- Early morbidity
- Maturity of population
- Complication rate
- Early mortality rate

Quality of care
- Quality and quantity of medical and nursing staff
- Quality of equipment
- Use of protocols based on scientific data

factors, differences in treatment being the prime suspect. Their overall incidence of classic BPD in VLBW infants was 22%. A number of the general factors that could affect the incidence of CLD are listed in Box 29-1.

Against this uncertainty, secular trends in birth weight–adjusted prevalence have clearly occurred. Within single institutions, increased survival of VLBW infants has been associated with a rise in CLD in the whole population (but not necessarily as a proportion of survivors), whereas for larger infants, the figures have fallen markedly.[16] Interestingly, despite or perhaps because of longer survival times, the prevalence of CLD has not fallen in the very smallest babies, those who weighed less than 750 g at birth.[17] Although much of the change in prevalence may be accounted for by the factors listed in Box 29-1, specific changes in perinatal care have brought overall survival benefits to preterm babies, increasing the risk in some cases of severe CLD.[18] The reduction in RDS by obstetric and early neonatal interventions has played a major part (see Chapter 28).

Early perinatal interventions have been exhaustively reviewed.[19-21] Corticosteroids have been used to accelerate lung maturation for many years, but their effect on the incidence of CLD is inconsistent and at most marginal,[19] although survival is significantly enhanced. Although long-term adverse effects have not been demonstrated in humans,[19] a number of animal studies have shown persistent,[22] transient,[23] or no effects[24] from fetal corticosteroid exposure. There are little data on human lung growth.[25]

One of the main advantages of population studies is the identification of risk factors, which can then be subjected to detailed investigation, often by randomized, controlled trial. The potential for bias in identifying risk factors from small, poorly controlled samples is largely a consequence of the network of interrelated risks in neonatal medicine

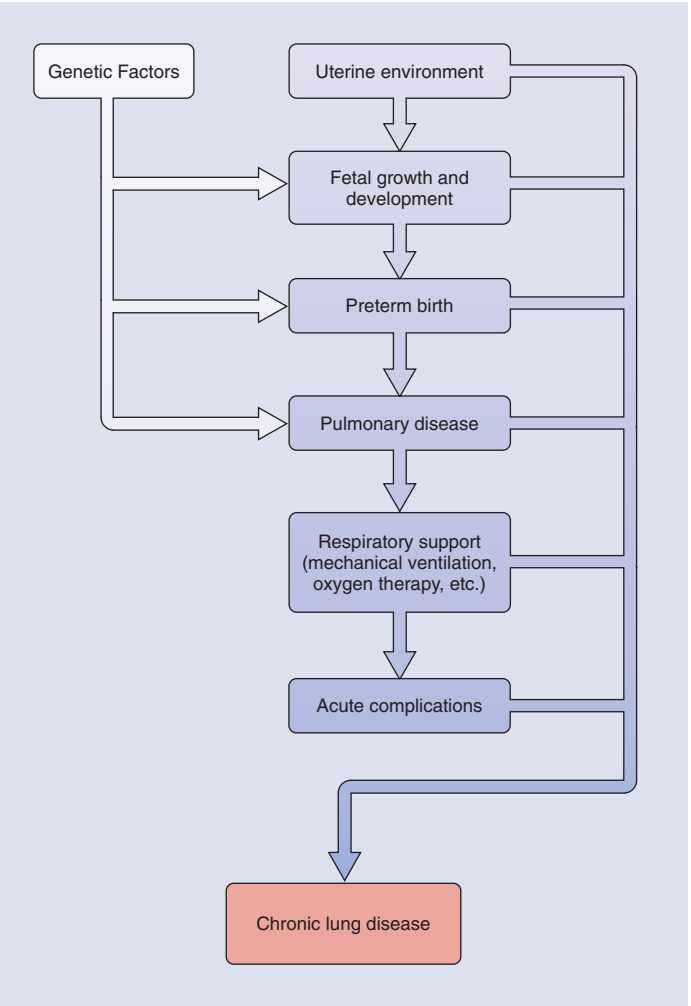

Figure 29-1 There is a great deal of interaction among risk factors in chronic lung disease (CLD).

(Fig. 29-1). The possibilities of bias are numerous and explain some of the conflicting results that have been reported from outcome studies. Many early studies identified mechanical ventilation and oxygen therapy as major risk factors for BPD on the basis of comparative outcome studies of infants whose lungs were mechanically ventilated compared with controls whose lungs were not ventilated. Such studies were confounded by the interaction of factors illustrated in Figure 29-1 and biased by the selection of unrepresentative samples of the population. The analysis of Kraybill and coworkers[26] illustrates some pitfalls. A crude analysis of the risk factors for oxygen dependency at 28 days of age in babies weighing less than 1000 g at birth indicated significant risks associated with low gestational age, male gender, high rate of ventilation at 96 hours of age, and low arterial P_{CO_2} at 96 hours of age. However, logistic regression analysis left male gender and low arterial P_{CO_2} as the only independent factors (the latter being a weak association).

The age at which the risk of an adverse outcome is determined may be important, not only because lung pathology, symptoms, and lung function may become less obvious with time,[10,27,28] but also because it is possible that the risk factors for acute lung damage (classic BPD) may differ from those of CLD later in childhood. The CLD could, for instance, be

determined to a greater extent by disturbed long-term growth related to prematurity itself,[29,30] whereas acute lung damage might result from mechanical ventilation.[31]

Secular trends in prevalence almost certainly affect the assessment of risk because classic BPD is more common and may have a different spectrum of risk factors in VLBW infants, who are increasingly represented in the most recent studies. This can lead to bias if there is a parallel change in some important aspect of management, such as the earlier introduction of lipid-based intravenous feeding regimens.[18] Even the definition of risk factors may be important. One cannot, for instance, assume that low birth weight (LBW) and prematurity are equivalent, because Rona and colleagues[32] showed in a cross-sectional study that at school age, decreased lung function was the predominant outcome for children of LBW for age, whereas prematurity led to an increase in symptoms, confirming the longitudinal data of Chan and coworkers.[33] Finally, neonatal death from respiratory causes may itself introduce major selection bias into the analysis of the risk of CLD by removing from the equation the possible major risk factors for the most severe form of CLD.

