childhood.[27-30,130] Lung function tends to improve with age, however.[27] The long-term outcome is unknown, but recent evidence linking fetal and infantile somatic and pulmonary development with CLD in adulthood suggests that chronic airway disease with accelerated aging processes may be in store for infants with CLD.[142,143]

ACQUIRED UPPER RESPIRATORY TRACT COMPLICATIONS

Disorders of the intrathoracic airways are important and common in infants with CLD. They include subglottic stenosis, laryngeal granulomas, laryngomalacia and tracheomalacia, vocal cord paralysis, and laryngeal perforation resulting from direct endotracheal tube trauma. In one series of 196 bronchoscopies in 132 neonates with respiratory complications, the most common findings were laryngomalacia or tracheomalacia (24%), tracheal obstruction resulting from stricture or granulation tissue (17%), obstructive mucus plugs (17%), tracheobronchitis (8%), and laryngeal perforation (2%).[144] Vocal cord paralysis secondary to thoracic surgery should be considered.

The true incidence of subglottic stenosis is unknown and probably varies according to local practice. In one study, it was reported in 5 from 845 newborns who required artificial ventilation.[145] Arguments rage concerning the cause of upper airway damage. Direct laryngeal and tracheal trauma is likely to lead to shedding of the respiratory epithelium with subsequent re-epithelialization and squamous metaplasia, scarring, and contraction (Fig. 29-7).[44,146]

Large airway damage includes stricture, granuloma, cyst formation, and excessive collapsibility resulting from bronchomalacia.[147-149] A number of animal studies show how airway collapsibility (compliance) decreases with age.[150] Airway collapsibility may be exacerbated by bronchodilators, which reduce airway smooth muscle tone, and conversely stabilized by active smooth muscle contraction induced by methacholine.[137] There are major species differences. Tracheomegaly may result from positive pressures applied to compliant airways, possibly exacerbated by using bronchodilators at earlier stages of disease.

The management of upper airway pathology may require lateral neck and chest radiographs, barium swallow, MRI scans and echocardiography to exclude extrinsic obstructive lesions, and direct visualization by laryngoscopy or bronchoscopy to identify specific abnormalities. Tracheobronchography with dilute, nonionic contrast medium is a safe procedure but less frequently used. In the infant whose lungs are intubated, weaning may be facilitated by a 24-hour course of corticosteroids. Postextubation stridor was reduced in a double-blind trial, with a suggestion that late subglottic stenosis was reduced.[151] Management of subglottic stenosis remains controversial, but the experience in Liverpool, United Kingdom, suggests that conservative treatment with tracheostomy achieved success in 73% of patients; corrective surgery and laser treatment are reserved for the more difficult cases.[152] Tracheobronchial stenosis is less amenable to effective treatment.[153]

EXTRAPULMONARY COMPLICATIONS

Growth and Nutrition Problems

Several controlled and uncontrolled studies have demonstrated suboptimal growth in survivors with CLD. Although weight and length are appropriate for gestational age at birth, they are commonly at or below the third percentile at 40 weeks' corrected gestation. As the pulmonary status improves, accelerated growth is seen in infants who recover from CLD. Infants with CLD may fail to grow satisfactorily because of increased work of breathing, hypoxemia, GER, poor feeding with inadequate nutritional intake, heart failure, neurodevelopmental handicap, and socioeconomic factors (including inadequate parenting skills and emotional deprivation).

Hypoxemia appears to be particularly detrimental to growth in infants with CLD. Groothuis and coworkers[154] noted that when oxygen was abruptly and inadvisably discontinued by the parents of 7 infants, weight gain dramatically

decreased to a mean of 1.4 g/day compared with 16.0 g/day in 15 infants who continued to receive supplemental oxygen. Growth restarted when oxygen recommenced, but infants failed to catch up with their peers. Although the BOOST trial did not find retarded growth in the lower range of oxygen saturations (91% to 94% versus 95% to 98%), it remains to be seen if this still holds true for oxygen saturations of less than 90%.[155] Factors other than hypoxemia are important because under other circumstances (e.g., cyanotic congenital heart disease), growth may be satisfactory with lower values of oxygen saturation than values that occur in CLD.

Infants with CLD have increased energy expenditure, particularly resulting from increased work of breathing secondary to abnormal lung mechanics. Improved growth may be obtained by increasing the caloric intake of these infants and, if necessary, by increasing the caloric density of their food. Vomiting, heart failure, and feeding difficulties may contribute to undernutrition and growth failure.

Gastroesophageal Reflux

GER, which is common in infants with CLD, has recently been extensively reviewed by Vandenplas.[156] It may manifest by obvious vomiting, poor feeding, failure to thrive, or irritability, but in some cases, even mild possetting is absent. Pulmonary effects include deteriorating lung function, hypoxic spells, and overt radiographic evidence of aspiration. Other complications may include anemia, hematemesis, esophageal stricture, laryngospasm, chronic stridor, and apnea.[157-159] Hrabovsky and Mullett[153] demonstrated that symptoms were usually evident by 4 to 6 weeks of age and that 14 of 22 infants with CLD (64%) had GER. An improvement in growth and a decrease in oxygen requirement were noted in infants with CLD who had surgery for symptomatic GER.[160,161]

Esophageal pH monitoring for 24 hours and radionuclide scan on occasion are the most useful investigations for diagnosing GER.[162] Barium swallow and meal should be performed if mechanical obstruction is suspected. Hypertrophic pyloric stenosis is, for example, more common in preterm than in term infants. Examining the bronchoalveolar lavage fluid for lipid-laden macrophages is of limited value.

Cardiovascular Complications

Heart failure is common in infants with CLD and is often overlooked. Contributory factors include pulmonary hypertension, right and left ventricular hypertrophy, right-to-left shunting through the foramen ovale (particularly as the right atrial pressure rises as a consequence of pulmonary hypertension), and systemic hypertension. Persistent PDA often complicates the early course of CLD and contributes to respiratory failure. A high index of suspicion is required in these patients because there are many similarities between exacerbations of pulmonary dysfunction resulting from infection and those resulting from cardiac failure and because one condition may lead to the other. Poor feeding, tachypnea, increased oxygen requirements, and inappropriate weight gain may be present. Hepatomegaly is a late sign and is difficult to elicit in infants with obstructive airway disease. Treatment with additional supplemental oxygen, fluid restriction, and diuretics may be necessary.

The possibility that unsuspected congenital heart disease may predispose to CLD should always be considered.[163] Of the author's 75 patients with severe CLD who were dependent on domiciliary oxygen therapy, 2 had structural heart disease requiring surgical procedures within the first year of life. In both cases, clinical status improved markedly in the postoperative period. Another factor in the development of pulmonary hypertension in CLD is the presence of systemic pulmonary shunt vessels, which have been described by two groups.[164,165] Histologically, these have been demonstrated as dilated bronchial arteries.[166] The relevance of these vessels is unclear, as is the appropriate means of management.

Pulmonary hypertension is the most important cardiovascular complication of CLD. It can lead to cor pulmonale, which was in the past a major cause of death in CLD. There are two components: variable oxygen sensitive (hypoxic) vasoconstriction and a relatively fixed component. Recent observations suggest that even in the presence of high concentrations of inspired oxygen, a further variable element can be uncovered by the use of inhaled nitric oxide. The underlying structural basis for pulmonary hypertension has been described by Hislop and colleagues[167] and Hislop and Haworth.[168] At the severe end of the spectrum, treatment with prostacyclin, nitric oxide, sildenafil, and calcium blockers may be tried but has variable success.

Noninvasive diagnostic methods of investigation include echocardiography with continuous-wave Doppler flow measurements and (rarely) radionuclide angiography. Cardiac catheterization is risky and should be performed only if required for the diagnosis of structural disease or a life-threatening complication.

In the past, M-mode echocardiography was extensively used to investigate the natural history and management of pulmonary hypertension in CLD.[169,170] Halliday and colleagues[169] established the importance of an oxygen-sensitive element to pulmonary hypertension, with a clear implication that adequate oxygenation was an important aspect of management. Abman and coworkers[171] used cardiac catheterization to study oxygen-dependent infants with CLD and made the very important observation that there were great individual differences in the response to oxygen (Fig. 29-8). Even mild degrees of hypoxemia were associated with unacceptable pulmonary artery pressure in some individuals. A very poor prognosis (50% mortality rate) was found in 10 infants with pulmonary hypertension who were unresponsive to oxygen therapy.[164]

Cardiac catheterization has been used in a number of studies.[171-174] These studies have indicated significant disparities between the measurements made during catheterization and M-mode and Doppler ultrasound techniques.

Advances in echocardiography suggest that indirect methods of assessing pulmonary artery pressure using Doppler time intervals (e.g., the ratio of pulmonary artery acceleration time and right ventricular ejection time)[175] or the more direct method for determining right ventricular pressure in the presence of tricuspid regurgitation[176-178] may be reliable and practical for monitoring children and their responses to oxygen therapy in clinical practice. Newer methods of echocardiography including tissue Doppler studies and assess-

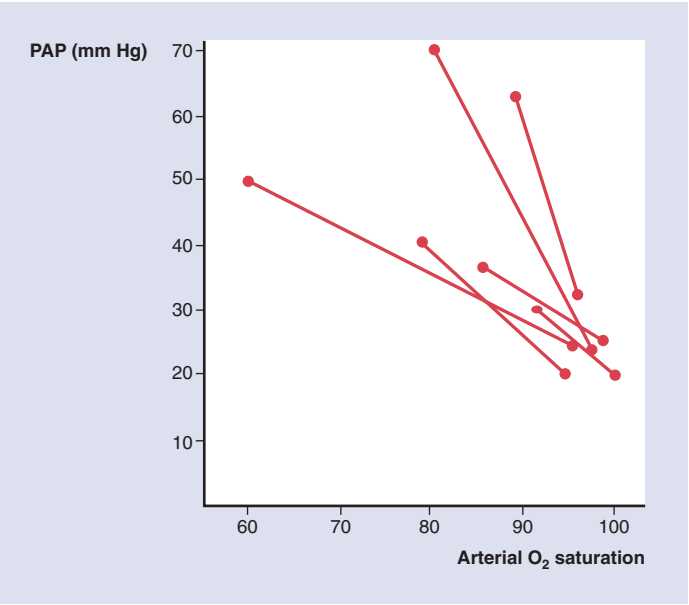

Figure 29-8 Relationship of mean pulmonary artery pressure (PAP) to systemic arterial oxygen saturation in infants with bronchopulmonary dysplasia (BPD), measured during cardiac catheterization. There are great individual differences in both the degree of oxygen-sensitive (reversible) pulmonary hypertension and the fixed component that remains when hypoxia is abolished. (Redrawn from Abman SH, Wolfe RR, Accurso FJ, et al: Pulmonary vascular response to oxygen in infants with severe bronchopulmonary dysplasia. Pediatrics 75:80-84, 1985.)

ment of strain and strain rates show promise but have not been applied to the newborn as yet.[179]

Neurodevelopmental Problems

Because infants with CLD come from the smallest, sickest population of preterm infants, it is not surprising that neurodevelopmental problems are relatively common. Although direct comparability among studies is impossible, most studies appear to suggest that half the survivors are free of any handicap at follow-up but that half are either moderately or severely handicapped, cerebral palsy being the most frequent condition reported. Furthermore, 4% of survivors in studies reviewed by Bregman and Farrell[180] were blind as a result of severe retinopathy of prematurity. This is likely to be an underestimate because many studies exclude from follow-up any infants with significant retinopathy of prematurity. Similarly, not all studies reported the presence of sensorineural hearing loss, but the prevalence appears to be approximately 4% in survivors of CLD.[180]

Of particular importance in CLD are feeding problems and control of breathing. Many infants with CLD exhibit dysphagia. This rarely has an obvious mechanical or even neurologic cause but seems to be an acquired behavioral problem, probably on the basis of swallowing difficulties during weaning from tube to oral feeds. Hypoxia during feeding may complicate matters.[181,182] Later in infancy, fear of lumpy foods may complicate feeding.

Sleep-disordered breathing is generally secondary to mechanical disturbances and is enhanced by upper airway floppiness or obstruction. However, hypoxic arousal mechanisms may not work as well in preterm infants,[183] which in a condition known to be associated with a greater likelihood of hypoxemia,[182,184] is clearly a potentially life-threatening complication.

CLINICAL PULMONARY PHYSIOLOGY

Background

LUNG DEVELOPMENT AND DISEASE

Disturbances in lung mechanics and gas exchange in CLD must be measured against the changing pattern imposed by growth and development (see Chapter 3). Abnormalities of lung function may be the result of CLD or its complications, may be causally related (see Fig. 29-1), or may be independently associated with CLD (see Table 29-2). Disturbed physiology changes with time[27]; follow-up studies have reached early adulthood,[2] but it is likely that abnormalities persist for the patient's lifetime, possibly accelerating the aging process itself.[152]

Physiologic Measurement

Functional assessment has several purposes and requires methods appropriate to the age group concerned. The most important and widely used physiologic measurements relate to gas exchange and especially oxygenation, because appropriate oxygen therapy appears to be the key to the successful long-term outcome of established CLD.

Gas Exchange

PATHOPHYSIOLOGY

By definition, hypoxemia is a feature of BPD and, therefore, is a feature of the early stages of CLD. The degree of severity varies with the stage of disease, so in the severest cases of CLD in the neonatal unit, artificial ventilation with 100% oxygen is required. The factors leading to hypoxemia follow:

1. Mechanical disturbance leading to alveolar underventilation, as indicated by raised values for the arterial P_{CO_2}, and in the chronic state, a compensatory increase in the bicarbonate concentration (positive base excess)
2. Ventilation-perfusion mismatching, which can be measured by calculating the degree of right-to-left shunting, assuming that there is no extrapulmonary shunt
3. Extrapulmonary shunt through the foramen ovale in the presence of pulmonary hypertension in the first few months of life
4. Abnormalities of control of breathing, leading to episodic breathing, apnea or hypopnea, or chronic underventilation

In practice, these processes interact to produce the characteristic instability of arterial oxygenation from which children with CLD seem to suffer (Fig. 29-9).

There are several important consequences of hypoxemia (Table 29-4). The most important is pulmonary vasoconstriction; although a structural basis for increased pulmonary vascular resistance is undoubtedly present in many children with CLD,[168] a reactive, oxygen-sensitive element is almost always detectable.[164,169,171,177] The mechanism of the reversible element of pulmonary vascular resistance is unclear. Even in

Table 29-4
Consequences of Hypoxemia in Chronic Lung Disease

Target	Acute Effects	Long-Term Effects
Airways	Increased airway resistance	Smooth muscle hypertrophy
Pulmonary vasculature	Increased pulmonary vascular resistance with or without shunt via the foramen ovale	Cor pulmonale
Central nervous system	Arousal or apnea with sleep disturbance	Sudden unexpected death Growth failure

the presence of 100% oxygen during mechanical ventilation, a reversible element can still be demonstrated by a response to inhaled nitric oxide. The large individual differences in the degree of pulmonary vascular oxygen responsiveness among individuals[171] (see Fig. 29-8) imply either the need to measure the effect in each infant or to maintain a level of oxygenation above which hypoxic vasoconstriction is abolished in all infants with CLD. There is presumably a critical level of pulmonary hypertension at which right atrial pressure exceeds left atrial pressure, leading in young infants to shunting across the foramen ovale. The long-term benefits of a reduction in pulmonary vascular resistance include better right ventricular function[185] and probably (although unproved) increased long-term survival.

Acute hypoxic airway narrowing has been demonstrated in two physiologic studies.[186,187] Because the large airways are normally exposed to ambient concentrations of oxygen, the effect must occur in peripheral airways, where gas mixing in CLD may be poor, leading to localized hypoxia, or the effect must be the result of hypoxemia. The contribution of hypoxic airway narrowing to clinical disease is unknown but clearly represents a potential vicious cycle when added to any underlying disorder of lung mechanics in CLD (see Fig. 29-9).

Control of breathing may be disturbed in some infants with CLD. Sleep-disordered breathing with more frequent and prolonged pauses than normal is found, in general, in babies born prematurely.[188-190] The hypoxic arousal response was abnormal in 8 of 12 infants in one study of CLD.[183] The significance of the finding is unclear, but these results could provide an explanation for sudden unexpected death in CLD.[134,135] Recent studies showed that spontaneous desaturations during sleep are more likely if the usual level of oxygenation is low—a complex way of demonstrat-ing that the oxygen-hemoglobin dissociation curve is not linear.[184,191] Whether growth failure in hypoxic infants with CLD is related to sleep disruption is unclear.[154]

The pattern of hypoxemia during sleep, feeding, and wakefulness changes with age during infancy. Early in infancy, oxygen-dependent babies with CLD become more hypoxic during feeding,[181,182] but from about 6 months of age, their lungs generally oxygenate better. Postural effects on oxygenation are also more marked in young infants, with falls in the PaO_2 of 7.5 to 15 mm Hg in the supine position in infants recovering from RDS.[192,193] Acute viral infections may be associated with transiently worse hypoxemia, especially if lower respiratory tract symptoms develop. A decline in the arterial oxygen saturation occurs even 1 to 2 days before the onset of upper respiratory tract symptoms in oxygen-dependent infants. The mechanism is unknown but provides a useful warning. Other major complications such as pulmonary aspiration and heart failure may be detected by worsening respiratory symptoms with increased hypoxemia. Whether chronic mild hypoxemia may persist to school age or is exacerbated by exercise remains to be confirmed.[140]

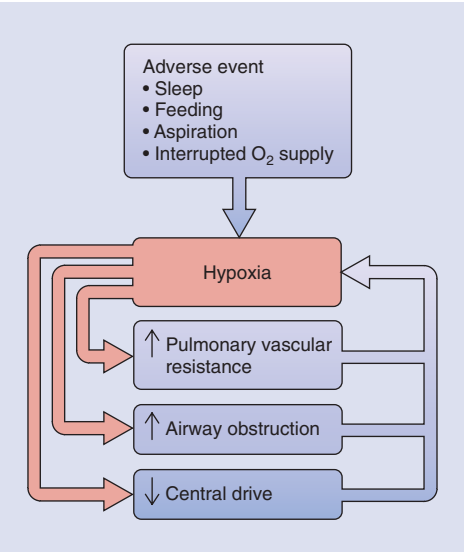

Figure 29-9 Interacting cycles of hypoxia. The cycles may be broken by termination of the adverse event or by arousal of the infant.

Clinical Measurement

Full arterial blood gas measurement is indicated only during the early phase of severe CLD with respiratory failure or during an acute exacerbation. Radial artery puncture through anesthetized skin should be performed by an expert, ideally while the infant sleeps. The disturbance caused by the infant often renders all but the value of the base excess useless. Because the latter is measurable from a capillary sample, in the absence of an indwelling arterial cannula, arterial sampling is an unrewarding exercise that should be performed only if the information obtained is likely to affect clinical decision making.

The advent of oximetry has rendered most other techniques obsolete. Certainly, transcutaneous monitors are useful only for detecting trends.[194] The effects of age and sleep state need to be taken into account.[195] Recording oximeters provide the information relevant to the management of oxygen therapy. However, operators should be familiar with their mode of operation (beat-to-beat or averaging) and the detection of motion artifact. For domiciliary use, oximetry is preferable to the more complex and less relevant transcutaneous monitors.[40,196,197]

Lung Mechanics and Lung Volumes

NEONATAL INTENSIVE CARE

For technical reasons, there have been few measurements of lung volumes during neonatal intensive care. Newer techniques such as the use of SF6 remain largely research based and have yet to reach the clinical arena.[198,199] Although diffi-

cult, measurements of lung mechanics have been made, most commonly as part of trials of medication therapy or techniques of mechanical ventilation. Both static compliance (using the occlusion technique) and dynamic lung compliance (using an esophageal balloon) are low at this stage. The precise interpretation of these data is unclear because compliance is volume dependent and dynamic compliance is frequency dependent; both measurements are therefore influenced by the technique of mechanical ventilation itself. Some of the problems inherent in intensive care measurements have recently been reviewed.[200,201]

Resistance cannot reliably be measured by the single-breath technique under intensive care conditions because of the alinear characteristics of the respiratory system and endotracheal tube.[202] Very high pulmonary resistance values have been demonstrated by the esophageal balloon technique, even allowing for the endotracheal tube. The main value of such observations has been in relation to clinical trials of diuretics, bronchodilators, or corticosteroids (see later section). By briefly applying a powerful negative pressure of about 100 cm H_2O to the endotracheal tube, Motoyama and colleagues[203] devised a system for producing maximal expiratory flow-volume curves in infants whose lungs are ventilated and used the technique to demonstrate bronchodilator responsiveness.

The site of airway obstruction cannot be determined from this type of study. Anatomically, there are abnormalities of both the large central airways and the small peripheral airways with major dynamic changes in resistance that are demonstrable (see later section). From a practical viewpoint, few simple techniques can reliably provide information about lung mechanics during intensive care.[201] Responses to therapeutic interventions and changes in disease state can be determined more precisely using ventilatory or gas-exchange measurements[204] or their combination in such indexes as the ventilatory efficiency index.[205] A sequential trial of intermittent positive-pressure ventilation guided by a pulmonary mechanics monitor failed to demonstrate a reduction in CLD.[206]

INFANTS

A wide range of physiologic measurements have been made on freely breathing infants with CLD, but again, there are many technical limitations[201,207]—especially in infants who require continuous oxygen therapy. The short-term variability of lung function tests is great in infants with CLD.[208] Sedation for lung function testing often worsens hypoxemia. Interpretation of data is affected by the normalization procedures used to compare infants with CLD to healthy infants or to compare one age group or disease state with another. If, for instance, body weight is used to correct lung volume or compliance measurements, differences in body mass index (weight/length) affect the results. Most simple normalization procedures implicitly assume a linear relationship (without any intercept) between lung function and body size; this is rarely the case. However, subject comparisons over short periods of time are not affected by these constraints, so short-term clinical trials are possible.

Lung volumes measured by helium dilution or nitrogen washout underestimate the functional residual capacity (FRC) in the presence of poor gas mixing. Values of FRC are invariably reported as low in the first 6 months of life in infants with CLD compared with those in healthy infants or controls whose lungs are ventilated,[28] exceeding the normal value by 12 months. The author has found helium equilibration times to be as long as 12 minutes in severe CLD; measurements taken over shorter times tend to underestimate the FRC. Plethysmographic lung volumes, which detect all of the gas within the chest, are higher than normal,[209,210] again recovering to normal by 12 months. One direct comparison of the two methods[211] illustrates this discrepancy, showing that preterm infants whose condition was symptomatic (although not specifically with CLD) had a greater difference and, therefore, by implication more "gas trapping" than full-term infants or infants whose condition was asymptomatic. "True" lung volume cannot, therefore, be determined. Nevertheless, changes in lung volume over short periods have been used to measure response to treatment, although the physiologic interpretation of the change may be highly speculative.

During the latter part of infancy, FRC normalizes or may even exceed normal values,[208-212] suggesting true hyperinflation. The increase in FRC may result from worsening obstructive airway disease or a loss of elastic recoil as a consequence of alveolar underdevelopment and, hence, over-enlargement and remodeling of the lungs with removal of excess collagen and elastin.

Lung mechanics has been extensively measured in groups of infants with and without CLD. Respiratory system compliance is always low,[208] returning toward normal by 1 to 3 years of age.[208,213] The weighted spirometer technique is worth considering in infants.[214] Resistance values are mostly high, an indication of the severity but not the site of airway obstruction.[211] Changes in resistance (or its reciprocal, conductance) with age can be judged only in relation to changes in lung volume with growth and disease. Specific airway conductance is low in infancy (about 60% of that predicted) and increases only a little in CLD over the first 3 years of life to about 70% of that predicted.[208,212,215] In healthy VLBW infants, plethysmographic airway resistance is lowest at about 6 months of age, improving thereafter.[210,216] Airway function seems to "track" from 12 months to 9 years in preterm infants.[43]

Flow-volume curves occurring during tidal breathing and generated by the squeeze technique in infants with CLD are clearly abnormal, exhibiting severe flow limitation, even at rest. Measured values of maximum flow at FRC of around 50% of the reference value with little improvement over the first year have been reported by Tepper and associates.[217]

The concept of a single value for compliance or resistance hides the fascinating process of dynamic airway function. Changes in cross-sectional area and, hence, resistance and changes in wall elastance and, hence, maximum sustainable flow[218] may be brought about because of structural abnormalities in the airways, such as bronchomalacia[147] or airway wall thickening with glandular or smooth muscle hypertrophy,[44] because of developmental changes,[150] or because of the administration of bronchodilator or bronchoconstrictor agents. With the use of computed tomography scans, dynamic tracheal narrowing during tidal breathing is far greater in infants with CLD (63%) than in control infants (9%).[148] These observations have been confirmed using different techniques.[149]

The work of breathing in CLD is markedly increased as a result of mechanical factors combined with an increase in overall metabolic rate.[219] This is not a simple relationship between pulmonary mechanics and total metabolic rate.[220]

SCHOOL-AGE AND OLDER CHILDREN

Many studies of preterm babies have been taken through to school age, although the numbers with classic BPD in these groups is small.[29,30,33,101,130] The general conclusions are that preterm babies at school age have reductions in the 1-second forced expiratory volume and forced vital capacity, which are largely matched, suggesting mainly restriction rather than obstruction as the basic mechanical problem. There is an increase in the total lung capacity and the ratio of residual volume and total lung capacity (to 0.4 to 0.45 compared with a predicted value of 0.22), a reduction to about one half in specific airway conductance. These studies suggest that children with BPD are little different from the other preterm cohort members whose lungs have or have not been ventilated and that prematurity is the main determinant of functional impairment at school age. To interpret earlier studies in which selected groups of children with BPD differed from healthy control children as implying that there are long-term effects from BPD is to be swayed by selection bias.

One longitudinal physiologic study that demonstrated tracking in airway function from the age of 8 to 12 months through 9 years[43] is explained by the model illustrated in Figure 29-10. The resolution and remodeling of acute lung injury are largely complete by 1 year, and further changes in lung function represent subsequent growth. At school age, the physiologic findings of restrictive disease with a large residual volume are compatible with a reduced alveolar component, perhaps resulting from the disturbed alveolarization associated with prematurity. This hypothesis awaits confirmation because no methods for measuring alveolar number or surface area in the living child are available, although newer methods show promise.[221]

Northway and colleagues[222] have provided data on lung function in late adolescence that indicate persistent, largely reversible airway obstruction affecting the large and small airways and persistent overinflation resulting from small airway disease. The latter could represent narrowed peripheral airways or a loss of elastic recoil. Airways responsiveness to methacholine or a β-agonist was found in 52% of the group, and fixed obstruction was found in 24%. This contrasts with the findings in preterm and term controls, in whom 31% and 17% of the airways, respectively, were reactive to methacholine but there was no fixed obstruction.

The presence and interpretation of airway responsiveness in children who were born prematurely is controversial. In a small study, Bertrand and coworkers[99] found increased methacholine responsiveness in children born prematurely and their mothers, suggesting that premature labor was itself due to excessive familial smooth muscle responsiveness, a finding confirmed by Riedel and associates.[100] These findings were not confirmed in a population study of LBW infants and their mothers,[101] although a marginal increase in bronchial responsiveness was reported in the LBW group to a much lesser degree than might be expected in groups with asthma. This may simply be a reflection of altered airway caliber or airway wall thickness.

For clinical purposes, the most valuable measurements in school children are based on forced expiration; these measurements are supplemented by bronchodilator challenge to assess acute reversibility. Marked deviation from normal is an indicator for more detailed assessment with plethysmography, which is supplemented as indicated by specialist imaging (computed tomography or ventilation-perfusion scans). Exercise testing may reveal additional abnormalities such as exercise-induced asthma or exercise-induced hypoxemia and hypercapnia.[140]

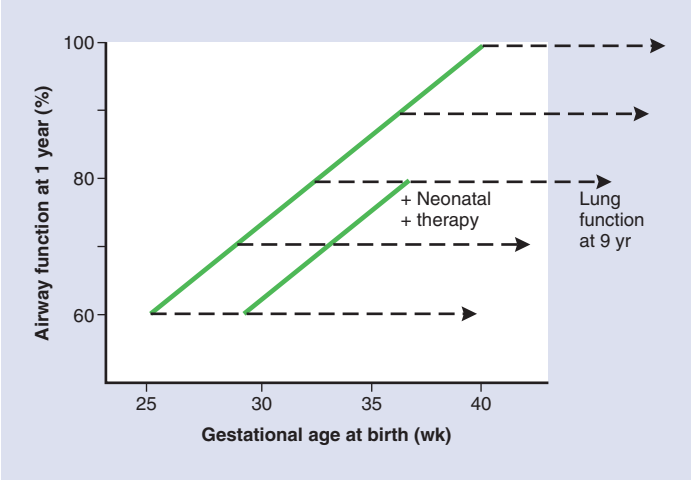

Figure 29-10 Tracking of infant lung function. Airway function at 1 year of age depends on gestational age (or birth weight) and to a lesser extent on neonatal therapy *(green lines)*. Thereafter, airway function seems to "track."

MANAGEMENT

General Aspects of Management

BACKGROUND

CLD is rare in infants weighing more than 1500 g at birth. Because pulmonary disability occurs in the smallest, sickest infants, it is almost always accompanied by other disorders; sensory and neurodevelopmental handicaps, growth impairment and nutritional difficulty, congenital anomalies, and cardiovascular problems are among the most prominent. Only the aspects that have a bearing on pulmonary disease are considered in this chapter, but it is a prerequisite of good care that management should be carried out by a team and not by a disparate group of independent experts. Discharge from the hospital requires careful joint planning by hospital and community health professionals, even for infants who do not require domiciliary oxygen therapy, aerosol therapy, or tube (gavage) feeding. Avoidance of cigarette smoke, minimal contact with other preschool children,[223] attention to immunization programs, and ready access to the hospital in an emergency are all important. There is no evidence that apnea monitoring is of any value, although some parents demand a monitor for their own peace of mind. Where a monitor is provided for high-risk infants (e.g., those who have had apneic attacks, have GER, or are oxygen dependent), cardiopulmonary resuscitation should be taught and simple suction equipment may be necessary. Domiciliary oxygen therapy and monitoring are discussed later.

Hospital visits should be kept to a minimum. This means that the pulmonologist, follow-up team, nutritionist, speech therapist, physical therapist, home-care nurse, and possibly the pediatric cardiologist or echocardiographer should all be available for consultation at a joint clinic.

The rational management of CLD presupposes an understanding of the mechanisms of the disease and its resolution. This information is rarely available. Management also requires data from clinical trials of sufficient power to provide valid results. Much of clinical practice is still based on consensus or local custom, but where possible, the conclusions of scientifically valid data are preferred to anecdotal studies to back up management schemes. Several thorough reviews of CLD and its therapy have recently been published.[224-227]

GROWTH AND NUTRITION PROBLEMS

The frequent occurrence of poor growth in CLD has been discussed (see section on clinical features). Contributory factors may include behavioral feeding problems, swallowing disorders, GER, chronic hypoxemia, and heart failure. Excessive use of diuretics to control respiratory or heart failure may impair growth, presumably as a result of a critical reduction in the extracellular fluid volume or total body sodium levels, even in the absence of hyponatremia. There are no nutritional deficiencies that are specific to infants with CLD. Corticosteroid therapy also has growth-suppressing effects.

After remediable causes have been identified and treated, caloric supplementation can be achieved by increasing feed density. Carbohydrate supplements alone may exacerbate respiratory failure by increasing the metabolic rate; lipid/carbohydrate combinations should be used. A speech therapist skilled in infant feeding problems may be able to retrain the child who has a behavioral or neurologic feeding disorder. It is the author's impression that very small stature in infants with severe, chronically oxygen-dependent CLD is a manifestation of a fundamental disorder of somatic growth, of which failure of resolution of neonatal lung "injury" leading to CLD may be a component.

GASTROESOPHAGEAL REFLUX

The relationship between GER and respiratory symptoms in infants is not easy to disentangle. GER is certainly common in preterm infants in general and in infants with CLD in particular[156,228] (see section on clinical features). Obvious xanthine-resistant apnea, massive aspiration, recurrent vomiting, or failure to thrive may draw attention to it. A causal relationship between GER and hypoxic spells in CLD has never been demonstrated, although both are common in CLD. It is the author's experience that GER is a sequel to, rather than a cause of, obstructive apneic spells.

Some clinicians prefer to institute simple medical management (e.g., posture, food thickening with carob extract and agar-based demulcents), pursuing further investigations if this fails. Failure of simple medical therapy should be followed by the addition of drugs such as gaviscon, domperidone, histamine$_2$ receptor blockers or proton pump inhibitors—although evidence of their efficacy in preterm infants with GER or CLD is limited. Diarrhea is a common side effect. H_2-blockers or proton pump inhibitors should be used if there is evidence of esophagitis. Fundoplication should be considered if life-threatening symptomatic reflux continues despite such medical therapy. Several observational studies have shown improvement in such patients.[157,160,161]

CARDIOVASCULAR COMPLICATIONS

Clinical features that suggest impending heart failure, usually secondary to severe pulmonary hypertension, include excessive or sudden weight gain and increased breathlessness or hypoxemia (or an increase in oxygen requirement) and on physical examination, edema and hepatomegaly. Chest radiographs may show cardiac enlargement.

Oxygen therapy is the mainstay of management. In the absence of an echocardiographic assessment to demonstrate the presence and reversibility of pulmonary hypertension and to determine the appropriate target level of arterial oxygen saturation in individuals, clinicians should aim for a target level of 94% to 96%.[164,171] Many subjects can be safely managed, at least for short periods, below this range, provided that they are not highly sensitive to hypoxic vasoconstriction. Diuretic therapy should be instituted or increased if the features of heart failure occur. For short-term therapy, furosemide is useful; long-term use may lead to nephrocalcinosis.[229] A combination of a thiazide with a potassium-sparing diuretic (spironolactone or amiloride) is more appropriate for long-term treatment. Excessive sodium excretion may cause alarming hyponatremia within the first week of treatment, whereas subsequent growth failure relieved only by sodium supplementation is often a problem. The separate effects of diuretic therapy on pulmonary function are considered later.

Pulmonary vasodilators have very unpredictable effects in babies with severe oxygen-unresponsive pulmonary hypertension.[172] These infants should be individually evaluated by a pediatric cardiologist either during cardiac catheterization or by using reliable echocardiographic measurements. Pulmonary artery vasodilators such as prostacyclin, inhaled nitric oxide, sildenafil, and calcium channel blockers such as nifedipine may be considered for severe pulmonary hypertension on an individual basis. Responses to these drugs during cardiac catheterization may be necessary. These drugs may have actions additive to oxygen, e.g., on the systemic vascular resistance or any abnormal systemic pulmonary shunt vessels.[165,166]

Systemic hypertension has been recorded in oxygen dependent infants with CLD; it is occasionally severe enough to lead to left ventricular hypertrophy. In one study, 13 of 30 infants had a systolic pressure higher than 113 mm Hg,[230] and 6 received antihypertensive therapy for a mean of 3.7 months. The hypertension resolved. Electrocardiography may not be sensitive enough to detect left ventricular hypertrophy. Echocardiography should be performed in hypertensive children with CLD. The cause of systemic hypertension is unknown, but corticosteroid treatment, segmental renal disease, renal vascular complications of prematurity, long-term inotropic support (or even theophylline therapy), and possibly hyperoxia might be contributory factors. Left ventricular hypertrophy is a common finding at autopsy.[44] Unsuspected congenital heart disease was found in association with CLD by two groups.[163,174] This sort of observation implies that severe CLD should be seen as a marker of other, causally important anomalies or defects.

Respiratory Management

For almost all modes of respiratory therapy, there are no definite indications, no objective methods of evaluating the response in individuals (except in the very short term), and no randomized clinical trials of adequate power. Moreover, when any of these defects has been remedied, the information applies only to a specific stage of CLD (e.g., ventilated BPD or wheezy infants), and the results cannot be generalized throughout this evolving disorder. Despite many Cochrane reviews and meta-analyses, the call from most of these publications is for better-powered, designed, randomized, controlled trials to address clinically relevant questions rather than shorter-term benefits of unknown value.[231-240]

BRONCHODILATORS

One of the striking pathologic features of CLD is airway smooth muscle hypertrophy.[241] It would seem reasonable to expect bronchodilator agents (β-agonists, anticholinergic agents, and methylxanthines) to be effective. Little is known, however, of the ontogeny of β-receptors or muscarinic-receptor subtypes in preterm babies or even healthy infants, so no one can predict the long-term outcome of stimulating these receptors during a period of rapid pulmonary development. The β-agonist controversy should promote caution. Neuroendocrine cell hypoplasia suggests a role for nonadrenergic, noncholinergic mechanisms in CLD.[242,243]

Moreover, there is reason to suppose that airway smooth muscle tone may be important in stabilizing the compliant airway of the neonate to minimize dynamic changes during breathing (see previous section). The removal of this tone could render airways more collapsible, with adverse effects on expiratory flow during spontaneous breathing, or more distensible, with the potential for enhanced tracheomegaly during positive-pressure ventilation (see later section). Bronchodilation might also remove the potential focal protective function of narrowed airways.[244] There is no logical basis for their use, except that these drugs are often effective in relieving airway obstruction in other situations.

In addition to these unknowns, the appropriate dose and means of administration of bronchodilators have not been determined (see Chapter 16). For ventilator-dependent infants, the most effective method for delivering aerosol is probably by metered dose inhaler (MDI) and small volume spacer (such as the Aerochamber).[245-247] Jet and ultrasonic nebulizers are extremely inefficient.[248-251] For older infants whose lungs are extubated, all methods of delivery are certainly inefficient.[252] The choice of device has recently been reviewed.[253] The nose acts as an all-too-effective filter.[254] In wheezy infants, in general, nebulized bronchodilators often have transient adverse effects on oxygenation and airway function.[255-259] The effect is not seen when an MDI is used.[260] Changes in air entrainment during infancy mean that drugs administered by jet nebulizer are available in relatively high doses to young infants.[261]

A recent well-designed multicenter randomized control trial starting caffeine within 10 days of birth in infants with a birthweight between 500 and 1250 g showed that 350 (36%) of 963 treated infants alive at 36 weeks' corrected gestation were on supplemental oxygen compared to 447 (47%) of 954 infants receiving placebo (adjusted odds ratio ± 95% confidence interval 0.63 (0.52 to 0.76), $P > 0.001$).[262] The mechanisms of this benefit are unclear. Beyond the early neonatal period, there is only one satisfactory study of methylxanthines, which found that in 4-month-old oxygen-dependent infants, 4 days of oral theophylline therapy gave significant benefits in lung mechanics and work of breathing.[263] The open, placebo-controlled study of a single oral dose of caffeine[264] showed significant short-term mechanical benefits during mechanical ventilation. One other brief open study of theophylline gave a marginal result.[265]

Whether given by nebulizer or by the oral or subcutaneous route, in every study, β agonists have produced short-term improvements in lung mechanics as measured by a variety of techniques. Several studies of single doses of nebulized salbutamol given to ventilator-dependent infants younger than 1 month of age have shown clear benefits in terms of respiratory system compliance and resistance.[266-268] In infants who have CLD and whose lungs are mechanically ventilated, reversible airway disease was demonstrated by changes in maximum forced expiration after nebulized metaproterenol[203] and by measurements of classic lung mechanics.[269] The only full-scale clinical trial of bronchodilators in preterm infants concerns symptomatic (i.e., wheezy) infants who were born prematurely, not infants specifically with CLD.[270] This was an open, sequential study of β_2-agonists administered by MDI. Symptomatic and physiologic improvements were demonstrated. De Boeck and colleagues investigated both albuterol and ipratropium in clinically stable 1-year-old infants with CLD and did not note a significant decrease in pulmonary resistance with either drug, but individual infants either improved or deteriorated.[271] It is interesting that a recent Cochrane review of the use of bronchodilators in CLD only included the study by Denjean and colleagues for prevention of CLD and none was included for established CLD.[268]

The results for the nebulized anticholinergic agents atropine and ipratropium bromide are similarly positive but of limited significance. There is evidence that ventilator-dependent babies with CLD respond to single doses of nebulized ipratropium bromide,[269] but again, long-term randomized trials in CLD are lacking. One double-blind, randomized trial in older preterm infants whose conditions were symptomatic was effective,[272] although the same authors caution its use in infants whose condition is asymptomatic.[273] There is weak evidence for synergy between β_2-agonists and anticholinergic agents.[274]

In practice, salbutamol (albuterol) or ipratropium bromide given by MDI and small volume spacer may be used for ventilator-dependent infants, older infants with CLD who have severe airway obstruction, and wheezy infants with CLD. There is little to support the use of bronchodilators in acute viral episodes in infancy in general and even less in acute viral exacerbations of CLD.

There are no dosage regimens, but the author has noted that salbutamol (albuterol), 100 to 200 μg every 4 to 6 hours, and ipratropium bromide, 20 to 40 μg every 6 hours, do not seem to cause undue tachycardia or any detectable side effects. The efficacy of treatment can be judged only by general clinical features or the ventilatory efficiency index during mechanical ventilation.[204] Short-term measurements of lung function may lend support but are generally too vari-

able over days or weeks to guide long-term therapy in individual cases.

ANTI-INFLAMMATORY AGENTS

Data on sodium cromoglycate (cromolyn sodium) are sparse and consist of one open study on ventilator-dependent infants that suggested cytologic improvement,[275] a pilot study that showed no benefit,[276] and one properly conducted, double-blind, randomized, controlled trial in older preterm infants symptomatic at follow-up.[277] In the last study, there was a significant reduction in symptoms after 3 weeks of treatment by MDI and spacer.

The pharmacologic effects of corticosteroids on the lungs can be considered at the molecular or cellular level, at the functional or physiologic level, and at the level of clinical disease. There are data on all these outcomes of corticosteroid therapy in preterm infants. The common theme of most studies is the anti-inflammatory action of corticosteroids. There are, however, several other potentially relevant actions, some studied only in animal models, including enhancement of β-receptor density, increased transduction of the genes for several antioxidant enzymes, altered gene expression for a variety of cytokines and growth factors, enhanced surfactant production, and suppression of inducible nitric oxide synthase. Recent data linking the early use of corticosteroids in the neonatal unit with neurodevelopmental abnormalities including cerebral palsy are of clear concern and have been reviewed recently by Grier and Halliday.[278]

Clinical trials of systemic corticosteroids in developing CLD or established CLD (BPD) have been thoroughly reviewed by series of Cochrane reviews, with most reviews pleading for more appropriate studies to be adequately performed especially for established CLD.[231-236] The only clear evidence for the use of corticosteroids remains the ability of these drugs to facilitate extubation of ventilator-dependent infants. Most clinicians are much more cautious than earlier due to the association of these drugs with adverse neurodevelopment.[278-280] In contrast to ventilated preterm infants, adequate studies of the use of both systemic and inhaled corticosteroids in established CLD are lacking.

Administration and dosage regimens are poorly worked out. Dexamethasone is the most popular corticosteroid in neonatal practice, and parenteral (usually intravenous) administration is the usual route. Recent attempts to evaluate other corticosteroids such as hydrocortisone have been affected by significant side-effects.[281,282] Although unable to recruit the intended number of participants, the DART study showed promise using a lower dose of dexamethasone (0.89 mg/kg over 10 days) but the need for either a second course or of rescue therapy with dexamethasone was increased in the treated group.[283] Despite known differences among corticosteroids in the degree of penetration into the lungs after parenteral administration, no study of this important aspect of therapy has been reported in young infants.

Pulmonary mechanics have been reported in a number of small, mainly sequential observations.[284-288] Individually, these studies have major flaws, but their consistency is remarkable. Within 12 to 72 hours, falls in respiratory resistance of about 30% and increases in compliance of 60% to 70% are typically seen (Fig. 29-11).

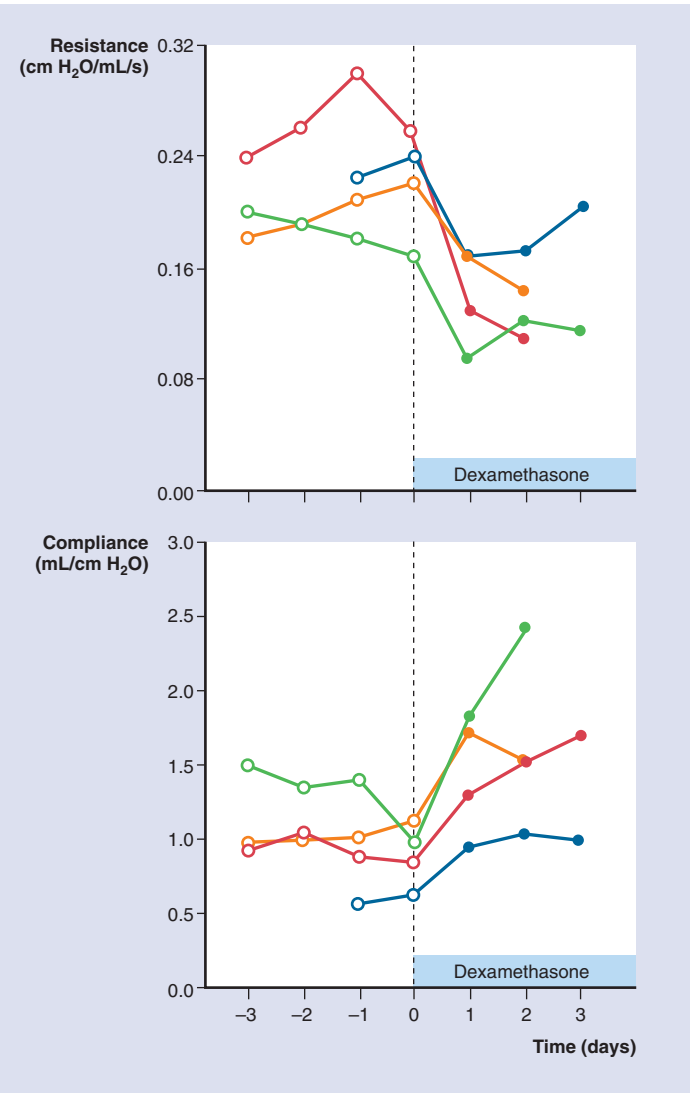

Figure 29-11 Dexamethasone and ventilator-dependent chronic lung disease (CLD) at 3 weeks. Changes in lung mechanics occur within 24 hours. Data shown for individual patients. (Redrawn from Brundage KL, Mohsini KG, Froese AB, et al: Dexamethasone therapy for bronchopulmonary dysplasia improved respiratory mechanics without adrenal suppression. Pediatr Pulmonol 12:162-169, 1992.)