The analysis of risk should be based on studies of complete populations, using simple clinical variables to avoid bias[34] and appropriate types of statistical analysis to eliminate confusion.[26] It may then be possible to start to predict risk[26,35-38] for early intervention or to identify specific factors with a view to identifying remediable causes of BPD.[18,26,33,34]

The public health burden of CLD has yet to be accurately calculated. Studies revealing that certain percentages of preterm babies cough, wheeze, or require readmission to the hospital are of little intrinsic interest unless they provide information that can be used in planning or calculating the cost of health care provision. Domiciliary oxygen therapy clearly has such implications.[39,40] The effect of therapeutic or preventive regimens using surfactant and corticosteroids on the overall cost of neonatal care has been assessed.[41] The budgetary and ethical results of this study are at variance: It is cheapest to give no antenatal steroids or postnatal surfactant because of the high early mortality rate, but clinically and ethically it is better to use both because the chance for healthy long-term survival is then far greater.

MODELS

The epidemiologic model used for this chapter is represented in Figure 29-1. Its applications have already been discussed. As a framework for understanding the interactions of growth and repair that underpin CLD and are described by techniques in pathology, the evolution of this disorder is considered in four overlapping stages representing early inflammation, its resolution, repair and modeling, and finally lung growth and development (Fig. 29-2). The earliest stages relate to acute neonatal lung disease and its management (see Chapter 28). The evidence to support this general scheme (see section on pathology) is based on a combination of histopathologic data collected in infants who die, supported by cytologic findings from bronchoalveolar lavage in infants whose lungs are ventilated, and by developmental physiology later in life. Animal models have provided support for this analysis.[42]

The value of this model lies not only in its contribution to understanding the pathogenesis of CLD but also in its management. Because the disorder has such a huge clinical spectrum—from fatal cardiorespiratory failure in the neonate to the mildest symptoms and dysfunction in the school child who had a premature birth—and because it covers such a wide age range, therapeutic schemes must be tailored to the various clinicopathologic stages. It is convenient to separate the management of the acute stage in the neonatal unit from the management of CLD in the infant at home. By the end of the first year, when repair and remodeling may be largely completed and growth tracks along the channel thereby determined,[43] management issues again alter, focusing on symptom management and health maintenance rather than potentially preventive measures and health enhancement.

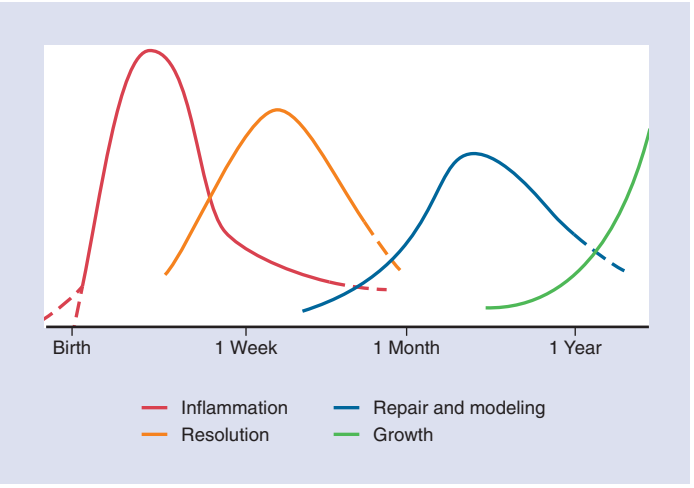

Figure 29-2 Speculative model of the clinicopathologic phases of chronic lung disease (CLD).

Pathology

Pathological changes described in infants who have died from respiratory failure have evolved as CLD has changed from a disease of more mature infants to one of extremely preterm infants. Macroscopically, during acute RDS, the lung is firm with a smooth surface that, during the second week, becomes more irregular if CLD is evolving; the lung weighs approximately 25% to 75% more than expected.[44] By the third and fourth weeks, the lung surface has a cobblestone appearance as a result of variable underlying alveolar distention and collapse. As the reparative process progresses, deep fissuring into the lung depths may occur (Fig. 29-3A). The fissuring may resemble the major normal fissures of the lung. During the second year of life, a smooth surface contour returns, with only the deepest fissures remaining.

Histologically, classic BPD was characterized as an early exudative inflammatory phase followed by a subacute fibroproliferative phase of resolution and finally a chronic fibroproliferative phase[44] characterized by growth and remodeling. Microscopically, during the inflammatory phase, the most frequent finding is extensive residual hyaline membranes.[45] During the subacute, fibroproliferative stage of resolution, which occurs from the second to fourth weeks of life, there is progressive replacement of the hyaline membrane with interstitial and perialveolar fibrosis. The septal walls are thickened and myofibroblast proliferation is seen by electron microscopy.[45] Type II pneumocyte hyperplasia lines the

restructured alveolar walls. During the ensuing month, remodeling occurs. Hyaline membranes are no longer seen, but interstitial fibrosis of varying severity is evident. Emphysematous areas are interspersed with areas of collapsed alveoli.

More recently with survival of the most preterm infant, the disease process has resulted in less of a fibroproliferative disorder and more of dysregulated lung growth.[46] In particular, far less fibrosis is observed and far more simplified, enlarged alveoli/saccules are prominent (Table 29-3; see Fig. 29-3). The population most at risk of developing CLD is at the 24 to 26 weeks of gestation—this is the canalicular stage of lung growth. Alveolarization occurs at a later date but by being born early, dysregulated lung development occurs. Margraf and coworkers studied eight infants between 24 and 30 weeks of gestation at autopsy and noted a markedly decreased alveolar count for these infants who died between 2 and 28 months of age when compared to control infants who died from nonrespiratory causes between 2 weeks and 4 years of age.[47]

Table 29-3
Evolution of Pathology In Bronchopulmonary Dysplasia

"Old" CLD
• Altered inflation pattern of atelectasis and overinflation
• Severe airway epithelial lesions (hyperplasia, squamous metaplasia)
• Airway smooth muscle hyperplasia
• Extensive fibroproliferation
• Prominent vascular hypertensive lesions
• Decreased internal surface area and alveoli
"New" CLD
• Decreased, large and simplified alveoli (alveolar hypoplasia, decreased acinar complexity)
• Decreased, dysmorphic capillaries
• Variable interstitial fibroproliferation
• Less severe arterial/arteriolar vascular lesions
• Negligible airway epithelial lesions
• Variable airway smooth muscle hyperplasia

CLD, chronic lung disease.
From Coalson JJ: Pathology of new bronchopulmonary dysplasia. Semin Neonatol 8:73-81,2003, with permission.

Many of these studies predate the introduction of antenatal corticosteroids and exogenous surfactant treatment. Husain and colleagues investigated 14 surfactant-treated and 8 untreated lungs at autopsy from infants with CLD and 15 age-matched controls. They reported mild to moderate septal fibrosis but no necrotizing bronchiolitis in the surfactant-treated infants. They also observed simplified dilated alveoli/saccules much in keeping with dysregulated lung growth with abnormal acinar development.[48] In another elegant study by Thibeault and colleagues parenchymal elastic tissue was quantified in control infants and infants with varying severity of CLD.[49] They reported an increase in volume density of parenchymal elastic tissue with gestation in control infants but this was markedly increased in the CLD group, with the increase being greatest in the infants with the highest respiratory scores (integrated area under curve of average inspired oxygen × mean airway pressure). The septal thickness was increased in the most severe form of CLD. Although many of the factors including transcription factors associated with normal lung development are known especially in animal models, our understanding of these factors in the developing human lung is rudimentary and, indeed, almost nonexistent in the injured human preterm lung.

An alternative theory for the dysregulated lung growth seen in infants who develop CLD is that their vascular development may be abnormal, which leads to abnormalities of lung growth. In a series of experiments in rodents, Abman and colleagues demonstrated that chronic inhibition of vascular endothelial growth factor (VEGF) receptors led to pulmonary hypertension, as well as abnormal lung growth.[50] The angiogenic growth factor VEGF is a potent endothelial cell growth and permeability factor and highly expressed in the lung. Expression of different VEGF isoforms and their receptors (Flt-1 and Flk-1) appear to be developmentally regulated, with increased expression toward term coincident with the phase of active microvascular angiogenesis. VEGF and its receptors are significantly decreased in CLD, possibly leading to failure to expand the capillary network. Interestingly, addition of nitric oxide to the rodent model led to improved alveolarization.[51] It is likely that injury to either epithelial cells or endothelial cells will disrupt the normal pattern of lung development and maturation.

In summary, the pattern of acute lung injury observed in the lungs of infants who die from CLD has altered significantly with the survival of the most preterm of infants. The previously observed fibroproliferative disorder is replaced with one of decreased alveolarization, enlarged rudimentary gas exchanging air sacs that appear to undergo dysregulated alveolar growth. Whether these infants will develop clinical emphysema in young adulthood is currently speculative but is of great concern.

Risk Factors

Although the etiology of CLD is unknown, since the earliest description of BPD by Northway,[1] many of the risk factors have been identified. Multivariate analysis has demonstrated that CLD is more common in the extremely premature infant when compared with mature infants, and other independent risk factors include male gender, white race, surfactant deficiency, oxygen toxicity, barotrauma resulting from mechanical ventilation (including air leaks), chorioamnionitis, sepsis, patent ductus arteriosus (PDA), and fluid overload. The significance of many of these risk factors is unknown, but animal models have been used to identify the importance of some. In particular, several groups have focused their attention on the relative importance of oxygen toxicity and barotrauma to the pathogenesis of CLD and, more recently, on the role of antenatal infection in the development of CLD. As discussed earlier, these factors might be important causes of acute lung damage, but with healing by remodeling and growth, the long-term risk of CLD depends on the degree of prematurity and the degree of disruption of the normal pattern of alveolarization in late fetal life and infancy.

OXYGEN TOXICITY

Oxygen has long been recognized as being toxic to the lung. The extents of its effects are determined by its concentration, and the susceptibility of the host. The latter is greatly influenced by the stage of development of the subject. In adults, the administration of 100% oxygen to the lung for prolonged periods leads to the development of acute respiratory distress syndrome (ARDS). An initial destruction of endothelial cells is followed by epithelial type 1 cell necrosis. This results in an alveolar leak, resulting in diffuse exudation of plasma into alveolar spaces. Accompanying this cell injury is the release of proinflammatory cytokines and subsequent recruitment into the lung of inflammatory cells. Release of cytokines such as IL-6 results in a systemic acute phase response. These pathophysiologic changes result in the clinical correlate of ARDS, characterized by severe respiratory failure with diffuse pulmonary infiltrates in the absence of congestive heart failure.[52]

It has long been recognized that neonates of most species are more resistant to the toxic effect of hyperoxia than are adults. Classically in infant CLD, the prematurity, hyperoxia, and ventilator-induced lung injury have been regarded as prerequisite risk factors. This observation has been demonstrated in animal models with the increased survival of newborn rats exposed to 100% oxygen when compared to adult counterparts who all perish within 1 week of exposure.[53]

More recent studies have demonstrated the link between hyperoxia and inflammation in the developing animal lung. Warner and colleagues utilized the newborn mouse as a model of hyperoxic lung injury as alveolar development progresses in the early postnatal period.[54] Exposure of these animals to 85% oxygen for 1 month resulted in 40% mortality. Survivors demonstrated decreased alveolar septation with increased terminal airspaces similar to those found in CLD. Lung lavage studies have shown that hyperoxia results in a neutrophilic infiltrate, peaking 2 weeks after exposure to hyperoxia. Analysis of neutrophil mRNA revealed an upregulation in expression of proinflammatory cytokines IL-1β and macrophage inhibitory protein (MIP-1α).