Attempts to understand the mechanism of corticosteroid action in CLD have led to a bewildering number of measurements of cytokines and other cell products in bronchoalveolar lavage fluid or tracheal aspirate. This is definitely a growth area. Sadly, the majority of observations were not designed to answer any useful hypotheses. Again, there are methodological defects in many studies: inadequate control data, sequential observations, lack of attention to the expression of bronchoalveolar lavage fluid concentrations (by reference to a reliable denominator), and very variable and small patient groups. The most comprehensive and carefully conducted study showed parallel changes in tracheal fluid neutrophil cell counts, cell products, lung mechanics, and clinical status within 3 days of starting dexamethasone therapy in a randomized, controlled trial.[285]

The use of topical corticosteroids to prevent CLD has also been reviewed by a Cochrane review.[236] By far the largest study by Cole and associates used a high dose of inhaled

beclomethasone (starting dose of 1000 μg/kg/day with an estimated 4% delivery at the endotracheal tube, i.e., 40 μg/kg/day) for 4 weeks in 253 preterm infants between 3 and 14 days of age. Although a decrease in inflammatory cytokines was noted,[289] the rate of CLD (either oxygen dependency at 28 days or at 36 weeks' corrected gestation) with treatment was not decreased, although a subsequent need for systemic corticosteroids was reduced.[290] The potential range of devices, medications, and doses is huge, although there are now sufficient data from human and model lung experiments to devise regimens for clinical trials.[228-230]

Corticosteroids are often used in older infants and children, but very little data are available to support their use except where clear clinical benefits are observed in symptomatic infants. In the most recent Cochrane review of the use of inhaled corticosteroids in established CLD by Lister and coworkers only one study published as an abstract was included in their analysis.[236,291] In the study, by Dunn and colleagues,[291] nonventilated infants of at least 36 weeks' corrected gestation and who were oxygen dependent were included. Budesonide (1 mg) was administered by an Airlife Misty-Neb jet nebulizer three times a day for 7 days. A significant reduction in oxygen requirements was observed by the authors. In another study of 18 preterm infants at a mean postnatal age of 10.5 months, the use of inhaled beclomethasone for 6 weeks was associated with an improvement in respiratory tract symptoms and functional residual capacity.[292] Because this study did not specify the number of infants with oxygen dependency, it is difficult to extrapolate the results to infants with established CLD.

Adverse effects of corticosteroids are obviously a major concern. Brief and probably insignificant systolic hypertension, hyperglycemia, and neutrophilia are reported in many of the dexamethasone trials. Of more concern is the evidence of adrenal suppression of up to 1 month's duration even after 1 week of therapy.[293,294] Gastrointestinal perforation has been reported.[295,296] Whether this rare complication can be safely prevented by the routine use of H_2-blocking agents during dexamethasone therapy remains to be investigated.

One of the most worrisome potential effects of corticosteroids on the growing lung is suppression of alveolar development. There are certainly effects on somatic growth and lung morphology from brief exposures of neonatal rats to modest doses of dexamethasone.[297,298] Measurements of lung function in infants and children exposed to antenatal dexamethasone do not suggest any persistent adverse effects.[299,300] However, the studies are small, are open to bias, and depend on an assumption that lung function is equivalent to lung growth. Transient growth suppression is demonstrable by knemometry, with apparent catch-up after cessation of steroid treatment.[301]

In practice, the approach adopted by most is to consider the clinical need (e.g., wheezing) and clinical response to the use of inhaled corticosteroids in infants with established CLD and to continue treatment in those who respond but to cease treatment when an adequate response is not observed. Pulmonary function tests may be useful but remain largely a research tool for this group of infants. As this set of children forms a large group in the community, there is a clear need for adequately powered, randomized, controlled trials to examine the role of both systemic and inhaled corticosteroids in infants with established CLD.

DIURETICS

In addition to their cardiovascular indications (see previous section), diuretics are frequently used to treat the pulmonary problems of CLD. The role of diuretics has been extensively documented by several Cochrane meta-analyses.[238-240] Their efficacy is based on experimental reductions in pulmonary vascular resistance and in extravascular lung water in experimental animals by furosemide treatment. In CLD, there is evidence of a disturbance in water balance[302,303] and peribronchial edema.[304] The mechanism of clinical improvement in response to diuretics is unclear. Local actions on the distribution of lung water and on the pulmonary vasculature may be as important as renal effects on total body water levels. For instance, furosemide has a number of such actions. Potential actions on the airway epithelium are especially interesting because they open the possibility that aerosol therapy may be effective, thus avoiding troublesome renal actions.[305]

There is striking uniformity of the results of clinical trials with furosemide (1 mg/kg once or twice a day intravenously or 2 mg/kg twice a day orally) despite the variety of trial designs and methods of measuring outcome. All results demonstrate an increase in pulmonary or respiratory system compliance, and some also demonstrate falls in resistance and oxygen requirement over intervals of between 1 hour and 8 days of therapy.[305-307] The rapid onset suggests a local effect,[305,308] a conclusion supported by the presence of changes in lung mechanics in the absence of measurable diuresis.[307]

Three of four studies on the combination of thiazide and spironolactone (chlorothiazide, 20 mg/kg, or hydrochlorothiazide, 1.5 to 2 mg/kg every 12 hours, with spironolactone, 1.5 mg/kg every 12 hours by mouth) showed significant improvements in compliance with variable improvements in resistance and oxygen requirement, albeit to a less marked extent than the changes found after furosemide.[309-311] One study using a lower dose[312] found no significant effect, despite diuresis. There are no dose-ranging studies. In the author's clinical experience (with chlorothiazide, 10 to 20 mg/kg twice a day and spironolactone 1 to 2 mg/kg twice a day), some adjustments of dose are often necessary.

The conclusion from these small studies is that diuretics are effective over periods of up to 8 weeks. Long-term side effects may be troublesome. Furosemide enhances calcium excretion and often leads to nephrocalcinosis and osteopenia. Electrolyte imbalance is common, and serum electrolyte measurements must be performed twice a week. Alternate-day therapy should be considered, although it is uncommonly used in practice. The combination of thiazide and spironolactone leads to lower calcium levels and potassium loss but may cause troublesome hyponatremia soon after the onset of therapy.

A trial of diuretic therapy for 1 to 2 weeks is indicated for the following:

1. Chronic ventilator-dependent cases
2. Infants on very low-flow oxygen therapy (100 mL/min or less) who are to be discharged home shortly
3. Sudden deterioration or sudden weight gain

There is no standard weaning process. The author simply allows infants to outgrow their therapy and withdraw when the dose has fallen below the accepted therapeutic range.

MISCELLANEOUS THERAPIES

Anti-infective agents are commonly used to treat episodes of "sepsis" in the neonatal intensive care unit. Most infective pulmonary exacerbations later in childhood have a viral etiology—respiratory syncytial virus being an especially virulent agent.[145] The use of the monoclonal antibody against RSV (palivizumab) appears to be efficacious in decreasing the severity of RSV in vulnerable infants.[313] Antibiotics are indicated only for specific reasons: high index of suspicion of bacterial disease, host defense defect, and cystic fibrosis-like pattern of illness with frequent severe exacerbations. There are no clinical trials to back up these assertions. Complete immunization including influenza during winter periods is vital for infants with CLD.

RESPIRATORY FAILURE

The management of CLD consists largely of attempting to identify remediable causes of respiratory failure or (in milder cases) respiratory dysfunction and trying to tackle them. Respiratory failure itself, defined as the failure of the respiratory system to adequately exchange oxygen and carbon dioxide for whatever reason, often needs to be tackled directly by mechanical ventilation and oxygen therapy. The classification and causes of respiratory failure in general are discussed in Chapter 19.

Upper airway obstruction is often overlooked as a cause of weaning failure in infants whose lungs have been intubated for a prolonged period. If laryngeal or subglottic edema is suspected, a short course of corticosteroids may be effective.[314] In modern neonatal practice, clinically significant structural (as opposed to transient) upper airway damage appears to be less common.

MECHANICAL VENTILATION

Mechanical ventilation has a role in the etiology of acute lung injury (see previous section), but its role in CLD is speculative. The safest technique has not been established despite large clinical trials and an array of modern modes of mechanical ventilation. There are even less data to guide the neonatologist in the ventilatory management of established CLD.[315] No clinical trials of techniques of mechanical ventilation have been reported. Because small numbers of infants with established CLD are likely to require mechanical ventilation, adequately powered clinical trials are unlikely to be performed in the immediate future. Devices would be welcome that could allow the clinician to avoid intubation. There has been some resurgence of interest in continuous or intermittent negative extrathoracic pressure.[316]

OXYGEN THERAPY

Appropriate oxygenation is essential. Too little oxygen is clearly harmful, but excess has adverse effects too. These include toxic effects on the airway epithelium, including inhibition of ciliary action; possibly systemic hypertension; and the physical, emotional, and economic costs on the child, family, and society for unduly prolonged treatment.

Although the optimal oxygen saturation is unknown, it is likely to be higher than 90%. Win Tin and colleagues (U.K.) in a retrospective analysis of their data suggest that oxygen saturations as low as 70% may not be harmful to preterm infants, but this needs to be confirmed with an adequately powered prospective study which at the time of writing has been funded (BOOST2). The STOP-ROP and BOOST trials showed that oxygen saturations of between 91% and 94% may be preferable to oxygen saturations of between 95% and 98%—with the former not being associated with poor growth and the latter associated with greater need for home oxygen and respiratory illness.[155,317] It is unknown whether brief hypoxic spells during feeding or interruption of the oxygen supply or during apneic pauses has a cumulative long-term effect on cardiovascular function, neurodevelopmental progress, or growth regulation. It seems prudent to supply sufficient oxygen to prevent even brief changes in saturation below 90% because this provides a safety margin at the upper end of the oxygen-hemoglobin dissociation curve for those "natural" variations in breathing resulting from feeding, posture, the sleep state, crying, and upper respiratory infection that may depress the partial pressure of arterial oxygen and, therefore, the arterial oxygen saturation.[181-184] There are no data from controlled trials, only some observational support, to justify these figures.[191]

There are several techniques for administering oxygen to infants with CLD.[318] Each has its advocates. Head-box delivery of oxygen is less frequently used and most prefer delivery with nasal cannulae. Humidification is unnecessary in most instances of infants with established CLD.

Domiciliary therapy[40,196,197,319-321] is most conveniently and cheaply provided by an oxygen concentrator with a low-flow meter (range about 100 to 1000 mL/min or 25 to 200 mL/min), but back-up cylinders and portable devices are also needed for emergencies and for mobility. A liquid oxygen-based system is indicated if higher flow rates (of greater than 1 L/min) are required. The supervision of a dedicated home care nursing team in collaboration with other community health professionals is advantageous.

Monitoring is vital. The limitations of transcutaneous devices have been discussed. They may be useful in the hospital but are too inaccurate, slow responding, and technically demanding for domiciliary use. Oximeters in averaging mode have allowed safe and stable domiciliary therapy and have arguably been responsible for the enormous recent improvement in long-term prognosis. The frequency of monitoring may vary depending on the stability of the patient's condition.

Implicit in oxygen monitoring is the need for regular echocardiographic assessment of the pulmonary circulation because one of the primary aims of oxygen therapy is to reduce pulmonary vascular resistance to normal levels. The author recommends an echocardiographic evaluation before discharge from the hospital and at 3-month intervals thereafter until oxygen therapy ceases. Measurements are made on each occasion of right ventricular systolic times (ratio of right ventricular acceleration time and ejection time) and, where possible (50% of cases), right ventricular systolic pressure from the tricuspid regurgitant jet both in and out of oxygen therapy during sedated sleep. The information is particularly useful during weaning from oxygen therapy.

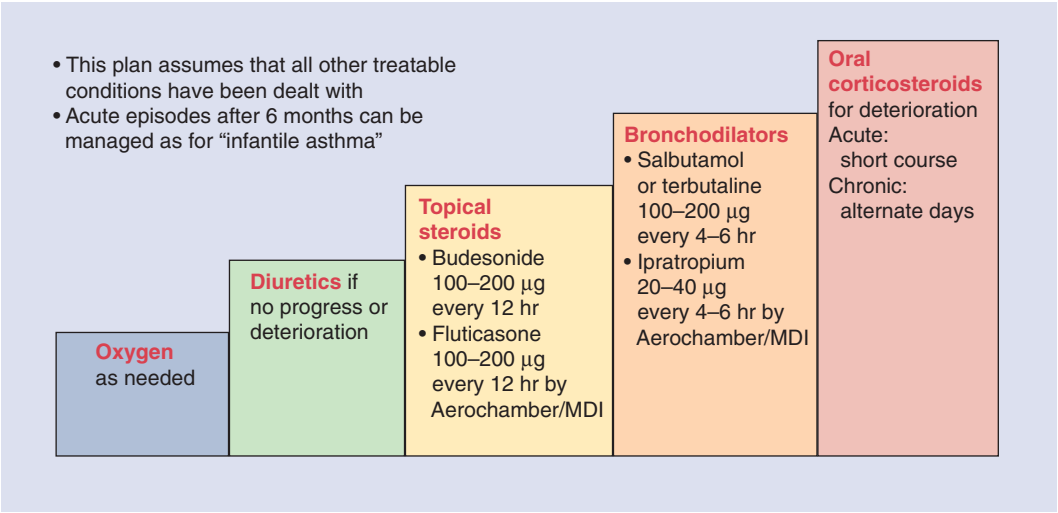

Figure 29-12 Suggested stepwise management plan for oxygen-dependent infants whose conditions are symptomatic.

The indications for referral to the hospital for reassessment or readmission include:

1. Sudden or gradual decline in arterial oxygen saturation requiring a marked increased in oxygen flow
2. Frequent catheter blockage resulting from nasal obstruction
3. Hypoxic spells or an acute life-threatening event

Monitoring should continue for 2 to 3 months after withdrawal of oxygen because secondary deterioration may occur and is often precipitated by a viral respiratory tract infection. It is probable that oxygen saturation never reaches truly "normal" values (98% to 100%) in children who have had prolonged severe CLD in infancy.

MANAGEMENT PROTOCOLS

With individual institutions, management protocols evolve by consensus and experience backed by scientific data. As such, change is inevitable. Protocols should be seen as advisory and not prescriptive. Examples of a consensus approach to the management of ventilator-dependent respiratory failure and symptomatic infantile CLD are given in Figure 29-12.

Domiciliary management demands the sort of guided self-management approach that has become the norm in the management of asthma (see Chapter 59). Thus parents can be provided with information, training (in oxygen administration, cardiopulmonary respiration, and the use of inhaler devices), and written instructions that allow them to vary their child's therapy according to clear guidelines and within agreed limits. Open access is essential for parents of infants with children on home oxygen to either an emergency room or preferably to inpatient wards with expertise in respiratory management of infants with oxygen dependency.

Future Directions

The short-term outcome of preterm birth has already improved considerably by interventions such as antenatal corticosteroid therapy and the early use of surfactant for babies at risk of RDS (see Chapter 28). Given the fact that the long-term outcome at school age appears to be more closely related to prematurity itself than to acute lung injury, the prospects for preventive intervention, assuming that prematurity cannot be prevented, are more speculative. Areas that may benefit from further intense study include:

- Prevention of premature labor (e.g., better understanding of the role of antenatal infection)
- Use of current knowledge to improve respiratory outcomes (e.g., does targeted treatment to eradicate *Ureaplasma* spp. prevent the development of CLD?)
- Better understanding of the mechanisms that can lead to better management (e.g., mechanical ventilation to avoid pulmonary inflammation)
- Identification of optimal oxygen saturations while avoiding adverse events—including poor growth, pulmonary hypertension, and adverse neurologic outcome
- Although corticosteroids are the main available drug treatment to facilitate extubation from mechmical ventilation, identify ideal dosage, timing, and length of treatment for corticosteroids. Seek suitable alternatives to dexamethasone treatment.
- Alternative therapies to corticosteroids include the use of proteins such as alpha$_1$ antitrypsin, CC10; antibodies monoclonal antibodies toward proinflammatory cytokines or adhesion molecules
- Better assessment of lung growth using more powerful techniques of magnetic resonance imaging
- Better assessment of pulmonary hypertension using modern imaging techniques of echocardiography
- Long-term follow-up studies to assess if CLD predisposes to premature respiratory morbidity in adulthood

CHAPTER 30

Apnea of Prematurity, Sudden Infant Death Syndrome, and Apparent Life-Threatening Events

Christian F. Poets

TEACHING POINTS

- Factors involved in the pathogenesis of apnea of prematurity (AOP) are the infant's low lung volume, diaphragmatic fatigue, the unique response of the preterm infant to hypoxia, and the propensity to upper airway obstruction.
- Treatment should be incremental, starting with prone positioning followed by methylxanthines and nasal continuous positive airway pressure (CPAP) or intermittent positive pressure ventilation (IPPV).
- Primary prevention such as the supine sleep position, room but not bed sharing, pacifier use, use of a sleeping bag, and adherence to a smoke-free environment will prevent >90% of SIDS cases, even though its pathophysiology remains unknown.
- Pathologic studies in SIDS suggest that the final pathway leading to SIDS involves large intrapulmonary pressure swings. These could result from upper or lower airway obstruction or asphyxic gasping.
- Numerous disorders may materialize as an apparent life-threatening event (ALTE), with hypoxia being a common end point in many. Management involves careful history taking and the use of a memory monitor to gather objective data if further events occur.

APNEA OF PREMATURITY

Apnea of prematurity (AOP) is a developmental and thus self-resolving disorder, which nonetheless can cause serious problems. Attempts to improve its treatment require an understanding of its pathophysiology, and this will be the focus of this chapter. Equally important, but completely unclear, are treatment indications (i.e., how much intermittent hypoxia and bradycardia can be tolerated without putting an infant at risk of neurodevelopmental impairment, and will this risk be reduced or even enhanced by some of the treatments currently available?).[1]

Almost every infant born at less than 29 weeks of gestation exhibits AOP.[2] No study, however, has yet identified a threshold in either frequency or severity of accompanying bradycardia or hypoxemia above or below which there is an increased risk for neurodevelopmental impairment. Most studies even suggested that within the frequency and severity of AOP tolerated in their institution, there is little indication that AOP, by itself, leads to impaired neurodevelopment.[3-7] This is surprising, given that *after* hospital discharge, infants with 5 or more apneas (>20 seconds) or bradycardias during at least 175 hours of documented home monitor use scored 5 points less on the Mental Development Index (MDI) at 1 year of age than those without such monitor alarms.[8] Other studies found that infants who had received theophylline or doxapram during their initial hospital stay had worse neurodevelopmental outcome (see later),[9,10] but these latter analyses cannot distinguish whether it is the symptom (AOP) or its treatment that is responsible for the neurodevelopmental impairment.

Given the lack of good outcome data, indications for treatment or a step-up in its intensity are bound to be arbitrary. From a physiologic point of view it is not the apnea but its effect on oxygenation and/or heart rate that is relevant to the well-being of an infant. For example, in German guidelines for AOP, this threshold has been set at six or more bradycardias (to <80/minute) or desaturations (to <80% pulse oximeter saturation [SpO_2]) occurring in a 6-hour period, with a reduction being suggested if less than two occur in the same period.[11] It has to be kept in mind, however, that these thresholds strongly depend on the averaging time used in the instrument with which they were measured (Fig. 30-1). Thus, their role is more in helping to standardize treatment than in defining a uniform threshold that is relevant to outcome.

Pathophysiology

RELATION BETWEEN APNEA, BRADYCARDIA, AND DESATURATION

One of the most striking findings in recordings of respiration, heart rate and SpO_2 in preterm infants is the close temporal relationship between apnea, bradycardia, and desaturation.[12] Early studies suggested that the bradycardia resulted from a chemoreceptor reflex elicited by the rapid development of hypoxemia during apnea.[13,14] Subsequent investigators, however, claimed that the fall in heart rate commenced too early during the apnea to be attributed to apnea-induced hypoxemia, and suggested instead that bradycardia was

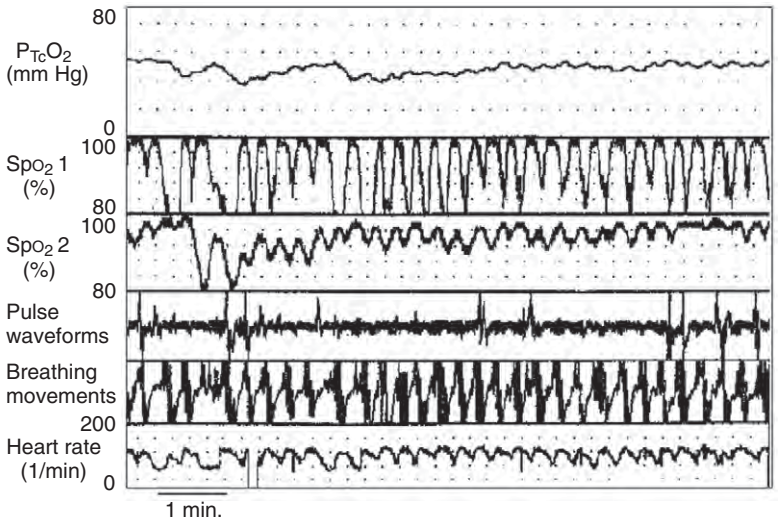

Figure 30-1 Influence of averaging time of the pulse oximeter on rates of intermittent hypoxia. Two pulse oximeters (Nellcor N200) are attached to the right and left foot of a preterm infant during periodic apnea. The upper pulse oximeter saturation trace (Spo_2 1) was recorded in a beat-to-beat mode, the lower one (Spo_2 2) in a 6-second averaging mode. Note that with the oximeter set in a non-averaging mode, 15 alarms to ≤80% Spo_2 would have been counted, in contrast to only two with the 6-second averaging mode. Unaccounted for, this purely technical difference might have resulted in different treatment decisions. Abbreviations: $P_{Tc}O_2$, partial pressure of transcutaneous oxygen tension; Spo_2, pulse oximeter saturation.

caused by a reflex response to the cessation of lung inflation.[15,16]

In an analysis of the relation between these three phenomena in 80 preterm infants (mean gestational age [GA] at study 36.3 weeks), most bradycardia (86% and 83%, respectively) was accompanied by hypoxia (SaO_2 < 80%) and apnea (>4 seconds) and commenced almost always *after* the onset of both apnea and hypoxia (median interval, 4.8 and 4.2 seconds, respectively). This was predominantly because the interval between the onset of apnea and that of desaturation, corrected for the time it takes for the blood to travel to the pulse oximeter sensor, was extremely short (median 0.8 seconds; Fig. 30-2).[17]

These temporal observations support the concept that hypoxemia causes bradycardia (e.g., via stimulation of peripheral chemoreceptors).[18] But why was it apparently not the hypoxemia per se, but its coincidence with an apneic pause that resulted in the development of bradycardia? The answer to this may be found in cross-perfusion experiments in dogs, where the fall in heart rate was far more pronounced if there was a combination of both apnea and hypoxemic excitation of arterial chemoreceptors than with either apnea or hypoxemia alone.[19] Thus, the appearance of bradycardia during apnea may be dependent on there being no overriding effect from the pulmonary inflation reflex, which is known to cause an increase in heart rate.[19] One possible explanation for the comparatively high frequency of bradycardia in preterm infants is, therefore, that bradycardia is primarily caused by hypoxemia, and that the resultant effects on heart rate are potentiated if there is no lung inflation. This would also explain why, despite a similar severity of the accompanying hypoxemia, bradycardia is more common with central than with mixed or obstructive apnea.[20]

Changes in Lung Volume During Apnea

A surprising finding in the aforementioned study[17] was the brevity of the interval between the onset of apnea and that of desaturation. It is tempting to speculate that there would have been far less bradycardia had the hypoxemia not occurred so early during apnea. It remains unclear, however, whether this early onset of hypoxemia was due to preceding hypoventilation, nonapneic mechanisms, or both. Hypoventilation was suggested to precede apnea[21] by Adams and colleagues, who found that 62% of events with Spo_2 less than 80% were preceded by breaths with a tidal volume of less than 50% of baseline.[21]

Figure 30-2 Example of the close temporal relation between apnea, bradycardia, and desaturation. The delay caused by the time it takes for the blood to travel from the lung to the pulse oximeter sensor attached to the foot can be estimated from the delay between the first breath following an apnea and the onset of the recovery in Spo_2 (C). This was subtracted from the interval between the onset of apnea and that of desaturation (A) and from the interval between the onset of bradycardia and that of desaturation (B; see text). Dekker, New York, 2003, pp 295-316.

A nonapneic mechanism that could explain the early onset of hypoxemia during apnea is a low lung volume. This is particularly relevant to young infants, whose relaxation volume is only 10% to 15% of total lung capacity and thus very close to residual volume, predisposing them to the development of airway closure.[22] To compensate for this disadvantage, both term and preterm infants actively maintain their end-expiratory lung volume above relaxation volume (which is one reason for their high respiratory rate),[23-25] whereas lung volume falls if respiration ceases.[26] During repeated measurements of functional residual capacity (FRC) in 48 "healthy" preterm infants (mean GA at study 36.6 weeks) during unsedated sleep, breathing movements and SpO_2 were recorded throughout and analyzed for apneas (>4 seconds), sighs, and desaturations ($SpO_2 < 90\%$) during the last 2 minutes prior to each FRC measurement.[27] Apneas resulted in a significant decrease in FRC: mean FRC was 20.0 mL/kg following an apnea, 26.0 mL/kg after a sigh ($P < 0.001$), and 23.9 mL/kg if there had been neither a sigh nor an apnea ($P < 0.05$). The interval between the apnea and the FRC measurement had no effect on FRC. Thus, apneas resulted in a persistent reduction in FRC, which was restored by a sigh. These findings provide further evidence for the hypothesis[28,29] that one of the main functions of sighs in preterm infants is to reverse falls in lung volume caused by apneas.

What does this have to do with the interval between apnea and desaturation? The FRC serves as a buffer to stabilize oxygenation during brief periods of apnea. Lung volume is an important determinant of the speed with which desaturation develops during voluntary breathholding,[30] and preapneic lung volume was found to have a strong influence on the hypoxemia that occurs during sleep apnea in adults.[31] Preterm infants also show such a relationship: the lower the lung volume *following* an apnea, the more rapid is the fall in SpO_2 *during* the apnea.[27]

A clinical scenario where the potential influence of lung volume on oxygenation becomes particularly evident is periodic apnea. During this respiratory pattern, SpO_2 was observed to fall twice as fast as during isolated apneas (8.4% versus 4.3% per second, $P < 0.005$).[12] Although other factors (e.g., a fall in mixed venous SO_2[32] may also play a role, the main reason for the more rapid fall in SpO_2 likely is a progressive fall in lung volume during the repeated apneas.

Another potential consequence of the reduction in lung volume occurring during spontaneous apneas is a further inhibition of respiration via activation of the Hering-Breuer deflation reflex. In term infants this vagally mediated reflex, which acts around FRC, terminates expiration while initiating inspiration. In preterm infants, however, induction of this reflex via chest compression resulted in a shortening of inspiratory time and a tendency to have short apneas (2 to 5 seconds).[33] A similar inhibition of breathing may result if lung volume falls spontaneously, for example, during apnea.

These considerations provide a theoretical basis for the effectiveness of strategies that increase or stabilize lung volume in reducing the frequency and/or severity of both bradycardia and desaturation in preterm infants.[34] In fact, Thibeault and coworkers[35] observed as long as 40 years ago that recurrent apnea may be abolished by increasing FRC via the application of negative extrathoracic pressure. The same effect can also be achieved by continuous positive airway pressure (CPAP; see later).[36]

The Role of Feeding and Gastroesophageal Reflux (GER)

A frequent observation in infants with AOP, first noted over 80 years ago,[37] is that symptoms increase during and after feeding. The hypothesis that this association could be a result of "the full stomach interfering with the action of the diaphragm" was put forward in 1936.[38] Since then the effects of feeding on respiration have been studied extensively.[39-49] It is now clear that some preterm infants, particularly those with bronchopulmonary dysplasia (BPD), may become severely hypoxemic during and immediately after bottle feeding,[38-42] and that gavage feeding may also cause a significant reduction in blood oxygen levels.[43-46] Hypoxemia *during* feeding may be caused by a reduction in minute ventilation due to an immature coordination between breathing, sucking, and swallowing,[42,46-48] activation of the laryngeal chemoreceptor reflex,[49] gastroesophageal reflux (GER), diaphragmatic fatigue,[50] or combinations of these mechanisms. Hypoxemia *after* feeding was suspected to be due to a reduction in lung volume and an increased work of breathing resulting from gastric distention.[47] If this were true, avoidance of gastric distention via slow or continuous gavage feeding should ameliorate the problem.

However, in a study on the effect of bottle feeding, as compared to slow and fast (10 min) gavage feeding, on AOP, there were 3 times more falls in SpO_2 to less than 80% with bottle than with bolus gavage feeding, but no further reduction with slow gavage feeding. With all three feeding techniques there were significantly more desaturations in the hour the feeds were given. The deleterious effects of bottle feeding were most evident during the hour of feeding, but desaturation frequency remained significantly higher than with gavage feeding during the following 2 hours. In contrast, there was no significant effect of feeding technique on the frequency of apnea or bradycardia.[51]

Although the deleterious effects of bottle feeding on respiration may be avoided by postponing bottle feeds in infants with severe AOP, it is puzzling that slow gavage feeding offered no advantage over bolus feeds, because it should have prevented gastric distention.[52] This hints toward GER as an explanation for the observed increase in desaturation with feeding

A relation between GER and AOP has long been suspected[53,54] but was difficult to prove because most GER in this age group is nonacidic and, thus, undetectable by pH-monitoring, which is the current standard for GER detection. Using the multiple intraluminal impedance (MII) technique, however, which allows pH-independent reflux detection,[55] the frequency of apnea, bradycardia, or hypoxia occurring within ±20 seconds of a reflux episode (RE) was *not* found to be significantly different from that found during reflux-free epochs.[55] Also, RE occurred similarly often within 20 seconds before or after an apnea. Thus, it appears that both cardiorespiratory events and GER are common in preterm infants but, with few exceptions, do not appear to be temporally related.[55,56]

Thus, the widespread practice[57] of giving antireflux medications to infants with AOP most likely is futile. It remains unclear, however, why AOP is so closely associated with feeding. One alternative explanation is diaphragmatic fatigue. Diaphragmatic work increases significantly after gavage feeding, whereas FRC decreases,[47] but whether this is sufficient to cause diaphragmatic fatigue in relation to feeding remains, at present, unknown.

Chest Wall Distortion, Anatomic Dead Space, and Diaphragmatic Fatigue

What is the evidence that diaphragmatic fatigue plays any role in the pathophysiology of AOP? Because of their highly compliant chest wall, preterm infants are disadvantaged with regard to their respiratory mechanics. Chest wall distortion, clinically apparent as paradoxical breathing, is common in infants and is especially visible in preterm infants. It has been suggested that this distortion increases the volume displacement of the diaphragm during inspiration.[50,58] In longitudinal studies, Heldt showed that the minute volume displacement of the diaphragm was almost twice as large as pulmonary ventilation at 29 to 30 weeks GA and fell to approximately 90% of pulmonary ventilation at 36 weeks GA. Concomitantly, diaphragmatic work was almost halved.[59] The author speculated that this additional workload may represent not only a significant energy expenditure in these infants but may also contribute to the development of diaphragmatic fatigue and apnea.[59] Further contributing to this fatigue is the fact that, because of their relatively large head size, anatomic dead space is approximately 45% of tidal volume in newborns compared to 25% in adults.[21,25]

Circumstantial evidence that muscle fatigue may indeed be involved in neonatal apnea stems from the time course of apnea in term and preterm infants. This was already noted over 40 years ago to become more problematic toward the end of the first week of life,[60] whereas chemoreceptor resetting, which otherwise might also explain this phenomenon, is essentially complete within approximately 24 to 48 hours of birth.[61] Periodic apnea also starts usually only after day 2 of life, reaching a maximum during the second and third week.[62] In our own studies, preterm infants studied at around 4 weeks of age showed more desaturation than those studied during their first week of life, but at a lower postconceptional age: although the 95th centile for desaturation frequency was 8 per 12 hours in the latter group, it was 61 in the former.[63] A similar relation between postnatal age and desaturation rate was found for term infants (Fig. 30-3).[64] A mechanism through which labored breathing may produce apnea in preterm infants is the intercostal-phrenic inhibitory reflex. This may be elicited both by rib cage distortion[65] and respiratory loading,[66] and is known to inhibit respiratory effort in infants. Also, frequency spectrum analysis in diaphragmatic EMG recordings in preterm infants showed that, in 7 of 15 infants studied, EMG segments indicating diaphragmatic fatigue were followed by periods of apnea.[50] Thus, it is conceivable that similar to the obstructive sleep apnea syndrome in adults, where an increased work of breathing can lead to more central apneas, it may also play a role in the pathophysiology of AOP.

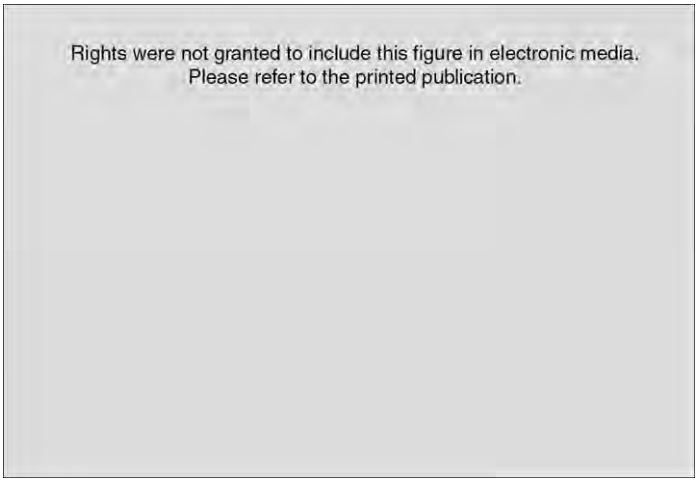

Figure 30-3 Data on the proportion of 12-hour recordings containing prolonged episodes of desaturation (SpO_2 < 80% for >4 seconds) and on the 95th centiles for desaturation rate per 12 hours in various groups of term (*right half*) and preterm (*left half*) infants. Note that intermittent hypoxia in both term and preterm infants is less frequent shortly after birth than at 2 to 3 weeks of age and decreases again thereafter. Median age at study for each group is given both as postconceptional (week) and postnatal (day) age. Dekker, New York, 2003, pp 295-316.

Upper Airway Obstruction

Traditionally, apnea has been divided into central, obstructive, and mixed. However, analyses of artefacts on the nasal thermistor signal, produced by the transmission of cardiac impulses on the patent airway, revealed that airway obstruction may also occur during apparently central apneas.[67] By amplifying these cardiac oscillations, Rigatto's group found indications for airway narrowing during 13% of apparently central apneas, starting after only 1 second. They speculated that their finding reflects a loss of upper airway muscle tone during apnea.[68] The same group also reported that diaphragmatic action is not needed to occlude the airway in mixed apneas, and speculated that airway closure during these apneas most likely reflects a lack of upper airway muscle tone that is not reinstated at the time the diaphragm starts to contract again.

An alternative explanation for the airway occlusion potentially occurring during apparently purely central apneas originated from continuous EMG recordings of the laryngeal adductor muscle in lambs, which found continuous EMG activity throughout 88.4% of all apneas and 98.4% of those occurring during periodic breathing, independent of sleep state.[69] EMG activity, however, was less likely to be continuous during apneas that were triggered by a sigh or a swallow. The authors concluded that active glottic closure, similar to that preventing outflow of lung water during the prolonged apneas that occur in utero,[70] would prevent gas from flowing out from the lungs, thereby preserving lung volume during apnea. Although evidence for active glottic closure has also been reported during obstructive apneas in human preterm infants and in a case report on a term infant during periodic breathing,[71,72] it is not yet known whether active glottic

closure generally occurs during central apneas also in the human preterm infant.

Not only can apparently central apnea result in upper airway obstruction, but also vice versa. Upton and colleagues studied the response to airway obstruction in 23 preterm infants born at less than 33 weeks' gestation.[73] Of 398 obstructions recorded, apnea occurred *during* the obstruction in 19%, and *upon relief* of the obstruction in 32%. This happened independently of where in the respiratory cycle the obstruction occurred. They speculated that their observation on the response to airway occlusion may be important in the prolongation of initially short respiratory pauses during which airway closure may occur.[74]

Waggener and coworkers[75] analyzed oscillations in breath-by-breath ventilation of preterm infants, and observed that central, mixed, and obstructive apneas all occurred at the minimum phase of spontaneous ventilatory oscillations, suggesting that all three patterns had one common underlying mechanism. Hence, it appears that all three apnea types form a continuum (i.e., that obstructive components are also involved in apparently purely central apneas and vice versa). This is probably related to the fact that the narrow upper airways of preterm infants are actively maintained open via a respiratory center input, and that it depends on which component stops being activated first (diaphragm or upper airway) whether an apnea will appear as central or obstructive. At autopsy the upper airway of young infants is closed, again suggesting that a neuromuscular mechanism is necessary to maintain airway patency during life.[76] The mechanism(s) through which airway closure occurs during apnea, however, is largely unclear. One factor may be flow- or pressure-sensitive airway receptors. In animal experiments, flow up and down the upper airway resulted in the maintenance of pharyngeal patency via increased genioglossus activity.[75] Thus, when flow ceases genioglossus activity falls and the airway collapses. Alternatively, cessation of respiratory drive may cause an immediate loss of lower (and probably also upper) airway tone,[77] or airway closure occurs as an active reflex as suggested from the preterm lamb data mentioned earlier.[69] Whatever the precise mechanism for both apnea types, the strict separation into apparently purely central or purely obstructive apneas cannot be maintained in the light of these data.

Hypoxic Ventilatory Depression (HVD)

It has been known for nearly 70 years that respiration in the fetus is diminished if oxygen supply via the placenta is reduced.[78] This is in contrast to adults, who show a sustained increase in ventilation in the presence of hypoxia. Although this is probably beneficial in fetal life, where respiratory movements are a waste of energy that the fetus cannot afford if oxygen supply via the placenta is reduced, this pattern is counterproductive ex utero. The switch-over from the fetal to the adult hypoxic ventilatory response only occurs some time after birth,[79] probably not before 35 weeks postconceptional age. This correlates well with the age at which AOP usually resolves.[80] When investigating the role of hypoxic ventilatory depression in AOP, however, infants with more apnea were found to have *less* ventilatory depression during a hypoxic challenge.[81] This issue requires further study.

Below what Pa_{O_2} level does HVD occur? This has not been studied systematically in infants. An early study suggested, however, that breathing already becomes irregular, and apnea starts to occur, if Pa_{O_2} falls below 75 to 97 mm Hg, levels close to or even above those associated with an increased risk of retinopathy of prematurity.[82] Weintraub and colleagues measured minute ventilation in 15 preterm infants (mean GA 29 weeks, age 20 days) at 21%, 25%, 30%, 35%, and 40% oxygen. With the increase in F_{IO_2}, breathing became more regular, apneas decreased, but minute ventilation did not change significantly; only breath-to-breath variability in expiratory times and tidal volume decreased. They concluded that oxygen facilitates the appearance of regular breathing independently of an increase in minute ventilation.[83] Interestingly, their study subjects had a relatively low Sp_{O_2} in room air (mean, 90.8%), which increased to 92.5% in 25% O_2. Even this relatively small increase in F_{IO_2} was associated with a decrease in apnea rate (>3 seconds) from 128 to 63 per hour ($P < 0.05$). Thus, although not necessarily resulting in a fall in minute ventilation, breathing irregularities and an increased propensity for short apneas may already develop at a Pa_{O_2} below 60 to 90 mm Hg. Whether this response to changes in Pa_{O_2} is mediated via the same mechanisms that elicit the HVD, however, is not yet known.

The molecular mechanisms responsible for HVD and the switch-over to the adult pattern are also unknown. One potential mechanism involves the creatine-phosphocreatine (Cr-PCR) system. In the absence of oxidative phosphorylation, provision of phosphate for generation of adenosine-triphosphate (ATP) relies predominantly on the PCR pool, before anaerobic glycolysis, with increased production of lactate and H^+, is activated.[84] This may also be relevant to the adaptation of ventilation during hypoxia. Investigations of the cytosolic levels of PCR during moderate hypoxia in adult rats by 31P nuclear magnetic resonance spectroscopy of the brain stem showed that the occurrence of HVD was preceded, by 30 seconds, by a significant decrease in PCR levels. This reached its minimum level 30 seconds after maximal respiratory depression and occurred without a significant change in ATP levels.[85] In the neonatal rat brain, total creatine kinase activity increases two to three times over the first month of life, reflecting a doubling of PCR content during this time span.[86] Thus, the neonatal brain is relatively deficient in creatine, and it is tempting to speculate that the much earlier onset of the HVD in this age group is related to a decreased availability of PCR in the neonatal brain stem. PCR is also important in muscle metabolism, where it serves as an energy buffer to guarantee provision of sufficient substrate for the phosphorylation of ADP to ATP.[87] In adults, creatine supplementation resulted in an increased exercise performance[88] and less muscular fatigue.[89] Wilken and coworkers recently showed that brain stem slices from pups of creatine-fed mice (2 g/kg/day) showed higher phosphocreatine contents and significantly less HVD (–14% versus –41%), than those from nonsupplemented control animals. This corresponded to nearly constant cerebral ATP levels in the former versus a 54% decrease in the latter animals after 30 minutes of anoxia.[90] Also, measurements of the maximal respiratory amplitudes in such pups during hypoxia showed an increase by 51%, compared to 22% in control animals.[91] Although the newborn apparently is creatine deficient, it

remains unclear whether creatine supplementation can ameliorate the characteristic HVD seen in this age group (see later).

Relevance of the CO_2 Apneic Threshold

Respiratory drive depends not only on O_2, but also on CO_2. A baseline concentration of CO_2 is essential for breathing to occur; conversely, if P_{CO_2} falls considerably below eupneic baseline, apnea occurs. The P_{CO_2} value at which this occurs is called the apnea-hypopnea threshold; it is approximately 3.5 mm Hg below eupneic P_{CO_2} in healthy adults.[92] It has been suggested that the closer this eupneic P_{CO_2} is to threshold P_{CO_2}, the more unstable breathing becomes, as minor behavioral changes in ventilation would be sufficient to propel the P_{CO_2} to below threshold, thereby inducing apnea.[92] Recently, Khan and associates measured the apneic P_{CO_2} threshold before and after an epoch of periodic breathing in term and preterm neonates. They found that the spontaneous pre-apneic threshold in both groups was only 1 to 1.3 mm Hg below eupneic values and speculated that this closeness between eupneic and apneic thresholds destabilizes respiration in neonates compared to older subjects, as minor oscillations in breathing may already lead to apnea.[93] Whether the logical clinical consequence of these findings, namely CO_2 inhalation as an apnea treatment, has any long-term effect on apnea rates remains to be seen.[93]

Therapeutic Implications

Based on the pathophysiology just discussed, interventions can be grouped according to three underlying mechanisms of action: those aimed at (1) reducing work of breathing, (2) increasing respiratory drive, and (3) improving diaphragmatic contractility. When considering the pros and cons of the interventions currently applied, the reader should keep in mind that the long-term benefit (or harm) of any intervention for AOP currently applied has never been proved, nor has the role of AOP in affecting long-term outcome ever been identified.[94]

Interventions Aimed at Reducing Work of Breathing

PRONE HEAD-ELEVATED POSITIONING

In the prone position, the chest wall is stabilized and thoracoabdominal asynchrony is reduced.[95] Several studies have demonstrated that the prone position reduces apnea rate in preterm infants, with some also reporting a decrease in desaturation rate.[95-98] An extension of the prone position is the head-elevated prone tilt position, which in a cross-over study on 12 neonates was associated with a 49% reduction in desaturations to less than 85% compared to the horizontal prone position.[99] Recently, however, two studies reinvestigated the issue, driven by the observation that infants appear more comfortable when only the chest rather than the entire body is being tilted. Whereas one found a slight (–13%) but statistically significant reduction in desaturation rate compared to the horizontal position,[100] the other did not find an advantage for either position (own unpublished data). Thus, the effect of head-up positioning on bradycardia and intermittent hypoxia may be less pronounced than previously thought. As it does not appear to have any deleterious effect, we continue to consider it a first-line intervention for infants with AOP. Infants, however, should be placed in supine position approximately 1 week prior to discharge to set an example for the sleep position that should be adopted at home (see primary prevention).

REMOVAL OF NASOGASTRIC TUBES

A nasogastric tube increases nasal resistance by 50%.[101] In line with these data, less apnea and a higher P_{O_2} were reported after removal of a feeding tube,[102] but this observation was based on only seven infants. Further study is required, which should also clarify whether an orogastric tube, or a nasal tube placed in the *smaller* of the two nares,[101] has a similar effect.

CONTINUOUS POSITIVE AIRWAY PRESSURE AND NASAL VENTILATION

CPAP has been shown to reduce extubation failure in preterm infants,[103] despite the fact that most systems currently available do *not* reduce work of breathing.[104] It has been suggested that CPAP reduces only the frequency of obstructive, not central apneas,[105] but it may also act via a stabilization of lung volume and thereby oxygenation (see earlier). CPAP can be applied via a nasopharyngel tube or binasal prongs. A Cochrane meta-analysis showed that reintubation rates were 40% lower with the binasal prongs (relative risk [RR] 0.59 [0.41;0.85]; number needed to treat [NNT] 5),[106] which is why this mode should be preferred when applying CPAP. An extension of CPAP treatment is nasal positive pressure ventilation (N-IPPV), which compared to CPAP has an extremely high effectiveness in preventing extubation failure (RR 0.21 [0.10;0.45]; NNT 3).[107] Typically, an inspiratory pressure of 15 to 20 cm H_2O, applied at a rate of 10 to 20 per minute, is combined with an expiratory pressure level of 5 to 6 cm H_2O.[108] There is theoretical concern that this might result in gastric distention because the peak pressure applied to the larynx exceeds the opening pressure of the upper esophageal sphincter. In clinical practice, however, gastric distention is not a relevant side effect.[107]

Interventions Aimed at Increasing Respiratory Drive

OXYGEN ADMINISTRATION

That oxygen stabilizes neonatal respiration was first observed in 1923[37]; its uncritical use following this discovery led to the first epidemic of retrolental fibroplasias, now known as retinopathy of prematurity, 20 years later. Nonetheless, several cross-over trials in infants with and without BPD have shown that the application of low-flow oxygen results in a reduced rate of intermittent hypoxia and both isolated and periodic apnea,[62,83,109,110] but application of this therapy has to be weighed against side effects potentially resulting from oxygen toxicity.[111] These issues must be addressed in a large, randomized controlled trial (RCT) before recommending this therapy for routine use in preterm infants.

RED BLOOD CELL TRANSFUSIONS (RBC)

An increase in respiratory drive resulting from an increased tissue oxygenation is also one of the proposed mechanisms for red cell transfusion to potentially ameliorate AOP, and

anemia has indeed been implicated in the pathophysiology of AOP and also of cyanotic episodes in infants.[112,113] It would seem logical to hypothesize that blood transfusion is an effective treatment modality in infants with AOP who are anemic. Data on the effect of blood transfusion on the frequency of these episodes, however, are conflicting. Some authors found less apnea and/or bradycardia following transfusion,[114-118] others did not.[119-121] Two cross-over studies including data on SpO_2 also found no improvement in intermittent hypoxia and bradycardia following transfusion.[122,123] Recently, however, Bell and colleagues published the results of an RCT comparing a liberal with a more restrictive transfusion policy in 100 very low birth weight (VLBW) infants.[124] Hematocrit was kept at >45% versus >35% if intubated; >38% versus >28% if on CPAP, and >30% versus >22% if no respiratory support was required. Mean rate of apneas requiring stimulation was 0.23/hour in the liberal versus 0.46/hour in the restricted transfusion group. A potential explanation for this apparent effect of red cell transfusion, however, could be that significantly more infants in the restrictive transfusion group happened to have brain lesions and were more likely to develop AOP. Nonetheless, a subanalysis only in the restrictive group also showed a 55% reduction in apnea rate following transfusion ($P < 0.01$). Based on these conflicting findings, no clear recommendation on the role of RBC in anemic VLBW infants with AOP can be given.

METHYLXANTHINES

Methylxanthines increase chemoreceptor sensitivity as well as respiratory drive and can also improve diaphragmatic contractility. Of the substances available, caffeine has a wider therapeutic range, fewer side effects, and better effect on bradycardias than theophylline.[125,126] Methylxanthines, however, are adenosine antagonists. Because adenosine increases tolerance to hypoxia, they may also be harmful in the VLBW infants who need them most (i.e., those with recurrent hypoxia resulting from severe apnea).[1] In addition, the only RCT investigating the effect of caffeine on recurrent hypoxia did not show an effect.[127] Also, a follow-up study reinvestigating 130 of 154 consecutive VLBW survivors at 14 years of age found that 13% of 69 infants exposed to theophylline had cerebral palsy versus 1.6% of those not exposed; this association remained after controlling for confounders.[9] The concerns surrounding the use of methylxanthines could only be addressed by performing an RCT, and first results from such a trial, enrolling more than 2000 infants, were recently reported.[128] Caffeine or placebo was started during the first 10 days of life in infants of 500 to 1250 g birth weight and was given at a dose of 5 to 10 mg/kg caffeine citrate until no longer needed for AOP treatment. Mechanical ventilation, CPAP, and oxygen could all be discontinued approximately 1 week earlier in infants treated with caffeine. Somewhat unexpectedly, and not a primary end point, was the finding of a 40% lower risk of BPD (36% versus 47%; odds ratio [OR] 0.6; 95% CI 0.5;0.8) and a 30% lower risk of developing a symptomatic patent ductus arteriosus (OR 0.7; [0.5;0.8]) in the caffeine group.[128] Results from the 18-month follow-up have been published in abstract form. They show a reduced rate of cerebral palsy and less cognitive delay in infants in the caffeine group.[129]

DOXAPRAM

Doxapram stimulates peripheral chemoreceptors at low, and central chemoreceptors at high, doses.[130-132] It shows a dose-response curve with a 50% reduction in apnea rate occurring in 47%, 65%, 82%, and 89% of infants at a dose of 0.5, 1.5, 2.0, and 2.5 mg/kg/hour, respectively. Most studies used a continuous intravenous infusion, although some suggest that the intravenous solution may also be given orally at twice the dose[133-135] (enteral absorption is approximately 50%).[136] Short-term side effects become quite common at doses above 1.5 mg/kg/hour and include irritability, myoclonus, elevated blood pressure, and gastric residuals.[131] Of most concern, however, is the fact that nothing is known about the long-term neurologic outcome after doxapram treatment. This is particularly unsatisfying given that doxapram is a centrally acting drug. A study on factors associated with poor motor development in extremely low birthweight infants used a case-control design to match variables such as GA, sex, intraventricular hemorrhage, and socioeconomic status for 40 patients with a mental development index (MDI) less than 70 and an equal number of controls. The only difference found was that subjects had received a mean cumulative doxapram dose of 2233 mg, compared to 615 mg in controls ($P < 0.01$).[10] Although such a retrospective analysis cannot distinguish whether this reflects the severity of apnea for which doxapram had been given or a direct drug effect, it clearly raises concern about long-term side effects of this drug. Without such data, doxapram cannot be recommended to treat AOP.

CREATINE

As mentioned earlier, creatine is likely involved in HVD. An RCT on creatine supplementation (200 mg/kg/day) or placebo in 38 infants, however, showed no effect on the combined rate of bradycardia and desaturation, but it remains unclear whether the dose, duration, and timing of treatment were sufficient for an effect to be achieved.[137]

Interventions Aimed at Improving Diaphragmatic Strength

If muscle fatigue is involved in AOP, then improvements in diaphragmatic strength should be beneficial. This consideration, however, remains speculative. Our own results on creatine supplementation, which should improve muscular exercise performance (see earlier), were disappointing. Another study enriched total parenteral nutrition (TPN) solutions with branched-chain amino acids, which improve diaphragmatic function in vitro, and found a decrease in the average number of episodes of apnea from 58 during standard TPN to 11 with the enriched solution infusion during matched 12-hour periods ($P < 0.01$) in an unblinded cross-over study design.[138] This somewhat original approach to the treatment of AOP should be investigated further.

Others

OSCILLATING WATERBED

The theory behind this intervention is that entrainment can be achieved between an infant's own breathing rhythm and an external rhythm generator (e.g., an inflatable mattress

connected to a respirator). A meta-analysis of 3 RCTs testing this intervention, involving a total of 165 infants, showed no effect on apnea or bradycardia (RR 1.06; 95% CI 0.82;1.36).[139] This may be explained by the observation that synchronization with an external rhythm generator is significantly better beyond 35 weeks GA than before that,[140] but at that age AOP is no longer a major issue. As a result, this intervention has largely been abandoned in recent years.

OLFACTORY STIMULATION

A French group made the chance observation that odors modulated an infant's respiratory pattern, particularly during active sleep, when apnea is more common.[141] This led them to study the effect of exposure to vanillin, a stimulus known selectively to affect the olfactory nerve, on apnea and bradycardia. In a group of 14 infants born at 24 to 28 weeks GA (mean age at study 22 days) and unresponsive to both caffeine and doxapram, they found that exposure to 15 drops of saturated vanillin solution applied on the periphery of an infant's pillow led to a 45% reduction in the frequency of apnea associated with bradycardia to less than 70 per minute.[142] They hypothesized that the presence of a pleasant odor helped the infants better to regulate their psychological and physiologic states. Although many questions remain, this is another approach that is worth more investigation.

Summary of Data on Apnea of Prematurity

Despite some evidence of brain stem immaturity in infants with AOP,[143] there is nothing to suggest that these infants have gross deficits in respiratory control.[144] As suggested by the data summarized earlier, it appears that the early (and frequent) occurrence of hypoxemia during apnea in preterm infants is related to their low expiratory lung volume, which falls even further during apnea, while the accompanying bradycardia results from this combination of apnea and hypoxemia. Feeding is an important trigger for AOP. While hypoxemia *during* feeding is most likely related to an immature coordination between sucking, swallowing, and breathing, that *after* feeding may be caused by diaphragmatic fatigue; GER does not appear to play a major role. The time course of AOP (i.e., its increased occurrence during the second and third rather than the first week of life, together with data from physiologic studies), also suggests a role for diaphragmatic fatigue in AOP. Additional factors include upper airway obstruction and the unique response of the preterm to hypoxia. Treatment may follow an incremental treatment plan, starting with infant care procedures such as prone positioning, followed by methylxanthines and CPAP/N-IPPV (Table 30-1). What is urgently needed are data on how much intermittent hypoxia/bradycardia can be tolerated in an individual infant without putting her/him at risk, and whether pharmacologic treatments such as caffeine or doxapram are safe, although this has now been demonstrated for caffeine.[129]

Table 30-1
Incremental Treatment Plan for Apnea of Prematurity (AOP)

Step 1: Changes in neonatal care procedures
15-degree head tilt—prone position
Gavage feeding via orogastric tube
SpO_2 at upper limit of range used in the unit
Step 2: Caffeine
Step 3: Nasal continuous positive airway pressure (CPAP)
Step 4: Nasal intermittent positive pressure ventilation (N-IPPV)
Step 5: Intubation and mechanical ventilation*

*Doxapram may be considered as an alternative to intubation in infants who have been found to exhibit recurrent hypoxia and bradycardia during mechanical ventilation, e.g., those with chronic lung disease.

SUDDEN INFANT DEATH SYNDOME (SIDS)

History

Sudden and unexpected infant deaths have been recognized since biblical times (I Kings 3:19: "And this woman's child died in the night; because she overlaid it"). As in the Bible, these deaths were believed to be caused by the parents accidentally or intentionally overlaying their children. For example, a law issued in medieval Germany in 1291 forbade parents to take children younger than 3 years of age into their bed[145]; a very similar law still existed in Prussia in 1791.[146] In 1834, Fearn was the first who argued against overlaying as the cause of death. He used the term "sudden and unexplained death" in his description of two infants "who, without having been previously indisposed, were found dead in bed" and in whom he could not discover any "lesions . . . sufficient to produce death."[147]

One of the first scientific attempts to explain sudden and unexpected infant deaths was made by Paltauf, an Austrian pathologist, in 1889. He observed an enlarged thymus, a narrowing of the aorta and an over-development of the lymphatic system in infants who had died suddenly and unexpectedly and introduced the concept of "status thymicolymphaticus."[148] Despite good evidence against it, this concept persisted into the first half of the 20th century, leading to the prophylactic irradiation of the thymus, with subsequent malignancy of the thyroid, in the 1920s. With the decline of this theory in the 1930s, voices accusing the parents of having killed or neglected their babies grew again, and it was only in the 1950s and 1960s that doctors became aware that these deaths might form a distinct entity of unexplained natural deaths. From today's perspective, the concept of "status thymico-lymphaticus" may be regarded as one of the first "modern" attempts to explain these deaths, and its uncritical adoption, resulting in potentially harmful preventive measures, bears similarities to the apnea theory developed some 80 years later.[149]

In 1970, Bergman and colleagues[150] coined the term *sudden infant death syndrome* (SIDS), which they defined as the "sudden death of an infant or young child, which is unexpected by history, and in which a thorough postmortem examination fails to demonstrate an adequate cause for death." This definition clearly has its weaknesses, which predominantly relate to the fact that it defines a syndrome by exclusion.[151] Nevertheless, it helped with transmitting to the public that the vast majority of sudden unexpected deaths in infants have a natural cause.

Terminology

The term SIDS was recently redefined by an expert panel as "the sudden unexpected death of an infant less than 1 year

of age, with onset of the fatal episode apparently occurring during sleep, that remains unexplained after a thorough investigation, including performance of a complete autopsy and review of the circumstances of death and the clinical history." To facilitate research, this definition was stratified into cases with the "classic" features of SIDS present and completely documented (so-called Category IA SIDS), those with these features present, but incompletely documented (IB), and those meeting Category I criteria except for any of the following: age less than 3 weeks or more than 270 days; similar deaths in siblings; close relatives or infants in the custody of the same caregiver; perinatal conditions such as a history of premature birth; suspected mechanical suffocation; or marked inflammatory changes not sufficient to be assigned a cause of death (Category II SIDS).[152] According to this definition, all cases not meeting criteria for category I or II SIDS, including those for which an autopsy has not been performed, are now called "unclassified sudden infant death."[152] The practicality of this new definition, and its subclasses, remains to be seen.

An apparent life-threatening event has been defined as "an episode that is frightening to the observer and that is characterized by some combination of apnea (central or occasionally obstructive), color change (usually cyanotic or pallid but occasionally erythematous or plethoric), marked change in muscle tone (usually marked limpness), choking, or gagging."[153] In clinical practice, the acronym "ALTE" has been restricted to events that fulfill the above criteria and involve vigorous stimulation or resuscitation. This somewhat narrower definition will also be used in this chapter.

There is no consistent definition for apneas. In this chapter, the term "apneic pause" will be used to describe spontaneous interruptions in breathing movements and nasal airflow, lasting for 4 to 20 seconds, and "prolonged apneic pause" for those apneic pauses that last for more than 20 seconds. The term "periodic apnea" will describe a pattern during which three or more apneic pauses, each followed by less than 20 breaths, occur in sequence. An "obstructive apnea" is characterized as an episode of continuous breathing movements, but absent airflow, presumably caused by intermittent upper airway closure, and a "mixed apnea" is a combination of an obstructive event and an apneic pause of any length.

Epidemiology

INCIDENCE

In contrast to previous centuries, when sudden unexpected deaths accounted for only a small fraction of total infant mortality, SIDS is now the leading cause of post-perinatal mortality in developed countries, accounting for approximately 2600 deaths per year in the United States alone.[154] In the early 1970s, an alarming trend toward an increase in SIDS rates occurred, which at that time was related to the recent introduction of SIDS as a cause of death (i.e., to changes in diagnostic fashion). Only in the late 1980s was the discovery made that SIDS rates had begun to increase shortly after general advice had been given that babies should be put to sleep in the prone position.[155,156] SIDS rates then decreased again after this advice was reversed[157] (Fig. 30-4; Table 30-2). Although the initial increase and subsequent decrease reflected a true change in incidence, as they were paralleled by similar changes in postneonatal mortality, there is now a trend to classify many deaths previously diagnosed as SIDS into other categories such as (positional) asphyxia. In fact, a

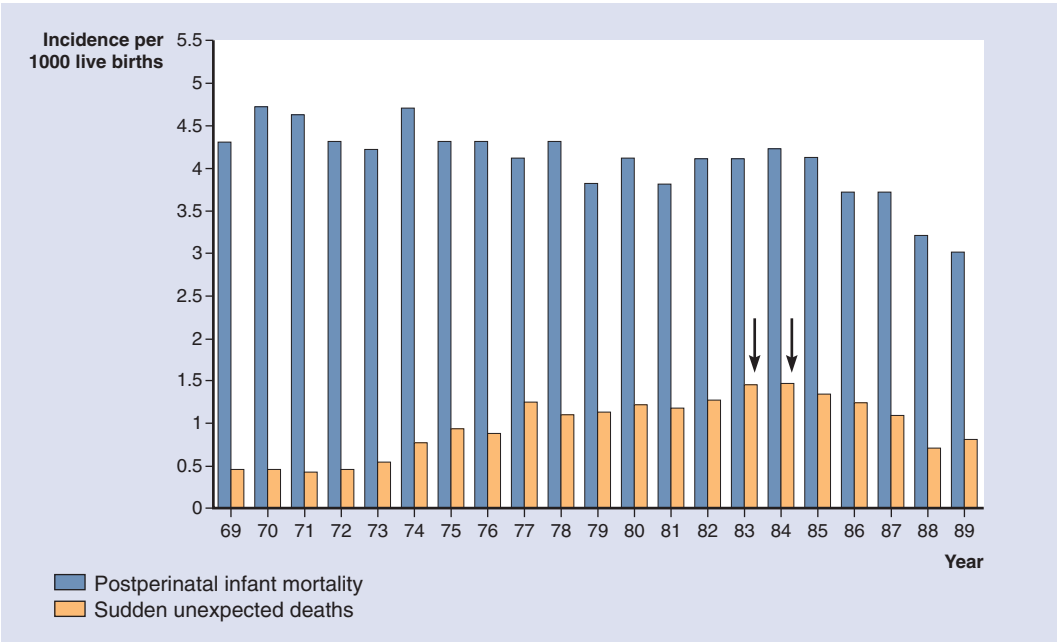

Figure 30-4 Changing trends in post-perinatal infant mortality (*blue bars*) and sudden unexpected deaths (*yellow bars*) in The Netherlands, 1969 to 1989. *Arrows* indicate years when sudden death incidence was not corrected for autopsy data—the given incidences during these 2 years are, therefore, estimated as being 10% too high. The prone sleeping position was publicly recommended in 1972. A campaign aimed at avoiding the prone sleeping position was started in October, 1987. (Redrawn with permission from Engelberts AC, de Jonge GA, Kostense PJ: An analysis of trends in the incidence of sudden infant death in The Netherlands 1969-89. J Paediatr Child Health 27:329-333, 1991.)

Table 30-2
Sudden Infant Death Syndrome (SIDS) Incidence in Different Countries, 1987 Versus 1997*

Country	Rate (deaths/1000 live births) 1987	Rate 1997
Australia	2.18	0.60
Austria	1.63	0.58
Canada	1.06	0.47
England/Wales	2.40	0.60
Germany	1.64	0.88
Hong Kong	0.30	0.16*
Netherlands	0.91	0.17
New Zealand	4.30	1.50
Sweden	0.90	0.41†
United States	1.37	0.77

recent analysis of U.S. mortality data showed that concurrent increases in postneonatal mortality rates for unknown and unspecified causes and suffocation accounted for 90% of the decrease in SIDS rates in 1999 to 2001.[158] Agreement on a more standardized approach to certifying sudden infant death may help to avoid this worrying development, as was attempted with the introduction of the new SIDS definition (see earlier).

In addition to differences between countries, SIDS rates also differ between ethnic groups within a country.[159-161] These differences may be related to both socioeconomic and genetic factors.[162,163] For example, Mitchell and coworkers, in a nationwide study in New Zealand, found a decrease in OR from 3.8 to 1.4, the latter being no longer significant, when they controlled their results on SIDS rates in Maori versus non-Maori infants for socioeconomic confounders.[161] In recent years, differences in the efficiency with which the Reduce-The-Risk campaigns reached the different groups also contributed to this ethnic variation in SIDS rates.[164,165]

AGE AND TIME OF DEATH

One of the most striking epidemiological features in SIDS is its characteristic age distribution (Fig. 30-5). There is a relative sparing of the neonatal period, then a sharp increase in the second month of life, a peak at around 3 months of age, and a gradual decrease thereafter. Hence, 75% of deaths occur between 2 and 4 months of age, and 95% before 9 months of age.[154,166] This age distribution is related to gestational, not postnatal age: in VLBW infants (≤1500 g), the peak incidence occurs about 6 weeks later.[166] Early beliefs that SIDS is extremely rare in the neonatal period cannot be maintained: 6% to 7% of SIDS victims are younger than 1 month of age,[154,166] and 11% of neonatal deaths in term infants are due to SIDS.[167]

Throughout the year there used to be a clear preponderance of the cold season. In the northern hemisphere, up to 95% of deaths occurred between October and April.[168] This seasonal distribution has been related to respiratory tract infections, which show a similar distribution and are frequently reported to precede death.[169] Infections may also be the explanation for observations of a clustering of deaths,

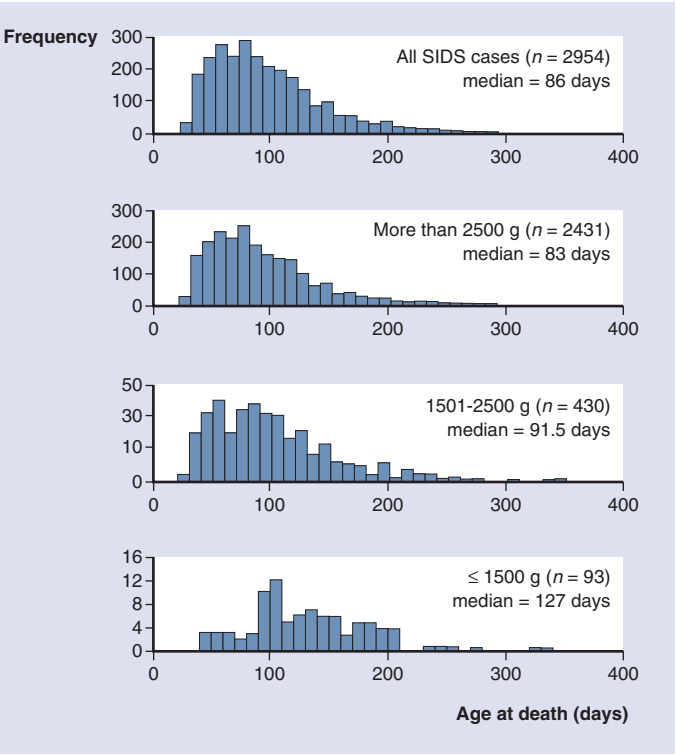

Figure 30-5 Histograms for age at death for three birth weight groups of SIDS cases in California from 1978-1982. (Reprinted with permission from Grether JK, Schulman J: Sudden infant death syndrome and birth weight. J Pediatr 114:561-567, 1989.)

with multiple cases on one day and long "silent" periods on others.[170] This clustering of deaths may coincide with the outbreak of viral or pertussis epidemics in the same region.[171,172] Indirect evidence for the role of respiratory tract infections in SIDS has been given by several reports that infants immunized against pertussis are less likely to die of SIDS.[173-175] The winter peak, however, has almost disappeared following the campaigns to place infants to sleep on their back.[154] In a recent study from the United Kingdom, only 27% of deaths occurred between December and February.[176] The reason(s) for this remains unclear.

There appears to be a tendency for SIDS to occur more frequently on weekends and public holidays.[154,159,177,178] This has been related to the fact that the infant's daily routine and environment are more likely to be disturbed or changed on these days.[177,178] In a nationwide study from New Zealand, however, visits to and by friends or relatives, which would certainly disturb the infant's daily routine, appeared to have a *protective* effect on SIDS.[179] Hence, the mechanisms responsible for the increased occurrence of SIDS on weekends and public holidays remain poorly understood.

SIDS apparently occurs predominantly during the night, a time when both parents and infants are most likely to be asleep. For example, in a study from Hannover, Germany, 61% of 270 SIDS victims were found in the morning (6 AM to noon).[180] This does not prove, however, that SIDS occurs during sleep.

RISK FACTORS

A large number of factors associated with an increased risk of SIDS have been identified from epidemiologic

Table 30-3
Risk Factors for Sudden Infant Death Syndrome

Maternal Factors	Infantile Factors
Young age	Male gender
Multiparity	Low birth weight
Smoking during pregnancy	Low birth length
Maternal drug abuse	Premature birth
Previous fetal deaths	Blood type B
Anemia during pregnancy	Low Apgar scores
Placenta previa	Low hematocrit at 48 hours
Premature rupture of membranes	Not using a pacifier
Low social class	Prone or side sleeping position
Low family income	Bed-sharing
Short inter-pregnancy interval	Overheating
Unmarried mother	Not breastfed
Partner unemployed	Siblings in family
Late attendance of antenatal clinic	Sleeping in own room
Postnatal depression	Previous SIDS in family
Attendance to psychiatrist	Previous cyanotic episode
Urinary tract infection in pregnancy	

SIDS, sudden infant death syndrome.
From references 163, 181-186.

studies[163,181-186] (Table 30-3). Many of these risk factors underline the importance of social factors in the pathogenesis of SIDS (although the mechanisms through which these social factors affect the risk of SIDS are poorly understood); others, like maternal smoking or anemia during pregnancy, suggest that there must already be a disturbance during intrauterine life that puts an infant at risk. In the following, we will concentrate on risk factors that are potentially amenable to modification, namely maternal smoking, not breast feeding, not using a pacifier, overheating, bed sharing, and a nonsupine sleeping position.

Maternal smoking has long been recognized as a risk factor for SIDS. The increase in SIDS risk is dose dependent.[187] With the decline in other SIDS risk factors in several countries, smoking is now considered the single most important preventable risk factor for SIDS.[181,187] There is a further increase in SIDS risk if both parents smoke[188] or if the mother not only smokes but is also anemic.[189] Smoking may be related to SIDS via a number of mechanisms, including fetal hypoxia,[189] an inhibition of airway growth and development,[190] a decreased ability to arouse to noxious stimuli,[191] and an increased susceptibility to respiratory tract infections.[192]

Not breast feeding was only recently confirmed as a risk factor for SIDS.[193,194] The beneficial effect of breast feeding may be related to its protective effect on the infants' susceptibility to respiratory tract infections. In some studies, however, the protective effect was lost after controlling for socioeconomic factors.[195]

Not using a pacifier was reported as a risk factor for SIDS in several studies and was confirmed in a recent meta-analysis, where the pooled OR for pacifier use during the last sleep was 0.39 (0.31 to 0.50).[196] In an even more recent population-based study from California, the adjusted OR for SIDS associated with using a pacifier was 0.08 (0.03 to 0.21).[197] Although pacifiers become dislodged from the mouth of more than 80% of infants within the first hour of sleep, they have been shown to reduce the arousal threshold (i.e., facilitate arousal from sleep).[198] Reluctance to promote pacifier use results from the belief that it interferes with breastfeeding, although data on this issue are sparse. One randomized controlled trial found infants who started using a pacifier at 2 to 5 days of age were slightly less likely to be exclusively breast fed at 1 month compared to non-users.[199] After 1 month, no detrimental effect has been shown.[196] Taken together, current evidence suggests that it is no longer justified to *discourage* parents from using a pacifier, but data are not yet sufficient to *recommend* pacifier use.[200]

Evidence that overheating (arising from overwrapping and/or high room temperatures) may be a risk factor for SIDS was initially largely circumstantial.[201,202] Several case-control studies found that the level of bedding and clothing was significantly higher among SIDS cases.[203,204] Heavy wrapping may become particularly important if occurring in combination with other risk factors for SIDS (e.g., the prone sleeping position[205] or a respiratory tract infection).[206] Gilbert and colleagues found an OR for SIDS of 51.6 for the combined presence of heavy wrapping (more than 10 togs) and a viral infection.[206] There is also physiologic evidence supporting the concept that hyperthermia may be a risk factor for SIDS: it has deleterious effects on respiratory control[207,208] and may also impair lung mechanics.[201]

Bed-sharing as a risk factor for SIDS was first observed in 1972,[209] but has not received much attention until it was confirmed by Mitchell and coworkers,[181] who found that 24% of the SIDS victims but only 10.5% of the controls had shared the bed with their parents. These data apparently reconfirm the concept already mentioned in the Bible that accidental suffocation through overlaying may be a mechanism for SIDS, but they can also be interpreted as supporting the hypothesis that hyperthermia, resulting from the infant sleeping close to his parents, may play a role as a trigger for SIDS (see earlier). Although it is now widely accepted that bed-sharing is unsafe for infants of smoking mothers, there is controversy for infants of nonsmoking mothers because bed-sharing purportedly promotes breast feeding.[210] The magnitude of its effect as a risk factor for SIDS, however, has frequently been underestimated because bed-sharing is often compared with not bed-sharing as reference. The latter includes sleeping in a separate room, a previously described risk factor for SIDS.[211] In a recent study from Scotland, sharing a bed when less than 11 weeks of age was associated with a 10-fold increase in SIDS risk (OR 10.2; 3.0 to 34.8) when compared to room-sharing, which remained statistically significant if analysis was restricted to infants of nonsmoking mothers (OR 8.0; 1.2 to 53).[212] Thus, bed-sharing should not be promoted regardless of smoking status, at least not in the first 3 months of life.

The prone sleeping position was first reported as a risk factor for SIDS in 1944,[213] but was not widely noticed until 1989, when a Dutch group, based on results from their own retrospective study, started a campaign in their country advising parents to avoid the prone sleeping position.[156] This is particularly tragic because a recent cumulative meta-analysis of 40 comparative studies on infant sleep position found that the association between death and the prone compared to the supine position had become statistically significant by 1970, 20 years before the Dutch group started their campaign.[214] Uptake of the advice to place infants on their backs

was hampered by physiologic studies suggesting that the prone position may be advantageous, although these data were not from healthy infants, but from hospitalized preterm neonates or infants with respiratory tract infections.[96,97,215-218] Mechanisms through which the prone position can become dangerous to some infants include a higher risk to develop hypercapnia (due to rebreathing of expired air,[219] hypoxemia,[220] upper airway closure,[221] or an arousal deficit[222] while sleeping in the prone position.

Whatever the pathophysiological mechanism, propagation of the "back-to-sleep" message has been one of the most successful public health campaigns ever launched, resulting in a 50% to 70% decline in SIDS rates around the world (see Table 30-2). With an increasing number of infants sleeping non-prone, one could better differentiate between supine and side sleeping. This showed a two- to sixfold increased risk of SIDS in the side position.[223-225] The most likely explanation for this is that the side position is inherently unstable,[225] and that the risk of SIDS is particularly high for infants not accustomed to the prone sleeping position.[226,227]

Pathology

INTRATHORACIC PETECHIAL HEMORRHAGES

As implied by its definition, there is no morphologic finding in SIDS that sufficiently explains the occurrence of death. There are, however, a number of characteristic findings in these infants, some of which are so consistent that they appear to support the concept that SIDS may indeed form a specific disease entity. The most consistent among these findings, first described by Fearn in 1834,[147] are intrathoracic serosal petechiae, which are found on the surfaces of lungs, pericardium, and intrathoracic portion of the thymus. In a study involving 1144 sudden unexpected deaths, serosal petechiae were found in 99% of infants who did not have any morphologic finding that could possibly explain death (true SIDS).[228] The distribution of these hemorrhages has led some researchers to suggest that large intrathoracic pressure swings are involved in their production.[229] These large pressure swings may result from breathing efforts against a closed (upper) airway.[230,231] Petechial hemorrhages were also observed following repetitive airway obstruction with intermittent recovery.[232,233] Guntheroth, however, found no petechiae in rats if these were killed by unremitting airway occlusion (i.e., total occlusion until death). Only if death was induced by *intermittent* tracheal occlusions, or by the administration of 100% N_2, did petechiae occur.[234] He later reported that lung volume in rats killed by unremitting airway occlusion was 24% smaller than that of rats killed with nitrogen asphyxiation, suggesting that a fully expanded lung might be required to produce petechial hemorrhages.[235]

Risse and Weiler confirmed these findings from animal experiments in observing that infants who had been intentionally suffocated and had thus died very rapidly exhibited much less petechiae than those who had died from prolonged asphyxia or SIDS, and concluded from their findings that an episode of prolonged asphyxia is required to produce these bleedings.[236] Others supported these findings in reporting that abrupt death due to sudden airway occlusion, unresolving until death, did not produce pulmonary hemorrhages, whereas slower forms of hypoxic death did.[237,238]

An alternative explanation why petechiae do not always occur in lethal airway obstruction had already been offered in 1897. Brouardel, a French pathologist, occluded the nose and mouth of dogs in whom a window had been placed in the parietal wall of the thorax and saw that petechiae appeared only during the second stage of asphyxia (i.e., with the onset of gasping, but not initially, when the animals made vigorous inspiratory efforts against the closed upper airway).[239] These observations were confirmed by Winn, who found that young rats exposed to an oxygen-free gas developed petechiae (and frothy pink fluid in their nares, see later) only if there had been gasping, regardless of whether they subsequently recovered or died.[240] It is thus possible that the petechiae so frequently observed in SIDS are indicative of a period of prolonged asphyxia (during which gasping occurred) rather than of a specific disease mechanism (e.g., upper airway obstruction) that has led to death.

BLOOD-STAINED FROTHY SECRETIONS IN THE AIRWAYS AND LUNGS

Another characteristic finding in SIDS is the occurrence of froth around the nose and mouth (occasionally blood-stained), which is found in approximately 60% of SIDS victims.[241] This latter phenomenon again may be caused by a combination of pulmonary edema and high transpulmonary pressures (e.g., due to vigorous breathing movements) immediately prior to death.[240,242] *Frank* nasal or oral bleeding, however, was originally *not* considered a typical feature of SIDS and was instead related to intentional suffocation. This view was supported by Meadow[243] who reported that 39% of infants from parents who had been legally convicted of causing their death had frank blood in the mouth, nose, or on their face. In a recent analysis of data from the nationwide New Zealand study, however, nasal hemorrhage was reported in 15% of 385 cases whose parents were interviewed.[244] It was associated with younger infant age, bed-sharing and non-prone sleeping position. According to these and other recent data, nasal hemorrhage is more common in SIDS than previously thought and is not necessarily indicative of smothering.[244,245]

INFECTION

The majority of SIDS victims (56% to 79%) show histologic evidence of an upper respiratory tract infection,[246,247] and infectious agents, mostly viruses, have been isolated in 40% to 80% of SIDS.[171,248,249] Similarly, grossly increased lung immunoglobulin concentrations have been found in SIDS victims.[250] The histologic changes caused by these agents are apparently not severe enough to explain death as being directly caused by respiratory infection, but the latter may function as a trigger for SIDS. This is still an area of ongoing research, particularly given the recent finding of impaired immunologic function in some SIDS infants (see later).

HYPOXIC TISSUE MARKERS

Following the concept that SIDS may be related to the repeated occurence of apneic pauses (see later), a search for morphologic changes indicative of chronic tissue hypoxia began. As a result, a number of so-called hypoxic tissue markers was found. These include, among others, the retention of periadrenal brown fat, gliosis of the brain stem, hyperplasia of pulmonary neuroendocrine cells, and an increased

wall thickness of both pulmonary arteries and airways.[251-254] Although there has been some debate about the specificity of these hypoxic tissue markers for SIDS,[252] the fact that they are present in SIDS suggests that these deaths may not be a sudden event without antecedent illness. This is also supported by the observation of elevated hypoxanthine levels in the vitreous humor[255] or of upregulated vascular endothelial growth factor (VEGF) expression in SIDS,[256] indicating that death must have been preceded by an episode of prolonged (4 to 5 hours) tissue hypoxia.

ABNORMALITIES IN BRAIN STEM SEROTONINERGIC SYSTEM

Serotonin is a neurotransmitter involved in regulating various processes potentially related to SIDS (e.g., sleep and arousal, control of breathing, airway reflexes, and autonomic function).[257] Endogenously released serotonin is also required for gasping.[258] Comparative studies on the binding properties of neurotransmitter receptors in SIDS infants found the most marked differences to controls in serotonin receptors located in the arcuate nucleus and caudal raphe.[257] SIDS infants also have different serotonin transporter genotypes compared to controls.[259,260] Finally, there is evidence that serotonin binding in the arcuate nucleus is influenced by toxic exposures to nicotine and alcohol, substances associated with an increased risk of SIDS.[257] This suggests that a disturbance in serotonin metabolism may not only be genetically determined, but may also be influenced by the environment in a way compatible with the epidemiology of SIDS.

GENETIC STUDIES IN SIDS

For many years, it has been known that some infants who die suddenly and unexpectedly do so because they have an inherited disease such as the A984G mutation in the medium-chain acyl-CoA dehydrogenase (*MCAD*) gene.[261] More recently, mutations in genes encoding cardiac ion channels have been identified (see later). These well-defined diseases, however, contribute only a few percent to all cases of sudden infant death (and, by definition, prohibit defining SIDS as the cause of death). More relevant to SIDS are recent data on gene polymorphisms that may predispose infants to SIDS under certain circumstances, such as those found in the serotonin transporter gene (see earlier). Specific polymorphisms in the gene coding for interleukin-10 have also been found in SIDS (and also in infectious deaths).[262] More recently, mutations in genes pertinent to the embryologic origin of the autonomic nervous system were found in 14 of 92 SIDS cases investigated; only 1 mutation was identified in 2 of 92 controls.[263] This exciting new field of research has just begun to evolve. Future genomic studies will enhance our understanding of the polygenic risk factors associated with SIDS, but have to be carefully related to phenotype (i.e., require particularly careful history taking and postmortem examination).

SUMMARY OF PATHOLOGIC FINDINGS IN SIDS

The following conclusions can be drawn from the studies summarized above: (1) respiratory tract infections appear to play an important role as a trigger for SIDS; (2) most SIDS victims have either suffered tissue hypoxia for some time prior to death, or have an increased reactivity of their pulmonary airways and vessels, or both; (3) the final pathway leading to death apparently involves large intrapulmonary pressure swings, but whether these are caused by upper airway obstruction, lower airway occlusion, or asphyxic gasping, is unknown; and (4) recent data on gene polymorphisms or mutations in SIDS are intriguing but incompletely understood.

Pathophysiology

Investigations into the pathophysiology of SIDS have been hampered by the fact that the occurrence of death is unpredictable. They have, therefore, predominantly been confined to prospective studies in large numbers of infants, aiming to obtain data in future SIDS victims, and to studies on infants who are known to be at increased risk of SIDS, particularly those who survived a near-death event (i.e., an ALTE). Although both approaches have provided invaluable data about the development of respiratory control in infancy, they are unlikely to ever provide conclusive evidence about the pathogenesis of SIDS. This would be possible if data were collected only *during* deaths or near-death events. With the introduction of memory monitors, which record physiologic signals during alarms on home monitors, such data are now available.

DATA RECORDED IN FUTURE SIDS VICTIMS

The first large population-based study that prospectively collected physiologic data in future SIDS victims was carried out by Southall and colleagues, who performed 24-hour tape recordings of ECG and breathing movements on 9856 infants, 29 of whom subsequently died of SIDS.[264] None of the recordings in the SIDS infants showed a prolonged apneic pause (≥20 seconds), cardiac arrhythmia, pre-excitation, or a prolonged QT-interval. Compared to surviving matched controls, the SIDS cases did not show significantly increased numbers of short apneic pauses or quantities of periodic breathing.[265] In fact, SIDS victims studied after 1 month of age showed significantly *fewer* apneic pauses (≥4 seconds) than control infants.[266] However, the infants who died exhibited, as a group, higher mean heart rates[267] and higher levels of sinus tachycardia than the controls.[268] Since then, this unique data set has been used for more refined analyses—only to confirm that recordings of breathing movements and ECG cannot serve as predictors for SIDS.[269]

Studies of the autonomic cardiovascular control in the SIDS victims produced mixed results. Analysis of overall heart rate variability by power-spectral techniques showed no differences between SIDS cases and controls.[270] More detailed analysis, however, revealed that the extent of respiratory sinus arrhythmia was lower in the SIDS victims across all sleep-waking states,[271] and that heart rate variability was diminished in the SIDS cases during waking and rapid eye movement (REM) sleep, but not during quiet sleep.[272] A dynamic analysis of beat-to-beat heart rate variability showed a reduced dispersion of interbeat intervals across all sleep-waking states.[273] These findings indicate a disturbance in autonomic control mechanisms, namely either an increased sympathetic or a reduced vagal tone, or some interaction of the two, in infants who succumb to SIDS.

A study on sleep state organization in 22 recordings from 16 term future SIDS victims in the above data set and 66 recordings from age-matched controls showed less waking and more sleep during the early morning hours.[274] Interestingly, the future SIDS victims also showed fewer body movements during REM sleep compared to controls. Unfortunately, sleeping position was not recorded; it is, therefore, not clear whether these findings indicate a disturbance in sleep organization and/or arousal responsiveness, or are merely related to a higher proportion of future SIDS victims sleeping prone. The latter position is associated with less motility and longer sleep times.[275,276]

André Kahn's group analyzed polygraphic sleep studies in 40 future SIDS victims and 607 healthy infants matched for sex and age, taken from a data set of 27,000 infants who had been studied polygraphically in 10 Belgian sleep laboratories between 1977 and 2000.[277] The only group difference between SIDS cases and controls was an increase in the number of obstructive apneas, defined as a pause in airflow for more than 2 seconds and observed in 75% of future SIDS victims, but in only 42% of controls. Also, the decrease in frequency of apneic pauses with age was smaller in the SIDS infants than in the control group. All other polygraphic parameters (duration of different sleep states, number and duration of apneic pauses, heart and respiratory rates) were not significantly different in the two groups. However, the group of future SIDS victims included 6 siblings of SIDS victims and 9 infants who had experienced an ALTE.

A number of investigators prospectively recorded electrocardiograms in future SIDS victims to define the incidence of a prolonged QT interval because the latter is associated with an increased susceptibility to potentially fatal ventricular arrhythmias.[278] The results of those studies are controversial. Schwartz[279] found a "markedly prolonged" QT interval in 6 of 9 SIDS victims, identified in a population of 8000 infants. In contrast, Southall and colleagues in the prospective study mentioned earlier,[264] and in a second prospective study involving standard ECGs on 7254 infants—15 of whom suffered SIDS—found no abnormal prolongation of the QT interval.[280] Weinstein and Steinschneider[281] were also unable to identify a prolonged QT interval in any of their eight prospectively studied SIDS victims. By 1998, however, Schwartz and coworkers had increased their original data set to more than 34,000 infants, including 24 who subsequently died of SIDS.[282] Twelve of these infants (50%) had a corrected interval (QTc) above 440 ms, the 97.5th centile in the underlying population, giving an OR of 41 (17; 98). These impressive data, however, were widely criticized (e.g., for insufficient blinding and unclear criteria for the selection of QRS complexes or SIDS cases).[283] Moreover, it remains puzzling that torsades-de-pointes tachycardia, the proposed death mechanism related to a prolonged QT interval, has never been observed in the more than 35 ECG recordings obtained during sudden infant death on a monitor (see later). Recent genetic studies suggest that a molecular diagnosis of SIDS related to long-QT-syndrome (LQTS) genes is rare and only valid if corroborated by a electrophysiologic characterization of the mutated ion channel.[284,285] A general screening for LQTS, therefore, cannot be recommended.[286]

The results from these prospective studies can be summarized as follows: (1) no marker has yet been identified from physiologic recordings obtained some weeks prior to death that would identify future SIDS victims with a sensitivity and specificity high enough to justify a specific intervention; (2) short or prolonged cessations of breathing movements, if analyzed some weeks prior to death, bear no unequivocal relation to SIDS; (3) the same applies to cardiac arrhythmias; (4) episodes with an intermittent absence of airflow, but continued breathing movements ("obstructive apnea") may be found significantly more frequently in future SIDS victims than in controls; and (5) there are indicators to suggest a disturbance in autonomic control and/or in sleep state organization in some future victims of SIDS, but the exact mechanism(s) through which these disturbances can lead to sudden death has not yet been determined.

It should be made clear that the differences identified between SIDS victims and controls were only group differences and could not be used to identify individuals at risk. Some of the studies involved multiple analyses for which statistical corrections were made. Such corrections may have over- or underestimated statistical significance.

DATA RECORDED DURING DEATHS ON A HOME MONITOR

There are now a number of recordings from cardiorespiratory monitors that were obtained during SIDS.[287-291] Despite some limitations, these recordings have for the first time provided us with objective data on the pathophysiologic mechanisms immediately preceding SIDS. In an analysis of nine recordings of chest wall impedance and heart rate from infants who had an autopsy diagnosis of SIDS or mild BPD, gasping was the predominant pattern, being already present at the time of the monitor alarm in three infants and occurring within 3 minutes after the alarm in a further four infants (Fig. 30-6).[290] One infant began to gasp only 13 minutes after the first monitor alarm. The duration of gasping ranged from 3 seconds to 11 minutes in those five

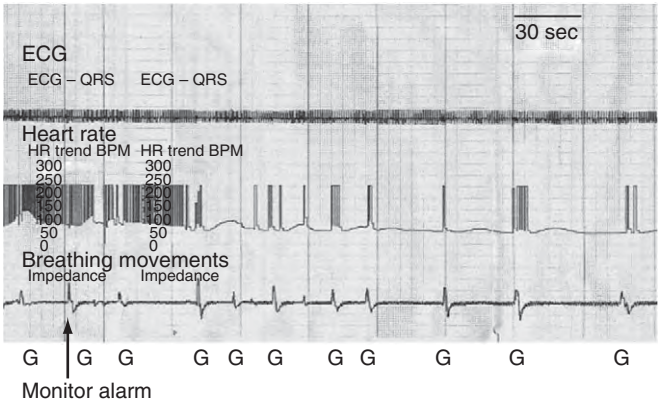

Figure 30-6 Section from a memory monitor printout of a 1-month old infant born at 34 weeks' gestation and with an autopsy diagnosis of SIDS. There are 11 gasps (G) which progressively decrease in amplitude. There is an increase in heart rate from 72 to 140 beats per minute (bpm) during the first 20 seconds of recording, followed by several smaller increases in heart rate that appear to occur in response to the gasps and are also decreasing in amplitude over time. (Reprinted with permission from Poets CF, Meny RG, Chobanian MR, Bonofiglo RE: Gasping and other cardiorespiratory patterns during sudden infant death. Pediatr Res 45:350-354, 1999.)

infants in whom it was not interrupted by resuscitation. Primary trigger for the monitor alarm had been bradycardia in all but two infants, but there was no indication of heart block or ventricular tachycardia. Prolonged apnea (>20 seconds) began up to 13.7 minutes (median 2.7) after this alarm in five infants and 7 to 20 seconds before the alarm in three infants; in the remaining infant, stimulation occurred prior to any apnea.