The association between hyperoxia and CLD is believed to stem from oxidant stress. The increased availability of oxygen results in leaking of reactive oxygen species (ROS) from the mitochondrial electron chain. This oxygen load cannot be dealt with by the immature antioxidant enzyme system present in preterm infants when compared to term infants.[55] The formation of these oxygen radicals also results

from the process of hypoxia/reoxygenation, whereby the conversion of xanthine dehydrogenase to oxidase results in the generation of superoxide.[56] Another source of ROS, once inflammation has been initiated, is from activated neutrophils recruited to the lungs in RDS. Via the NAPDH oxidase pathway, these cells produce and release hydrogen peroxide, superoxide, and hydroxyl radicals.

A number of pathways exist by which ROS exert their effect. A major determinant is the direct toxicity they possess, inherent from their ability to react with cellular constituents. In particular, lipid peroxidation leads to cellular membrane disruption, followed by cellular necrosis. The variety of intracellular constituents released has chemotactic properties, resulting in the recruitment of neutrophils to the lung.[57] Evidence for increased lipid peroxidation in early CLD infants has been demonstrated by Pitkanen[58] by the measurement of the expired lipid by-products, ethane and pentane.

Supplementing the immature antioxidant system of the preterm infant has been attempted using a number of pharmacologic agents including vitamin E, vitamin A, and superoxide dismutase (SOD).[59,60] Vitamin A supplementation has been associated with a modest reduction in CLD among survivors at 36 weeks. However, administration is via repeated intramuscular injections.[61,62] No clinical improvement has been demonstrated after the use of vitamin E in infants less than 1500 g.[59]

Animal studies have shown a reduction in lung injury after intratracheal administration of antioxidants including SOD, alpha-tocopherol, and *N*-acetylcysteine.[63,64] Human studies have demonstrated a reduction in inflammatory mediators with the use of CuZn SOD, but as yet no improved clinical outcomes have been demonstrated conclusively—other than reduced admissions for respiratory illnesses in the first year of life.[65,66] This limited effect may be secondary to limited ability to deliver these agents to the lung. Newer methods of delivery may show promise, in particular, recombinant human CuZn SOD used in combination with a surfactant vector.[67,68]

VENTILATOR-INDUCED LUNG INJURY

In their pathologic description of CLD, Taghizadeh and Reynolds[69] found a significant association between the most severe pathologic changes of CLD and peak inspiratory pressures of more than 35 cm H_2O during mechanical ventilation. Using newborn piglets, Davis and colleagues[70] investigated the relative contribution made to the pathogenesis of CLD by barotrauma and oxygen toxicity. Of the four groups investigated, the groups exposed to 100% oxygen with or without hyperventilation developed the most significant lung injury. Animal lungs normally ventilated in air developed no injury, and the group hyperventilated in air developed intermediate lung injury. The conclusions are that hyperoxia causes the most significant inflammatory and histologic changes but the barotrauma alone may also result in a lesser degree of lung injury. However, the importance of barotrauma to the development of CLD is provided by several studies. Premature lambs whose lungs were supported by mechanical ventilation developed more severe lung injury than lambs allowed to mature while supported by their placentae.[71] Similarly, using preterm lambs, Penn and coworkers[72] have demonstrated the susceptibility of tracheal segments to mechanical ventilation. Because bronchomalacia is one of the long-term adverse outcomes of CLD, this form of barotrauma could be very important. It is likely that the smaller airways are similarly affected by mechanical ventilation. It may be that volutrauma may be more important than barotrauma as suggested by Hernandez and colleagues, who limited chest wall expansion (volume) by plaster casting the chest walls and noted that increased volutrauma may cause significantly more lung injury than barotrauma.[73] Acute lung injury may even commence at birth owing to volutrauma from inflationary breaths because five sustained breaths at 8, 16, and 32 mL/kg resulted in a dose-dependent lung injury in preterm lambs.[74]

Many studies of different ventilatory modes have shown improved physiologic outcome, but systematic review of such trials has failed to identify any ventilatory method that has a significant impact on CLD. Interpretation of ventilation trials is complicated by differing uses of ventilatory modes because this may affect their efficacy. For example, high frequency oscillatory ventilation (HFOV) has been used either with a low-volume strategy in which pressures are minimized to decrease lung injury or a high-volume strategy to optimize alveolar recruitment. Meta-analysis of the results of eleven trials in which infants were randomized to receive HFOV or conventional ventilation in the first 24 hours after birth has shown that HFOV is associated with modestly decreased CLD.[75] Some ventilatory modes have not undergone such rigorous testing. CPAP is often used in preference to mechanical ventilation, which necessitates tracheal intubation. Decreased lung injury has been documented in a baboon model using CPAP, but only small clinical studies have addressed this question.