These observations should be interpreted with caution because all infants had been born at less than 37 weeks' gestation. This, however, reflects only the population monitored in the centers providing these recordings. Nonetheless, prolonged apnea seems unlikely to be a primary mechanism in the sequence of events leading to most cases of SIDS. Also, bradycardia is unlikely to be a primary mechanism, and there was little evidence for an arousal reaction (e.g., body movements). Finally, gasping occurred in the majority of these SIDS victims, but was obviously not successful as an autoresuscitative mechanism. The latter data were confirmed in a similar study observing gasping in 23 of 24 infants immediately preceding death.[291] In animal studies, gasping occurs only if PaO_2 has fallen to below 5 to 10 mm Hg (i.e., once the animal is severely hypoxemic).[292] Thus, many SIDS infants who die on a monitor may have already been severely hypoxemic at the time of their first monitor alarm, with the progressive decrease in heart rate being due to hypoxic cardiac depression.

Hence, it appears from these recordings that the sequence of events finally resulting in these deaths was initiated by a slowing of the heart, which in turn was most likely caused by hypoxemia. In addition, there seems to be some failure or depression of the two most important mechanisms involved in autoresuscitation, namely arousal and gasping. The underlying causes of both the hypoxemia and the failure of these infants to resuscitate themselves from this hypoxemia remain to be determined.

Prevention

PRIMARY PREVENTION

As stated earlier, dissemination of advice on a safe sleeping environment has been one of the most effective health interventions ever performed. These information campaigns on safe child care practices, based on epidemiologic data on modifiable risk factors, have to be reviewed in regular intervals to incorporate new data. The current advice given by the American Academy of Pediatrics includes the following (abbreviated):[293]

- Infants should be placed in a supine position for every sleep.
- Use a firm sleep surface. Pillows or sheepskins should not be placed under a sleeping infant.
- Keep soft objects and loose bedding out of the crib.
- Let your baby share your room for sleep, but not your bed.
- Do not smoke during pregnancy, and keep infant in smoke-free environment after birth.
- Consider offering a pacifier at nap time and bed time.
- Avoid overheating. Bedroom temperature should be comfortable for a lightly clothed adult.

Similar advice is given in countries around the world, although differences exist (e.g., the Dutch campaign recommends use of a sleeping bag; the English campaign does not discourage bed sharing, whereas the Scottish campaign does). In general, however, there is broad agreement, and it is this kind of information, not any secondary prevention, that is primarily responsible for the impressive reduction in SIDS rates seen around the world in recent years (see Table 30-2).

One group of infants still commonly placed to sleep on their side is preterm infants. Recent data from the United Kingdom, however, suggest that the risk of SIDS for infants who are "small at birth" (<37 weeks or <2500 g) and placed to sleep on their side is 15 times higher (multivariate OR 14.93 [5.1; 54.9]) than for normal birth weight infants placed on their backs. An even higher risk was found in this group for bed sharing with parents who smoke (OR 37.4 [5.5; 239.9]).[294] Because preterm infants initially benefit from prone sleeping, but observed nursery staff behavior has a strong influence on parental behavior after discharge,[295] it is our practice to start placing preterm infants on their back and in a sleeping bag, and to provide advice on safe sleeping to parents, approximately 1 week prior to discharge. In the delivery hospital, infants should be placed on their backs starting on their first day of life.

SECONDARY PREVENTION

For many years, the use of home monitors in specific risk groups (i.e., secondary prevention) has been the only method to prevent SIDS. Its effectiveness in reducing the incidence of SIDS, however, has never been proved. This is largely for methodologic reasons: with the current incidence of SIDS, more than 110,000 infants would have to be randomized in a controlled population-based trial to gain sufficient power to demonstrate (or exclude) a reduction in SIDS rate from 1 to 0.5/1000 as a result of home monitoring. This seems impractical. Despite its unproven effect, however, there are still specific patient groups in whom home monitoring appears indicated. Thus, home monitoring may be prescribed as a diagnostic tool or as an early warning of potentially dangerous pathophysiology. The first group comprises infants after an ALTE (see later) and infants from families who had two or more sudden unexpected infant deaths. The second group involves technology-dependent infants (e.g., with a tracheostomy), infants with respiratory control disorders (e.g., Pierre-Robin sequence), and preterm infants with persistent AOP. The latter is not associated with an increased risk of SIDS,[296] but monitoring may be indicated to prevent potential sequelae (e.g., cerebral palsy).[297] Whether monitoring at home (or in hospital) can prevent such sequelae, however, has never been proved, and this indication remains controversial. For all of these infants, we recommend a pulse oximeter with motion-resistant technology to reduce the frequency of false alarms.[298] Although there are no controlled trials on this issue, there is evidence to suggest that apnea and hypoxemia may occur too late during the events leading to death to allow for intervention in time for successful resuscitation.[290] Monitoring should continue for 4 weeks after the last (true) monitor alarm except for siblings from families with multiple deaths who should be monitored until the age of the oldest infant who died.[298]

Summary of Data on Sudden Infant Death Syndrome

The mechanisms responsible for SIDS remain a mystery. However, there is a growing body of evidence to suggest that approaches to investigate its possible pathophysiology should focus on the regulation of auto-resuscitative mechanisms (arousal and gasping). Although we do not understand the exact mechanisms leading to these deaths, a large proportion can be effectively prevented. The success of primary prevention programs based on epidemiologic data has been rather impressive. Only if the links between the epidemiologic, pathologic, and physiologic characteristics observed in SIDS can be elucidated, however, will we be able to better understand and possibly finally prevent these tragedies.

APPARENT LIFE-THREATENING EVENTS

There is no disease that invariably results in death, and SIDS is no exception to this rule. Hence, there are events during which an infant was about to die, but was found early enough for successful resuscitation. Although there is controversy about the epidemiologic similarities between ALTE and SIDS,[299,300] they are often regarded as a living model for SIDS. However, there are some problems with this approach. First, as is probably the case with SIDS, a large number of treatable disease entities can cause ALTE. These cannot always be identified from investigations performed after an event has occurred (see later). A proportion of apparently idiopathic ALTE will be caused by an identifiable mechanism, which is temporary and, if identified, can be treated and does, therefore, not bear any relation to SIDS (e.g., pneumonia, meningitis, etc.). Second, it will always be impossible to say whether an infant that was resuscitated by his parents would indeed have died without this intervention. Third, certain "abnormalities" identified between ALTE may be coincidental and irrelevant to the ALTE themselves (e.g., gastroesophageal reflux, see later). Hence, there are some inherent ambiguities in the relationship between SIDS and ALTE, and this must be kept in mind if one draws conclusions from studies performed in infants with ALTE to the pathophysiology of SIDS.

Apnea in Infants with Apparent Life-Threatening Events

Alfred Steinschneider was the first to infer a potential pathomechanism for SIDS from observations made in infants who had experienced an ALTE. He reported prolonged (≥15 seconds) cessations in breathing efforts in three infants who had experienced an ALTE and two of their siblings. Two of these five infants (one with ALTE and her brother) subsequently died, and Steinschneider concluded that prolonged apnea is part of the final pathway resulting in SIDS.[301] This paper soon formed the scientific basis for the so-called *apnea hypothesis*, which was enthusiastically received by the scientific community at its time and resulted in the prescription of thousands of apnea monitors around the world.[302] Twenty-five years later, however, legal evidence emerged suggesting that the two SIDS infants on whom the apnea hypothesis was predominantly based had not died of SIDS but had instead been killed by their mother.[303] This does not only highlight the complexity and heterogeneity of the phenomena currently called SIDS and ALTE, but does also raise doubts about the true relevance of the apnea hypothesis to the pathophysiology of these two phenomena.[304] Whatever its validity, the apnea hypothesis clearly stimulated many researchers to look for apneas in infants considered to be at risk of SIDS. Some investigators found larger quantities of periodic breathing and higher numbers of apneic pauses in infants with ALTE; others did not.[305,306]

Apneas that were associated with an intermittent closure of the upper airway at the level of the larynx, documented by means of an ultrafine fiberoptic endoscope during spontaneous sleep, were observed in three previously preterm infants with ALTE.[71] These infants were selected from a group of 25 term and preterm infants with a history of ALTE because they had demonstrated some obstructive apneas during an initial routine sleep study. Interestingly, the laryngeal closure occurring in these infants did not appear to happen as a passive collapse of the airway structures, but as a much more abrupt action, suggestive of an active process. The authors speculated that this abrupt closure might have been caused by stimulation of the laryngeal chemoreflex. Although this observation corresponds to prospective data showing an increased number of obstructive apneas in future SIDS victims,[277] it should be noted that this mechanism was found in only 3 of the 25 infants with ALTE enrolled in the study; all 3 had been born at less than 32 weeks' gestation. It is interesting to note that (passive) upper airway collapse was more likely to occur in the prone compared to the supine position in term infants under general anesthesia,[221] again suggesting that airway closure may be related to SIDS.

Impaired Arousal from Sleep

Based on the hypothesis that SIDS may be related to an impaired arousal responsiveness to hypoxic and/or hypercapnic stimuli, a number of investigators studied the response to hypoxic or hypercapnic gas mixtures in infants with ALTE. Results, however, were inconclusive, and it was concluded that hypoxic or hypercapnic challenge tests do not appear to have any value as a screening tool for SIDS risk.[307]

Nevertheless, a disturbed arousal response has been reported in several well-defined SIDS risk groups or behaviors (e.g., infants with ALTE[308] or nicotine exposure,[191,309] or healthy infants studied in the prone position or without a pacifier[310,311]). These observations point toward a common pathophysiologic mechanism for SIDS, namely an impaired ability of SIDS infants to arouse to noxious stimuli such as hypoxia or hypercapnia (e.g., during re-breathing of expired air), which may, therefore, progress in some of these infants until they are becoming potentially life-threatening.

Ventilation/Perfusion Mismatch and Small Airway Function

Most studies on the pathogenesis of SIDS and/or ALTE have concentrated on the neurologic control of breathing. However, investigations performed during apneic/cyanotic episodes in infants revealed a number of physiologic phenomena that could not be sufficiently explained on the basis of primary disturbances in the central control of the respiratory genera-

tors or of upper airway patency. These include (1) the extremely rapid development of hypoxemia during some episodes; (2) the occurrence of sudden hypoxemic episodes despite continuous ventilation (Fig. 30-7); (3) differences in the speed of desaturation between different forms of apneic episodes (Fig. 30-8); (4) the presence of continued breathing efforts and yet absent airflow despite bypass of the upper airway; and (5) evidence that apnea and hypoxemia may begin simultaneously.[312] These observations become explicable only if one assumes that a right-to-left shunt may cause or contribute to hypoxemic episodes in infants and young children. Such a shunt has, in fact, been demonstrated in patients with severe cyanotic episodes clinically resembling cyanotic breath-holding spells.[313]

Intrapulmonary right-to-left shunting may result from the flow of blood through unventilated areas of lung caused by atelectasis and/or distal airway closure, or from the flow of blood through discrete anatomic pathways that allow direct passage of deoxygenated blood from the pulmonary arteries to the pulmonary veins. The latter possibility has been suggested from postmortem data in SIDS victims,[314] but could not be demonstrated when injecting radioactively labeled microspheres (20 to 50 μm in diameter) during cyanotic breath-holding spells in infants.[315]

Distal airway closure may occur, for example, if small airway size is reduced. The potential role of small airway closure in SIDS was reviewed in an elegantly written hypothesis.[242] This concept is supported by reports of a reduced specific airway conductance and/or $\dot{V}max_{FRC}$ in ALTE infants.[316,317] These data confirm the hypothesis that a proportion of infants with ALTE may have abnormally small airways, and that this may predispose these infants to potentially life-threatening episodes of progressive peripheral bronchial occlusion.

Gastroesophageal Reflux

In 1978, Herbst and colleagues[318] reported on 14 infants with a history of cyanotic and apneic spells, all of whom had "severe GER" on a barium esophagogram. Five of these infants had a clinically apparent episode of apnea and cyanosis during and immediately following a decrease in esophageal pH. One infant died of SIDS 1 week after the parents had discontinued positional antireflux therapy. Although these data clearly showed that GER may be associated with apneic/cyanotic episodes or even sudden death, it remains questionable how relevant this potential pathomechanism is for the majority of infants with ALTE. For example, in the study by

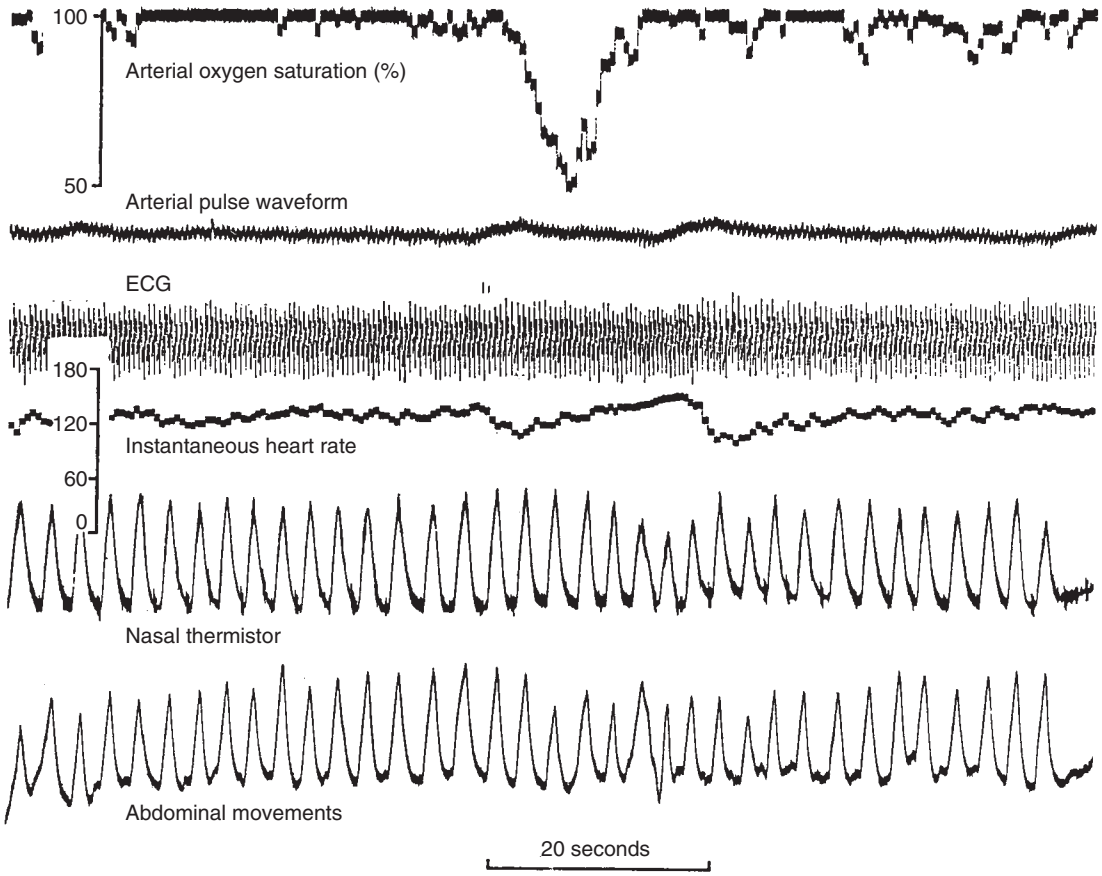

Figure 30-7 Section from a multichannel recording in a 6-month-old infant who had experienced an apparent life-threatening event. There is a fall in SaO_2 to 50%, lasting 12 seconds, which occurs without any significant change in either breathing movements or nasal airflow and can, hence, be best explained by a sudden mismatch between ventilation and perfusion in the lung. (Reprinted with permission from Poets CF, Samuels MP, Southall DP: The potential role of intrapulmonary shunting in the pathogenesis of hypoxemic episodes in infants and young children. Pediatrics 90:385-392, 1992.)

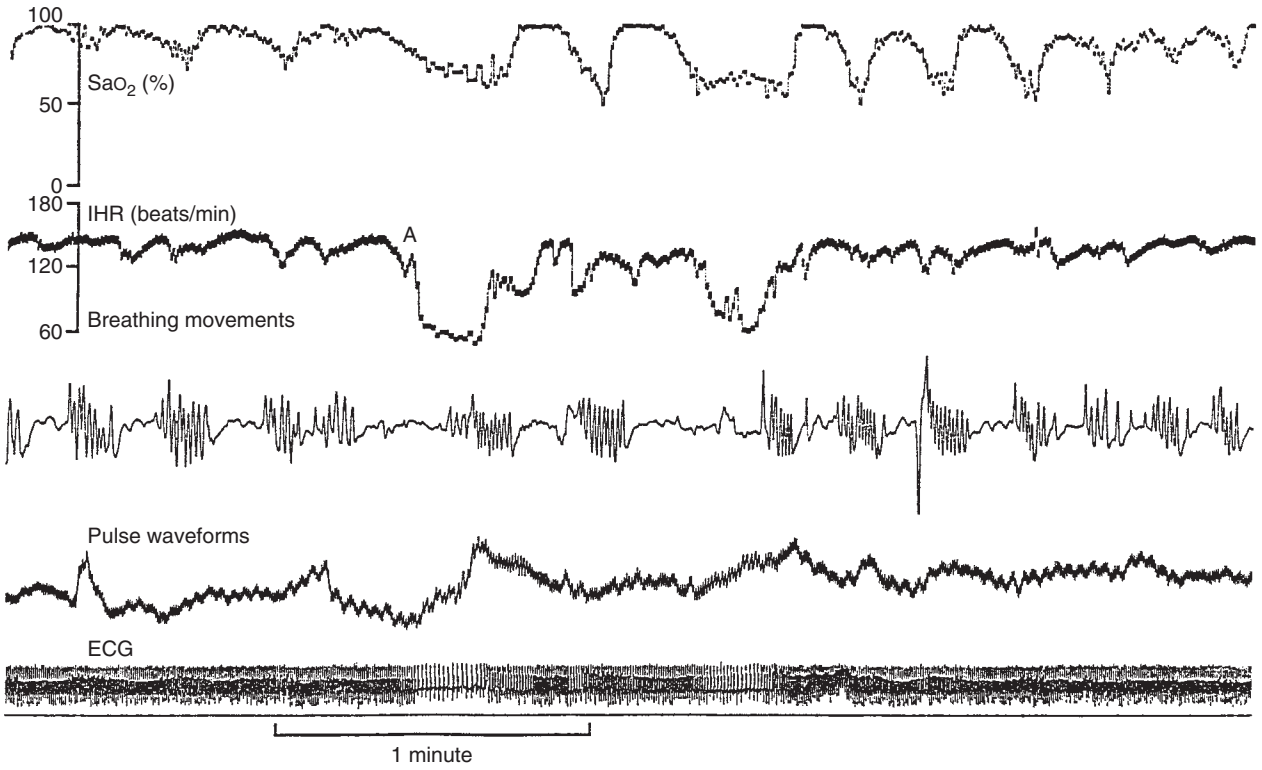

Figure 30-8 Section from a multichannel recording in a preterm infant, studied at 40 weeks' gestational age and showing periodic apnea. Note the much faster decrease in SaO_2 during the desaturations that follow a relatively severe desaturation that is also associated with a bradycardia (A).

Herbst and colleagues no mention was made about the size of the total group of infants with ALTE seen during the study period, and most of their 14 patients also appeared to have extremely frequent events (up to 10 per day), which is not a characteristic feature in the majority of infants with ALTE.[318]

Nevertheless, the possibility that ALTE or even SIDS is caused by GER remains intriguing, particularly because there are several potential pathways through which GER may cause apnea and/or cyanosis (e.g., via stimulation of the laryngeal chemoreflex[319] or via a vagally induced disturbance in pulmonary gas exchange).[320] Unfortunately, there is no study that has investigated the temporal relation between clinical events (i.e., ALTE) and GER, except for the above study by Herbst and colleagues[318] In addition, all but one study investigating the temporal relation between polygraphically recorded short *apnea* (not associated with clinical events such as cyanosis) and GER did *not* demonstrate that such a relation exists.[54,321-327] In the one study which did observe such a relation, all infants had been specifically selected because of a history of apneic spells and frequent regurgitations.[54] However, the majority of prolonged apneic spells even in these infants was not associated with regurgitation. Only one study investigated the temporal relation between hypoxemia and GER in infants with ALTE, but did not control their pulse oximetry data for motion artifact.[328]

In summary, it remains questionable whether GER accounts for a significant proportion of ALTE. This does not imply that GER should not be suspected and possibly treated if there are additional features (e.g., a history of vomiting immediately prior to an ALTE) suggesting GER. Further studies on the temporal relation between GER and ALTE are needed.

Data Recorded during Apparent Life-Threatening Events

Few studies analyzed recordings of breathing movements and ECG obtained with memory monitors at home. In a study using a device that recorded breathing movements, ECG, heart rate, SpO_2 and the pulse waveforms from the oximeter for approximately 20 minutes around an alarm in 94 infants with a history of at least two ALTEs, a total of 52 events was reported in 34 patients.[329] In 23 of the 45 further events in 19 of these infants, one of four characteristic patterns suggesting specific underlying mechanisms for events could be identified. These four patterns were as follows:

1. A sudden fall in $P_{Tc}O_2$ (to <20 mm Hg) but without a fall in SpO_2 (Fig. 30-9). This pattern was considered to represent changes in skin perfusion, not arterial hypoxemia, and was found during six events in five patients
2. A fall in both $P_{Tc}O_2$ and SpO_2 associated with an attenuation, irregularity, or absence of breathing movements and an increase in heart rate by at least 20% from baseline (Fig. 30-10). This pattern was seen in five patients (six events) and was considered to be suggestive of an epileptic seizure. This tentative diagnosis was subsequently proved during further events using continuous EEG recordings.[330]
3. A fall in $P_{Tc}O_2$ and SpO_2 preceded by the sudden onset and continued presence (for at least 40 seconds) of a clear increase in amplitude and irregularity of the breathing movement signal, and associated with an initial sinus

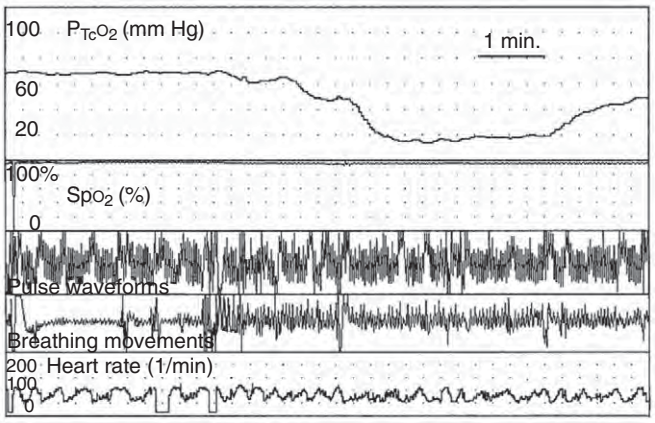

Figure 30-9 Section from a documented monitor recording in a 4-month-old infant with recurrent cyanotic episodes perceived by his parents as life-threatening. There is a fall in $P_{Tc}O_2$ to 15 mm Hg lasting 3 minutes, matching the parental report of cyanosis. The SpO_2 signal, however, remains unchanged, and there is also no change in breathing movements or heart rate. Thus, this episode most likely reflects a sudden change in skin perfusion that was not accompanied by any change in arterial oxygenation. (Reprinted with permission from Poets CF: Apparent life-threatening events and sudden infant death on a monitor. Pediatr Resp Rev 4 [Suppl 1], S397-S400, 2003.)

tachycardia and artifact on the ECG and plethysmographic signal—suggesting massive body movements. This pattern, when accompanied by false or varying descriptions of the time or sleep state of the infant, was considered suggestive of suffocation and was found during four events in four patients. This suspicion was subsequently proved with covert video surveillance.[331,332]

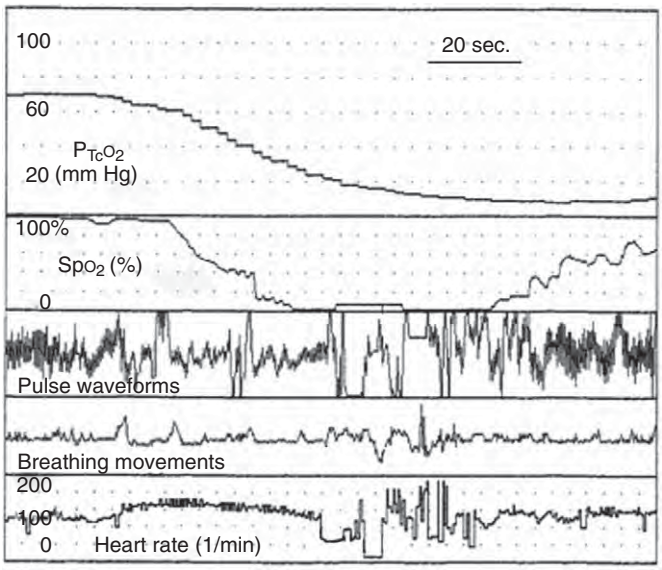

Figure 30-10 Section from a documented monitor recording in an 8-month-old infant with a history of recurrent apparent life-threatening events (ALTE) of unknown cause. A standard EEG had been normal. There is a fall in $P_{Tc}O_2$ and SpO_2 that is accompanied by shallow, irregular breathing movements and an increase in heart rate from 110 to 160 beats per minute (bpm). The child was subsequently shown to have seizure-induced cyanotic episodes. (Reprinted with permission from Poets CF: Apparent life-threatening events and sudden infant death on a monitor. Pediatr Resp Rev 4 [Suppl 1], S397-S400, 2003.)

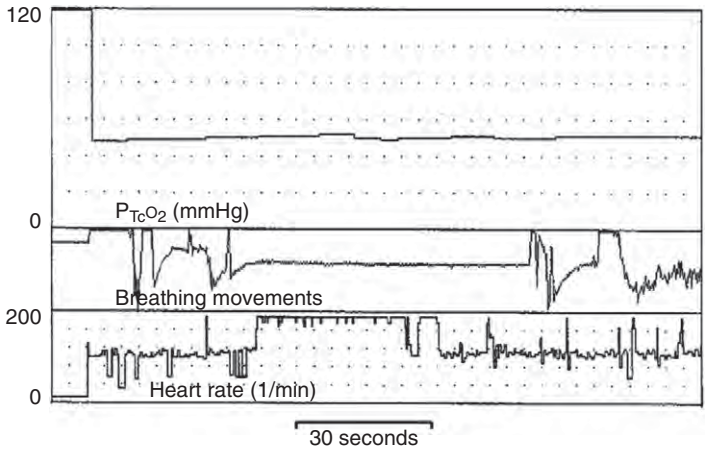

Figure 30-11 Home event recording of $P_{Tc}O_2$, breathing movements, and heart rate in a 7-month-old boy with a history of recurrent ALTE of unknown cause. There is a sharp deflection in the breathing movement signal, which then becomes electronically straight (for 28 seconds), before it abruptly starts to show breathing movements again. During this apparent prolonged apneic pause there continues to be sinus arrhythmia on the instantaneous heart rate signal (visible shortly before the end of the apnea). The events in this infant were subsequently found to be factitious (Münchausen syndrome by proxy); the prolonged apneic pause in this recording being caused by the mother temporarily disconnecting the breathing movement sensor (Graseby pressure capsule).

4. Data entries in the user log and changes in signals that were inconsistent with the parental history of the date, time, and clinical status of the infant and were also incompatible with natural pathophysiology. This would include, for example, the occurrence of an extremely prolonged pause in breathing movements without any accompanying change in heart rate or heart rate variability, reported to have occurred at night, but being in fact recorded during the day. Such inconsistencies suggested that the symptoms reported were fabricated (Münchausen syndrome by proxy; Fig. 30-11).

In all of these patients, specific measures were introduced to prevent or reduce the occurrence of further events, or parents could be reassured that the events they had considered life threatening were, in fact, of no clinical significance. Twenty-two events in 12 patients that could not be attributed to one of the above patterns[329] were regarded as idiopathic ALTE. All showed definite hypoxemia, but apneic pauses were found in only nine events (six infants) and only five of these lasted for more than 20 seconds. Bradycardia developed during only four events.

This study showed that documented monitoring can help to identify potentially preventable mechanisms for ALTE in a considerable proportion of patients who may otherwise be considered to have suffered idiopathic ALTE. However, there was certainly some referral bias, particularly with regard to infants with parentally induced or fabricated events. Nevertheless, these data clearly show that the majority (64%) of idiopathic ALTE involved severe prolonged hypoxemia that occurred without prolonged apneic pauses and without bradycardia and would not (or only much later) have been identified by a cardiorespiratory monitor. It could not, however, determine the mechanism(s) (e.g., rebreathing, hypoventilation) by which this non-apneic hypoxemia developed.

Table 30-4
Some Possible Underlying Diagnoses in Patients Presenting with ALTE

Respiratory Tract Disorders	***Neurologic Disorders***
Bronchiolitis	Intracranial infection
Pneumonia	Epileptic seizures
Pertussis	Congenital central hypoventilation syndrome
Tracheoesophageal fistula	Spinal muscular atrophy (Werdnig Hoffmann)
Aspiration	Hyperexplexia (startle disease)
Laryngomalacia; tracheomalacia	Joubert syndrome
Pierre Robin sequence	Arnold Chiari malformation
Laryngeal cyst or angioma	Myopathy
Cardiovascular Disorders	***Gastrointestinal Disorders***
Long QT syndrome	Gastroesophageal reflux
Cardiac arrhythmias	Volvulus; intussusception
Aortic stenosis	Aspiration and choking
Vascular ring	Toxic shock syndrome caused by gastroenteritis
Metabolic Disorders	***Others***
Medium chain acyl-CoA deficiency	Cyanotic breath-holding spells
Biotinidase deficiency	Anemia
Ornithine transcarbamylase deficiency	Intentional suffocation (smothering)
Glutaric aciduria type II	Münchausen syndrome by proxy
Systemic carnitine deficiency	
Reye syndrome	

ALTE, apparent life-threatening event.

Summary of Physiologic Data in Apparent Life-Threatening Events

Most idiopathic ALTEs appear to be caused by the progressive development of hypoxemia, which may progress until it becomes life-threatening or even fatal because of a failure of these infants to resuscitate themselves by arousal and/or gasping. This hypoxemia apparently does not, in most instances, result from a primary cessation of respiratory efforts, but is more likely to be caused by some form of upper or lower airway closure (e.g., obstructive apnea). The trigger(s) eliciting this airway closure remain unknown.

Management of Infants with Apparent Life-Threatening Events

The list of diagnoses possibly manifesting with an ALTE is long (Table 30-4), and an extensive diagnostic work-up is often required in these infants to exclude treatable causes of ALTE.[333] Some suggestions regarding issues that should be covered when obtaining the medical history and organizing the subsequent diagnostic work-up in these patients have been summarized in Table 30-5.

Because of the importance of obtaining objective data during an ALTE, and because the likelihood of further events

Tremor, profuse sweating	? Hypoglycemia, hypocalcemia
Face covered by bedding/in mattress	? Positional asphyxia
Hours/days prior to event	
Fever, cold, diarrhea	? Infection
Abnormal sleepiness and/or irritability	? Meningitis, Reye syndrome
Snoring	? Obstructive sleep apnea
Stridor	? Laryngo- or tracheomalacia
Wheezing	? Bronchiolitis
Seizures, turning of eyes, "staring"	? Epileptic seizure–induced events
Fasting for several hours (± infection)	? Medium chain acyl-CoA deficiency
Cyanosis during crying/feeding	? BPD, bronchiolitis, cardiac anomaly
Weeks/months prior to event	
Previous events with onset *always* in presence of the same person	? Münchausen syndrome by proxy, deliberate suffocation
Gradual reduction in spontaneous motor activity	? Spinal muscular atrophy, myopathy
Profuse sweating	? Disorder in autonomic regulation
Pertussis or RSV epidemic in area?	? Pertussis, bronchiolitis
Prematurity, bronchopulmonary dysplasia	? "BPD-spells"
SIDS/ALTE in sibling	Inheritable disease (metabolic disorder, long QT syndrome, startle disease) or parentally induced event more likely

Table 30-5
The Medical Interview and Diagnostic Work-up in Patients with ALTE*—Cont'd

Question/Investigation	Reason for Question/Investigation
Specific Features During Physical Examination	
Pallor	? Anemia
Stridor	? Laryngo- or tracheomalacia, vascular ring
Micrognathia	? Pierre Robin sequence
"TOF-cough"	? Tracheoesophageal fistula
Wheezing, dyspnea	? Bronchiolitis, pneumonia
Pronounced second heart tone	? Increased PVR, subclinical hypoxemia
Heart murmur	? Aortic stenosis or other heart defect
Muscular hypotonia, no spinal reflexes	? Spinal muscular atrophy
Chest wall recession	? Increased upper airway resistance; BPD
Specific Laboratory Tests	
Arterial or capillary blood gas analysis (as soon as possible after event)	Estimation of severity of event ? Metabolic disorder, hypoxic/ischemic insult
Complete blood count including differential	? Anemia, infection (e.g., pertussis)
C-reactive protein	? Infection
Serum glucose (preferably after fasting period)	? Hypoglycemia, metabolic disorder
Serum calcium and magnesium	? Hypocalcemia, hypomagnesemia
Nasal swab, including immunofluorescence	? Pertussis, RSV, adenovirus
Organic acids in urine	? Medium chain acyl-CoA deficiency
Serum ammonia	? OTCD carrier, glutaric aciduria, carnitine deficiency
Further Investigations	
Electrocardiogram	? Long QT syndrome
Chest radiograph	? Aspiration, pneumonia, cardiovascular anomaly, bronchopulmonary dysplasia
Electroencephalogram	? Epileptic seizure–induced events
Cranial ultrasound/NMR	? Intracerebral hemorrhage, brain stem abnormalities
Sleep study (only if treatable causes for ALTE have been ruled out)	? Baseline hypoxemia, hypoventilation, epileptic seizure–induced hypoxemia
Home event recording (only if above measures have not helped to identify mechanism)	Documentation of further events at home

*Note that this list is not complete; in particular, further investigations (e.g., barium swallow, esophageal pH monitoring, echocardiography) may be necessary depending on the results of the initial work-up.
ALTE, apparent life-threatening event; BPD, bronchopulmonary dysplasia; CPR, cardiopulmonary resuscitation; OTCD, ornithine transcarbamylase deficiency; PVR, pulmonary vascular resistance; RSV, respiratory syncytial virus; SIDS, sudden infant death syndrome; TOF, tracheoesophageal fistula.

is highest during the first 48 hours after the initial event,[334] all infants with a history of an ALTE should be admitted to hospital and immediately connected to a memory monitor. If a further event occurs, important clues to the underlying diagnosis may be gained. For example, if an increase in heart rate in association with a severe hypoxemic episode is observed on such an event recording, this may indicate the presence of epileptic seizure–induced hypoxemia as the underlying mechanism.[330]

If the diagnostic work-up summarized in Table 30-5 has failed to identify a treatable cause for the ALTE, a polysomnogram should be performed. This includes a continuous (>6 hours) recording of breathing movements, nasal airflow, ECG, SpO_2, transcutaneous partial pressures of oxygen and carbon dioxide, electro-oculogram and electroencephalogram. These recordings occasionally have been valuable in identifying respiratory control disorders such as sleep-related upper airway obstruction or epileptic seizure–induced hypoxemic episodes. As discussed earlier, however, they do not have any predictive value with regard to SIDS.

CHAPTER 31 Epidemiology of Respiratory Infections

Philip Keith Pattemore and Lance C. Jennings

TEACHING POINTS

- Technological developments in molecular biology are showing that known respiratory viruses are more prevalent than previously thought across the childhood age range. New viruses continue to be discovered in association with acute respiratory tract infections.
- The study of morbidity and mortality that is due to acute lower respiratory tract infection is hampered by lack of precise definitions and specific, practical diagnostic methods.
- Children in developing countries account for at least 70% of the global burden and mortality from acute lower respiratory tract infection.
- Malnutrition, poverty, indoor smoke, and comorbid conditions, including malaria, tuberculosis, and human immunodeficiency virus infection, greatly increase the risks of children acquiring and dying from acute lower respiratory tract infection.
- Emerging respiratory diseases present an ongoing risk for children in an era of globalization.

This chapter deals with three aspects of the epidemiology of respiratory infections in children: common respiratory viruses, acute lower respiratory tract infection (ARI), and emerging/reemerging organisms.

COMMON RESPIRATORY VIRUSES

Respiratory tract infections are among the most frequent diseases in early life. Many viruses are known to be associated with symptomatic respiratory tract infections, the most common being respiratory syncytial virus (RSV), influenza viruses types A and B, parainfluenza viruses, adenoviruses, and rhinoviruses. Viral infections are consistently more commonly found in younger children,[1,2] among whom viruses are the cause of as many as 90% of all lower respiratory tract infections (LRIs).[3] Increasingly, these viruses are also being associated with a substantial burden of respiratory disease in adults, including elderly persons, and in immunocompromised persons. The advent of molecular technologies has improved laboratory detection of virus in clinical samples and extended the ability to characterize the epidemiology of respiratory virus infections, but it has also led to the identification of subtypes and genotypes of known respiratory viruses and to the discovery of novel respiratory viruses.

Laboratory Detection

CONVENTIONAL DIAGNOSTIC METHODS

Conventional virologic methods, including antigen detection, serology, and culture, have clearly identified the viruses most frequently causing respiratory illnesses in children and associated with both upper respiratory tract (URI) and LRI infections. Table 31-1 shows the relative frequency of viruses identified within the Tecumseh, Michigan, community study, from 1976 to 1981.[4]

MOLECULAR DIAGNOSTIC METHODS

The inclusion of nucleic acid technologies (e.g., polymerase chain reaction [PCR]) for the detection of respiratory virus infections in children has substantially increased the diagnostic sensitivity for most respiratory viruses.[5-7] This technology has allowed the recovery of viruses that have been difficult to detect by conventional methods.[8] For example, PCR is three to five times as sensitive as cell culture for detecting rhinoviruses.[9,10] Figure 31-1 shows the viral identification breakdown in three recent studies of children[5,11,12] in different countries over the winter viral season using PCR techniques. This figure illustrates the differences between studies in patient sampling and methods and the consequent differences in results. However, in all three studies, rhinovirus and RSV are the dominant viruses, with the relative proportions of each differing even between the two studies in infants (studies A and B). Mixed viral infections, particularly with rhinovirus, are common. Finally, studies find only the organisms they look for—only study C tested for bocavirus.

Molecular methods have also allowed the rapid identification and characterization of previously unknown viruses causing respiratory illness. The human metapneumovirus (hMPV) was first identified in the Netherlands in 2000[13] and shows a wide geographic distribution.[14,15] Five new human coronaviruses have been discovered,[16] including severe acute respiratory syndrome (SARS) coronavirus (SARS-CoV),[17,18] human coronavirus NL63 (hCoV-NL63),[19] and human coronavirus HKU1 (hCo-HKU1).[20] Another virus, the human bocavirus (hBoV), has also been identified in association with respiratory illness in hospitalized patients.[21]

MULTIPLE INFECTIONS

Studies using conventional virology have detected multiple respiratory viruses in 1.8% to 15.8% of acute LRIs.[22] While more recent studies using nucleic acid technologies have identified multiple viruses in up to 27% of hospitalized

Table 31-1
Annual Isolation Rates of Respiratory Viruses, Tecumseh, Michigan, 1976-1981

Numerator	Annual Isolation Rate, Adjusted by Proportion of Illnesses Sampled. By age group		Percentage Isolated	Annual Number of Attributable Illnesses	Percentage of Illnesses Resulting in Consultation
Denominator	**100 Person-years**		**All Respiratory Illnesses**	**10,000 Population**	**Illnesses Attributable to Specific Agent**
				All ages: children and adults

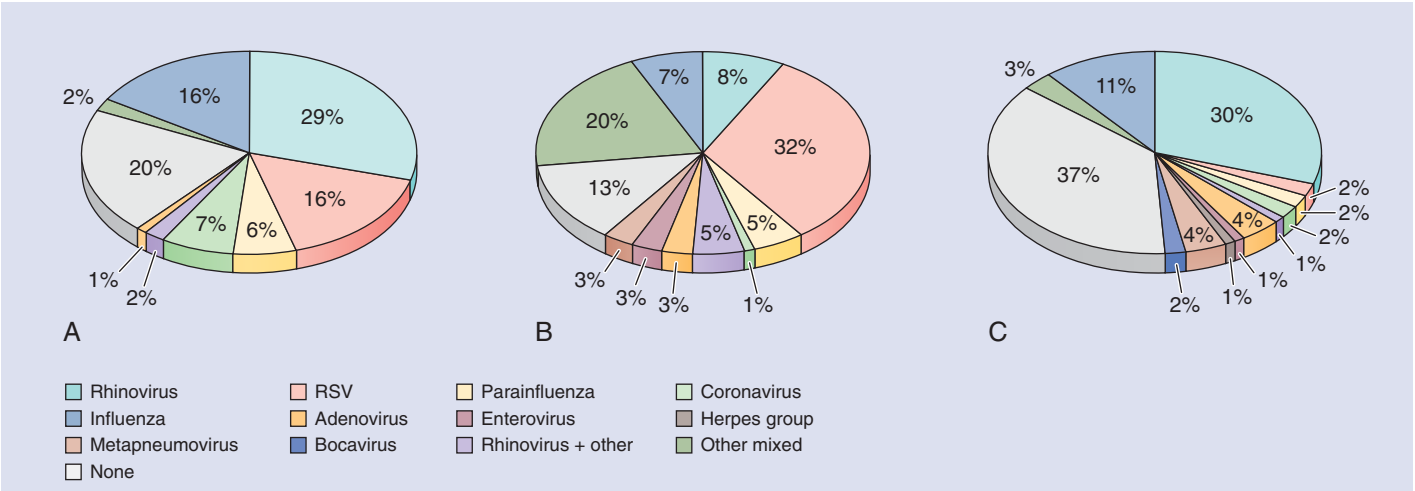

Figure 31-1 Three studies of virus isolation in childhood respiratory tract infection (RTI) over winter using molecular virology. Data sources and details are as follows: **A,** Legg et al.[11] *Denominator:* 123 RTIs in a cohort of 88 infants with at least one atopic parent, followed in Southampton, UK. *Specimens:* nasal lavage. *Virology methods:* individual RT-PCR for six virus groups including picornavirus (not specifically identified as rhinovirus), *M. pneumoniae*, and *C. pneumoniae*. **B,** Jennings et al.[5] *Denominator:* 75 children (65 under 12 months old) presenting to hospital in Christchurch, New Zealand, with acute respiratory illness suggesting lower RTI. *Specimens:* nasopharyngeal swabs. *Virology methods:* PCR/RT-PCR for 11 viruses as well as immunofluorescence and viral culture. **C,** Arden et al.[12] and personal communication, Ian Mackay. *Denominator:* 315 respiratory specimens obtained from people (1 day to 80 years old, 79% under 5 years old) presenting with RTIs to Brisbane hospitals, selected from all four seasons in 2003-2004. *Specimens:* not described. *Virology:* immunoassay, culture, and 17 PCR/RT-PCR assays.

children with LRI.[5] All of the common respiratory viruses have been identified as contributing to multiple infections. They have been recognized more frequently in younger children (≤4 years) and in hospitalized children. The presence of more than one virus may result in more severe or prolonged infection.[15,23,24] Alternately, because young children are immunologically naïve and experience a median of 4.4[25] to 5.5[26] respiratory illnesses per year and because viral shedding is commonly prolonged in young children, a continuum of residual virus or viral nucleic acid may be being detected.

Epidemiology

PERIODICITY AND SEASONALITY

Both the periodicity and the seasonality of viruses that cause respiratory tract infections are well established in temperate climates[3,11,26] (Fig. 31-2; also Fig. 31-1). Most viruses circu-

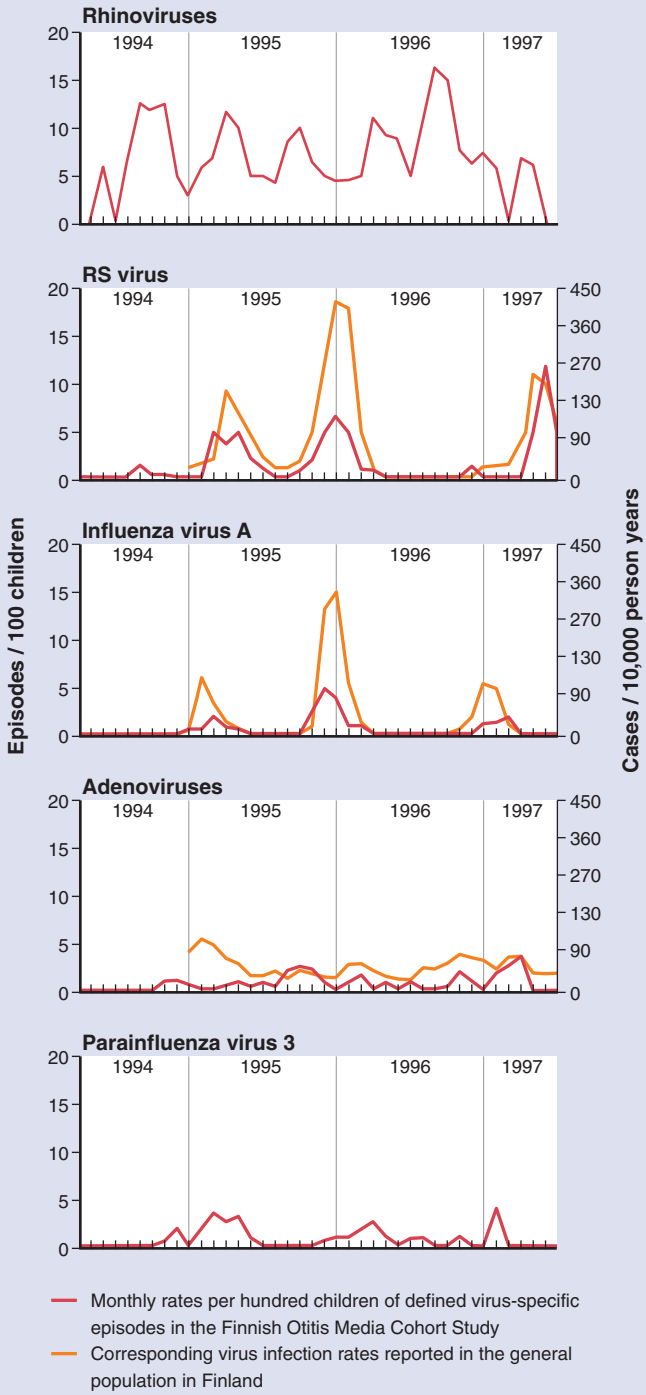

Figure 31-2 Monthly rates per 100 children of defined virus-specific episodes in the Finnish Otitis Media Cohort Study (*red lines*). This was a population cohort study. Corresponding virus infection rates (cases per 10,000 person-years) that were reported in the general population in Finland are also shown (*yellow lines*), although data for rhinoviruses and parainfluenza viruses were not available. (From Vesa S, Kleemola M, Blomqvist S, et al: Epidemiology of documented viral respiratory infections and acute otitis media in a cohort of children followed from two to twenty-four months of age. Pediatr Infect Dis J 20:574-581, 2001. Used with permission of Lippincott Williams & Wilkins.)

late in a community every year; however, some, especially influenza type B and the parainfluenza viruses, may cause epidemics at biennial or longer intervals.[3] Different viruses also predominate in a community during different seasons of the year; overlap invariably occurs and the actual timing and severity of each outbreak or epidemic can vary from year to year. In tropical climates, seasonality also exists. In these regions, RSV occurs predominantly in the rainy season, whereas influenza activity occurs throughout the year with a marked peak in activity during the dry season and a lesser peak during the rainy season.[27,28] Seasons of both higher and lower temperature have been associated with these viruses in different countries.[27] The reasons for the seasonality of respiratory virus infections and their variation by latitude are not clear. More important than the environmental conditions themselves may be their effect on behavior. Seasons when people spend more time indoors, in closer contact with other people (colloquially called "closed-in season" in some regions), will favor more rapid person-to-person transmission.

AGE

Respiratory viruses cause infections in children at specific ages. RSV causes the most severe LRI in children less than 1 year of age, with a peak occurring at a mean age of 3 months.[29] The peak age for hMPV infection is later than that for RSV,[30] but the majority of children have had clinical or subclinical infection by 2 years of age. Similarly, hPIV infections occur at an older peak age than RSV. Human parainfluenza virus-1 causes LRIs predominantly in infants aged 7 to 36 months, with peak infection occurring in the second and third years of life. The peak infection of hPIV-2 occurs in the second year of life, but hPIV-3 differs in that it infects infants younger than 6 months and most children experience infection in the first year of life. All age groups are at risk of infection from influenza type A and B viruses, but preschool-age children in day care and school-age children have the highest infection rates.[31] The very young, the elderly, and those with chronic conditions experience more severe disease. Rhinoviruses and coronaviruses commonly cause URI and infect individuals many times throughout their lives. Rhinoviruses are also clearly associated with LRI in children, but their role remains to be elucidated.[32]

Signs and Symptoms

The common respiratory viruses are often associated with specific clinical syndromes, although most can cause infection at any level in the human respiratory tract.

RSV is clearly the most important pathogen associated with bronchiolitis and pneumonia in infancy,[33] but it can infect all age groups, causing influenza-like illness.[34]

Infection of young children with *hMPV*, a newly described virus, causes illness that resembles hRSV bronchiolitis but also upper respiratory tract disease and diarrhea with fever.[13,35-38] Metapneumovirus now surpasses the parainfluenza viruses as the second most common cause of bronchiolitis and pneumonia among young children.

The *parainfluenza viruses* (hPIV 1-4) are also an important cause of LRIs and regularly cause pneumonia, bronchiolitis, and croup among infants and young children. The most frequent are hPIV-1 and hPIV-2 infections. hPIV-1 is most

commonly associated with croup, whereas hPIV-3 is an important cause of bronchiolitis and pneumonia in young infants. hPIV-2 is most commonly associated with croup, but all respiratory syndromes have been described. Studies rarely identify hPIV-4, although this virus has also been associated with all respiratory syndromes.[39]

Influenza viruses can cause any of the typical respiratory syndromes. Very young infants often present with fever only and no specific lower respiratory tract symptoms. School-age children and adolescents most often present with symptoms of classic influenza (i.e., febrile tracheobronchitis with myalgia and cough).[1]

The most common lower respiratory syndrome caused by *adenoviruses* is pneumonia, but all syndromes can occur.[40] Damage to bronchial architecture can occur with certain adenovirus strains, leading to life-threatening infections, and to bronchiolitis obliterans and bronchiectasis.

Rhinoviruses are the most ubiquitous respiratory pathogens. They cause the majority of cases of the common cold and may also commonly be associated with LRIs in children and adults.[32]

The *coronaviruses* (hCoV-229E and hCoV-OC43) are a frequent cause of URIs in children and adults.[41] Human *bocavirus*[42] and the newer coronaviruses (hCoV-NL63 and hCo-HKU1)[16,19,43] have been associated with respiratory tract infection in children, but their epidemiology remains to be fully elucidated.

ACUTE LOWER RESPIRATORY TRACT INFECTION

Scope and Limitations of Epidemiologic Study of Acute Lower Respiratory Tract Infection

DEFINITIONS AS USED IN THIS SECTION

Pneumonia: Inflammation of the lung with consolidation.[44] The term is usually used to indicate infection (most commonly bacterial or viral) of the lung parenchyma resulting in obliteration of alveolar air space by purulent exudate.

ARI or clinical pneumonia: These terms are commonly used in studies in developing countries for a clinical diagnosis of infection of the lower respiratory tract (below the larynx) based on the three signs of fever, cough, and rapid breathing. Other signs, such as grunting, indrawing, bronchial breathing, auscultatory crackles, etc., may or may not be present.

Community-acquired pneumonia (CAP): This term is most commonly used in studies in developed countries and usually includes a radiological finding of pneumonia. Used in distinction to hospital-acquired pneumonia, which follows injury, surgery, immobility, or immunosuppression or is due to unusual hospital pathogens.

To prove a diagnosis of "pneumonia" according to the first, pathologic definition requires proof that there is infection of the lung parenchyma and proof that there is airspace consolidation. The definition of ARI or clinical pneumonia, on the other hand, relies on clinical signs only and requires no such proof. The chief difficulty in studying cases of pneumonia, especially for epidemiologists, is that of reconciling these two definitions. Why is this important? When we describe the epidemiology of clinical pneumonia we need to know:

- What is the relationship between the condition we are describing and the more objective pathologic entity of pneumonia? *(Validity)*
- How confident are we that the studies we collect in our description are identifying the same condition? *(Reliability)*

The difficulties inherent in answering these two questions include the following.

1. *Limitations of identifying the organism:* Clinical signs and symptoms provide only a limited guide to the many possible organisms causing a respiratory infection. Different organisms require different types of sample and different specialized laboratory identification methods, few of which are in routine use, even in developed countries. For example, sensitive detection of RSV, *Streptococcus pneumoniae*, and *Mycobacterium tuberculosis* requires, respectively, immunofluorescent antigen detection on nasopharyngeal swab or aspirate, bacterial culture of lung biopsy tissue, and inoculation of bronchoalveolar lavage or gastric aspirate specimens into liquid broth with subsequent confirmation by PCR speciation.
2. *Limitations of identifying consolidation:* Chest radiography accurately identifies established pathologic consolidation but may miss early infection. However, as with microbial diagnosis, radiology is not routinely necessary for clinical management and is not consistently performed during respiratory infections.
3. *Limitations of availability of facilities and expertise:* Clinical, laboratory, and radiology facilities and diagnostic expertise are distributed in a very patchy fashion throughout the world. In many parts of the developing world, diagnosis and case management rely on poorly resourced village health workers with the support of a central clinic. Often, these are the regions with the highest incidence, morbidity, and mortality from childhood respiratory infection.

THE WORLD HEALTH ORGANIZATION CASE MANAGEMENT GUIDELINE

The difficulties and limitations of identifying ARI by microbial cause and radiologic consolidation, particularly in developing countries, have forced epidemiologists to develop tools using clinical pattern recognition to estimate the burden of respiratory disease. The World Health Organization (WHO) guideline for the management of ARIs and pneumonia (Fig. 31-3) was developed by Shann and others[45,46] in Papua, New Guinea, from 1980 onward. The aim was a simple step-by-step instruction in recognizing and treating respiratory infection, requiring minimal training, and usable by health workers in developing countries. By 1994, 130 developing countries were using the protocol with or without modification.[47] The guideline has been incorporated into the global Integrated Management of Childhood Illness (IMCI) program,[48] which had been adopted by 81 developing countries by 2000. For these reasons, the WHO guideline has become an important tool for measuring the incidence and mortality due to ARI.

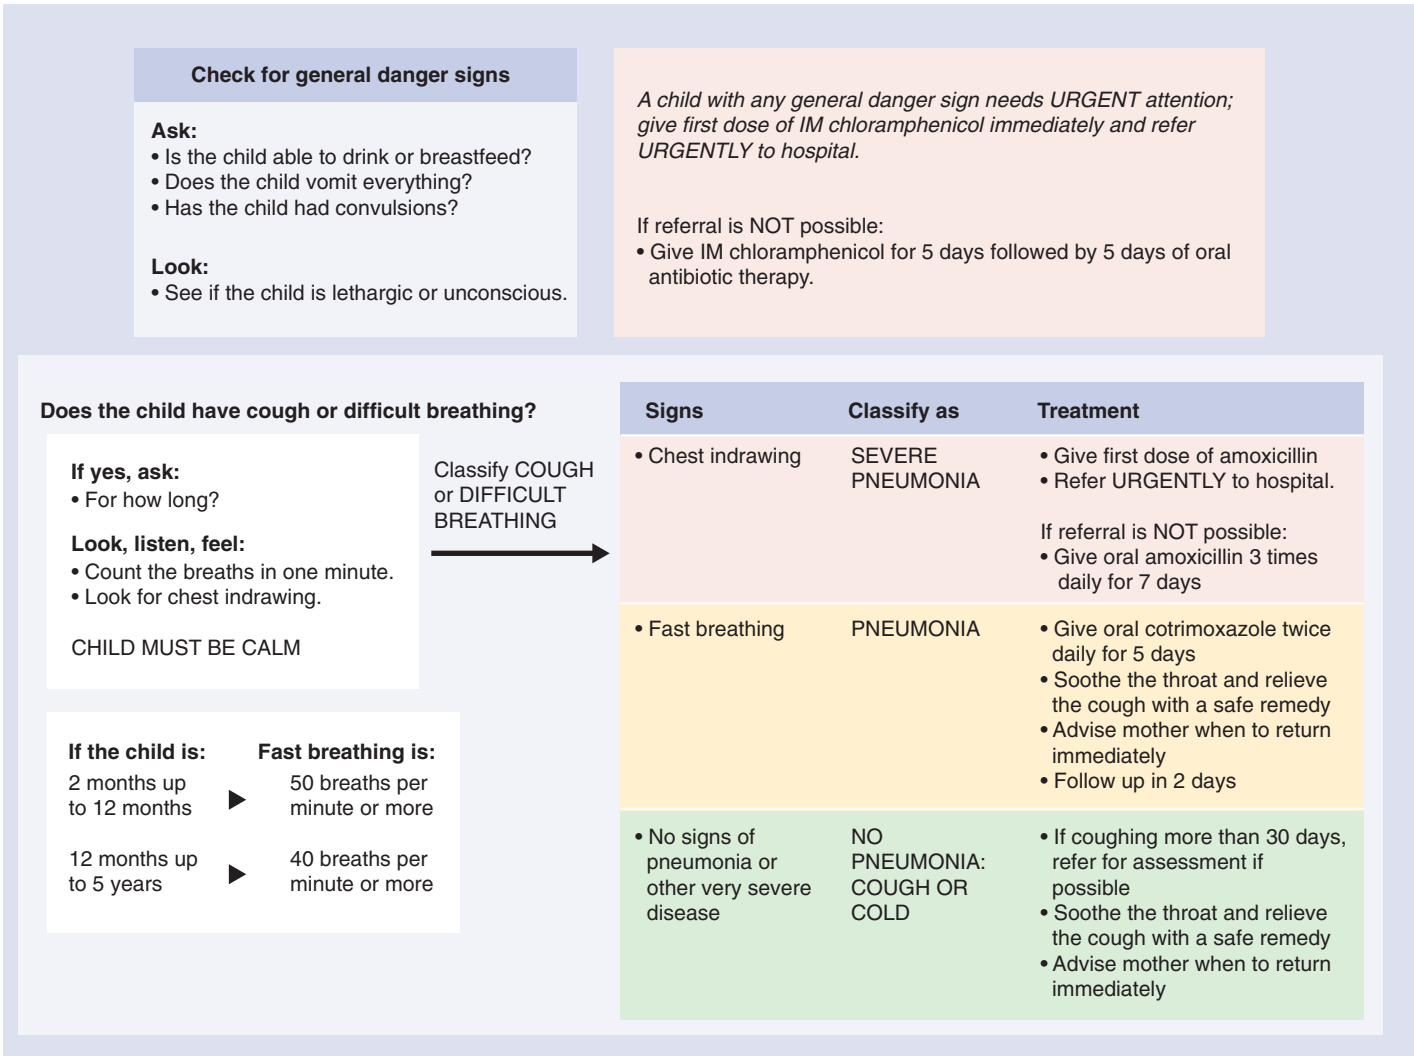

Figure 31-3 The modified WHO case management guideline for acute respiratory illness. (Used with permission. This chart and its explanation can be found at http://www.who.int/child-adolescent-health/Emergencies/ARI_chart.pdf.)

STRENGTHS AND LIMITATIONS FOR EPIDEMIOLOGY STUDIES IN THE WHO GUIDELINES

The strengths of the WHO case management guideline for epidemiological study of ARI are as follows:

- Minimal training required, needing no specialized facilities; therefore, low cost and wide applicability across geopolitical and socioeconomic boundaries
- Proved effective as a basis for management and reducing mortality

A meta-analysis of nine community-based trials[49,50] has shown that application of the WHO case management system reduced pneumonia mortality by 36% and total mortality by 24% in the 0- to 4-year-old age group (Fig. 31-4). The impact is most likely due to improved recognition of antibiotic treatable pneumonia due to *S. pneumoniae* and *H. influenzae*, but identification of malnutrition and other health factors may also contribute.

Compared to a radiologic definition of pneumonia, the WHO guideline lacks specificity due to:

1. Lack of distinction between viral bronchiolitis, virus-associated asthma, and viral or bacterial pneumonia
2. Possible inclusion of the following:
   - Measles and malaria in high prevalence areas, because they can also cause rapid breathing or may be comorbid with pneumonia[51-53]
   - Bacteremia due to nontyphoidal salmonella,[54,55] despite lack of evidence of lung tissue infection due to these organisms[56]
   - Any other cause of rapid breathing such as cardiac failure[57]
3. Respiratory rate, a key element of the WHO criteria, may be raised by increased body temperature[53,58] and high altitude[59] and lowered by malnutrition.[47,60]

In two studies in The Gambia[61] and Peru,[62] radiographs confirmed pneumonia in 24% and 36% of cases, respectively, identified by WHO criteria.

THE "VERBAL AUTOPSY": USE AND LIMITATIONS IN MORTALITY ESTIMATES

The "verbal autopsy," commonly used for gathering mortality data in developed countries, consists of a questionnaire (including the WHO criteria for ARI) administered to families about the final illness. This is a simple method of obtain-

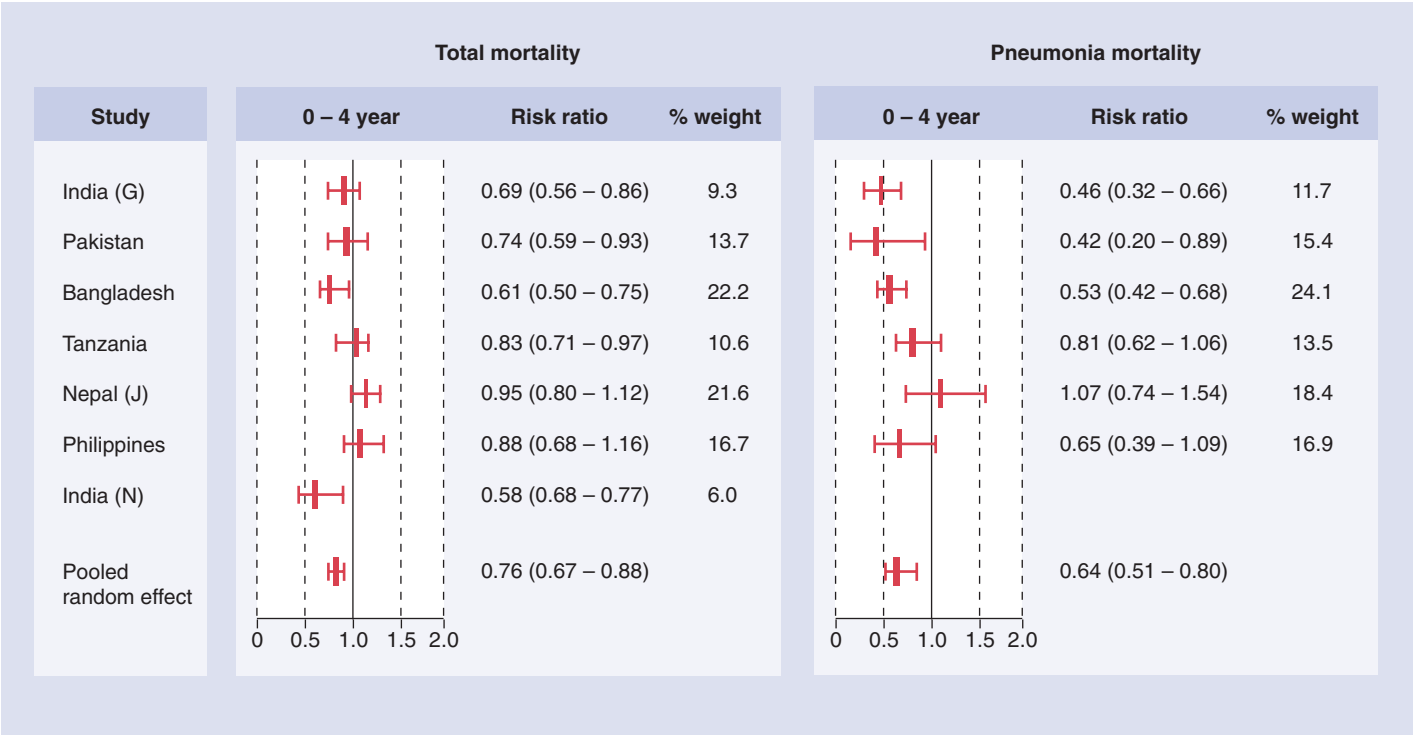

Figure 31-4 Risk ratio and 95% confidence interval for reduction in total and pneumonia mortality in children 0 to 4 years old, showing estimates in individual studies and random effects, pooled estimates, and weights for each study. Letters in study column refer to study locations (G, Gadchiroli, India; J, Jumla, Nepal; N; Navangwal, India). See source article for complete study references. (From Sazawal S, Black RE: Effect of pneumonia case management on mortality in neonates, infants, and preschool children: A meta-analysis of community-based trials. Lancet Infect Dis 3:547-556, 2003.)

ing circumstantial data regarding causes of death without the cultural problems often associated with medical autopsy. Verbal autopsies have a range of reported sensitivity for pneumonia of 28% to 72% and specificity of 60% to 90%.[49] Limitations of the verbal autopsy are similar to those listed for the WHO guideline; such as possible inclusion of deaths from malaria (where prevalent) among deaths from ARI[63] and frequent confounding of cause of death by comorbidities such as malnutrition, measles, or human immunodeficiency virus (HIV) infection in poor countries.[49] ARI is an associated cause or final mode of death even more often than it is a direct cause of death.[64]

LIMITATIONS IN COMPARING EPIDEMIOLOGY IN THE DEVELOPING VERSUS THE DEVELOPED WORLD

We should bear in mind the sensitivity and specificity of the tool used when comparing data. Compared with children in developed countries, children in developing countries have high exposure to risk factors, high rates of bacterial infection, low access to medical care, and high incidence of and mortality from pneumonia. The WHO criteria for ARI have been deliberately chosen to have high sensitivity, accepting the cost of lower specificity. This may have the effect of exaggerating differences in estimates of ARI between developed and developing countries. On the other hand, many researchers state that their best estimates of ARI in developing countries remain conservative and are likely to underestimate the rates. These differences in method should be kept in mind when discussing the estimates below.

OTHER LIMITATIONS OF METHODS

Global estimates and national estimates of ARI incidence and mortality usually depend on data derived indirectly by curve fitting, extrapolation, and applying one proportion to another. Studies at different time points and using different methods may be included. Many of the incidence studies go back to the 1980s,[65] whereas mortality estimates are based on more recent total and cause-specific mortality data.

LIMITATIONS OF AGE GROUPS STUDIED

The majority of international studies of the epidemiology of ARIs deal with children under the age of 5 years. There are fewer data for older age groups; nonetheless, several studies[66,67] have shown a decreasing incidence with age. For the remainder of this section, we confine our discussion to the child less than 5 years of age.

Incidence of Acute Lower Respiratory Tract Infection

Rudan and associates[65] recently estimated worldwide incidence for ARI in children under 5 years of age. They performed a meta-analysis of 28 studies completed mostly in the late 1980s in developing countries. They sought to confirm the directly reported rates in these studies with indirectly calculated rates using case-fatality, rates of severe pneumonia, and case-fatality of severe pneumonia. Their best estimate for the incidence of ARI in the developing world was 0.29 events per child-year, or 150.7 million new cases of ARI per

year, of which 11 to 20 million are severe enough to require hospital admission.

Rudan and associates were unable to find studies for the developed world that used active surveillance and WHO criteria for ARI. They based their estimate of 0.026 event per child-year (or 2.1 million cases of pneumonia per year) on four large population-based studies of community-acquired pneumonia in the United States and Europe.

The recent UNICEF/WHO report on pneumonia[68] indicates that in 2004, 15 countries accounted for three quarters of childhood pneumonia cases worldwide, amounting to approximately 113 million cases. These countries, and the estimated number of cases in 2004, were India (44 million), China (18 million), Nigeria and Pakistan (7 million each), Bangladesh and Indonesia (6 million each), Brazil and Ethiopia (4 million each), Democratic Republic of the Congo and Philippines (3 million each), followed by Afghanistan, Egypt, Mexico, Sudan, and Vietnam (2 million each).

Mortality Due to Acute Lower Respiratory Tract Infection

By country, the percentage of annual deaths of children under 5 years that are due to ARI is related in a logarithmic fashion to the total under 5-year mortality (Fig. 31-5).[49] Figure 31-6 shows the estimated percentage range of deaths from lower ARI among children of each country in 2000.[49] These data were estimated by extrapolating to the year 2000 the 1999 WHO total under-5 mortality data by country, and using the blue fitted curve in Figure 31-5 to estimate the percentage of deaths due to ARI. The authors estimated that between 1.6 and 2.2 million children died of ARI in 2000 and that 40% of these deaths occurred in Africa and 30% occurred in Southeast Asia. Mortality from ARI in excess of 25% of total under-5 deaths was estimated for Afghanistan, Sierra Leone, and Niger. The regions with the lowest proportions of deaths due to ARI were in Western Europe, North America, and Australasia. Other respiratory deaths in young children, estimated for 1998, fell into the following categories: upper respiratory infection and otitis media—37,000, neonatal pneumonia—215,500, pertussis—287,000, measles—594,700, and AIDS-associated ARI—87,500.[69]

Table 31-2 gives an updated summary of mortality due to ARI from the WHO 2005 report[70] by region averaged for the years 2000 to 2003. The numbers have slightly increased but are otherwise similar to those of Williams and associates.[49] Table 31-3 gives a summary of global statistics for ARI in children under 5 years of age, divided into those for the developing and those for the developed world. These figures are based on Rudan and colleagues[65] and the recent UNICEF/WHO report.[68]

If for the moment we ignore the potential errors due to the limitations mentioned above, it would seem that 90% of the child deaths from ARI occur in the developing world, with 75% of them in Africa and Southeast Asia. ARIs constitute about 20% of total mortality in the developing world but only 2% of total mortality in the developed areas of Europe, the Western Pacific, and the Americas. The differences in estimation and comparison are unlikely to have caused such large discrepancies.

Risk Factors for Acute Lower Respiratory Tract Infection

Table 31-4 shows well-established risk factors for developing ARI or pneumonia. Risk factors such as malnutrition are prevalent in developing countries, whereas vehicle emissions may be higher in developed countries.

Risk factors for dying from ARI (almost all from pneumonia) include most of the same factors, but comorbid diseases (especially diarrhea, malaria, measles, tuberculosis, and HIV infection) further increase the mortality risk.[49,71] Lack of adequate health care is also an important associated factor in

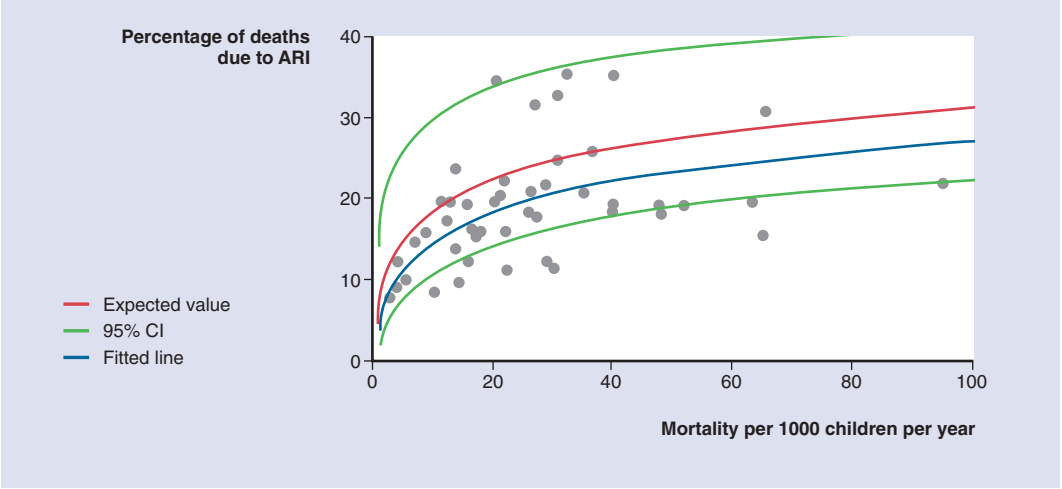

Figure 31-5 Percentage of deaths due to acute lower respiratory tract infection, adjusting for bias in verbal autopsies. The *blue curve* is a weighted log-linear fit to the data points, which are assembled from a number of studies. The *red* and *green curves* are (respectively) expected values and their 95% confidence intervals after correcting for the calculated underestimation and variability of reporting deaths from acute lower respiratory tract infection because of the use of verbal autopsies in many of the studies. (From Williams BG, Gouws E, Boschi-Pinto C, et al: Estimates of world wide distribution of child deaths from acute respiratory infections. Lancet Infect Dis 2:25-32, 2002.)

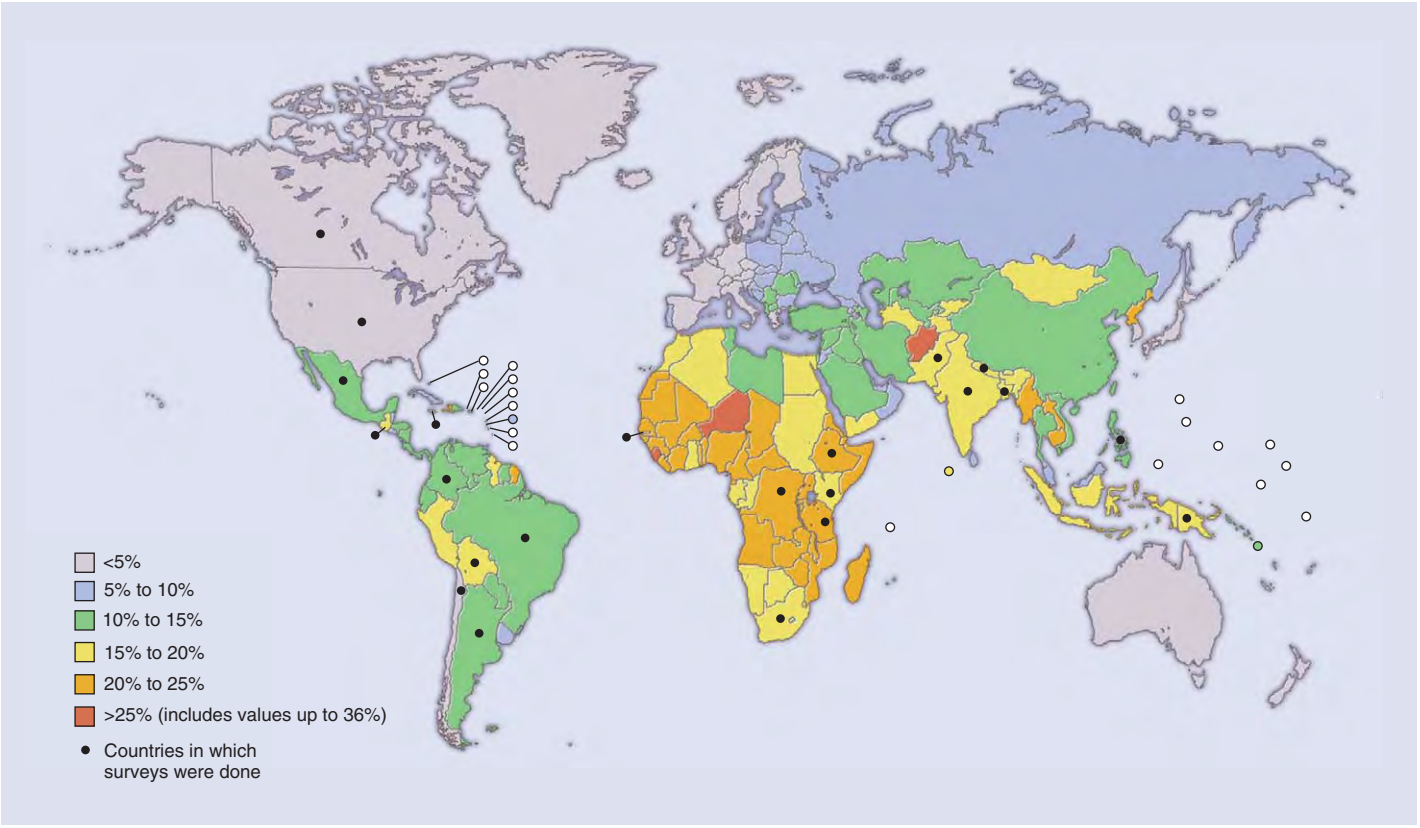

Figure 31-6 Estimates of the percentage of childhood deaths that are attributable to acute lower respiratory tract infection by country in 2000. The last category includes values up to 36%. deaths from pneumonia. Geography, education, access, and accessibility are all factors in the adequacy of health care. Where there is access to health care, the cost of life-saving treatment for pneumonia is relatively small.

According to a *Lancet* editorial in 2003,[72] 26% of the world's children under the age of 2 do not receive basic diphtheria, tetanus, and pertussis vaccination, 58% do not receive exclusive breastfeeding for the first 4 months of life, 25% have malnutrition, and 40% do not receive appropriate antibiotic treatment for pneumonia. These risk factors are of course bound together by many strands within communities. As Bawaskar[73] has pointed out, illiteracy is a major factor in infant malnutrition, and low income and illiteracy are enmeshed with impoverished, unsanitary and crowded living conditions, high rates of HIV infection, and lack of access to health care.

Table 31-2
WHO Report 2005: Data for 2000-2003 on Deaths Due to Acute Respiratory Infection (ARI) under 5 Years of Age

	ARI Deaths by Region	ARI as Proportion of All Deaths in Each Region	Distribution of Global ARI Deaths by Region
World	2,027,000	19%	100%
Africa	924,000	21%	45%
The Americas	54,000	12%	3%
Canada, United States	1000	2%	
Rest of the Americas	53,000	14%	
Southeast Asia	590,000	19%	29%

MALNUTRITION AND ACUTE LOWER RESPIRATORY TRACT INFECTION

Black and colleagues[71] have estimated that as many as 50% of the deaths from ARI/pneumonia in children are attributable to being underweight (Fig. 31-7). A study in Costa Rica in the early 1970s documented a 12-fold increased risk (71% versus 6%, respectively) of pneumonia among malnourished compared with normally nourished children.[74]

Rice and coworkers[75] presented a comprehensive review of the recent literature regarding the effects of malnutrition on death from diarrhea, ARI, malaria, and measles. They summarized three community studies and 12 facility-based studies. The results were consistent across all studies showing a major association between death from ARI and low weight-for-age (W/A) Z-scores or median W/A less than 80% of median. The odds ratios, risk ratios, or relative risks of dying from respiratory infection compared with that for normally nourished children ranged very widely from single figures up to an odds ratio of 26 for W/A Z-score = –2.0 (compared with >0) in a Brazilian study and an adjusted relative risk of 27 for children whose W/A was less than 60% of the local reference median (compared to ≥90%) in a Philippines study. All studies that analyzed risks by degree of malnutrition found a dose-response effect.

Figure 31-8, taken from Victora and colleagues[76] and based on Kirkwood and colleagues,[77] shows that 84% of deaths from pneumonia occur in the first 18 months of life and indicates the potential impacts of nutritional problems at different ages. Victora and colleagues' estimated reduction in pneumonia mortality by region and by intervention is shown in Table 31-5.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACUTE LOWER RESPIRATORY TRACT INFECTION

Graham and coworkers[78] have summarized recent data for the respiratory effects of HIV infection in African children. Approximately 90% of the HIV-infected children in the world come from sub-Saharan Africa. HIV infection greatly increases the incidence of and mortality from pulmonary disease, mostly in children under 5 years. Conversely respiratory disorders are the most common cause of death in HIV-infected African children. For children hospitalized for severe pneumonia, HIV-infected children in Malawi were three times as likely to die, and in South Africa six times as likely to die, as were non–HIV-infected children.

The high incidence of opportunistic infections (such as *Pneumocystis jirovecii*—formerly known as *Pneumocystis carinii*) of the respiratory tract in HIV infection is well

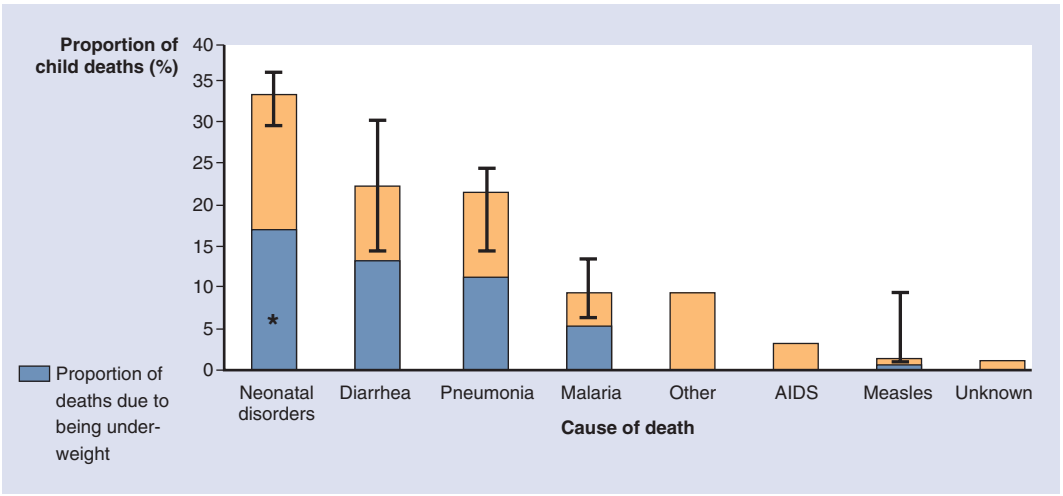

Figure 31-7 Distribution of global deaths by cause. *Bars* indicate uncertainty bounds. *Work in progress to establish the cause-specific contribution of being underweight to neonatal deaths. known. The common pathogens found in HIV-infected children with pneumonia are, in the United States, *S. pneumoniae* and *Salmonella* spp., and in Africa, *S. pneumoniae*, *H. influenzae*, *Staphylococcus aureus*, *Escherichia coli*, *Klebsiella* spp., and nontyphoidal *Salmonella* spp.[78]

HIV infection is commonly associated with other risk factors for pneumonia including poverty and malnutrition, such as children with marasmus.[78] As a result, it can be difficult to determine the relative importance of the HIV infection compared with other risk factors in determining the nature and outcome of pneumonia in regions with high HIV prevalence.

Epidemiology and Prevention of Pneumonia Due to *Streptococcus pneumoniae* and *Haemophilus influenzae*

Among causes of ARIs in young children, the two organisms responsible for the largest number of cases (and 70% of the deaths)[57] are *S. pneumoniae* and *H. influenzae*, the latter including nontypable strains, type B (Hib), and sometimes other typable strains.[79] We now have the means to prevent pneumonia due to Hib and to many strains of *S. pneumoniae*. Madhi and colleagues[80] demonstrated that Soweto children (both HIV positive and negative) immunized with pneumococcal conjugate vaccine had 31% fewer episodes of virus-associated pneumonia compared with placebo controls. This seems to imply that virus-associated pneumonia commonly involves mixed infections with bacteria.

STREPTOCOCCUS PNEUMONIAE

Isolation rates of *S. pneumoniae* in pneumonia are very dependent on sample and identification method and are highly variable in studies in developing and developed countries.[79,81] Berman[82] reported an overall isolation rate of 27% in 14 studies, and 60% of the studies reported isolation rates greater than 30%. The estimated incidence of pneumonia due to *S. pneumoniae* also varies greatly. Incidence rates from 18.1 to almost 200 per 100,000 children per year have been described in developing countries.[79,83,84] Incidence rates estimated in Southern California were 17 per 100,000 per year in 1996.[67,85] Serotypes 1, 2, 5, 7, 9, 14, 15, 18, 19, and 23 are common in both developing and developed countries.[79] Despite the frequency of isolation of *S. pneumoniae*, there are few specific estimates of pneumonia mortality due to this organism.

The peak season for pneumococcal pneumonia in developed countries is winter[66,86] (Fig. 31-9), closely corresponding to peak isolation rates of RSV and influenza. In tropical countries, studies have reported either little seasonal variation[84] or small peaks in the hot season and the monsoon season[83] (Fig. 31-10). The peaks observed could be explained either by secondary infection on the heels of seasonal viral infections or (in parallel to virus infections) by increased interpersonal transmission of bacteria during seasons when people spend more time indoors.

Studies in developing countries have indicated that both total child mortality and mortality due to pneumonia could be lowered by the use of pneumococcal vaccines. Black and coworkers,[87] in a double-blind randomized controlled trial of heptavalent pneumococcal conjugate vaccine in California, reported a 32.2% reduction in pneumonia with positive radiographs in children under 1 year, 23.4% in children under 2 years, and 9.1% in children over 2 years old. Cutts and coworkers[88] have reported a randomized double-blind placebo controlled trial of nine-valent pneumococcal conju-

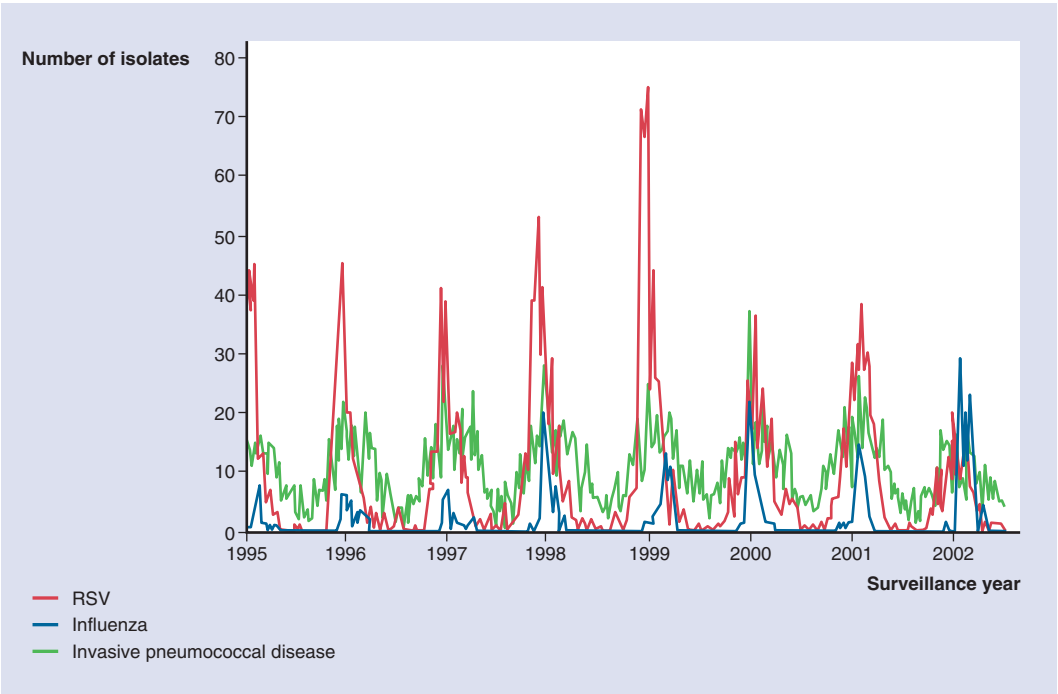

Figure 31-9 Weekly isolation of winter respiratory viruses RSV (*red line*) and influenza (*blue line*) and frequency of invasive pneumococcal disease (*green line*) from January 1, 1995, through June 30, 2002. Figure 31-10 Seasonal distribution of pneumococcal pneumonia in 103 children in Upper River Division, The Gambia, 1989 to 1991. (Data from O'Dempsey TJ, McArdle TF, Lloyd-Evans N, et al: Pneumococcal disease among children in a rural area of west Africa. Pediatr Infect Dis J 15:431-437, 1996. Used with permission of Lippincott Williams & Wilkins.)

gate vaccine in Gambian infants less than 1 year old. They estimated (based on intention-to-treat analyses) a reduction in first episodes of pneumonia of 6%, reduction of admissions to hospital of 13%, reduction of admissions due to potentially invasive pneumococcal disease of 19%, and reduction in all-cause mortality of 14%. Vaccine efficacy was 77% against invasive pneumococcal disease due to vaccine-related serotypes and 50% against invasive disease due to all serotypes.

HAEMOPHILUS INFLUENZAE

Levine and coworkers,[89] in a 1998 review, estimated that *H. influenzae* (all strains) caused 16% of all pneumonia deaths not due to measles or pertussis or 482,000 deaths from pneumonia each year in children under 5 years in developing countries. Peltola[90] conservatively estimated the annual prevaccination incidence of Hib pneumonia in children under 5 years in developing countries at 300 per 100,000 based on Gambian studies in the 1990s.[90,91] This represents 1.7 million cases and 220,00 to 400,000 deaths with a case-fatality rate of 13% to 24%. In developed countries, Peltola estimated a prevaccination incidence of 6 per 100,000, representing 5000 cases, 250 deaths, and a case-fatality rate of 5%.

Nontypable strains have been found to be as commonly or more commonly associated with pneumonia in several studies,[79,90] but only in developing countries. Levine and colleagues[89] reported that Hib accounted for a mean of 35% of all *H. influenzae* pneumonia cases in three studies of all *H. influenzae* pneumonias but for a mean of 71% of bacteremic *H. influenzae* pneumonias in eight studies. If most deaths occur in bacteremic pneumonia, as is supposed, then Hib may be responsible for up to 70% of the deaths from *H. influenzae* pneumonia in under-5 children.

Vaccination for *H. influenzae* type B has dramatically reduced all causes of invasive Hib in the developed world[92] (Fig. 31-11).

Trials of Hib conjugate vaccine in developing countries have included prospective case-control studies in Chile[93] and Brazil[94] and a double-blind randomized placebo controlled trial in The Gambia.[95] Vaccine efficacy in young children ranges from 21% to 31% against radiology-confirmed pneumonia from all causes in these studies. The Gambian study showed reduction of oropharyngeal carriage of Hib.[96]

Levine and co-workers in 1998[89] estimated the potential impact of routine immunization of infants with 3 doses of Hib conjugate vaccine in developing countries (Table 31-6). The estimates include all Hib disease (the majority being pneumonia and meningitis). They suggested that 60% of deaths and 67% of cases would be prevented if no herd immunity were operative. In the presence of herd immunity over 300,000 deaths (83% of deaths) and 2.5 million cases (85% of cases) might be prevented. Miller[97] estimated that among Asian countries, about 136,000 (87%) Hib deaths could be prevented annually with incorporation of Hib vaccine into the immunization programs at a cost of between 0.1% and 3.0% of per capita gross national product per child younger than 5 years. However, a recent Hib vaccine probe trial among 55,073 children in Lombok, Indonesia,[98] found no protective effect against radiology-confirmed pneumonia despite a protective effect against clinically defined pneumonia and against meningitis. Various reasons are discussed in the paper and the accompanying editorial.[99]

Conclusion

ARI and pneumonia contribute a massive burden of death and morbidity to young children and much more so in developing countries than in developed countries. Vaccination strategies to prevent disease are well proved for single-agent diseases with obligate human hosts. However, vaccine implementation, acceptance, and coverage are always going to offer challenges when different political, economic, health, and cultural systems have to be engaged. Other major factors that will be required to decrease the morbidity and mortality due to ARI in children must include the reduction or eradication of poverty, malnutrition, and HIV infection and improve-

ments in air quality through reduction of smoke exposure from cigarettes and biomass fuels.