ANTENATAL AND POSTNATAL INFECTION

Chorioamnionitis, the histologic inflammation of the placenta, is common in mothers who deliver prematurely.[76] The presence of chorioamnionitis has been reported to be protective against the development of RDS[77] but is a significant risk factor for the development of CLD and also of cerebral palsy.[78] Although only 30% of preterm infants with RDS had histologic evidence of chorioamnionitis compared to 82% without RDS, 63% exposed to chorioamnionitis developed CLD compared to 21% who were not.[79] It appears that the destiny to develop CLD is triggered in utero, as shown by the observation of Yoon and associates of increased proinflammatory cytokines in the amniotic fluid of women who deliver preterm infants who develop CLD when compared to preterm deliveries in which the infant does not develop CLD.[80]

The importance of antenatal inflammation in the development of CLD has been demonstrated using animal models. Intra-amniotic injection of *Escherichia coli* endotoxin to pregnant ewes has been shown to cause chorioamnionitis and, subsequently, lung inflammation with increased inflammatory cytokines in the newborn preterm animal.[81] Once delivered, these newborn preterm lambs develop less RDS, have better lung compliance, and increased surfactant proteins when compared to control animals. In spite of such improvements, the lung histology showed decreased alveolarization with fewer but larger alveoli when compared to control animals. In addition, preterm lambs born to mothers exposed antenatally with intra-amniotic endotoxin generated a greater

inflammatory response when mechanically ventilated compared to ventilated unexposed control animals. These findings suggest that antenatal inflammation is effective in rapidly maturing the fetal lung and, in particular, upregulating surfactant production, resulting in reduced incidence of RDS. However, this is at the expense of decreased alveolarization. Antenatal inflammation may also prime the preterm lung to respond with increased lung injury when subjected to mechanical ventilation and/or oxygen therapy.

An organism that has received particular attention in the development of CLD is *Ureaplasma* spp. *Ureaplasma* spp in humans is found on mucosal surfaces, primarily of the respiratory and urogenital tracts. It is present in the lower genitourinary tract of 40% to 80% of women of child-bearing age and is vertically transmitted to the fetus in 46% to 89% of cases—with the highest transmission rates being among preterm infants.[82] *Ureaplasma* spp colonization of the preterm lung has been associated with the development of CLD with a relative risk ratio of nearly 3 in a recent publication by Schelonka and colleagues[83]; unfortunately, an adequately randomized controlled trial to determine if eradication of *Ureaplasma* colonization of preterm lungs decreases the rate of CLD has not been performed.[84,85]

Postnatal infection has also been implicated in the pathogenesis of CLD. A study of 119 ventilated preterm infants with a birth weight less than 1000 g reported systemic sepsis to be a risk factor for CLD.[86] Of the 64 infants who had a positive blood culture with clinical or laboratory signs of sepsis, 35 (55%) developed CLD, compared to 9 (16%) without sepsis (odds ratio 4.4). This study also reported that a patent ductus arteriosus was a significant risk factor for CLD (odds ratio 6.2). If both these risk factors were combined, the odds ratio markedly increased to 48.4. Nosocomial infection such as *Staphylococcus epidermidis* has also been associated with the development of CLD with 64% of infants with *S. epidermidis* sepsis developing CLD compared to 24% of controls.[87] Ventilated preterm neonates frequently have endotracheal secretions colonized with gram-positive bacteria, particularly *S. epidermidis*. In some cases gram-negative bacilli, such as *Klebsiella pneumoniae, Enterobacter cloaca,* and *E. coli* can also colonize endotracheal secretions. Such colonization has been reported to significantly increase the incidence of CLD.[88]

Viral infections, particularly with adenovirus or cytomegalovirus (CMV), have been implicated in the development of CLD. Sawyer and coworkers identified 32 infants born with a birth weight less than 2000 g as being infected with CMV over a 5-year period.[89] Of these, 24 (75%) went on to develop CLD compared to 12 of 32 (38%) matched controls. It was believed that the CMV infection was acquired postnatally. Although adenovirus has been implicated in the development of CLD, it has not yet been confirmed by other groups.[90]

PATENT DUCTUS ARTERIOSUS AND FLUID OVERLOAD

An association has been noted by many workers between PDA and CLD.[91-93] The presence of a PDA has been associated with pulmonary inflammation—possibly via increased pulmonary blood flow.[94] However, a controlled, randomized study of prophylactic ligation of PDA did not demonstrate a significant improvement in oxygen dependency.[95] A multicenter, multivariate, risk-adjusted, case-control study reported an association between an increased fluid intake within 96 hours of birth and oxygen dependency at 30 days of age.[96] Similarly, in their prospective study, van Marter and associates[92] compared the medical practices of three different centers managing preterm infants with birth weights less than 1751 g. They reported that the center with the highest incidence of CLD administered higher-than-expected rates of colloids during the first 4 days of life. It has been proposed that increased fluid intake, either by direct means or by an increase in the incidence of PDA, may worsen any coexistent pulmonary edema, thereby reducing pulmonary compliance. The subsequent increase in ventilatory requirements, including oxygen toxicity and barotrauma, may further exacerbate the ongoing acute lung injury. However, when Lorenz and colleagues[97] randomized 88 infants weighing 750 to 1200 g to receive either low or high fluid intake, no difference was noted in the relative incidence of CLD between the two groups. Similarly, Kraybill and coworkers[26] did not find an association between the development of CLD and weight loss, furosemide, or pancuronium therapy in 147 surviving infants weighing 751 to 1000 g.

OTHER RISK FACTORS

The incidence of CLD is related to the gestational age of premature infants, with the incidence increasing as gestation decreases. However, because not all premature infants develop RDS or CLD and near-term infants may develop CLD, it appears that the immaturity of the lungs predisposes the infant to the development of CLD. It is, therefore, not surprising to note an association between infants with LBW and CLD because these are the infants most likely to have immature lungs. For reasons that are unclear, male infants are more prone to both RDS and CLD. Similarly, the incidence of CLD is decreased in people of color. Both gender and race are independent factors for the development of CLD. An increased incidence of CLD has been reported in infants from families with atopy.[98-100] This association was not confirmed by Chan and colleagues.[101]

Another area receiving attention is the role of genetic factors in the development of CLD. Many polymorphisms especially of surfactant proteins, pro- and anti-inflammatory cytokines, and of growth factors are being investigated. A recent study showed that twin preterm infants are at increased risk of developing CLD and that genetic factors may play a large part in the development of CLD.[102]

Pathogenesis

Animal models and lung lavage studies in human preterm infants have established a vast array of data of cells, cytokines, and growth factors for infants who develop CLD.[103] Often the significance or importance of such findings is unclear. Techniques to look at evidence for inflammation in living human preterm infants have relied principally on bronchoalveolar lavage (BAL). This methodology involves the instillation of saline via a catheter wedged into a lobar bronchus followed by the aspiration of terminal airway and alveolar contents.[104,105] This contrasts with the technique of tracheal aspiration, which predominantly samples the larger proximal airways. As with histologic samples, an inflammatory infiltrate has been repeatedly demonstrated in BAL from preterm

infants with lung disease. It has consistently been shown that persistence of neutrophils in the lung beyond 7 to 10 days of age is associated with the development of CLD (Fig. 29-4).[106-108] Although there were no differences in lymphocyte numbers noted in the study by Murch and coworkers, activated macrophages denoted by expression of the RM/3-1 marker were similarly found to be increased in the BAL of babies with CLD, peaking at 1 week of age and subsequently reducing in numbers over the following weeks.[107] This contrasted with neutrophil numbers in the same lavage samples, whereby progressive CLD was marked by an excess number of neutrophils over macrophages. This supports earlier work demonstrating an increased presence of macrophages at 96 hours in babies with uncomplicated RDS, as well as those with developing CLD, but with a relative paucity in macrophages in CLD patients at 4 weeks of age.[109]

Neutrophil recruitment is followed by resolution of lung injury by the recruitment of alveolar macrophages and of removal of senescent neutrophils by the process of apoptosis or programmed cell death. Alveolar macrophages, the cells of resolution, commence the process of repair and remodeling and also remove apoptotic neutrophils. Recent observations show that neutrophil apoptosis is delayed in the lungs of infants who develop CLD. There is some evidence to show that this delayed neutrophil apoptosis may be related to the gestational age of the preterm infant who is at most risk of developing lung injury.

The migration of neutrophils to the area of injury is mediated by a series of processes (Fig. 29-5). The adherence of neutrophils to the endothelial wall by attachment of the neutrophil ligand L-selectin, to P- and E-selectins expressed on endothelial surfaces, produces slowed movement of neutrophils at these vessel sites, termed *rolling*. The expression of L-selectin by endothelial cells is upregulated at inflamed areas owing to the effect of TNF-α and IL-1. Subsequent firm adherence of neutrophils and migration across the endothelium is partly mediated by the β_2-integrins (e.g. CD11b/CD18), which are upregulated on the neutrophil surface after activation, usually in response to IL-8. The β_2-integrins attach firmly to the receptor, ICAM-1 (intercellular adhesion molecule) expressed on endothelium.[110] In addition, the lipid mediators platelet activating factor (PAF) and leukotriene B4 (LTB4), together with complement, all of which are produced as part of an inflammatory response, act to increase vascular permeability.

Initiation of the inflammatory response is mediated by the proinflammatory cytokines TNF-α, IL-1 and IL-6. TNF-α, which possesses the ability of promoting the expression of IL-1β and IL-6, can be produced in response to infective agents via LPS, or injurious agents such as ventilator-induced lung injury or hyperoxia. Antenatal inflammatory response is believed to be related to infection in the amniotic fluid by

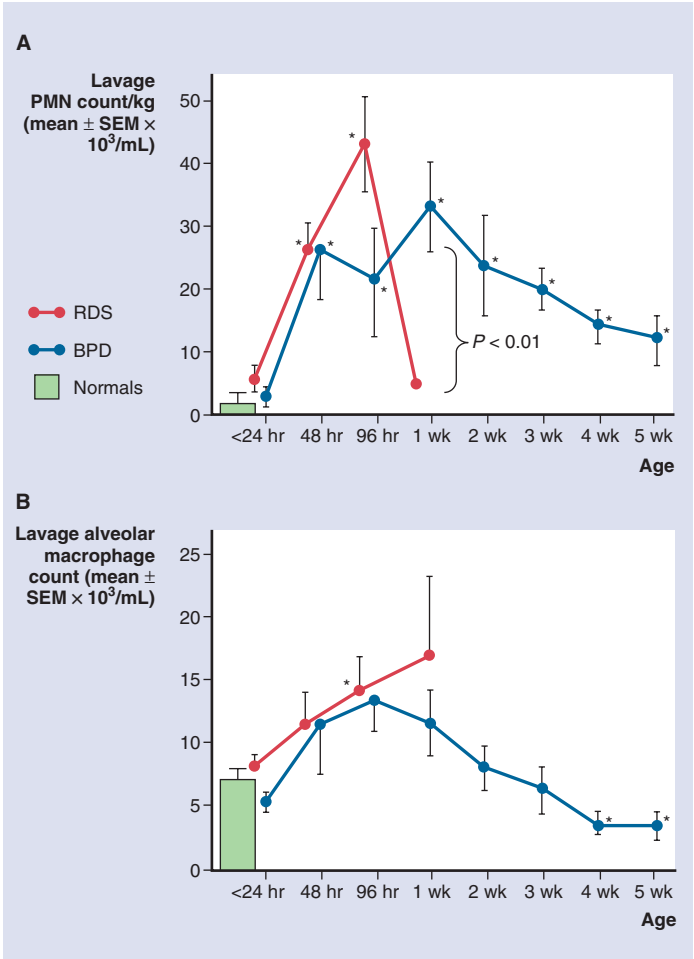

Figure 29-4 **A,** Absolute neutrophil (PMN) count divided by body weight in kilograms (mean ± standard error of the mean [SEM] (×200) 10^3/mL) at each lavage. **B,** Absolute alveolar macrophage count (mean ± SEM ± 10^{-5}) at each lavage. Asterisks indicate significant difference from normal control subjects ($P < 0.05$) by analysis of variance and Duncan's multiple range test. Figure 29-5 Speculative model for the pathogenesis of chronic lung disease (CLD) at the cellular level.