EMERGING AND REEMERGING DISEASES

Infectious diseases are the leading cause of death among young people under the age of 50 years.[100] The complex matrix of these diseases from endemic diseases, which pose an ongoing threat, through to new emerging and reemerging diseases that present new challenges[101] is shown in Figure 31-12. Respiratory pathogens, including SARS, influenza, and tuberculosis, are some of the emerging and reemerging threats that have recently received or are receiving ongoing attention as global public health concerns. These infections, many of which are zoonotic in origin, are creating unprecedented challenges, and spurring the development of new approaches. The application of epidemiology simulation modeling to identify the best public health responses under a variety of conditions[102] and for specific interventions with pandemic influenza[103] are examples.

Influenza

GENERAL EPIDEMIOLOGY

Of all the viruses that infect the human respiratory tract, influenza viruses cause the predominant number of serious acute respiratory tract illnesses.[104] There are three types of influenza virus, A, B, and C, of which the influenza A and B

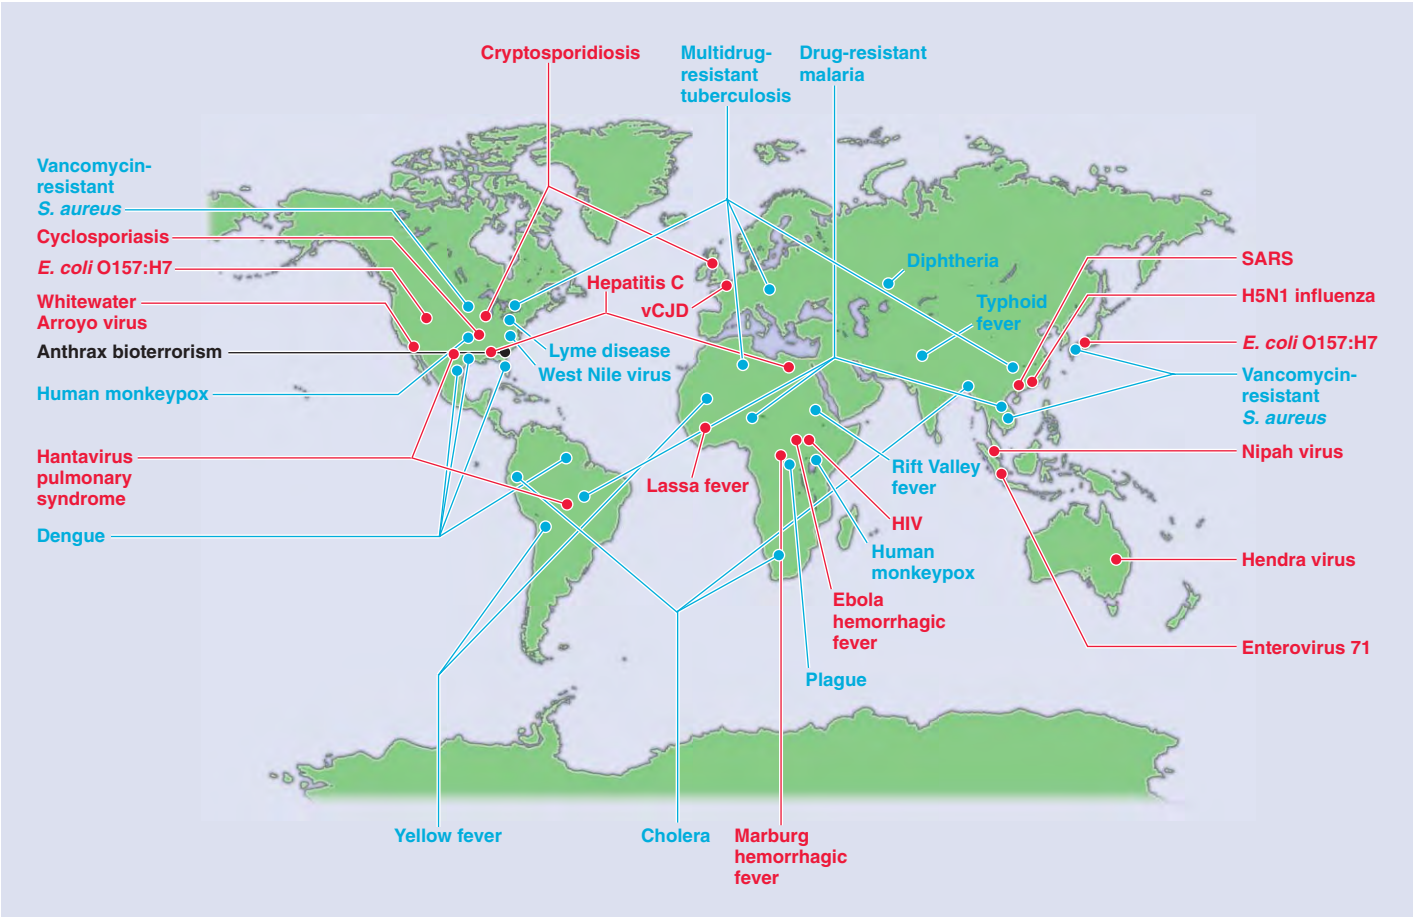

Figure 31-12 Global examples of emerging and reemerging infectious diseases. *Red* represents newly emerging diseases; *blue*, reemerging/resurging diseases; *black*, a "deliberately emerging" disease. (From Morens DM, Folkers SK, Fauci AS: The challenge of emerging and re-emerging infections diseases. Nature 430:242-249, 2004.)

viruses are clinically relevant in humans. Influenza B viruses have a human reservoir, whereas influenza A viruses have a reservoir in aquatic birds and are antigenically diverse. Influenza A viruses have two major antigenic surface proteins, the hemagglutinin (H) and neuraminidase (N). We recognize 16 different H antigens (named H1–16) and nine different N antigens (N1–9), and unique combinations of H and N antigens are called influenza A subtypes. All of these subtypes have been found circulating among wild aquatic birds, their primary natural reservoir. From time to time, these viruses cross the species barrier, with some becoming established in another avian or animal species. In the past century, the influenza A subtypes H1N1, H2N2, and H3N2 have been able to infect and establish sustained transmission among humans, whereas the H5N1 subtype has become established in domestic poultry (Fig. 31-13). The constant evolution of influenza A and B viruses occurs through the accumulation of mutational changes in the H and N antigens. This antigenic *drift* leads to the selection of new variants and regular epidemics of disease, while reassortment of the H and N genes of different influenza A subtypes (antigenic *shift*) leads to the emergence of a novel virus and pandemic influenza.[105] However, it is becoming clear that the emergence of human influenza virus lineages can occur through avenues other than drift and shift.[106]

EPIDEMIC INFLUENZA

Epidemics of influenza occur almost every year. They are caused by new variants of influenza A and B viruses that have evolved through antigenic drift, allowing them to evade the host's immune defenses. This requires regular updates of the composition in influenza vaccines. In countries with temperate climates influenza activity peaks during the winter months with influenza A epidemics occurring every 1 to 2 years and influenza B circulating every 2 to 4 years.

ATTACK RATES IN CHILDREN

Influenza incidence and illness are high in children. Attack rates can be 40% or more in preschool-aged children and 30% in school-age children, which is higher than the 10% to 20% rate commonly observed in young adults.[26,33,107-109]

DISSEMINATION

Children have an important role in spreading influenza. School provides an ideal environment for the spread of respiratory viruses, and school-age children serve as the main channels through which influenza A and B virus infections are introduced into households.[107,109,110] Exacerbations of COPD in adults were found to be correlated with epidemics of viral infections including influenza A and B in school children and to decline during school holidays.[111] In young children, influ-

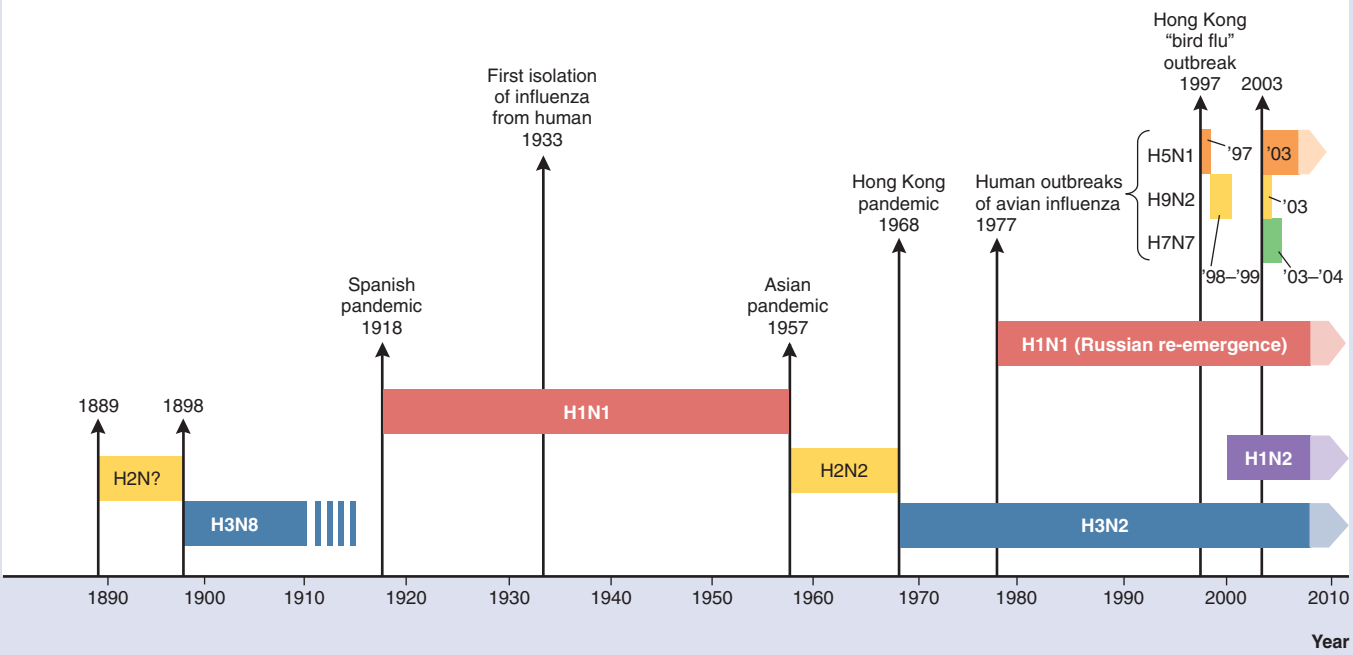

Figure 31-13 Time course of global spread of human influenza virus A subtypes and human outbreaks of avian influenza viruses. (Redrawn from Fauci AS: Emerging and reemerging infections diseases: The perpetual challenge. Acad Med 80:1079-1085, 2005.)

enza virus is detectable 1 to 3 days after infection and shedding often persists for 10 days to 3 weeks.[112]

HOSPITALIZATIONS

During childhood, influenza is the most significant cause of acute respiratory illness leading to hospitalization,[113] outpatient visits,[108] and courses of antibiotics in children of all ages.[114] Healthy children younger than 1 year are hospitalized at rates similar to those for adults at high risk for influenza.[115] The rate of hospitalization decreases with age. Similarly high hospitalization rates have been reported among children in the subtropics compared with those reported in temperate regions.[116]

PANDEMIC INFLUENZA

Human pandemics of influenza have been reliably described since the 16th century, with an average of three occurring every 100 years.[117] Over the 20th century, there have been the 1918-1919 "Spanish" H1N1 pandemic, which caused an estimated 20 to 50 million deaths, mainly in previously healthy persons aged 20 to 40 years old, and the 1957 "Asian" H2N2 and 1968 "Hong Kong" H3N2 pandemics, which caused large numbers of cases and a combined mortality estimated to be more than 3 million deaths, mostly in the very young, the elderly, and people with underlying chronic conditions (see Fig. 31-13).

Recovery of lung tissue from victims of the 1918 pandemic has allowed the isolation of viral RNA and the reconstruction of the complete 1918 pandemic virus in the laboratory.[118,119] These experiments support the hypothesis that the 1918 H1N1 virus was of avian origin and adapted to human infection and transmission. In contrast, the influenza viruses that caused the 1957 and 1968 pandemics are human-avian reassortant viruses, and this difference may be relevant to the severity of the 1918 pandemic.[120]

AVIAN INFLUENZA ASSOCIATED WITH HUMAN CASES

Human infections and outbreaks following interspecies transmission of highly pathogenic avian influenza viruses have rarely been reported before 1997.[121] Reports are increasing of human infections associated with direct or indirect contact with infected birds. In 1997, the infection of 18 humans, of whom 6 died, with an avian H5N1 virus raised the level of global concern of a possible human influenza pandemic. In 1999, H9N2 avian influenza infected two children in Hong Kong and there were other cases in mainland China. In 2003, H5N1 and H9N2 infections were confirmed in Hong Kong, while in the Netherlands, a large avian influenza outbreak involved an H7N7 virus. Up to 1000 cases among farmers and poultry workers occurred. Since late 2003, outbreaks of avian H5N1 have been reported among poultry in Southeast Asia.[122] Human infections and deaths were initially reported in Vietnam and Thailand. This virus has become endemic in domestic poultry in Asia and has spread globally after infecting migratory waterfowl.[123] Subsequently, there have been reports of human infections in an increasing number of countries. Clusters of human infection are small, suggesting that if human-to-human transmission is occurring, it is very inefficient.

As this H5N1 virus continues to circulate in and be spread by domestic and migratory avian species, there is an ongoing risk of human infection and a threat of the emergence of a human pandemic virus. Whether the H5N1 virus or one of the other potential pandemic subtypes (H2, H5, H7, or H9

viruses) will adapt to efficient human-to-human transmission remains unknown. Currently, no mechanism of prediction of the emergence of novel influenza A viruses exists, highlighting the importance of the ongoing global surveillance of animal and human influenza viruses by the WHO.

Severe Acute Respiratory Syndrome

GENERAL EPIDEMIOLOGY

SARS is an acute viral respiratory syndrome caused by a novel coronavirus, the SARS coronavirus (SARS-CoV), and recognized as a global threat in mid-March 2003. The virus is an animal virus that has crossed the species barrier to humans.[124,125] The first known cases are believed to have occurred in Guangdong Province, China, in November 2002.[126] Early cases were associated with occupational exposure to infected animals[127]; however, once the number of cases started to increase, health care workers and their close contacts were at greatest risk of infection. The epidemic was characterized by "superspreading events,"[128-130] which seeded outbreaks in Canada, China, Hong Kong, Taiwan, Singapore, and Vietnam (Fig. 31-14). By July 2003, the international spread of SARS-CoV presented a global public health threat resulting in 8098 SARS cases in 26 countries and 774 deaths.[131] The epidemic caused social and economic disruption in areas with sustained transmission of SARS, and on the travel industry internationally, in addition to the impact on health services directly.

Since July 2003, four sporadic community-acquired cases have occurred in Guangzhou, Guangdong Province, China,[132] while three incidents have been attributed to exposures in laboratories.[125,133]

RESERVOIR

The natural reservoir of SARS-CoV has been identified as the Chinese horseshoe bat.[134] Although many animals have been investigated as possible reservoirs,[124,135] bats are well suited to transmit zoonotic disease, as many people in Asia eat bats and use their feces for medicines.

CHILDREN

SARS runs a more benign and shorter clinical course in young children (less than 12 years of age) during the acute phase.[136] Infants born to mothers with the disease did not acquire the infection through vertical transmission. No deaths were reported in children.[137] Children appear to acquire the infection by close-contact household exposure to an infected adult.[138]

Tuberculosis

Tuberculosis (TB) remains a major global public health problem. It is estimated that in 2004, one third of the world's population was infected with the mycobacterium bacillus that causes TB and almost 4 million were smear positive.[139] A number of factors have facilitated the resurgence of tuberculosis. These include the advent of the AIDS epidemic, emigration from countries where prevalence of TB is high, noncompliance of patients, transmission in high-risk environ-

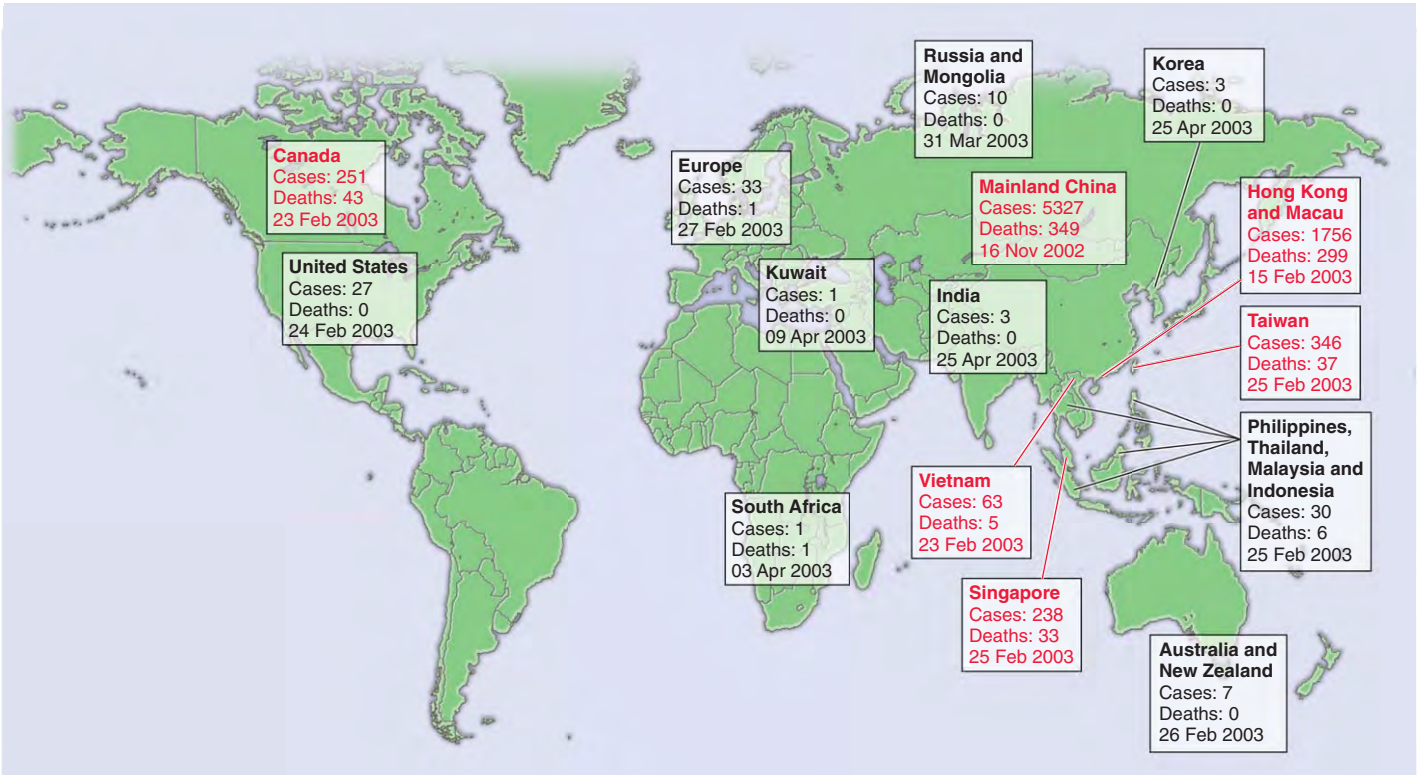

Figure 31-14 The global spread of SARS. The number of probable cases of SARS and the date of onset of the first case in each country (or group of countries) is denoted. The countries denoted in *red* are those where substantial local transmission occurred. (From Peiris JS, Guan Y, Yuen KY: Severe acute respiratory syndrome. Nat Med 10(12 suppl):S88-S97, 2004.)

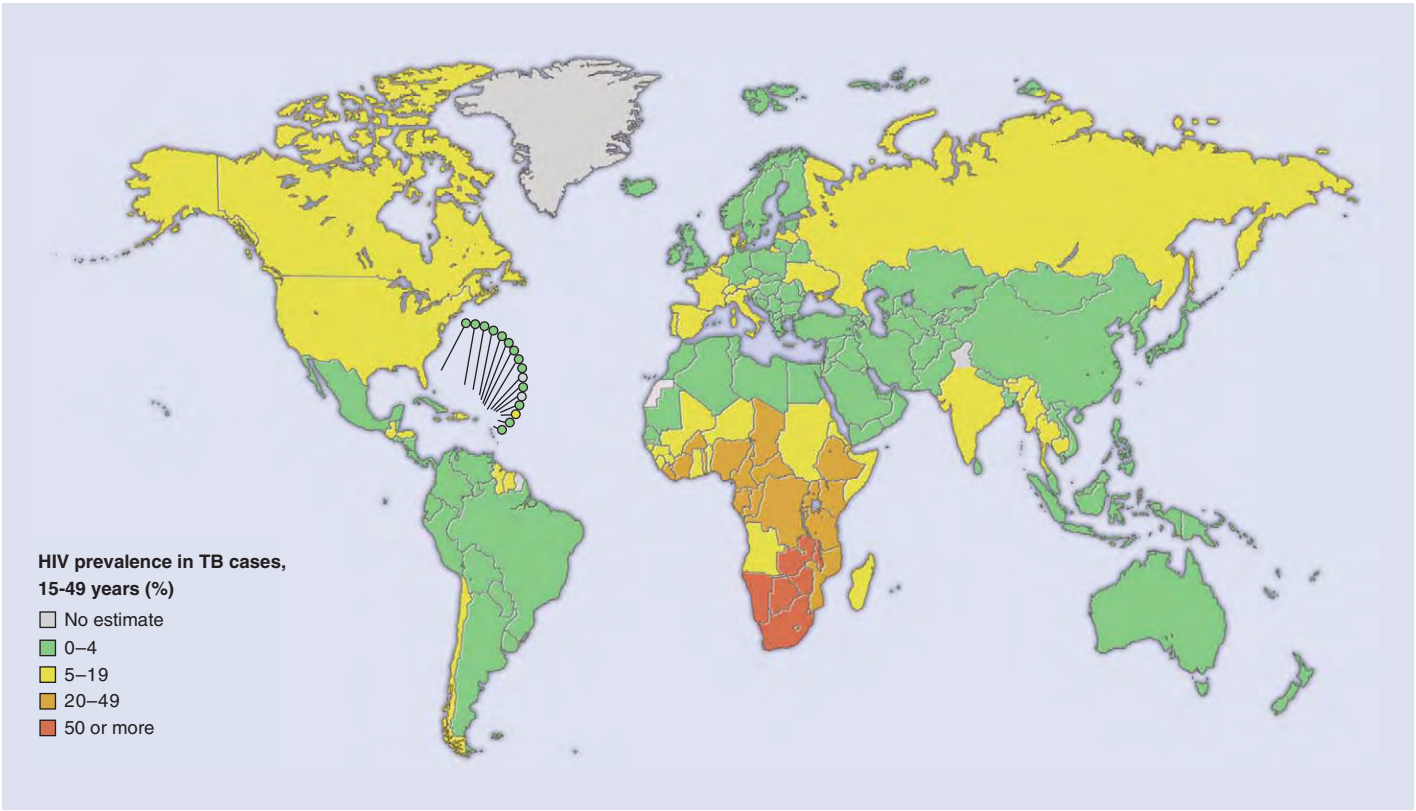

Figure 31-16 Estimated prevalence of HIV infection in TB cases, 2003. (From the Global Plan to Stop TB 2006-2015. Geneva, World Health Organization, Actions for Life, 2006.)

ments, and the coincident increase in the number of cases of multidrug-resistant tuberculosis (MDR-TB).

GLOBAL INCIDENCE

The estimated TB incidence globally is shown in Figure 31-15.[140] The largest number of cases occurs in the Southeast Asia region (190 cases per 100,000 population), which accounts for 33% of incident cases globally; however, in sub-Saharan Africa, the incidence per capita is nearly twice that of Southeast Asia, given by the WHO at 356 cases per 100,000 population in 2004.[139]

The WHO also estimated that 1.69 million deaths (27 deaths per 100,000 population) resulted from TB in 2004.[139] As with cases of disease, the highest number of estimated deaths is in the Southeast Asia region, but the highest mortality per capita (78 deaths per 100,000 population) is in sub-Sahaian, Africa, where HIV has led to rapid increases in the incidence of TB and increases the likelihood of dying from TB (Fig. 31-16).[140] TB accounts for about 13% of AIDS deaths worldwide.[141]

DRUG-RESISTANT TUBERCULOSIS

Drug-resistant TB is on the increase in many parts of the world.[142] The development of resistance is a result of inconsistent or partial treatment of cases. Of particular concern is multidrug-resistant TB, which is defined as resistance to isoniazid and rifampicin, the two most effective anti-TB drugs. It is estimated that 300,000 new cases of multidrug-resistant TB are developing each year.[139]

CHAPTER 32 Infections of the Upper Respiratory Tract

M. Innes Asher and Cameron C. Grant

TEACHING POINTS

- Treatment with antibiotics shortens the duration of symptoms and reduces the complications of tonsillitis and pharyngitis, otitis media, sinusitis, deep neck abscesses, epiglottitis, and bacterial tracheitis.
- Over-the-counter medicines for colds are not efficacious.
- Penicillin remains the treatment of choice for *Streptococcus pyogenes* pharyngitis.
- Airway obstruction occurs in deep neck abscesses, viral croup, epiglottitis, bacterial tracheitis, and recurrent respiratory papillomatosis.
- Clinical features and patterns of disease are different from those in adults.

Infections of the upper respiratory tract are very common in children. Their epidemiology is described in Chapter 31. Although infections of the upper respiratory tract often resolve completely without complications, treatment is indicated where it can achieve more rapid resolution of symptoms, prevent the illness becoming more severe, prevent complications, or prevent chronic disease.

The conditions covered in this chapter are the common cold, tonsillitis and pharyngitis, otitis media, sinusitis, deep neck abscesses, viral croup, epiglottitis, bacterial tracheitis, and recurrent respiratory papillomatosis.

THE COMMON COLD

I love the doctors—they are dears;
But must they spend such years and years
Investigating such a lot
Of illnesses which no one's got,
When everybody, young and old,
Is frantic with the common cold?
And I will eat my only hat
If they know anything of that![1]

Epidemiology, Risk Factors, and Pathogenesis

The common cold may be caused by one of over 100 different viral types; the major ones are listed in Box 32-1. The main clinical difference among colds induced by different viruses is in the duration of the incubation period.[2] Other types of organisms occasionally cause a syndrome that can overlap with the common cold. Such organisms include *Mycoplasma pneumoniae*, *Bordetella pertussis*, *Streptococcus pyogenes*, *Coccidiodes immitis*, *Histoplasma capsulatum*, *Chlamydia psittaci*, and *Coxiella burnetii*.[1]

With the use of polymerase chain reaction (PCR)-based assays, the proportion of common colds for which an etiologic organism is identifiable has increased to 70% to 80%. The discovery of human metapneumovirus as a cause of acute respiratory infections suggests that currently unidentified infectious agents cause at least a proportion of the remainder.[1]

Common colds vary in frequency with age and season. They are more frequent in autumn and winter in temperate regions and in the rainy season in tropical regions.[1] Children have more colds per year than do adults and can be expected to have approximately six colds annually from age 2 to 6 years.[3-5] For children, day care attendance increases the risk of illness, with a dose-response effect evident between the number of children in the day care setting and the number of colds.[1,6-8] Among adults, psychological stress is associated with an increased risk of having the common cold.[9] Colds occur less frequently in women who work outside of the home, suggesting that exposure to children is a risk factor for adults.[1,10]

The mode of transmission (hand contact with infected secretions versus small-particle aerosols versus direct hit by large-particle aerosols) varies between viruses. Rhinovirus, the most frequent pathogen, is transmitted mainly by hand contact with infected secretions followed by self-inoculation onto the nasal mucosa or conjunctiva, but it also spreads as an aerosol.[11,12]

The pathophysiology of the common cold is understood mainly from studies of adult volunteers infected with rhinoviruses.[1,11,13] After deposition of the virus on the nasal mucosa or from the conjunctiva via the lacrimal duct, the virus reaches the nasopharynx via mucociliary transport. After binding to specific cell surface receptors, the virus enters the epithelial cell. Once inside the cell, the virus starts to replicate rapidly. The infectious dose is small.[14] Up to 95% of people without serotype-specific antibodies become infected, with 75% of these infections resulting in symptomatic colds.[15]

Infection of nasal mucosal epithelial cells results in vasodilation and increased vascular permeability leading to rhinorrhea and nasal obstruction.[1] Sneezing and increased mucus

BOX 32-1 Viral Causes of the Common Cold

Most Common Cause

Rhinoviruses

Common Causes

Coronaviruses
Influenza viruses*
Parainfluenza viruses*
Respiratory syncytial virus*

Occasional Causes

Adenoviruses*
Enteroviruses*

*Most illnesses caused by these viruses include other symptoms in addition to those that are symptoms of the common cold.[1]

gland secretion occur as a result of increased cholinergic stimulation.[1] In contrast with influenza and adenovirus infection, epithelial destruction is not a feature of rhinovirus infection.[1,13]

Components of the upper respiratory tract other than the nasal cavity are affected by the common cold. Paranasal sinus abnormalities are evident on radiography.[16,17] These abnormalities resolve spontaneously. Eustachian tube dysfunction occurs frequently in both children and adults and predisposes the susceptible individual to otitis media.[18-21]

During the common cold, the greatest concentration of virus is in the nasal secretions, with little found in secretions generated by coughing or talking or in saliva. The greatest amount of virus comes from sneezing, nose blowing, and secretions from the nose transmitted on contaminated hands. Children have a greater concentration of virus in their secretion and tend to shed virus for longer periods than adults. Viral shedding is maximal 2 to 7 days after inoculation, although some shedding may continue for another 2 weeks.

Serum antibody and secretory antibody develop from the infection and appear to be protective against reinfections. Clinically abortive colds may be reinfection colds with early antibody recall.

Impairment of nasal mucociliary transport persists for approximately 1 month after a cold. Children who have four to six colds in a winter may have constantly impaired mucociliary transport.

Clinical Features

The common cold is an acute, highly infectious illness characterized by nasal stuffiness, sneezing, coryza, throat irritation, cough, and little or no fever; it occurs multiple times each year in each person. Although older children have an illness similar to that of adults, in infants, the symptoms and signs may be more varied. The minimal symptoms that define the diagnosis are nasal discharge, nasal obstruction, and throat irritation. At the onset of symptoms, there is a feeling of chilliness on exposure to cold, dryness and irritation in the nose, and a scratchy throat. This progresses rapidly to nasal stuffiness or obstruction, sneezing, watery nasal discharge, throat irritation, watering eyes or eye irritation, coughing, occasional muscular aches, general malaise, anorexia, and, sometimes, low-grade fever.[2] After 1 to 3 days, the nasal secretions may become thicker and purulent. Persistent nasal discharge may lead to excoriation around the nose. If nasal obstruction occurs, it leads to mouth-breathing, aggravating the irritation of the throat. The usual duration of the illness is about 7 days, but lingering nasal discharge may persist for 2 weeks or longer.

In infants, the onset is more likely to be associated with a fever of 38° to 39° C (100.4° to 102.2° F).[1,22,23] The infant may be irritable and restless, and the nasal obstruction may significantly interfere with both feeding and sleeping. Vomiting and diarrhea may also occur.

Diagnosis

If the clinical features and exposure history are specific, then investigations are not indicated. In infants, investigation for alternative diagnoses, including invasive bacterial infections, may be necessary, particularly if fever is a predominant symptom and/or nasal obstruction results in apnea. The early symptoms of many illnesses such as pertussis, epiglottitis, measles, and diphtheria are similar to those of the common cold, but in a short time, the other features of the specific illness appear. Allergic rhinitis may need to be distinguished from the common cold in the child with "recurrent colds." Assessment of the family history, possible allergic triggers, nasal eosinophilia, and serum immunoglobulin E (IgE) concentration help confirm or exclude this diagnosis. In children, intranasal foreign bodies should be searched for if the nasal discharge is atypical in terms of persistence, blood staining, or malodor.[1]

The features of the illness caused by different viruses overlap widely, making clinical differentiation unreliable. Laboratory confirmation of the specific viral cause is of little value to clinical practice with the exception of influenza. Several laboratory methods are available for identification of viruses. Isolation by cell culture is too slow to be clinically relevant. Rapid antigen tests are available for some organisms, for example, influenza virus. In comparison with cell culture, influenza antigen detection in respiratory specimens by immunofluorescent staining has a sensitivity of 70% to 100% and specificity of 80% to 100%. PCR assays are more sensitive than culture, but their laboratory requirements limit clinical applicability.[24] Near patient tests, which produce results within 30 minutes, have highly variable sensitivities and negative predictive values.[25]

Treatment and Prevention

The common cold in children usually resolves quickly, and no specific therapy is indicated in the majority of cases. Although the common cold is a relatively mild and self-limiting illness, it is enormously expensive in terms of lost productivity and money spent on various treatments, the majority of which have minimal or no efficacy.

In infants, nasal obstruction may be relieved by isotonic saline nosedrops, which can moisten irritated nasal mucosa, loosen nasal secretions, and induce sneezing. Gentle aspira-

tion of the nasal secretion using a blunt syringe or suction can provide temporary relief for an infant. Use of concentrated capsules of eucalyptus for inhalation to clear the nose is contraindicated in young children; these can be highly dangerous if applied incorrectly to the face.[26]

Frequent intake of fluid helps relieve the irritated throat. Environmental tobacco smoke aggravates all the symptoms and should be avoided.

The published literature on modalities used for symptomatic relief of cold symptoms has been summarized using systematic reviews as follows:

Antibiotics: In a meta-analysis of six trials that included 1147 patients (children and adults), people receiving antibiotics did no better than did those receiving placebo in terms of cure or persistence of symptoms.[27]

Vitamin C: In studies of adults, beneficial effects of vitamin C have been shown when it is used prophylactically for 2 to 3 months but not when started at the onset of symptoms. However, fewer trials have examined this later use.

In studies of adults, 200 mg or more per day of vitamin C does not reduce the incidence of colds, except in those exposed to brief periods of extreme physical exercise and/or cold environments.[28]

Vitamin C given prophylactically results in a small but significant reduction in the duration and severity of cold symptoms. In studies of children, there is an approximately 14% reduction in duration of symptoms. The severity of symptoms, as measured by "days confined to home" or "days off work or school," is significantly reduced in studies that include both children and adults.[28]

Zinc lozenges: There are no studies specifically of children, although some older children have been included in predominantly adult studies. There is no evidence that zinc lozenges are effective.

Echinacea: Most studies have examined the use of echinacea for treating rather than preventing colds. The results of placebo-controlled trials have been inconsistent, with some showing effect and others not. This variability is likely to be due at least in part to the large variability in composition of products that are sold as "Echinacea."[29]

Nasal decongestants (either oral or intranasal): The efficacy of these in children remains unproved.[5] In adults, a single dose of a nasal decongestant is moderately effective for the short-term relief of congestion.[5] The potential side effects are a concern, especially in young children. In children, they have a measurable sedating effect.[30] Excessive use of sprays and drops with vasoconstrictive medications can lead to rebound obstruction, which prolongs the illness symptoms.

Over-the-counter medicines for acute cough[31]: There is no good evidence that over-the-counter medicines provide any benefit greater than that seen with a placebo. These medications confer no protection against the development of otitis media.[32]

Antitussives: Neither dextromethorphan nor codeine is better than a placebo at reducing cough during the day or night.[33]

Expectorants (Guaifenesin): This has not been adequately studied in children.

Mucolytics (letosteine): One study involving 40 children showed a statistically but not clinically significant difference in symptom score in comparison with placebo (a difference of 0.2 point on a 4-point scale).[34]

Antihistamines as monotherapy: In children and adults, antihistamines do not significantly reduce cold symptoms (nasal congestion, rhinorrhea, sneezing) or alter subjective improvement.[35,36] First-generation antihistamines cause more sedation than does placebo.[35]

Antihistamine decongestant combinations: These are not effective in small children.[35] In older children and adults, a small amount of improvement in general and in nasal symptoms specifically may occur.[30,35,37]

Of the numerous etiologic agents that can cause colds, only for influenza virus is there commercially available antiviral therapy. The newer class of antiviral drugs, the neuraminidase inhibitors (zanamivir and oseltamivir), are effective against both influenza A and B viruses.[38,39] Oral oseltamivir, 2 mg/kg/dose, given twice daily, to children 1 to 12 years old shortens illness duration by 26% and reduces cough, coryza, duration of fever, and new diagnoses of otitis media.[39] In children 5 to 12 years of age, the nasally administered zanamivir has also been shown to decrease symptom duration and severity.[40]

Prevention by immunization is currently possible only for influenza. In addition to the present inactivated vaccine that is given intramuscularly, a live attenuated cold adapted intranasal vaccine has been shown to be efficacious in children.[41-43]

Clinical Course and Prognosis

The uncomplicated common cold has a uniformly excellent outcome with complete recovery. However, complications are common and include acute otitis media, otitis media with effusion, tonsillitis, sinusitis, lower respiratory tract infections, and acute exacerbations of asthma[44] (Box 32-2).

PHARYNGITIS AND TONSILLITIS

Pharyngitis is an inflammatory illness of the mucous membranes and underlying structures of the throat; it is invariably associated with the symptom of sore throat. Most cases of pharyngitis in children are caused by viruses and are benign

BOX 32-2 Common Cold Teaching Points

- Children have more colds than do adults. They have approximately six colds per year from age 2 to 6 years.
- Children are very effective spreaders of colds, having a greater concentration of virus in their secretions and longer duration of viral shedding than do adults.
- In infants, colds are more likely to cause fever, and at initial presentation, the colds may be clinically indistinguishable from serious bacterial infections.
- Vast amounts of money are wasted on over-the-counter products for colds. Meta-analyses of clinical trials have confirmed their lack of efficacy.

self-limiting illnesses. Group A β-hemolytic streptococcus (*S. pyogenes*) is the most important etiologic agent because of its potential to cause rheumatic fever. The prevention of rheumatic fever defines the management of pharyngitis.

Epidemiology, Risk Factors, and Pathogenesis

Pharyngitis includes tonsillitis, tonsillopharyngitis, and nasopharyngitis. The inflammation frequently also involves the nasopharynx, uvula, and soft palate. Pharyngitis with nasal symptoms (sometimes called *nasopharyngitis*) is usually caused by a virus, whereas pharyngitis without nasal symptoms can be caused by a wide variety of infectious agents.

When an infectious agent is inoculated onto the pharyngeal or tonsillar tissue, localized inflammation occurs. This may occur de novo or as a complication of the common cold, when the etiologic agent is more likely to be viral. A list of etiologic agents is presented in Boxes 32-3 and 32-4. *S. pyogenes* causes 15% to 30% of acute pharyngitis in children.[45]

Pharyngitis occurs more frequently during the colder months of the year. In temperate climates, pharyngitis due to *S. pyogenes* infection usually occurs in the winter and early spring.[45] Pharyngitis due to *S. pyogenes* is primarily a disease of children 5 to 15 years old. Group C streptococci are a common cause of pharyngitis in college students.[46] Group C streptococci are also described as the etiologic organism in epidemic pharyngitis spread by contaminated food.[47,48]

The inflammation causes erythema of the pharynx, the tonsils, or both structures. Exudate typically occurs with only some organisms, including adenovirus, herpes simplex virus, β-hemolytic streptococci, *Corynebacterium diphtheriae*, *Arcanobacterium haemolyticum*, Epstein-Barr virus, and *Candida* species. Ulceration is usually seen only with herpes simplex virus and enterovirus.

The pharyngeal involvement may be overshadowed by other symptoms, such as cough and coryza, when, for example, the infecting organism is the parainfluenza virus, and fever, exanthem, and meningitis when the infecting organism is an enterovirus.

The tonsillopharyngeal involvement with marked exudate caused by Epstein-Barr virus looks similar to that caused by *S. pyogenes*. It appears that bacterial adhesion is the cause of the exudate that occurs with this Epstein-Barr virus infection.[49]

Primary and recurrent herpes simplex virus infection occasionally has associated pharyngitis.[50] In almost all instances, there are herpes lesions in the anterior mouth, externally around the mouth, and at the mucocutaneous border.

Clinical Features

Children of any age can develop pharyngitis and tonsillitis. The onset is usually sudden with fever, sore throat, and anorexia. There may be headache, nausea, vomiting, lassitude, and sometimes abdominal pain. With viral infection, there are often other signs of respiratory tract infection, with more or less systemic involvement. The cervical lymph nodes are enlarged and tender. There is moderate to severe pharyn-

BOX 32-3 Viral Agents in Pharyngitis and Tonsillitis

Common Viral Causes

Adenovirus types 1 to 7, 7a, 9, 14 to 16
Coronavirus
Enteroviruses: coxsackievirus types A and B, echovirus type A
Epstein-Barr virus
Influenza virus types A and B
Parainfluenza virus types 1 to 4
Respiratory syncytial virus

Less Common Viral Causes

Cytomegalovirus
Herpes simplex virus
Measles virus
Poliovirus
Reovirus
Rhinoviruses
Rotaviruses
Rubella virus

BOX 32-4 Other Agents in Pharyngitis and Tonsillitis

Common Bacterial Causes

Streptococcus pyogenes

Less Common Bacterial Causes

Actinomyces spp.
Bacteroides melaninogenicus
Bacteroides spp.
Borrelia spp.
Corynebacterium diphtheriae
Corynebacterium pyogenes
Corynebacterium ulcerans
Francisella tularensis
Fusobacterium spp.
Haemophilus influenzae
β-Hemolytic streptococci B, C, and G
Legionella pneumophila
Leptospira spp.
Neisseria gonorrhoeae
Neisseria meningitidis
Peptostreptococcus spp.
Salmonella typhi
Streptobacillus moniliformis
Streptococcus pneumoniae
Treponema pallidum
Yersinia enterocolitica

Other Organisms

Candida spp.
Chlamydia pneumoniae strain TWAR
Coxiella burnetii
Mycoplasma hominis
Mycoplasma pneumoniae
Toxoplasma gondii

geal erythema, and there may be follicles, ulcers, petechiae, and generalized exudate. Petechial lesions on the soft palate may occur with pharyngitis due to *S. pyogenes*, Epstein-Barr virus, measles virus, and rubella virus.

In all cases of acute pharyngitis, streptococcal disease must be considered. Various clinical factors (exposure, season, incubation period, age of patient, and associated clinical findings) may distinguish among causative organisms in large epidemiologic studies, but in the individual child, the clinical distinction of streptococcal pharyngitis from viral pharyngitis is unreliable. If there is an obvious nasal infection, ulceration, or conjunctivitis, the etiology is most likely viral. In a child under the age of 4 years, pharyngitis with no exudate is almost always viral. In a child older than 4 years of age, pharyngitis with exudate or fever is most likely caused by *S. pyogenes*, but other bacteria may mimic this condition.[11,12] The clinical features of pharyngitis due to group A, C, and G β-hemolytic streptococci are similar.[45] The clinical and epidemiologic features that differ in pharyngitis due to *S. pyogenes* versus a viral cause are shown in Boxes 32-5 and 32-6 (see also Fig. 32-1).

Diagnosis

A throat swab is necessary to determine the presence of *S. pyogenes*. Identification can be with either culture or a rapid antigen detection test. For both, an adequate swab of the inflamed tonsillar area is required and the manner in which the swab is obtained is the main determinant of diagnostic accuracy.[51] The surfaces of both tonsils and the pharyngeal wall should be swabbed. Other areas of the mouth and pharynx should not be swabbed. If collected in this manner, a single swab has a sensitivity of 90% to 95% for the detection of *S. pyogenes* in the pharynx.[45,52]

BOX 32-5 Clinical and Epidemiologic Features Suggesting *Streptococcus pyogenes* Pharyngitis

Sudden onset
Sore throat
Fever
Scarlet fever rash
Headache
Nausea, vomiting, and abdominal pain
Inflammation of pharynx and tonsils and uvula
Patchy discrete exudates
Palatal petechiae
Excoriated nares (especially in infants)
Tender, enlarged anterior cervical nodes
Patient age 5 to 15 years
Presentation in winter or early spring
History of exposure

Modified from Gerber MA: Diagnosis and treatment of pharyngitis in children. Pediatr Clin North Am 52:729-747, 2005; and Bisno AL, Gerber MA, Gwaltney JM, et al: Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 35:113-125, 2002.

BOX 32-6 Clinical and Epidemiologic Features Suggesting Viral Pharyngitis

Conjunctivitis
Coryza
Cough
Hoarseness
Anterior stomatitis
Discrete oral ulcers
Diarrhea
Characteristic exanthems

Modified from Gerber MA: Diagnosis and treatment of pharyngitis in children. Pediatr Clin North Am 52:729-747, 2005; and Bisno AL, Gerber MA, Gwaltney JM, et al: Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 35:113-125, 2002.

The throat swab should be incubated for 18 to 24 hours on a sheep blood agar plate. Agar plates that are negative at 24 hours should be reexamined at 48 hours.[45]

Rapid antigen detection tests have been developed because of this 24- to 48-hour delay before a throat swab can inform clinical management. The results may be obtained in about 10 minutes. Most available rapid antigen detection tests have specificities of 95% or greater, and thus a positive result is a very good indicator of the need to treat.[53] Sensitivities range from 80% to 90%, so a negative antigen test does not exclude *S. pyogenes* infection.[53] When *S. pyogenes* pharyngitis is suspected clinically but the rapid diagnostic test is negative, a throat swab for culture should be obtained.[24] A large proportion of false-negative rapid antigen tests are true infections rather than *S. pyogenes* carriage.[54] Because of the limited number of direct test-to-test comparisons that have been performed, the relative sensitivities of different rapid antigen test have not been established.[45]

A positive culture or rapid antigen test for *S pyogenes* cannot differentiate a child with a true infection from another with a symptomatic viral pharyngitis who is a *S. pyogenes* carrier.