organisms such as *Ureaplasma urealyticum*, which have been linked to the development of CLD,[111,112] in particular the *new* form of CLD, which can occur in the absence of hyperoxic insult. Raised concentrations of TNF-α in BAL from patients who developed CLD have been found at 14 days of age, but have also been described as early as 3 days of age—with increased presence of immunoreactive cells in BAL.[113-115] IL-1 has been shown to be predictive of CLD in the first week of life.[114,116-118]

IL-8 is a neutrophil chemoattractant and has been consistently demonstrated to be raised in association with CLD when compared to infants who recover from RDS. We noted a significant rise in IL-8 BAL concentration at 10 days in CLD,[108] findings supported by Groneck and coworkers[119] and Baier.[120] Munshi noted a significant rise in IL-8 in babies with RDS progressing to CLD as early as 1 to 3 days postnatally.[121] Differences may be partly explained by the use of tracheal aspirates rather than bronchoalveolar lavage, resulting in sampling from central airways rather than distal lung.[122] The accumulation of IL-8 appears predominantly confined to the lungs. Serum concentrations of IL-8 do not appear to differ between CLD and RDS subjects and are an order of magnitude below lavage concentrations.[108]

The proinflammatory cascade is regulated to prevent an uncontrolled inflammatory response. In part, this is provided by the presence of a group of anti-inflammatory mediators that provide a counterbalance to the proinflammatory agents. These include IL-4, IL-10, IL-13, transforming growth factor-β (TGF-β), soluble TNF-α receptors (sTNFR1 and R2) and interleukin 1 receptor antagonist (IL-1RA). There appears to be an inadequate anti-inflammatory response to the proinflammatory cytokines in the development of CLD; whether this is, in part, due to gestational immaturity of the infants most at risk of developing CLD is unclear.

The activity of recruited neutrophils has been estimated by study of their released local effectors, principally elastase (see Fig. 29-5). The proteolytic properties of this enzyme are likely to impair the septation process in the lung necessary for normal alveolar development. The activity of elastase is counterbalanced by the presence of alpha$_1$-antitrypsin (alpha$_1$-AT). At birth, the ratio of elastase and alpha$_1$-PI in the BAL of normal controls and infants with RDS is similar. In infants who progress to develop CLD, however, a raised elastase/alpha$_1$-AT ratio develops within the first 48 hours of life and is maintained for several weeks.[109] This reflects increased elastase production by neutrophils, reduced macrophage contribution to the alpha$_1$-AT pool, and inactivation of alpha$_1$-AT by the oxidizing effect of toxic oxygen radicals.[123] Matrix metalloproteinases (MMPs) are a specialized subgroup of proteinases that form an important link in controlling tissue degradation during lung injury. A relative increase on MMP-9/tissue inhibitor of metalloproteinase (TIMP)-1 with decreased TIMP-1 has been noted in the tracheal fluid of infants who develop CLD.[124]

TGF-β has been associated with the development of CLD. Studies have demonstrated an increased presence of TGF-β protein in lavage from the lungs of infants who develop CLD within the first week of life.[125] These remain elevated in chronically ventilated babies with a need for home oxygen.[126] Physiologic release of TGF-β is intended to be short-lived, however, the maintenance of an inflammatory stimulus (e.g., hyperoxia, infection) leads to an exaggerated response that is perpetuated by the ability of TGF-β to stimulate its own secretion.[127]

Other growth factors such as epidermal growth factor (EGF), platelet-derived growth factor (PDGF), keratinocyte growth factor (KGF), and vascular endothelial growth factor (VEGF) have also been implicated in the pathogenesis of CLD. VEGF is of particular interest because it promotes vascular endothelialization. Chronic inhibition of vascular endothelial growth factor (VEGF) receptors led to pulmonary hypertension, as well as abnormal lung growth.[128] Expression of different VEGF isoforms and their receptors (Flt-1 and Flk-1) appear to be developmentally regulated, with increased expression toward term coincident with the phase of active microvascular angiogenesis. VEGF and its receptors are significantly decreased in CLD, possibly leading to failure to expand the capillary network. Interestingly, addition of nitric oxide to the rodent model led to improved alveolarization.[129] It is likely that injury to either epithelial cells or endothelial cells will disrupt the normal pattern of lung development and maturation.

CLINICAL FEATURES AND COURSE OF CHRONIC LUNG DISEASE OF PREMATURITY

Newborn Unit

In infants in whom classic BPD evolves, Northway[1] recognized four stages of clinical, radiologic, and pathologic change. Stage I is typified by the clinical, radiologic, and pathologic features of RDS (see Chapter 28). During stage II, which occurs during days 4 to 10, either the infant's respiratory status improves or the condition progresses to stage III. In infants who recover from RDS, a reduction in inspired oxygen levels, peak inspiratory pressures, and minute volume is possible. After weaning from mechanical ventilation and a variable period of supplemental oxygen (most frequently administered via a head box or, if prolonged, by nasal cannulas), the infant is weaned to room air. In infants whose condition does not improve, the lungs become less compliant, and ventilatory requirements may increase. Pulmonary interstitial emphysema and other air leaks, including pneumothorax and pneumomediastinum, may develop. The chest radiograph shows increasing opacification with or without air leaks. In infants who die during this stage, thick exudation into the airways with patchy bronchiolar and alveolar epithelial cell necrosis is seen at autopsy.

During stage III, occurring between the second and third weeks of age, the infant remains oxygen dependent. The respiratory status may slowly improve or progress to respiratory failure, particularly if it is complicated by chronic pulmonary interstitial emphysema, infection, or hemodynamically significant PDA. Compensated respiratory acidosis and hypoxemia are noted from the results of arterial blood gas tests. The chest radiograph shows cystic emphysematous areas interspersed with areas of reticular strands, atelectasis, and consolidation. Histologically, at autopsy, areas of emphysematous alveoli are seen adjacent to areas of atelectatic alveoli. Healing commences, and the necrotic bronchial and bronchiolar epithelial cells are replaced by mucosal metaplasia and hyperplasia.