Figure 32-1 Palatal petechiae in a child with *Streptococcus pyogenes* pharyngitis.

Treatment

Symptomatic relief may be obtained from drinking warm fluids or, in the older child, saltwater gargles. An analgesic such as acetaminophen is appropriate. Simple lemon-based throat lozenges may be soothing, but ones that contain potentially toxic substances should be avoided. Decongestants and antihistamines have no place in the treatment of pharyngitis and tonsillitis.

Antibiotics are used to treat symptomatic pharyngitis caused by infection with *S. pyogenes*. The aim is to prevent the development of rheumatic fever. If the rapid antigen test and culture are both negative, then antibiotics should be withheld or, if already started, discontinued.

In addition to preventing rheumatic fever, treatment of *S. pyogenes* pharyngitis reduces the duration of symptoms and the risk of spread and enables quicker return to school and work.[55]

Several different antibiotics are effective, including penicillin, ampicillin and amoxicillin, many cephalosporins, macrolides, and clindamycin. Antimicrobial therapy options for *S. pyogenes* pharyngitis are summarized in Table 32-1. Penicillin remains the recommended treatment because of its proved efficacy, narrow antimicrobial spectrum, low cost, and excellent safety profile.[56] *S. pyogenes* has never developed resistance to penicillins or cephalosporins. The minimum inhibitory concentration of penicillin has not increased over the past 50 years.[45,57]

Penicillin can be effective in preventing rheumatic fever even when therapy is started up to 9 days after the onset of the acute illness. Although the conventional oral dosage regimen is penicillin V, 250 mg 3 to 4 times a day,[24] a twice-daily dose of 250 mg, if reliably given, is as effective.[58] In children over 12 years of age, a higher dose of 500 mg twice a day is recommended.[58] Intramuscular benzathine penicillin is very effective and should be considered for children who are particularly unlikely to complete a course of oral treatment.

Although the efficacy of penicillin in eliminating *S. pyogenes* from the tonsils and pharynx has not diminished after 40 years of use,[59] the failure rate in practice may be at least as high as 18% in certain communities. Ampicillin and amoxicillin are associated with a 95% risk of skin rash in infectious mononucleosis[24]; therefore, they are not recommended in the treatment of pharyngitis.

The course of oral antibiotic must be 10 days; courses of shorter duration are associated with lack of effective treatment. A child must complete a full 24 hours of therapy before returning to school or day care; otherwise, he or she remains infectious to other children.[60]

Both suppurative and nonsuppurative (acute rheumatic fever, acute post streptococcal glomerulonephritis, and post streptococcal reactive arthritis) complications can develop from pharyngitis.

Scarlet fever is a streptococcal pharyngitis with a characteristic rash. The rash occurs if the *S. pyogenes* causing the infection produces a pyrogenic (erythrogenic) toxin and infects an individual who does not have antitoxin antibodies. The rash is either the first sign of the illness or occurs within 24 to 48 hours of illness onset. It begins around the neck and chest, spreads downward and is often more intense in the skin creases of the neck, axillae, elbows, groins, and knees (Pastia's lines). The palms and soles are spared as is the face, where there is characteristic circumoral pallor and flushed cheeks. The rash is diffuse, bright red, papular, and rough to the touch. The sandpaper texture is caused by occlusion of sweat glands. The rash fades over a week and is followed by desquamation for several weeks. In addition to palatal petechiae, the tongue has a white strawberry (yellowish white coating through which the red papillae are seen) and then, when the coating disappears, a red strawberry appearance (red swollen papillae).[45,61]

Clinical Course and Prognosis

Pharyngitis is self-limited, lasting 4 to 10 days, and it has an excellent prognosis. However, in 0.3% to 3.0% of untreated *S. pyogenes* throat infections, the serious complication of rheumatic fever results. Suppurative involvement of both adjacent and more distant tissue is a well-recognized complication of *S. pyogenes* pharyngitis.[62]

Table 32-1
Antimicrobial Therapy for *Streptococcus pyogenes* Pharyngitis

Route of Administration, Antimicrobial Agent	Dosage	Duration
Oral		
Penicillin*	Children: 250 mg bid or tid	10 days
	Adolescents and adults: 250 mg tid or qid	10 days
	Adolescents and adults: 500 mg bid	10 days
Intramuscular		
Benzathine penicillin G	1.2×10^6 U (for patients ≥27 kg)	1 dose
	6.0×10^5 U (for patients <27 kg)	1 dose
Mixtures of benzathine and procaine penicillin G	Varies with formulation†	1 dose
Oral, for Patients Allergic to Penicillin		
Erythromycin	Varies with formulation	10 days
First-generation cephalosporin‡	Varies with agent	10 days

*Amoxicillin is often used in place of oral penicillin V in young children because of the acceptance of the taste of the suspension, not because of any microbiologic advantage.
†Dose should be determined on basis of benzathine component.
‡These agents should not be used to treat patients with immediate-type hypersensitivity to β-lactam antibiotics.
Modified from Gerber MA: Diagnosis and treatment of pharyngitis in children. Pediatr Clin North Am 52:729-747, 2005; and Bisno AL, Gerber MA, Gwaltney JM, et al: Practice guidelines for the diagnosis and management of group A streptococcal pharyngitis. Clin Infect Dis 35:113-125, 2002.

Follow-up cultures should be performed in children who have had rheumatic fever.[45] Such testing should also be considered in patients living in communities where there are outbreaks of *S. pyogenes* infections, post streptococcal glomerulonephritis, or rheumatic fever.[63] Follow-up throat cultures are not indicated in patients who have completed an appropriate antibiotic course and are asymptomatic. If tested, most of such children in whom *S. pyogenes* is identified are carriers.[63]

Tonsillectomy is sometimes considered in the child with recurrent pharyngitis. The frequency of symptomatic episodes diminishes with time whether or not tonsillectomy is performed. Tonsillectomy results in a small additional reduction in number of symptomatic episodes, days of symptoms, and days of school missed[64] (Box 32-7).

RETROPHARYNGEAL, PARAPHARYNGEAL, AND PERITONSILLAR ABSCESSES

Deep abscesses in the neck may cause serious problems because of local pressure, local destruction, or airway obstruction. They are classified by location into peritonsillar abscess (also known as *quinsy*), retropharyngeal abscess, and parapharyngeal abscess. Multiple abscess types can coexist. They have become sufficiently uncommon that they can be overlooked in the differential diagnosis when a young child presents with nonspecific symptoms of sepsis or of an acute pharyngeal infection. They have the potential to be catastrophically fatal or to result in significant morbidity if not detected early.[65]

BOX 32-7 Pharyngitis and Tonsillitis Teaching Points

- Most cases of pharyngitis in children are caused by viruses and are benign self-limiting illnesses.
- The prevention of rheumatic fever defines the management of pharyngitis.
- In the individual child, the clinical distinction of streptococcal pharyngitis from viral pharyngitis is unreliable.
- The manner in which the throat swab is obtained is the main determinant of diagnostic accuracy.
- Penicillin remains the recommended treatment because of its proved efficacy, narrow antimicrobial spectrum, low cost, and excellent safety profile.
- Tonsillectomy results in a further small reduction in number of symptomatic episodes of tonsillitis, in addition to the decrease in frequency that occurs with time without tonsillectomy.

Epidemiology, Risk Factors, and Pathogenesis

Key features and differences between these abscess types are summarized in Table 32-2.

RETROPHARYNGEAL ABSCESS

An abscess can form in the retropharyngeal space, which is a potential space immediately anterior to the pre-

Table 32-2
Clinical Features of Retropharyngeal, Parapharyngeal, and Peritonsillar Abscesses

	Usual Age	Sites of Origin	Location	Clinical Findings	Complications/Extension Site	Management
Retropharyngeal abscess	<4 yr	Pharyngitis, dental infection, trauma	Between posterior pharynx and prevertebral fascia	Unilateral posterior pharyngeal bulging; neck hyperextension, drooling, respiratory distress	Spontaneous rupture and aspiration; contiguous spread to posterior mediastinum, parapharyngeal space	Antibiotics, drainage; artificial airway
Parapharyngeal abscess	>8 yr, adolescents, adults	Tonsillitis, otitis media, mastoiditis, parotitis, dental manipulation	Anterior and posterior pharyngomaxillary space	Anterior compartment: swelling of the parotid area; trismus; tonsillar prolapse. Posterior compartment: septicemia; minimal pain or trismus	Carotid erosion; airway obstruction; intracranial, lung, contiguous spread to mediastinum; septicemia	Antibiotics, drainage; artificial airway
Peritonsillar abscess	Adolescents, adults	Tonsillitis	Tonsillar capsule, and space below superior constrictor muscle	Swelling of 1 tonsil, uvular displacement; trismus, muffled voice	Spontaneous rupture and aspiration; contiguous spread to parapharyngeal space	Antibiotics, drainage

From Brook I: Microbiology and management of peritonsillar, retropharyngeal, and parapharyngeal abscesses. J Oral Maxillofac Surg 62:1545-1550, 2004.

vertebral fascia. It extends inferiorly from the skull base for the length of the pharynx.[66] This space receives lymphatic drainage from many surrounding structures, including the middle ear, pharynx, nasopharynx, nose, and paranasal sinuses.[67]

The retropharyngeal space is continuous laterally with another potential space, the parapharyngeal space. The fascia that separates these two spaces is an ineffectual barrier to the spread of infection.[65] Infection may result from suppurative adenitis of the lymph nodes in the retropharyngeal space, or penetrating trauma, or foreign body aspiration.[68-70]

PARAPHARYNGEAL ABSCESS

The parapharyngeal space (or lateral pharyngeal or pharyngomaxillary space) is in the upper neck above the hyoid bone. It is an inverted cone-shaped potential space that extends from the hyoid bone to the base of the skull. Medially, it is bound by the pretracheal fascia, and laterally, by the pterygoid muscles and mandible.[71] Anteriorly, it is bound by the submandibular space, and posteriorly, by the retropharyngeal space.[72] The clinical manifestations of a parapharyngeal abscess are determined by the structures involved around the abscess cavity. An abscess in the posterior component of the space may result in medial displacement of the lateral pharyngeal wall. Extension can result in serious local nerve and life-threatening vascular complications (the internal carotid artery, internal jugular vein, cranial nerves IX, X, XI, and XII, and the sympathetic chain pass posteriorly through the parapharyngeal space).[73] An anterior compartment abscess can cause trismus from irritation of the internal pterygoid muscle. The source of the abscess is often unclear, but it seems likely to result from extension of infection from nearby tissues.

PERITONSILLAR ABSCESS

The peritonsillar space is limited medially by the fibrous wall of the tonsil capsule and laterally by the superior constrictor muscle.[74] Pus may be found in a single pocket or in several pockets. The majority occur following tonsillitis, presumably from local extension of the infection through the tonsillar capsule.[75] The three types of abscess have similar microbiology. The microbiology reflects the flora of the oropharynx and nasopharynx. Most are polymicrobial infections with an average number of five isolates.[71] Anaerobic bacteria can be isolated from most abscesses if appropriate culture techniques are used.[71] The predominant anaerobic organisms are *Prevotella*, *Porphyromonas*, *Fusobacterium*, and *Peptostreptococcus* spp.[71] Retropharyngeal abscesses in young children are more likely to have pathogenic aerobic isolates, most frequently, *S. pyogenes*, *Staphylococcus aureus*, and *Haemophilus* species.[71,76]

Retropharyngeal Abscess

CLINICAL FEATURES

The clinical presentation of a retropharyngeal abscess can be very nonspecific, particularly in younger children. Torticollis is a key clinical sign, particularly in combination with fever and dysphagia.[65,67,77] Other clinical manifestations include drooling, airway stridor, dyspnea, tachypnea, stiff neck, and ipsilateral cervical adenopathy. There is sometimes midline or unilateral swelling of the posterior pharynx. Presenting symptoms and signs in infants include neck swelling, fever, dysphagia, and stridor.[65]

DIAGNOSIS

An acute inflammatory response will be demonstrable with measurement of, for example, the peripheral white blood cell count and C-reactive protein, but radiologic investigation is necessary to confirm the diagnosis.[65]

A lateral neck radiograph can yield diagnostic information. To prevent the false appearance of a retropharyngeal mass when none exists, it is important that the neck be in true lateral orientation and in extension and the image be obtained on full inspiration.[78] The lateral neck radiograph may show an increase in the thickness of the soft tissue space anterior to the cervical spine (>7 mm at the level of the second and >14 mm at the sixth cervical vertebra)* with narrowing of the oropharyngeal aiway[65,79] (Fig. 32-2). Other radiographic signs include straightening of the cervical vertebra, reversal of the normal lordotic curve of the cervical spine, and presence of air in the soft tissues.[80] A negative ultrasound examination cannot exclude a retropharyngeal abscess.[65] A computed tomography (CT) scan is the preferred investigation for distinguishing deep neck abscesses from cellulitis of the neck and for defining any extension into adjacent areas.[67] However, even with a CT scan, it is not always possible to differentiate cellulitis from abscess[78,81,82] (Fig. 32-3).

Magnetic resonance imaging (MRI) has the potential to provide better definition of any complications such as venous thrombosis and impending carotid artery erosion or rupture.[65,72]

TREATMENT

Intravenous antibiotics and incision and drainage are the necessary treatments. Intubation and, rarely in severe cases, tracheostomy may be necessary to secure the airway.[65,72,75,84]

Antibiotic choice needs to acknowledge the polymicrobial nature of the infection and the frequent presence of one or more anaerobes. Appropriate first-line choices include amoxicillin–clavulanic acid, clindamycin + cefuroxime, ceftriaxone plus metronidazole, gentamicin, and ampicillin plus sulbactam.[65,75,84]

The decision to operate should be based on the clinical course, including response to antimicrobial therapy, rather than just on the CT scan findings.[65] Antimicrobial therapy alone may be sufficient in children without severe systemic toxicity, who have no respiratory difficulties, who are able to swallow their secretions adequately, and in whom airway examination by indirect mirror or direct flexible endoscopy confirms a lack of airway compromise.[73,82]

*In adults these measurements are greater than 7 mm at the level of the second and greater than 22 mm at the sixth cervical vertebra.[79]

If the abscess is medial to the great vessels and confined to the retropharyngeal space, the abscess can be drained intraorally.[72,85,86] Large abscesses, particularly those that extend laterally or that involve other spaces in the neck, may need external drainage.[75] External drainage in children has the potential to damage important structures such as the great vessels and cranial nerves VII, IX, X, XI, and XII.[65] Successful drainage of uniloculated abscesses using ultrasound and CT to guide either needle aspiration or catheter insertion has been reported.[87,88]

Figure 32-2 Lateral neck radiograph showing increased thickness of the retropharyngeal space.

Abscesses can extend laterally, posteriorly into the posterior mediastinum, and cranially, causing a cerebral abscess or meningitis.[71] Abscesses left untreated can rupture into the pharynx, leading to aspiration. Direct pressure, sudden rupture, or hemorrhage can all result in asphyxia. Death can occur from aspiration, airway obstruction, erosion of a major vessel, extension into the posterior mediastinum, or from dissemination and sepsis.[71]

Other complications include abscess recurrence (1% to 5%), epiglottitis, empyema, pyopneumothorax, pneumomediastinum, and purulent pericarditis.[65,83]

Peritonsillar Abscess

CLINICAL FEATURES

Clinical features include sore throat (occasionally with unilateral pain), malaise, low-grade fever, chills, dysphagia, and reduced oral intake. Trismus can result from irritation and reflex spasm of the internal pterygoid muscle. A muffled voice can result from edema, impairing movement of the palate. There may be signs of toxicity, drooling, and sometimes dehydration. The soft palate and uvula are displaced away from the affected side by swelling. The tonsil is displaced medially, and there is ipsilateral tender cervical adenopathy. Untreated peritonsillar abscess may spontaneously rupture into the mouth or extend into the parapharyngeal space with potentially fatal complications.

Figure 32-3 Computed tomography scan of a 6-month-old child at the level of mandible demonstrating a retropharyngeal abscess. (From Cheema B, Grant CC, Mahadevan M, Beca J: An infant with a persistent empyema. Acta Paediatr 88:1168-1171, 1999.)

DIAGNOSIS

Identification of the organisms from aspirated pus is highly desirable. The peripheral white blood cell count is elevated, with a predominance of neutrophils.

TREATMENT

A combination of broad-spectrum parenteral antibiotic therapy that is active against anaerobes and drainage of the abscess is required.[75] Needle aspiration is also effective definitive therapy.[75,89] Tonsillectomy can be performed either during the same procedure or after an interval. It is indicated in those presenting with a peritonsillar abscess who have a history of recurrent tonsillitis, who have recurrent peritonsillar abscess, or who have tonsillar hypertrophy causing airway obstruction.[75]

Parapharyngeal Abscess

CLINICAL FEATURES

Clinical features include tender cervical swelling, induration and erythema of the side of the neck, sore throat, dysphagia, trismus, hoarseness, malaise, chills, and fever, which may be low grade. In addition to evidence of toxicity, there may be respiratory distress, medial displacement of the lateral pharyngeal wall and inferior tonsil pole, and drooling. Sometimes the presentation is of a high cervical mass palpable in the neck that progresses to fluctuance. Other signs arise if there is further extension or complications. Initially, a parapharyngeal abscess may be difficult to differentiate from a peritonsillar abscess, but the child with the latter is usually less toxic and has obvious palatal fluctuance.

DIAGNOSIS

The peripheral white blood cell count is elevated, with a predominance of neutrophils. Radiographs may be helpful. A submental vertex skull radiograph typically shows pharyngeal fullness on the side of the abscess. An anteroposterior view of the upper airway shows ipsilateral edema and obliteration of the pyriform sinus. As with retropharyngeal abscesses, a CT scan is able to localize the inflammatory process to the parapharyngeal space but cannot always differentiate an abscess from cellulitis.[82,90]

TREATMENT

The definitive treatment is incision and drainage and intravenous antibiotic therapy. In patients with larger abscesses or an unstable airway, emergency drainage with postoperative airway management, including intubation for several days, is indicated.[90] In the stable child, drainage can be deferred for 24 to 48 hours to determine whether intravenous antibiotics alone are sufficient to treat the infection.[90] Children with abscesses that are limited to this space and who demonstrate clinical improvement with intravenous antibiotics can be managed without drainage.[73] If drainage is required, this can be intraoral rather than external in most, unless the abscess is lateral to the great vessels or involves multiple spaces.[91]

Parapharyngeal abscesses can cause life-threatening complications, including internal carotid artery pseudoaneurysm or rupture, internal jugular vein thrombophlebitis, mediastinitis, and dysfunction of cranial nerves IX to XII (Box 32-8).[90,92-94]

BOX 32-8 Retropharyngeal, Parapharyngeal, and Peritonsillar Abscesses Teaching Points

- Deep neck abscesses are potentially fatal infections that cause significant morbidity.
- Multiple abscess types can coexist.
- The deep neck potential spaces are in close proximity to vital structures, including the airway, carotid arteries, and many cranial nerves.
- Retropharyngeal abscesses are more common in the preschool-age group, and parapharyngeal and peritonsillar abscesses are more common in older children and adolescents.
- The three types of abscess have similar microbiology; most are polymicrobial infections.
- The clinical presentation of a retropharyngeal abscess can be very nonspecific, particularly in younger children. Torticollis is a key clinical sign, particularly in combination with fever and dysphagia. A lateral neck radiograph can be diagnostic, but care needs to be taken to perform it correctly. Even with a CT scan, it can be difficult to differentiate an abscess from cellulitis.
- A peritonsillar abscess usually presents with a sore throat, with systemic signs of infection. Trismus and a muffled voice can be present. The soft palate and tonsil are usually displaced by the abscess.
- A parapharyngeal abscess presents with dysphagia, trismus, and hoarseness and tender cervical swelling, which is indurated. It can sometimes be difficult to differentiate clinically from a peritonsillar abscess. A CT scan is required to define the extent of the abscess and the potential for complications.
- All abscess types require intravenous antibiotics. Anaerobic cover must be provided.
- Drainage is frequently required. The decision to drain and timing of surgical drainage are determined by the clinical course.

OTITIS MEDIA

Otitis media is a very common condition in childhood. There are three categories of otitis media: *acute otitis media*, *otitis media with effusion* (secretory otitis media), and *chronic suppurative otitis media*. The widespread use of antibiotics for acute otitis media in the developed world has drastically reduced the previously fairly common suppurative complications of otitis media, but otitis media with effusion has become more common.

Epidemiology, Risk Factors, and Pathogenesis

A higher rate of acute otitis media and chronic suppurative otitis media is found in children in developing countries[95] and in indigenous populations in developing countries, including

New Zealand Maori,[96] Australian Aborigines, Alaskan Inuit, and North American Indians.

Acute otitis media is an acute infection of the middle ear, and most children have at least one episode by the age of 7 years.[97] Acute otitis media is particularly common in the preschool-age child and more common in boys than girls. Exclusive breastfeeding for at least 4 months appears to protect against otitis media in the first 12 months of life.[98] The increased environmental exposure to respiratory tract infections in day care centers increases the risk of acute otitis media.[99] Side-stream smoking increases the risk of otitis media with effusion and recurrent acute otitis media.[100]

Acute otitis media may occur de novo; more commonly, it occurs as a complication of the common cold. It may occur in the context of infection with recognized respiratory viruses such as respiratory syncytial virus, influenza viruses, adenoviruses, parainfluenza viruses, enteroviruses (coxsackievirus, echovirus), rhinoviruses,[101] and even herpes simplex virus type 1 and cytomegalovirus.[102] Viral infection in isolation is a rare cause of otitis media (5%), but up to 20% of cases are combined viral and bacterial infections.[101] The remainder are caused by bacteria alone. Bacterial causes of acute otitis media are listed in Box 32-9.

Two or more organisms are found in about 7% of cases. A different organism may be found in each ear in about 20% of children with bilateral otitis media. In neonates, there may be a higher incidence of *S. aureus* and gram-negative bacilli than in older children.[103]

The organisms isolated from acute otitis media with tympanostomy tubes are different in prevalence from acute otitis media with an intact tympanic membrane, being mainly *Streptococcus pneumoniae*, *S. aureus*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*, *Moraxella catarrhalis*, anaerobes, and fungi.[104-106]

Acute otitis media occurs when viral infection causes respiratory epithelial injury in the nasopharynx, which is colonized with pathogenic bacteria, leading to hyperemia and edema of the eustachian tubes with consequent obstruction. Bacteria may arise in the middle ear by positive or negative forces through the eustachian tube or occasionally through the bloodstream or by direct spread through a damaged tympanic membrane. The inflammation of the tympanic membrane and infected inflammatory exudate in the middle ear are caused primarily by bacteria, polymorphonuclear leukocytes, and edema. The eustachian tubes are believed to play a part in the pathophysiology of this process. The eustachian tubes in a young child are shorter, wider, straighter, and more horizontal and patulous than in the older child, allowing more ready access of organisms to the middle ear.

Otitis media with effusion is the presence of fluid in the middle ear without signs or symptoms of acute ear infection. It can result from prolonged negative pressure in the middle ear after viral infection, and stimulation of inflammatory mediators can promote fluid leakage from the mucous membrane. Persistent middle ear fluid results in decreased mobility of the tympanic membrane and serves as a barrier to sound transmission.[95] Recurrence of bilateral otitis media with effusion after tympanostomy tube placement was more likely in children with a combination of low IgA or IgG2 levels with poor eustachian tube functioning and decreased levels of mannose-binding lectin.[107] However, eustachian tube functioning is not predictive of risk of recurrence of otitis media with effusion.[108] Eustachian opening and closing functions are dynamic and highly variable in ears with otitis media with effusion.[109]

Chronic suppurative otitis media is a stage of ear disease in which there is ongoing chronic infection of the middle ear without an intact tympanic membrane (presence of a perforation or tympanostomy tube).[95] It is one of the most common infectious diseases of childhood and is most common in developing countries, in certain high-risk groups in developed nations, and among children who have had tympanostomy tubes inserted.[95] Risk factors that have been attributed to the high rates of chronic suppurative otitis media are lack of breastfeeding, overcrowding, poor hygiene, poor nutrition, passive smoking, high rates of nasopharyngeal colonization with potentially pathogenic bacteria, and inadequate health care.[95] Bacteria isolated in chronic suppurative otitis media are listed in Box 32-10.

BOX 32-9 Bacterial Causes of Acute Otitis Media and Bacteria Found in Otitis Media With Effusion

Common Causes

50% *Streptococcus pneumoniae* serotypes 1, 3, 4, 6, 7, 9, 14, 15, 18, 19, and 23
25% Nontypable *Haemophilus influenzae* and *H. influenzae* type b
25% *Moraxella catarrhalis*

Rare Causes

Mycoplasma pneumoniae
Chlamydia trachomatis
Chlamydia pneumoniae
Enteric bacteria
Staphylococcus aureus
Staphylococcus epidermidis
Streptococcus pyogenes
Pseudomonas aeruginosa

BOX 32-10 Bacterial Isolates in Chronic Suppurative Otitis Media

Enteric gram-negative bacilli
Mixed aerobic and anaerobic bacteria
Mycobacterium tuberculosis
Pseudomonas aeruginosa
Staphylococcus aureus

Clinical Features

Acute otitis media typically presents with generalized symptoms of malaise, earache, and often fever. An older child

complains of muffled hearing, a sense of fullness, and discomfort of the ear. In a younger child, there are more likely to be systemic signs such as high fever, nausea, vomiting, loss of appetite, malaise, generalized muscle pain, nasal congestion, flushed face, and, occasionally, diarrhea and restlessness. The pain may be severe and accentuated by swallowing, and occasionally there may be throbbing tinnitus. The fever, pain, deafness, and tinnitus may worsen, and there may be tenderness over the mastoids, but there is immediate relief of pain and systemic symptoms if the drum ruptures and the pus drains.

The clinical suspicion of otitis media is confirmed by appropriate otoscopic examination. Typical signs of acute otitis media are retraction, diminished light reflex, and poor mobility of the drum. The light reflex may completely disappear, and the drum becomes opaque. There is injection of vessels around the margin of the tympanic membrane and adjoining external auditory canal skin. The tympanic membrane moves but less freely with insufflation, and such movement is painful. The drum becomes red, and the pars tensa becomes thick and convex and bulges, with loss of landmarks. In young children, there may be swelling of the posterosuperior aspect of the adjacent external auditory canal skin. As the condition progresses, the drum becomes convex, tense, and whitish, and it bulges, with no mobility and hyperemic vessels on the periphery. There may be yellowish necrotic areas. The drum may rupture in the pars tensa, causing a gush of purulent material, blood, or serosanguineous fluid. Drainage usually stops after 1 to 2 days and the perforation becomes dry. The perforation is generally small and does not enlarge, and after the infection subsides, it usually heals completely (Fig. 32-4).

Although viral infection may be associated with otitis media, there is no clinical way of distinguishing between viral and bacterial otitis media. If purulent conjunctivitis is also present, acute otitis media is most likely due to nontypable *H. influenzae,* and these clinical signs in combination should influence antibiotic choice. *M. pneumoniae* is a more likely cause if pneumonia is present.

Otitis media with effusion causes fluctuating hearing loss, which may have an adverse effect on speech, language, and cognitive development, although there seems to be a catch-up to normal by age 7 years. The clinical suspicion is confirmed by persistence of middle ear effusion without signs of inflammation. Cases may occur with infection, tubal obstruction, allergic or immunologic disorders, enlarged adenoids, or, rarely, nasopharyngeal tumors.

In chronic suppurative otitis media, the cardinal feature is chronic otorrhea, which is often smelly. Hearing loss occurs in 96% and is more severe than in otitis media with effusion.[95]

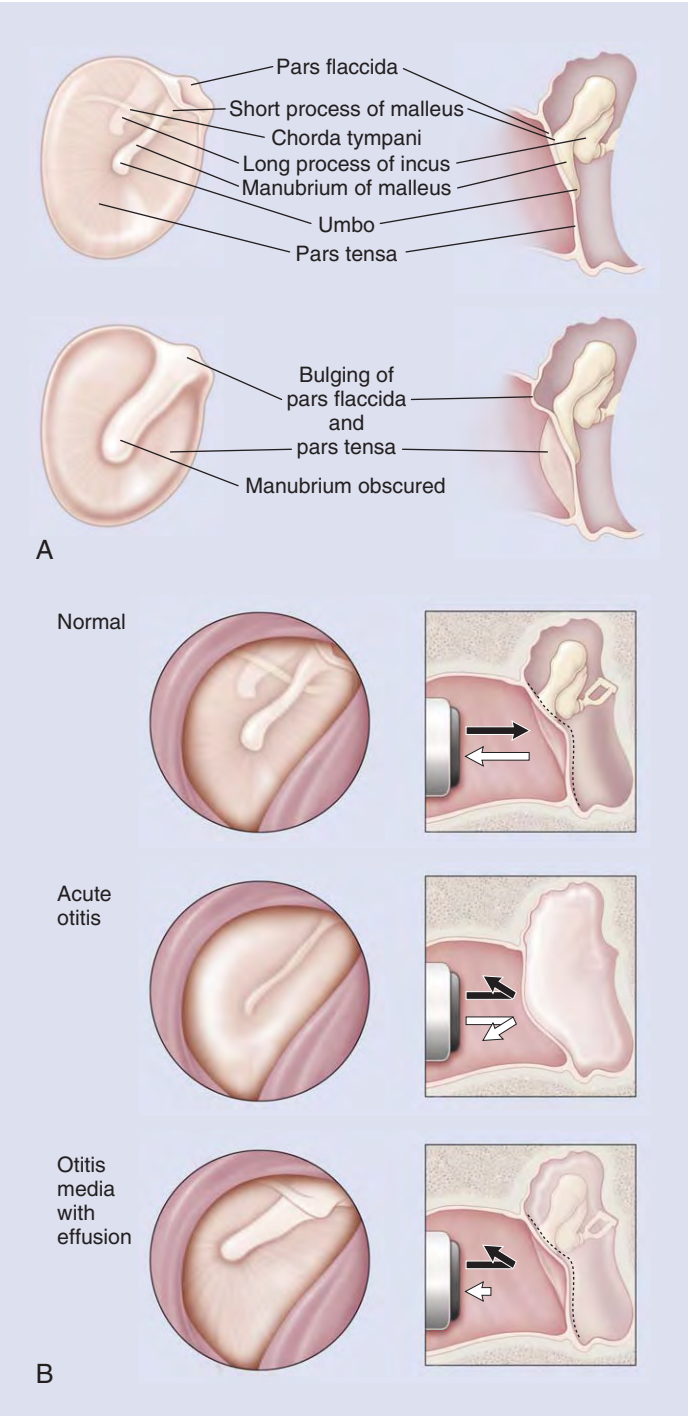

Figure 32-4 **A,** Visual assessment of middle ear status: normal and bulging. **B,** Visual assessment of tympanic membrane: normal, acute otitis media, otitis media with effusion. (From Pelton SI: Otoscopy for the diagnosis of otitis media. Pediatr Infect Dis J 17:540-543; discussion 580, 1998.)

Diagnosis

When acute otitis media has classic symptoms and signs, making the diagnosis from clinical features is not difficult. However, uncommonly, acute otitis media may have no localizing symptoms or less impressive signs of inflammation. Sometimes, the tympanic membrane is difficult to visualize. In this situation, the clinical distinction between acute otitis media and otitis media with effusion is difficult. The critical distinguishing factors are signs of acute inflammation versus otoscopic evidence of middle ear effusion. If otoscopic examination cannot be satisfactorily completed, tympanometry is indicated.

A strong light source and adequate magnification are necessary. Where possible, debris in the canal is removed. The

mobility of the drum should be tested, by occluding the external canal completely with a large ear speculum and using pneumatic otoscopy, permitting the application of positive and negative pressure. Visualization of the tympanic membrane and assessment of mobility are the standard for the diagnosis of otitis media.[110]

There is a poor correlation between qualitative and semiquantitative cultures of the nose and throat and those of the middle ear. Tympanocentesis is the only reliable way of detecting middle ear pathogens, but it is primarily a research tool and is seldom done in clinical practice.

Tympanometry gives an objective, reproducible measure of middle ear function. It is particularly useful in situations in which otoscopy is difficult or unreliable. In the infant under 6 months of age, it can be unreliable because of collapsing ear canals. Normative values have been established for 7- to 24-month-old children.[111] The findings of whether there are signs of acute inflammation are of a type B (flat) tympanogram or C2 (peak at less than –200 mm H_2O). Tympanometry is at least as sensitive in detecting middle ear fluid as pneumatic otoscopy[112] (Fig. 32-5).

Clinicians should document the laterality, duration of effusion, and presence and severity of associated symptoms in the child with otitis media with effusion at each assessment.[113] Children with otitis media with effusion who are at risk for speech, language, or learning problems need to be distinguished from all other children with otitis media with effusion. Those at risk include children with permanent hearing loss independent of otitis media with effusion, suspected or diagnosed speech and language delay or disorder, autism-spectrum disorder, syndromes such as Down syndrome that include cognitive, speech, and language delays, uncorrectable visual impairment, cleft palate with or without associated syndrome, and developmental delay.[113] In such children intervention may be required more promptly. In healthy children not at risk, watchful waiting for 3 months from the date of effusion onset (if known) or diagnosis (if onset is unknown) is recommended.[113]

The symptoms of acute otitis media need to be distinguished from those of acute systemic illness. The specific diagnosis can usually be made by noting the general symptoms and performing an adequate and complete inspection of the tympanic membrane. There can be difficulties when the external canal or debris within it does not allow adequate visualization.

Ear pulling in the absence of other symptoms is not related to ear infection.[114] Hyperemia of the tympanic membrane can occur with crying, trauma to the external auditory canal, or mild upper respiratory tract infections. These situations can be distinguished from acute otitis media because other abnormal features of the drum, in particular reduced mobility, would be lacking in them. Acute bullous myringitis can occur with acute otitis media. It causes more severe symptoms with blisters on the tympanic membrane, but it has a good clinical outcome.[115] Otalgia may be caused by referred pain from infections in the adenoids, tonsils, teeth, nasopharynx, hypopharynx, or larynx through the tenth cranial nerve. Tumors of the palate, nasopharynx,

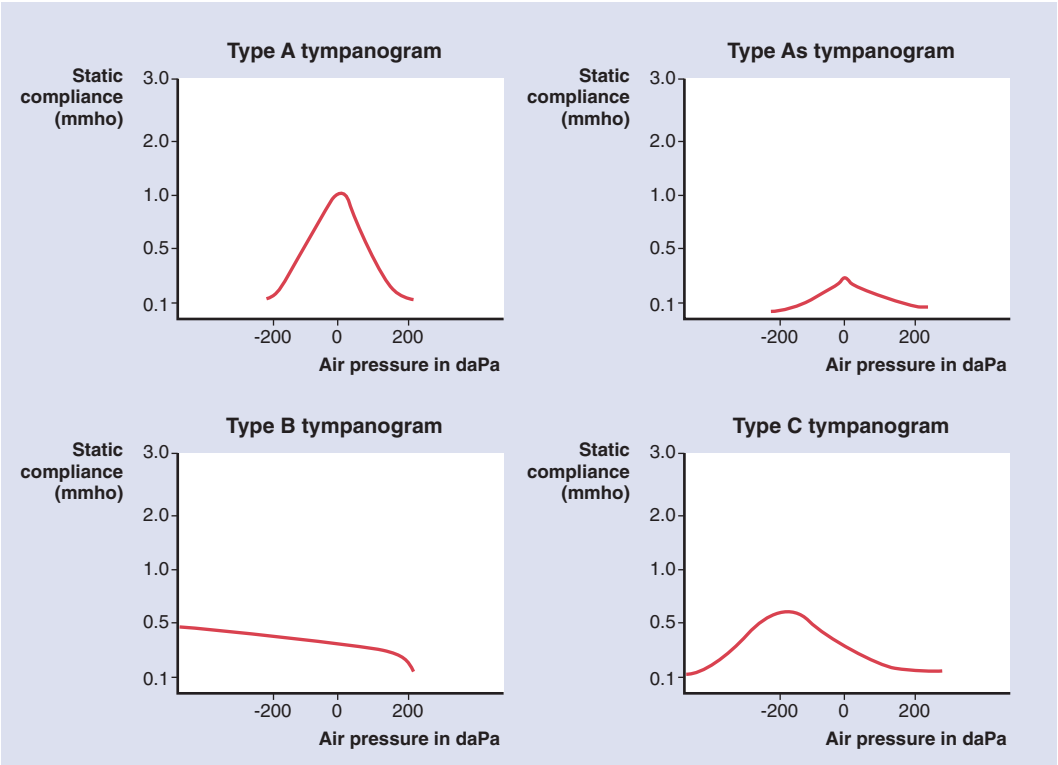

Figure 32-5 Tympanogram: classification system for low-frequency tympanograms. Based on Jerger (1970). (From Harris PK, Hutchinson KM, Moravec J: The use of tympanometry and pneumatic otoscopy for predicting middle ear disease. Am J Audiol 14:3-13, 2005.)

or base of the skull eventually occlude one or both eustachian tubes.

Treatment

The goals of treatment are to shorten the duration of symptoms of acute otitis media, to prevent complications, to prevent progression to chronic suppurative otitis media, and to prevent long-term hearing loss.

ACUTE OTITIS MEDIA

The management of acute otitis media varies within the Western world,[116] but the development of evidence-based guidelines may lead to a more standardized approach. In the past decade, several randomized controlled trials and meta-analyses have advanced knowledge about treatment strategies for this condition and otitis media with effusion.

All randomized clinical trials of antibiotic use for acute otitis media are from developed countries. They have shown that about 15 children needed to be treated to prevent one child from having pain on days 2 to 7 (no benefit on day 1). The effect on hearing is inconclusive.[117] Antibiotic use in groups where mastoiditis is common may reduce the risk of its development.[118]

Patients with acute otitis media are treated as outpatients if there is no systemic infection, unless there is frequent vomiting requiring hospital care. Children should be allowed to rest until the fever has resolved for 24 hours. Pain relief with acetaminophen is indicated. The complications of bacterial otitis media can be so serious that every child with acute inflammation should be seriously considered for antibiotics. The only indication for withholding antibiotics is a situation in which there is redness and no other sign of inflammation and the child can be reliably monitored every 1 to 2 days by otoscopy, with the parent bringing the child between visits if the condition deteriorates. The indications for antibiotics are absolute in children under the age of 6 months, regardless of symptoms, and in children of any age who have severe symptoms such as fever or vomiting. Observation with monitoring is allowable for nonsevere illness.

The choice of antibiotics for acute otitis media is determined by the known likely pathogens and local sensitivity patterns. Other factors influencing choice of therapy include the age of the patient, likelihood of compliance with the dosing frequencies, hypersensitivity to antibiotics, the cost of the antibiotics, and the patient's previous experience with the medication.[119] As illustrated in Figure 32-6, amoxicillin, 80 mg/kg/day in three divided doses, is the usual first choice of treatment.[120] If the patient is allergic to penicillin, trimethoprim-sulfamethoxazole is the usual alternative (8 mg of trimethoprim and 40 mg of sulfamethoxazole per kilogram per day in two doses). If the child has had no symptomatic response within 3 days, a change of an antibiotic is indicated. Alternatives are amoxicillin-clavulanate potassium, 40 mg/kg/day in three doses; cefixime, 8 mg/kg/day in one or two doses[121]; and erythromycin-sulfisoxazole, 50 mg/kg/day in four doses. Cefaclor (40 mg/kg/day in two or three doses) is less efficacious. If the child is vomiting, a single intramuscular dose of ceftriaxone, 50 mg/kg/day, is as effective as 10 days of oral amoxicillin.[122] All these antibiotic regimens seem to have comparable efficacy in resolving the clinical features of acute otitis media. Paradoxically, there can be a good clinical response to amoxicillin despite the presence of middle ear pathogens that produce β-lactamase. In acute otitis media in the neonate, special vigilance is required because infection may progress. If there is accompanying systemic infection, hospital admission with parenteral therapy covering *S. aureus* and gram-negative bacilli is indicated.

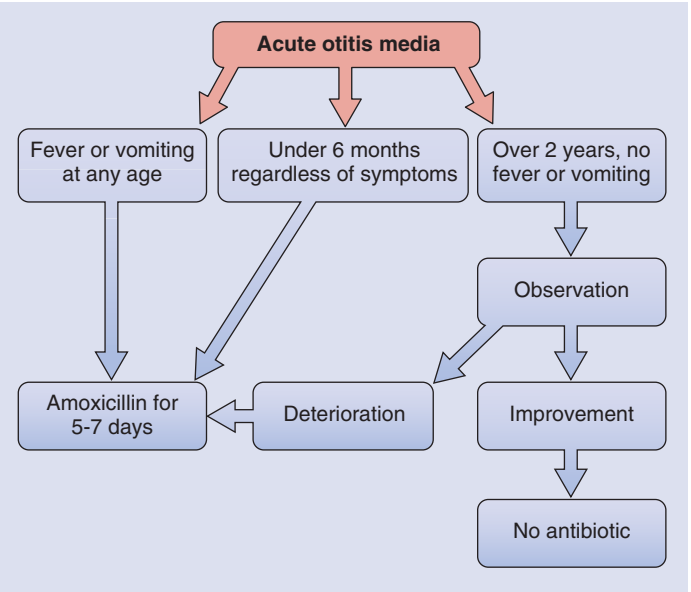

Figure 32-6 Antibiotics for acute otitis media.

When antibiotics are given early, the length of the symptomatic period may be reduced, and the infection is usually arrested before the drum ruptures. Immediate antibiotic treatment brings more rapid relief of pain and malaise compared with delaying the onset of treatment by 48 hours.[123] Early eradication of pathogens from middle ear fluid during antibiotic treatment of acute otitis media is associated with improved clinical outcome.[124] However, improved clinical outcome does not necessarily predict bacteriologic outcome. Bacteriologic failure occurs most often in children under 18 months of age.[125] Incomplete eradication could be one reason that otitis media with effusion may develop.

There is no consistent evidence from randomized, controlled trials that nasal decongestants, mucolytic agents, or antihistamines help prevent or treat any form of otitis media.[126] Intranasal steroids given to children with viral upper respiratory infections do not provide symptomatic relief or decrease episodes of acute otitis media and may even increase this undesired outcome.[127]

Myringotomy is indicated when there is severe, persistent pain and failure to respond to initial antibiotic therapy or when there is a complication of otitis media with an intact drum or persistent conductive hearing loss. In clinical practice, myringotomy is seldom performed despite these indications.

The role of adenoidectomy and adenotonsillectomy in reducing recurrence of acute otitis media is not established. Coyte and colleagues[128] found that among children over 2 years old, adenoidectomy and adenotonsillectomy at the time of insertion of tympanostomy tubes reduced the likelihood of additional hospitalizations and operations related to otitis

media. However, Hammaren-Malmi and colleagues[129] found in children 1 to 4 years of age that adenoidectomy did not reduce the incidence of acute otitis media in children who have recurrent acute otitis media, or otitis media with effusion with tympanostomy tubes. Paradise and colleagues[130] found that in children with recurrent acute otitis media with or without otitis media with effusion, that adenoidectomy and adenotonsillectomy showed limited short-term benefit but did not recommend it as a first intervention because of adverse events and cost.

Following interventions by an otolaryngologist, there was a significant disease-specific improvement in quality of life, physical suffering, emotional distress, and caregiver concerns, regardless of the treatment given.[131,132]

Adjuvant treatment with prednisone 2 mg/kg/day versus placebo for 3 days has been shown in a randomized controlled trial to reduce the duration of otorrhea from 3 days to 1 day in children also treated with amoxicillin/clavulanate who have acute otitis media with tympanostomy tubes.[133]

Myringotomy with insertion of tympanostomy tubes is indicated for persistent otitis media with effusion with hearing loss, taking into account that in an otherwise healthy child 50% of cases resolve spontaneously. The timing of tympanostomy tube insertion depends on the clinical risk of the child (Fig. 32-7). Tympanostomy tube insertion has become very common and is the main reason a child in the United States receives a general anesthetic. Waiting for spontaneous resolution in otherwise healthy children may reduce the number of children receiving this operation. If otitis media with effusion has been present for 9 to 12 months with decreased hearing, tympanostomy tubes are indicated. This can result in improvement in hearing (average, 12 decibels [dB]) in the short term, but there is no evidence that there is a beneficial effect on development or behavior. At the time of insertion of tympanostomy tubes, the clinician should conduct a preoperative assessment, including a developmental assessment, history of hearing difficulty or speech or learning problems, documentation of actual hearing impairment, and pneumatic otoscopy and tympanometry.

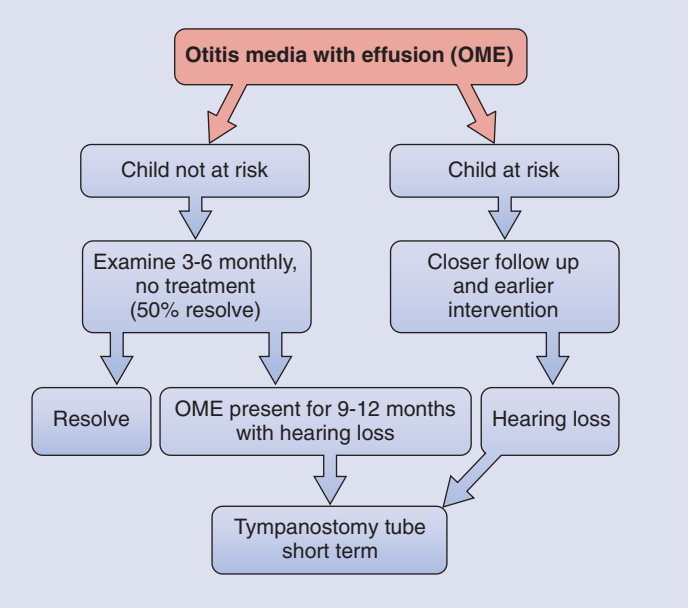

Figure 32-7 Management of otitis media with effusion (OME).