In stage IV, occurring after 4 weeks of age, the infant is in stable or progressive respiratory failure. An infant whose respiratory status is stable is weaned from mechanical ventilation and supplemental oxygen over the ensuing weeks and months; many of these infants require long-term domiciliary supplemental oxygen. However, in an infant whose condition continues to deteriorate, ventilatory needs increase, requiring increased amounts of inspired oxygen, peak inspiratory pressure, and minute volume. The condition may be complicated by right-sided heart failure and pulmonary hypertension. The prognosis is poor. The chest radiograph usually demonstrates persistent CLD with hyperinflated and cystic lungs, particularly in the lower lobes, and in the most severe cases, striking areas of atelectasis and scarring. The pathologic features have been described.

In many infants with "new" CLD who remain oxygen dependent, the radiograph does not have the classic appearance of stage IV disease. More frequently the chest radiograph shows homogeneous or patchy, ill-defined pulmonary opacities lacking any coarse reticulation ("small gray lungs"). This radiographic appearance has been classified as type I CLD with type II disease, showing similar radiographic changes to Northway's stage IV bronchopulmonary disease[5] (Fig. 29-6). This simpler classification is useful at 1 month of age because type I disease has a better prognosis than type II disease, which more frequently follows pulmonary interstitial emphysema. Many other radiographic features, including segmental atelectasis resulting from mucus plugging and upper lobe shadowing secondary to repeated aspiration, are commonly seen (see Fig. 29-6).

Infant and Preschool Child

A useful and practical definition of CLD is a simple one of oxygen dependency at 36 weeks' corrected gestation.[3] Therefore, the typical infant diagnosed as suffering from CLD is usually a preterm infant who has needed supportive mechanical ventilation, including supplemental oxygen, during the neonatal period for RDS. Clinically, features of obstructive airway disease are often evident. An abnormally increased respiratory rate with retractions and a variable degree of hypoxemia (in air) are noted. The arterial P_{CO_2} may be raised. At discharge, these infants may require domiciliary oxygen. The infant may feed poorly, and weight gain is usually inadequate. Vomiting and GER are common. The chest radiograph may show changes compatible with CLD, including cystic, consolidated, fibrotic, and atelectatic areas or may simply show "small gray lungs" (see Fig. 29-6A). Pulmonary function tests demonstrate an increased airway resistance, low dynamic compliance, and a variable thoracic gas volume with gas-mixing inefficiency (see later section). Echocardiography may demonstrate right ventricular hypertrophy with evidence of pulmonary hypertension and tricuspid regurgitation.

The differential diagnosis of obstructive airway disease in infancy is dealt with in Chapter 10. In addition to intrathoracic disorders, the differential diagnosis includes a number of upper airway disorders such as laryngomalacia and tracheomalacia, subglottic stenosis, laryngeal webs, vascular rings, and enlarged tonsils and adenoids.[130,131] Surgical procedures on the upper respiratory tract were performed in 30% of VLBW infants in one study.[131]

Exacerbations of respiratory symptoms are common in infants born prematurely, especially those with CLD. Potentially, the most serious exacerbating factor is viral infection. In a series of 40 infants who were born prematurely and who needed mechanical ventilation for respiratory insufficiency, 70% had one or more episodes of pneumonia or bronchitis during the first 2 years of life.[132] A direct relation was noted between the presence of CLD and respiratory infections. In a 4-month prospective study of children younger than 2 years of age with CLD, 27 of 30 children had one or more respiratory illnesses.[133] Respiratory syncytial virus was isolated from 59% of the children, and 70% of these required hospitalization. Adenovirus is particularly troublesome because it may result in bronchiolitis obliterans, which may make CLD irreparable. A full immunization program, including the recommenaded use of monoclonal antibody against RSV (palivizumab) and immunization against influenza, is vital for preterm infants. Other causes of exacerbations include aspiration events, heart failure, and "wheezy" episodes. Apneic events or sleep-disordered breathing with hypoxemic spells frequently complicate the situation.

Sudden infant death has been reported more frequently in infants with BPD. A recent population-based study showed that the proportion of SIDS attributable to prematurity increased from 12% to 34 %.[134] One small study suggested an odds ratio of 8 (11% mortality) in comparison with healthy infants weighing less than 1000 g at birth.[135] In the author's experience of 100 very severe cases of CLD in which the infants were dependent on domiciliary oxygen therapy, one infant died suddenly and unexpectedly. In a multicenter trial of corticosteroids for CLD, there was a 3.4% mortality (7 of 209) from sudden unexpected death in infancy.[136]

Adolescent and Adult

A large number of infants with CLD who survive to childhood, adolescence, and adulthood have some degree of pulmonary dysfunction. Most studies of these populations are biased by extreme selectivity, inadequate control data, and small numbers. Yu and associates[137] studied 16 survivors of CLD at a mean age of 8.4 years (range, 7.2 to 9.6 years) and reported an 81% prevalence of wheezing. Respiratory symptoms are most troublesome in the preschool years and seem to decline thereafter.[138] One study of a population-based cohort of 120 LBW children and 100 full-term controls studied at the age of 7 years found troublesome cough with colds to be the only persistent symptom[33]; wheeze was no longer a problem. Exercise tolerance has been studied in small numbers of children. "Normal" preterm children have no limitation,[139] but 10-year-old survivors of BPD are commonly reported to develop exercise-induced asthma, hypoxemia, and hypercapnia.[140] This was further supported by Halvorsen and colleagues, who reported increased use of bronchodilators, decreased FEV_1, and increased bronchial hyper-responsiveness in young adults (mean age 17.7 years) who had CLD in infancy.[141]

Most adult survivors of CLD have a degree of pulmonary dysfunction, including hyperinflation, airway obstruction, and airway hyper-responsiveness.[2] However, LBW infants who never had any neonatal respiratory abnormalities have a degree of respiratory dysfunction when they reach middle