Anesthetic complications of bilateral tympanostomy tube placement in a tertiary care children's hospital are infrequent, and all can be successfully treated. A minor adverse event occurred in 9% (agitation or prolonged recovery) and a major event occurred in 1.9% (upper airway obstruction or laryngospasm), most commonly in a child with an acute or a chronic illness.[134]

In otherwise healthy children younger than 3 years of age who have persistent otitis media with effusion, prompt insertion of tympanostomy tubes does not improve developmental outcomes at 3 and 6 years of age.[135,136]

Sequelae of tympanostomy tubes are common but are generally transient (otorrhea) or cosmetic (tympanoslerosis or focal atrophy). Nonetheless, the high incidence suggests the need for ongoing surveillance of all patients with indwelling tubes and for a reasonable time period after tube extrusions. Long-term tubes should be used rarely for unusually severe cases.[137] Acute otitis media with tympanostomy tubes responds better to topical antibiotics than oral antibiotics[138,139] (Box 32-11).

Eustachian tube inflation by mechanical means, using nasal balloons (Otovent), appears to be associated with short-term improvement in otoscopic findings in 3- to 10-year-old children compared with findings in controls.[140] Its place in the treatment of otitis media with effusion has yet to be established.

The components of treatment of chronic suppurative otitis media include aural toilet, topical antibiotics, and closure of prolonged tympanic perforation. There are few randomized controlled trials for this condition. Treatment of chronic suppurative otitis media with aural toilet and topical antibiotics, particularly quinolones, is effective in resolving otorrhea and eradicating bacteria from the middle ear.[141] Aural toilet is ideally performed using the microscope and microinstruments to mechanically remove debris. Topical quinolone antibiotics can clear aural discharge better than no drug treatment or topical antiseptics. Studies are inconclusive regarding any differences between quinolone and nonquinolone antibiotics.[142] Topical antibiotics are more effective than oral antibiotics, probably because a higher local concentration of antibiotic is achieved.

Clinical Course and Prognosis

Chronic perforation without otorrhea can occur as a complication of acute otitis media or after tympanostomy extrusion.[95]

BOX 32-11 Tympanostomy Tubes

This is the most common operation in childhood in developed countries.

Complications include
- Anesthetic risks
- Purulent discharge
- Granulation tissue
- Chronic perforation
- Retraction pockets
- Atrophic scars
- Tympanosclerosis

Eighty percent of children with acute otitis media settle spontaneously in 7 days.[118] Intracranial or intratemporal complications can occur with acute otitis media. Antibiotic therapy is indicated to prevent these serious bacterial complications. Extension of inflammation and infection beyond the mucoperiosteal lining of the middle ear may result in mastoiditis or meningitis (especially with *H. influenzae*). The symptoms and signs of acute mastoiditis may be subtle, especially if they are partially treated by antibiotics or if the tympanic membrane is ruptured. The recurrence of pain and the presence of copious purulent discharge associated with low-grade fever suggest mastoiditis. Usually, there is tenderness over the mastoid process, and there may be edema of the mastoid periosteum, sometimes with postauricular pitting. In the external auditory canal, there is a sagging bulge in the posterior superior wall.

After acute otitis media, up to 20% of cases progress to otitis media with effusion. Some 50% of such patients recover after 3 months, but in about 5% the condition persists after 12 months. A large number of cases are transient, with episodes varying in duration and severity. Sometimes, there is recurrence of otitis media with effusion when acute otitis media does not recur.

In children with tympanostomy tubes for otitis media with effusion, 50% to 83% have episodes of otorrhea,[106] mostly nonsevere and self-limited, reflecting secondary inflammation of the eustachian tube and middle ear during viral upper respiratory infection.[137] These simple cases of otorrhea are inevitable and cannot be prevented by water precautions, prophylactic drops, or changes in surgical technique. Management with ototopical antibiotic drops such as ofloxacin alone is sufficient to treat purulent otorrhea.[138]

The hearing level at 14 years of age of healed ears after tympanostomy tubes is normal. In ears showing abnormalities (perforation, pars tensa retraction, otitis media with effusion) 25% have varying degrees of hearing loss.[143]

Prevention

The advent of pneumococcal vaccines has led to investigation of their role in the prevention of acute otitis media where 50% of bacterial causes are due to *S. pneumoniae*. A small benefit has been shown for pneumococcal polysaccharide vaccine in children over 2 years of age who have had previous episodes of acute otitis media.[144] There was also a small reduction in risk of recurrent disease with pneumococcal conjugate vaccine. An 11-valent pneumococcal vaccine conjugated with *H. influenzae*–derived protein D, given at 3, 4, 5, and 12 to 15 months of age, has been shown to have an efficacy of 34% against first episodes of otitis media in the first 2 years of life (95% confidence interval, 21% to 44%).[145]

Efforts to prevent chronic suppurative otitis media should be directed toward improvement in health care and living conditions in all populations that have a high prevalence of chronic suppurative otitis media, encouragement of breastfeeding, and reduction of cigarette smoking exposure.[95]

Pitfalls and Controversies

In neonates, otitis media may be overdiagnosed. The tympanic membrane often appears thickened and opaque during the first few weeks of life and lies in an extremely oblique position, making it difficult to distinguish it from the canal wall. The ear canal is particularly compliant, with positive pressure simulating the movement of the tympanic membrane.

There is frequently a gap in training in pneumatic otoscopy for most clinicians due to the lack of easy-to-use dual-headed equipment to enable training and evaluation of medical personnel. These skills can be learnt and result in high sensitivity and specificity.[110]

The method of use of antibiotics for acute otitis media and tympanostomy tubes for otitis media with effusion used to be highly controversial. However, many well-conducted randomized controlled trials and evidence-based Cochrane reviews have clarified most of the contentious issues. The challenge is to disseminate this knowledge to achieve evidence-based practice (Box 32-12).

BOX 32-12 Otitis Media Teaching Points

- In acute otitis media, there is acute inflammation with 5% viral only, 75% bacterial only, and 20% both bacterial and viral. The most common organism is *Streptococcus pneumoniae,* and the first-line antibiotic is amoxicillin.
- In otitis media with effusion, there is middle ear effusion, and up to 20% of cases of acute otitis media progress to otitis media with effusion.
- In chronic suppurative otitis media including perforation, there is otorrhea and deafness. This is an important public health problem.

ADENOIDECTOMY AND TONSILLECTOMY

Elective surgical removal of the tonsils and adenoids was once widely performed, usually with the hope of reducing the frequency of recurrent sore throats, but the rate for this surgery has fallen over the past three decades. However, it remains the most common major operation in children in the United States, although the scientific basis of this practice is not well established.[146] Children aged 3 to 8 years normally have up to nine respiratory tract infections a year. Prospective objective monitoring of symptoms demonstrates lower rates than frequency of symptoms recalled. In severely affected children with frequent, well-documented episodes of sore throat,[147] tonsillectomy reduces the occurrence of throat infection.[147] In children moderately affected with recurrent throat infection, however, the modest benefit conferred by tonsillectomy or adenotonsillectomy does not justify the inherent risks, morbidity, and cost of the operations.[148] Adenotonsillectomy was no more efficacious than tonsillectomy alone.[148]

The most important indication for adenotonsillectomy is obstructive sleep apnea, which can be serious and even life threatening. Removal of both tonsils and adenoids is usually of marked clinical benefit.[149,150] Tonsillar or adenoidal size is not always a reliable indicator of the potential benefit of tonsillar removal.

BOX 32-13 Adenoidectomy and Tonsillectomy Teaching Points

- The main indication for adenoidectomy and tonsillectomy is obstructive sleep apnea.
- Adenoidectomy and adenotonsillectomy are not recommended for prevention of recurrent otitis media.
- Tonsillectomy may be beneficial in children with recurrent severe tonsillitis.

Adenoidectomy has been used in children with otitis media, in an attempt to reduce recurrence of acute otitis media and persistence or recurrence of otitis media with effusion, but the indications remain unclear. Although adenoidectomy and bilateral myringotomy (without tympanostomy tubes) were beneficial in children 4 to 8 years old who were severely affected by otitis media with effusion,[151] adenoidectomy did not reduce the occurrence of acute otitis media in children who have recurrent acute otitis media, or otitis media with effusion with tympanostomy tubes.[129] Among children over 2 years old, adenoidectomy and adenotonsillectomy at the time of insertion of tympanostomy tubes for otitis media with effusion reduced the likelihood of additional hospitalizations and operations related to otitis media.[128] In a further study of children with recurrent acute otitis media, with or without otitis media with effusion, adenoidectomy and adenotonsillectomy showed limited short-term benefit and could not be recommended as a first intervention because of adverse events and cost[130] (Box 32-13).

SINUSITIS

Sinusitis is a bacterial infection of the paranasal sinuses that uncommonly complicates the common cold. The use of antibiotics dramatically reduces the occurrence of complications of sinusitis.

Epidemiology, Risk Factors, and Pathogenesis

In children, sinusitis almost always occurs as a complication of the common cold in developmentally aerated sinuses. It is more common in boys than in girls. The viral infection inflames the mucosa and causes damage to nasal ciliated epithelial cells, encouraging infection with bacteria colonizing the upper respiratory tract. Infection can occur in any of the paranasal sinuses as they develop (Box 32-14). Although the full development of the frontal sinuses may take 20 years, sinusitis can occur at any age.

The four-paired paranasal sinuses communicate with the anterior nose, with which they form a system of narrow channels. The mucosa of the sinuses, like that of the nose, is a continuous ciliated columnar epithelium with goblet cells and is covered in part by a mucous blanket. A continual flow of mucus from the frontal, maxillary, and anterior ethmoid sinuses is propelled toward the ostia and then posteriorly to the nasopharynx. The mucus contains IgA, IgG, IgM, and lysozyme, and the paranasal sinuses are usually sterile. Damage to mucociliary function allows the inoculation of large numbers of pathogens into the sinuses, which causes infection. Once started, sinus infection is aggravated by further inflammation of the ostia of the sinuses, resulting in progressive obstruction. Irritants, such as swimming underwater and drying of the mucosa during winter in cold climates, can set the stage for sinus infection. Host factors predisposing to sinusitis are listed in Box 32-15.

BOX 32-14 Development of Sinuses

Birth: ethmoid sinuses aerated but small
Birth: maxillary sinuses aerated but small
1 to 2 years: sphenoidal sinus aerated
5 to 7 years: frontal sinuses aerated
Developmentally poorly aerated sinuses appear radiologically opaque

The organisms causing sinusitis are listed in Box 32-16. The most common causes are *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. These organisms, along with *S. aureus* and *S. pyogenes*, account for over 90% of cases of sinusitis in children. In adolescents, penicillin-sensitive anaerobes become more common. There may be a vast array of enteric gram-negative and other bacilli recovered, mostly from those who have had antibiotic therapy before culture.[152,153]

Clinical Features

Acute sinusitis is heralded by failure of common cold symptoms to resolve after 10 days.[153,154] Older children have more specific complaints than younger children. Sometimes, the sinusitis can be more acute with severe initial symptoms: fever greater than 39° C and purulent nasal discharge. Acute sinusitis involves symptoms persisting from 10 to 30 days, and after this time, it is usually categorized as chronic. However, an international consensus panel has suggested that the term *rhinosinusitis* be used instead of *sinusitis* because of the coexistence of rhinitis and that the term *chronic* be reserved for those with symptoms persisting beyond 12 weeks.[155]

The main symptom is rhinorrhea (80%), which is frequently purulent but can be serous or watery. In a minority of patients, there is fever, cough (especially at night), pain, headache, sore throat, periorbital swelling, vomiting, and, occasionally, malodorous breath. Sinus tenderness is uncommon in children. Posterior pharyngeal pus is not usually seen in acute sinusitis and is very uncommon in chronic sinusitis. Periorbital swelling is usually a sign of acute ethmoid sinusitis. Acute sinusitis is more frequently unilateral, and chronic

BOX 32-15 Host Factors in Sinusitis

Common cold
Respiratory allergies
Defects of ciliary function
Cystic fibrosis
Immunodeficiency
Anatomic abnormalities
Gastroesophageal reflux

BOX 32-16 Organisms Causing Sinusitis

Most Common

Haemophilus influenzae
Moraxella catarrhalis
Streptococcus pneumoniae

Less Common

Acinetobacter spp.
Alcaligenes spp.
Citrobacter spp.
Diphtheroids

Curvularia lunata
Drechslera spicifera
Zygomycetes

sinusitis is usually bilateral. In chronic sinusitis, the symptoms may be minimal: vague unwellness with some persistent signs of upper respiratory tract infection.

Diagnosis

The diagnosis is usually made on clinical grounds alone. In acute sinusitis, clinicians seldom undertake investigations. If investigations are undertaken, nasal culture reveals the organism in the majority of cases, but it should be obtained with careful technique. A vasoconstrictor such as phenylephrine hydrochloride 0.25% should be applied to the anterior nose, and bilateral cultures should be obtained under direct vision using a wire cotton swab touching material as it comes from the sinus ostium. In children who have neurologic complications or in whom treatment fails, antral puncture for aerobic and anaerobic culture can identify the organism.

In acute sinusitis, the number of band neutrophils may be increased. Some cases of sinusitis have an elevated erythrocyte sedimentation rate.

The differential diagnosis includes chronic nasal allergy, foreign bodies in the nose, cysts in the maxillary antra, nasal structural defects, palatal defects, dental infections, and infection of the adenoids.

Sinus radiographs are not sensitive or specific in diagnosing sinusitis.[156] CT scans are more sensitive than radiographs in chronic sinusitis but have low specificity. CT scans are indicated when there are complications or surgery is contemplated.[155,157,158] Ultrasonography is of doubtful value unless there is one normal air-filled maxillary sinus for comparison.

In chronic sinusitis poorly responsive to treatment, clinicians should consider investigation for underlying abnormalities of host defense.

Treatment

The goals of treatment are to reduce symptoms rapidly and to reduce the possibility of persistence of symptoms. Antibiotics should not be started if symptoms are improving.[159] Analgesics such as acetaminophen may be useful for controlling headache, pain, or fever. The primary treatment is antibiotics. Amoxicillin, 40 mg/kg/day in three doses, is adequate for the majority of *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis* infections. A brisk response to treatment is expected in 3 to 4 days, in which case a 10-day course of treatment is satisfactory.[160,161] The benefits are modest: eight children must be treated to achieve one additional cure.[160] In communities with β-lactamase–producing *H. influenzae* and *M. catarrhalis*, the following antibiotics should be considered: amoxicillin–clavulanate potassium (40 mg/kg/day in three doses), trimethoprim-sulfamethoxazole (8 mg of trimethoprim and 40 mg of sulfamethoxazole per kilogram per day in two or three doses), and cefaclor (40 mg/kg/day in three doses).

Vasoconstrictive drugs are often used locally or systemically in an attempt to relieve obstruction at the sinus ostia to help establish drainage, but there is no evidence supporting their effectiveness.[161] Because topical medications can cause rebound vasodilation, these medications should be used only when there is considerable pain and then for no longer than 3 days.

Saline irrigation may have a role in the management of symptoms of chronic sinusitis,[162] but further studies are required.

Clinical Course and Prognosis

The outlook of sinusitis in otherwise healthy children receiving adequate treatment is excellent. Untreated sinusitis can

progress to orbital infection, meningitis, osteomyelitis, cavernous sinus thrombosis, and abscesses of the epidura, subdura, or brain.[163]

If the sinusitis is recurrent, fails to improve, or has more serious clinical features with high fever or periorbital swelling, consider amoxicillin–clavulanate potassium (40 mg/kg/day in three doses), trimethoprim-sulfamethoxazole (8 mg of trimethoprim and 40 mg of sulfamethoxazole per kilogram per day in two or three doses), and cefaclor (40 mg/kg/day in three doses).

If there are bacterial complications of sinusitis, the child should be hospitalized and given parenteral antibiotics. Initially, intravenous cefuroxime (100 mg/kg/day in three divided doses) is recommended; however, if *S. aureus* is a major concern, oxacillin or nafcillin should be added. Therapy should be adjusted on the basis of response to treatment and the results from culture.

Surgical drainage is rarely necessary in children. Fiberoptic endoscopic sinus surgery has replaced more invasive approaches. It is indicated only if there is lack of response to maximal medical therapy and continuing symptoms or in specific situations (Box 32-17). Optimal medical management, including 2 to 6 weeks of adequate antibiotics (intravenous or oral) and treatment of concomitant diseases, is indicated for uncomplicated sinusitis before medical treatment is regarded as failed, and surgery is recommended.

Pitfalls and Controversies

The relationship between sinus disease and lower respiratory tract infections and asthma has caused debate because of the lack of controlled studies. Nevertheless, treating sinus disease may be associated with improvement in concurrent lower respiratory tract symptoms through improved nasal airway or the direct effects of antibiotics on the lower airways[156] (Box 32-18).

BOX 32-17 Indications for Surgery

Complete nasal obstruction in cystic fibrosis due to massive polyposis or closure of the nose by medialization of the lateral nasal wall
Antrochoanal polyp
Intracranial complications
Mucoceles and mucopyoceles
Fungal sinusitis
Dacryocystorhinitis due to sinusitis and resistant to appropriate medical treatment
Chronic rhinosinusitis that persists despite optimal medical management and after exclusion of any systemic disease; endoscopic sinus surgery is a reasonable alternative to continuous medical treatment

From Clement PA, Bluestone CD, Gordts F, et al: Management of rhinosinusitis in children: Consensus meeting, Brussels, Belgium, September 13, 1996. Arch Otolaryngol Head Neck Surg 124:31-34, 1998.

BOX 32-18 Sinusitis in Children Teaching Points

- Acute sinusitis symptoms are present 10 to 30 days after common cold.
- Chronic sinusitis symptoms persist past 30 days.
- Main symptom is rhinorrhea.
- Sinus tenderness is uncommon in children.
- Postpharyngeal pus is seldom seen.
- First-line antibiotic is amoxicillin.
- Outlook is excellent in healthy children.

VIRAL CROUP

Viral croup is common, affecting approximately 15% of children. Although epiglottitis is less common, it is still necessary to consider this and other alternative diagnoses such as congenital airway abnormalities, foreign body, and bacterial tracheitis.

Many children with croup require no specific treatment. Oxygen, single-dose glucocorticoids, and inhaled epinephrine are effective therapies for those who have more significant airways obstruction.

Epidemiology, Risk Factors, and Pathogenesis

Acute upper airway obstruction in children is most commonly due to a viral infection causing laryngotracheitis or spasmodic croup. The term *acute laryngotracheitis* defines the site of inflammation, which always involves the larynx and trachea; if it is believed to extend to the bronchi, the name *laryngotracheobronchitis* is used. Spasmodic croup and recurrent croup are often regarded as separate diagnoses but may be part of the spectrum of the same condition.

Viral croup (which when used in this chapter will refer to both acute laryngotracheitis and spasmodic croup) is uncommon in the first 6 months of life. Under this age, preexisting abnormalities of the upper airway such as subglottic stenosis or hemangioma should be considered. These lesions may also be the cause of prolonged stridor because viral croup rarely lasts longer than 10 to 14 days.

Viral croup is a very common condition, affecting about 15% of children. The annual incidence of croup in children younger than 6 years old is between 1.5% and 6%.[164] It is most common between 6 months and 5 years of age, with a peak prevalence in the second year of life; the youngest reported patient is 3 months old.[165] The full picture of viral croup is rare over the age of 10 years. Boys are affected more often than are girls.

The symptoms and signs result from inflammation in the larynx, trachea, and sometimes the bronchi. They are almost always caused by viral infection. The causative viruses are listed in Box 32-19.

The parainfluenza viruses cause most cases of croup, with type 1 being most common, type 3 less common, and type 2 infrequent. Respiratory syncytial virus and several of the adenoviruses infrequently cause croup, as does influenza virus type A, which induces a particularly severe form.[166] Rhinoviruses, enteroviruses, herpes simplex virus, and reovirus

BOX 32-19 Viral Causes of Acute Laryngotracheitis

Common Causes

Influenza virus types A and B
Parainfluenza virus types 1 to 3
Respiratory syncytial virus

Uncommon Causes

Adenoviruses
Enteroviruses
Herpes simplex virus
Morbilli (measles) virus
Reovirus
Rhinoviruses

Viral, Bacterial, and Fungal Causes in an Immunodeficient Host

Candida albicans
Candida spp.
Herpes simplex virus type 2 (neonate)
Pseudomonas aeruginosa

have been associated with mild cases of croup. Morbilli (measles) virus may cause upper airway obstruction resulting from laryngotracheitis, sometimes severe enough to require intubation, and there may be complicating bacterial tracheitis. Rarely, the vesicular eruption of varicella may involve the larynx. Mild "viral" croup may also be caused by *M. pneumoniae* infection.

Primary bacterial croup is now uncommon. Immunization resulted in a rapid decline in croup due to C. *diphtheriae* infection. Bacterial croup became uncommon with the introduction of antibiotics.[167] Diphtheria must be considered if the child has not been immunized against C. *diphtheriae*. This organisms may cause a membranous obstructive laryngitis. In most cases now where bacterial infection occurs, this is secondary to a preceding viral infection. *S. aureus* is the most common bacteria implicated in this way. Others include *S. pyogenes*, *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*.[167]

Seasonal variability in croup reflects the epidemiology of the different etiologic viruses. Parainfluenza type 1 causes outbreaks of croup in autumn and croup due to parainfluenza type 3 occurs in spring. The seasonality of croup due to parainfluenza type 2 is more variable.[167,168]

After inhalation of the virus, the cells of the local respiratory epithelium become infected. There is marked edema of the lamina propria, submucosa, and adventitia accompanied by cellular infiltration with histiocytes, lymphocytes, plasma cells, and polymorphonuclear leukocytes.

There is redness and swelling of the involved airway, most marked in the lateral walls of the trachea just below the vocal cords. The subglottic trachea is surrounded by the fixed cricoid cartilage, forcing the inflammatory swelling to encroach on the internal airway lumen, narrowing it or reducing it to a slit (Fig. 32-8). The infant's glottis and subglottic region are normally narrow, and a small decrease in diameter results in a large increase in airway resistance and a decrease in airflow. As the airway diameter enlarges with growth, the impact of the subglottic airway swelling is reduced.

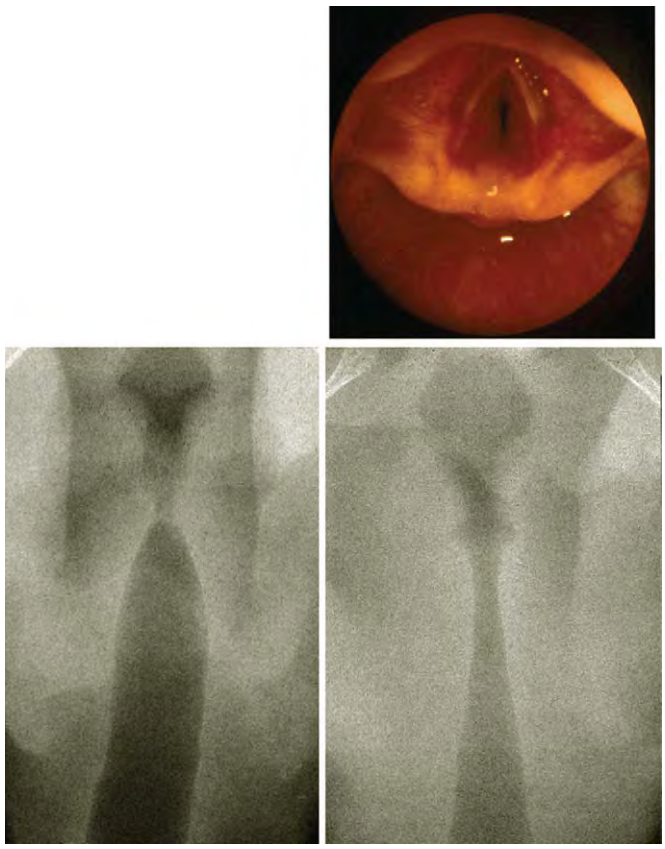

Figure 32-8 Endoscopic view of subglottic edema in viral croup (*top*). Radiologic presentation of subglottic edema in viral croup (*bottom right*) compared with normal trachea (*bottom left*). (From Hammer J: Acquired upper airway obstruction. Paediatr Respir Rev 5:25-33, 2004.)

In spasmodic croup, the direct laryngoscopic appearance shows pale, watery edema of subglottic tissues. There is an association with the same viruses that cause acute laryngotracheitis, but evidence suggests that the response to these viruses may be atopic rather than cytopathic.[167] Spasmodic croup occurs more frequently in children who are atopic.

Clinical Features

Typically, the illness starts with rhinorrhea, sore throat, and mild fever for a few days. Then the child develops a characteristic barking cough, hoarseness, and inspiratory stridor with or without low-grade fever.

An increasing severity of obstruction is evident with increasing heart and respiratory rate, flaring of alar nasi, and indrawing, especially suprasternal, intercostal, and sternal, in the younger child or infant. Increasing chest wall retractions occur as the intrathoracic pressure becomes increasingly negative and correlates with the severity of the upper airway obstruction.[169] Ribcage and abdominal asynchrony occurs as the condition deteriorates.[170]

Obstruction to airflow through the upper airway results in stridor and difficulty breathing and progresses to hypoxia when the obstruction is severe. Hypoxia with mild obstruction indicates lower airway involvement and ventilation-perfusion mismatch resulting from lower airway obstruction

or lung parenchymal infection or even fluid.[171] Hypercapnia occurs as a late change as hypoventilation progresses with obstruction.

As progressive hypoxia develops, the child is anxious or restless or may have depressed consciousness or cyanosis. Death can occur either from asphyxia or from respiratory fatigue.

On auscultation, breath sounds are normal with no added sounds except transmission of the stridor. Occasionally, there may be wheezing, indicating severe narrowing, bronchitis, or possibly coexistent asthma.

Becoming upset or worried may decrease the child's ability to manage the airway obstruction. Therefore, physical examination should be limited to the respiratory tract and reasonable exclusion of other diagnostic possibilities. Investigations are intrusive and should be avoided when possible.

The term *spasmodic croup* has been used to define a sudden onset of symptoms at night in a child who has been well. The symptoms are identical to viral croup but without fever, last for hours rather than days, and are seldom life threatening. The child may be well during the day and have attacks on three or four successive evenings. During the first attack, it is difficult to make an accurate diagnostic distinction from viral croup.

Diagnosis

The differential diagnosis includes any condition that causes obstruction in the region of the larynx. The most important are epiglottitis and laryngeal foreign body aspiration, both of which require emergency treatment. Acute angioedema usually presents with other evidence of swelling of the face and neck. Other conditions to be considered are retropharyngeal and peritonsillar abscess, bacterial tracheitis, subglottic stenosis, infectious mononucleosis, laryngeal diphtheria, and paraquat poisoning.

Investigations are seldom necessary in straightforward viral croup. When there is severe obstruction, neck radiographs or blood tests cause anxiety in the child, which may precipitate critically poor gas exchange. Pulse oximetry may support the clinical suspicion of hypoxia but should not be used as the only means of clinical assessment.

If radiography is deemed necessary to exclude epiglottitis or foreign body inhalation in a child whose airway is severely obstructed, it should be done in the presence of medical staff able to resuscitate and intubate a child with upper airway obstruction. However, epiglottitis is usually diagnosed clinically and confirmed under direct vision in the intensive care unit.

When radiography has been done, specific abnormalities are seen in 40% to 50% of cases (see Chapter 11). Posteroanterior neck radiographs may show a very narrowed subglottic region. In lateral neck radiographs, there may be widening of the hypopharynx and haziness in the subglottic region. Radiographic changes do not reliably reflect the severity of airway obstruction.

Treatment

Airway obstruction in croup can worsen rapidly; hence, repeated careful clinical assessment is a key component of management.[172,173]

Most children with viral croup have only mild airway obstruction that spontaneously settles; therefore, no specific treatment is indicated. Most of these children can be managed at home. By the time medical attention is sought, the airway obstruction often does not progress but usually lasts 4 additional days.

A commonly used home treatment is to sit the child in the bathroom with a parent with a hot shower running, in the belief that the warm mist will help the breathing. Trials of mist therapy have shown no evidence of efficacy. A single-blinded study of blow-by humidity showed it to result in identical changes in croup scores to those seen in children receiving no therapy.[174] A study of children with moderate croup that compared blow-by humidity with either 100% humidity or 40% humidity with smaller water particles generated by a nebulizer showed no significant difference between treatment groups in the change in croup score.[175]

In the child with obvious indrawing, anxiety, or other evidence of moderate or severe airway obstruction, it is vital to use a careful nonintrusive approach. A parent should stay with the child, and all interactions with the child should appear calm and reassuring. Mist treatment in the hospital is no longer recommended, and it may increase the child's anxiety.

Mild hypoxia with a hemoglobin oxygen saturation lower than 93% is common and closely correlated to the respiratory rate. When there are clinical signs of hypoxia such as restlessness, marked tachycardia, and cyanosis, or when there is significant oxygen desaturation ($SaO_2 < 90\%$) as measured by pulse oximetry, oxygen should be administered.[172]

At the same time, treatment to relieve the obstruction is needed. In a minority of children, the airway obstruction progresses to become severe. Admission to the pediatric intensive care unit is indicated for children with signs of hypoxia or progressive severity of obstruction. Among children hospitalized for viral croup, less than 1% require intubation. Rarely, idiopathic pulmonary edema occurs in severe obstruction.[176]

GLUCOCORTICOIDS

The theoretical mechanism of action of the steroids is suppression of local inflammatory reaction, shrinkage of lymphoid swelling, and reduction in capillary permeability. The mechanism by which glucocorticoids exert their effect in croup is unknown.[172] The place of steroids in the management of viral croup has been debated for 30 years. It was subjected to meta-analysis.[177]

In the large number of studies of corticosteroids for croup, treatment efficacy has been measured using clinical symptom severity scores and the need for return visits and hospital admission, length of hospital or emergency department stay, and the need for other additional therapy.[177] The validated scoring system that is most frequently used is the Westley score. This uses a 17-point scale to assess air entry (2 points), stridor (2 points), intercostal retractions (3 points), cyanosis (5 points), and level of consciousness (5 points).[178]

Efficacy of Glucocorticoids

As measured by improvement in Westley symptom scores: In placebo-controlled studies, glucocorticoids have been

shown to result in significant improvement in symptom scores at 6 and 12 hours but not at 24 hours after administration. The lack of significance of the effect at 24 hours may be due to low study power. The effect size seen at 24 hours is similar to that at 12 hours but has been examined in fewer studies. The number needed to treat at 6, 12, and 24 hours was five, with this considered sufficient to support the use of glucocorticoids over placebo.[177]*

As measured by return visits, length of stay, and use of additional therapy: In comparison with placebo, the rates of return visits and hospital admission are both significantly reduced (number needed to treat to prevent one return visit = 17). Length of stay in the emergency department or inpatient ward are both reduced, with the mean difference being approximately 12 hours. Children treated with glucocorticoids are approximately 10% less likely to be also treated with epinephrine.[177]

Different doses and routes of administration of glucocorticoids: Using symptom scores and return visits/readmissions as outcome measures, the efficacy of glucocorticoids versus placebo given by different routes of administration (oral, spray, intramuscular, subcutaneous) does not differ. Combinations of budesonide and dexamethasone versus either alone do not result in any increased effect.[179] Different doses of dexamethasone (0.15, 0.3, or 0.6 mg/kg) have similar efficacy.[177,180] The onset of action of nebulized budesonide is faster than that of oral or intramuscular glucocorticoids but slower than that of nebulized epinephrine.[172]

Efficacy of glucocorticoids for croup of varying severity: A single dose of glucocorticoid has been shown to be effective in croup of all grades of severity including mild croup defined as a score of 2 or less (of 17) on the Westley scoring system.[181]

Comparison with epinephrine: There is no significant difference in improvement in croup scores in studies that have compared glucocorticoids (dexamethasone or budesonide) with epinephrine.

Adverse effects of glucocorticoids: There is no evidence of any ill effects of a single dose of glucocorticoids given to a child with viral croup. The efficacy and safety of repeated doses of glucocorticoids in children with severe croup have not been established. However, there may be complications with steroids used inadvertently for diagnoses mimicking viral croup, such as epiglottitis or bacterial tracheitis, so the clinician must be certain of the diagnosis before administering them.[167] Both bacterial tracheitis and *Candida* laryngotracheitis have been reported to occur in children with croup being treated with glucocorticoids.[182,183]

EPINEPHRINE

Epinephrine (Adrenalin) was first introduced for viral croup in 1971. It is thought to stimulate α-adrenergic receptors in subglottic mucosa, producing vasoconstriction, resulting in less hyperemia and edema of the larynx and subglottic region. This results in increased airway diameter within 30 minutes. However, the effect is short lived, lasting about 2 hours because of dispersion of the epinephrine.[184] The first use of this treatment was with racemic epinephrine hydrochloride (Vaponefrin, equivalent to 2.25% epinephrine base), a mixture of equal parts of the inactive D-isomer and the active L-isomer. In some early studies,[185] this treatment was given with intermittent positive-pressure breathing, but a similar effect is seen without it.[186] Racemic epinephrine is not readily available in some countries, and it has been replaced by the use of L-epinephrine solution, which is cheaper.[184]

Epinephrine does not alter the natural history of the airway obstruction. Therefore, when the effects wear off, rebound may occur. The obstruction may be either as bad as before or worse if the overall condition is deteriorating. It is dangerous to discharge a child with croup who has been given nebulized epinephrine before ensuring that there is no rebound. The child should be observed for 6 hours after the dose. Epinephrine is used to provide immediate symptomatic relief in patients with moderate and severe croup and in those admitted to the intensive care unit in an attempt to avert the need for intubation.

Epinephrine is given via a nebulizer with a face mask and is driven with oxygen. The usual dose in infants weighing 10 kg is 5 mg, which may be given as 5 mL of 1 : 1000 solution of L-epinephrine or as 0.5 mL of 2.25% solution (22.5 mg/mL) of racemic epinephrine solution, which contains 5 mg of L-isomer. The latter is diluted with isotonic saline to a 3- to 5-mL volume. In young infants, graded doses based on body weight are appropriate: 0.5 mL/kg concentration of 1 : 1000 L-epinephrine to a maximum of 5 mL or 0.05 mL/kg of 2.25% solution to a maximum of 0.5 mL of racemic epinephrine. Doses may be repeated every 2 hours or even more often. Adverse reactions have not been reported. Nebulized epinephrine is relatively contraindicated in children with ventricular outflow tract obstruction, for example, tetralogy of Fallot.[172]

OTHER TREATMENTS

Intravenous fluids are not usually required in viral croup, but if a child is unable to drink, they may become necessary.

Admission to the intensive care unit is indicated when there is restlessness, anxiety, marked tachycardia, or cyanosis or when the child is tiring. In this situation, epinephrine and corticosteroids should be administered.

Helium and oxygen mixtures (helium : oxygen 80 : 20 or 70 : 30) improve gas flow when there is turbulent flow through high-resistance airways. This is because helium is one seventh the density of air, thereby increasing flow as well as allowing carbon dioxide to diffuse through it 4 to 5 times faster than it does through air.[187] Helium is an inert, nonflammable gas with no known pharmacologic effects.[172] Heliox (helium : oxygen 70 : 30) has been shown to be of similar efficacy to nebulized epinephrine in one small double-blind, randomized trial of children with croup who were receiving oxygen and glucocorticoids.[188]

Despite vigorous treatment with epinephrine and steroids, a child occasionally progresses to critical airway obstruction necessitating endotracheal intubation. This should be performed by a pediatric anesthetist or intensive care pediatri-

*In the studies included in the meta-analysis, improvement in the Westley score was defined in a number of ways.

cian experienced in endotracheal intubation using inhalational anesthesia. Intubation should be maintained until an air leak develops, indicating a reduction of airway edema, or until a maximum of 5 days passes, at which time a trial of extubation is attempted. Rarely, tracheostomy may be the only method of providing an alternative airway.

Clinical Course and Prognosis

About half the cases of croup progress to recurrent croup (at least two episodes). In a few individuals, numerous episodes occur. More of these children are boys; more have asthma, hay fever, eczema, and positive allergy prick tests; and more come from families with a history of atopy or croup than do children with nonrecurrent croup.[189] Pulmonary function studies have demonstrated lower expiratory flow rates, and increased airway responsiveness to histamine has been documented on inspiratory and expiratory flow-volume loops (Box 32-20).

EPIGLOTTITIS

Epiglottitis is a very serious infection of the epiglottis and supraglottic structures that results in acute airway obstruction and high risk of death if untreated. It is rare but must be considered in a child with dyspnea and stridor. If suspected, management must be initially focused on securing the airway.

BOX 32-20 Viral Croup Teaching Points

- Viral croup includes acute laryngotracheitis and spasmodic croup.
- Parainfluenza virus infections are the most frequent cause. Seasonal variability in croup reflects the epidemiology of the different etiologic viruses.
- Viral croup is common, affecting 15% of children, most commonly between 6 months and 5 years of age.
- Viral croup is uncommon in the first 6 months of life. Presentation in this age group necessitates consideration of alternative diagnoses such as congenital or vascular airway abnormalities.
- Characteristic clinical features are a barking cough, hoarseness, and inspiratory stridor with an absence of symptoms and signs of systemic toxicity.
- Investigations are seldom necessary in straightforward viral croup.
- Airway obstruction can progress rapidly; therefore, it is necessary to clinically reassess at frequent intervals.
- A single dose of a glucocorticoid has been shown to reduce clinical severity and decrease the need for hospital or emergency department care. Inhaled, oral, and parenteral routes of administration are all effective but do not have an additive effect. Beneficial effect has been shown for mild, moderate, and severe croup.
- Epinephrine provides rapid-onset, short-term relief of airway obstruction but does not alter the natural history of the disease.
- Some children get recurrent croup. Most of them are atopic.

Epidemiology, Risk Factors, and Pathogenesis

Since the introduction of vaccines that protect against *H. influenzae* type B (Hib) infection, epiglottitis has become a rare disease. Most cases now occur in adolescents and adults.[190,191] However, cases of epiglottitis due to Hib continue to be reported.[192] Other causative organisms include nontypable *H. influenzae*, *H. parainfluenzae*, *S. aureus*, and *S. pneumoniae*.[74] Occasionally, viruses[193-195] or *Candida* organisms are also causative.[196]

Direct bacterial invasion causes cellulitis with marked edema of the epiglottis, aryepiglottic folds, ventricular bands, and arytenoids. There is a large potential space for the accumulation of inflammatory cells and edema fluid where the stratified squamous epithelium is loosely adherent to the anterior surface and the superior third of the posterior portion of the epiglottis. There is diffuse infiltration with polymorphonuclear leukocytes, hemorrhage, edema, and fibrin deposition, and microabscesses may form. Infection of the supraglottic larynx may extend but does not usually reach the subglottis or the laryngeal lymphatic system.

Clinical Features

Up to half of the children have preceding upper respiratory tract symptoms. The onset of epiglottitis is typically abrupt, with early toxicity. The duration of symptoms before presentation to the hospital is usually less than 24 hours. Localizing symptoms are caused by supraglottic swelling and airway obstruction.

There is a very sore throat, difficulty swallowing because of pain, respiratory distress, drooling, a choking sensation, irritability, restlessness, and anxiety. The temperature is high, usually between 38.8° and 40° C (101.8° to 104° F). Sighing respirations, mild stridor, retractions, and mild tachypnea occur. Less common symptoms and signs are cough, which may be harsh, and occasionally barking, delirium, lethargy, hoarseness or aphonia, vomiting, chills, anorexia, cervical adenopathy, wheezing, and hypotonia.

The child naturally assumes a posture that maximizes the diameter of the obstructed airway: sitting and leaning forward with hyperextension of the neck and protrusion of the chin. A few may have shock with cyanosis, prostration, and loss of consciousness.

Children with epiglottitis are at risk for total airway obstruction. The enlarged, inflamed supraglottic ring can progress to respiratory obstruction with unexpected suddenness. Epiglottitis progresses to death in about 7% of children who do not have a secured airway. With accurate early recognition and elective intubation, the mortality rate should approach zero. Most deaths occur in the community, during transit to hospital or in the first few hours after arrival.

Chronic epiglottic enlargement may be seen with neck radiotherapy for cancer, granulomatous lymphangitis, or lymphangiectasis and in infection with the human immunodeficiency virus.[197] The chronicity of symptoms makes these conditions easily distinguishable from acute epiglottitis.

Similarly, congenital anomalies of the airway and laryngeal papillomatosis are usually quite distinct.

Diagnosis

Investigations should be left until the airway is secured. The diagnosis is confirmed under direct visualization. Detection of the responsible organism is important for guiding antibiotic management. Direct culture of supraglottic tissues reveals the causative organism in the majority of patients. The blood culture may also be positive. Blood leukocyte counts, mainly polymorphonuclear leukocytes, are increased. The numbers of immature neutrophils are increased in most cases. The level of C-reactive protein is usually raised.

The diagnosis is often clear from the specific clinical signs. However, it is sometimes difficult to differentiate epiglottitis from severe viral croup of a more rapid onset. Distinguishing features include the absence of spontaneous cough and the presence of drooling and agitation.[198] Toxicity, high fever, and sore throat may also occur with bacterial tracheitis, uvulitis, and retropharyngeal or parapharyngeal abscess. Nasopharyngeal diphtheria is now rare but may mimic acute epiglottitis and is associated with serosanguineous discharge. Noninfectious causes mimicking epiglottitis include angioedema, a pharyngeal burn, and a foreign body that is in the valleculae or larynx or that penetrates the posterior pharyngeal tissues.

Lateral radiographic views of the soft tissues of the neck may be needed if a laryngeal foreign body is suspected, but the patient's airway must be carefully monitored throughout the procedure. The best view of the anatomic structures of the upper airway is obtained with the patient upright. The hypopharynx is dilated, and the normal cervical lordosis may be replaced by a straight or kyphotic contour. The valleculae are narrowed and may be obliterated. A thickened mass of tissue extends from the valleculae to the arytenoid muscles (Fig. 32-9).

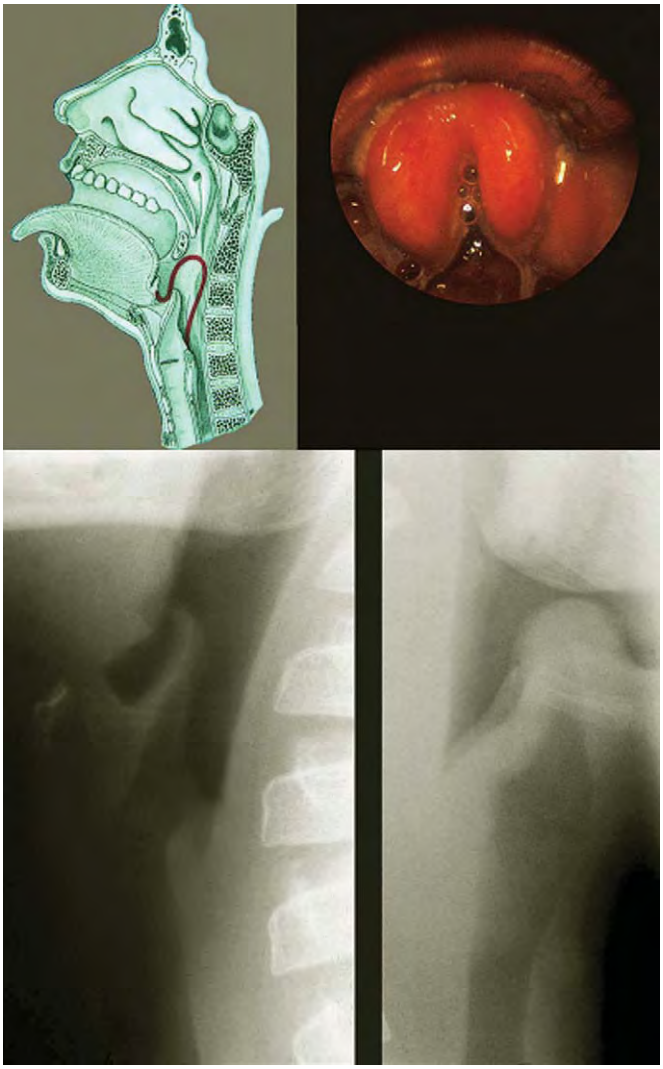

Figure 32-9 Schematic (*top left*) and endoscopic (*top right*) views of epiglottis. *Bottom,* Lateral neck radiographs of a normal child (*left*) and a child with the typical thumb sign (*right*). (From Hammer J: Acquired upper airway obstruction. Paediatr Respir Rev 5:25-33, 2004.)

Treatment

Because of the high risk of complete airway obstruction, great care should be taken in treating epiglottitis. Once a physician suspects this diagnosis, the child should be constantly attended by an individual skilled in resuscitation using the appropriate equipment for airway stabilization and ventilatory support. Delays of 2 to 3 hours have proved fatal. Every effort should be made to reduce the time needed to secure a patient's airway and initiate antibiotic therapy. During this waiting interval, unnecessary stress for the child should be prevented; the throat should not be examined. Extensive clinical assessment, transport delay, and blood tests should be avoided.

The airways should be secured as early as possible after diagnosis. A large body of literature attests to the safety and efficacy of elective nasotracheal intubation, which is the treatment of choice. A short period of airway maintenance is usually all that is required. A nasotracheal tube that is 0.5 mm smaller than that predicted by the patient's age is recommended. Expert nursing care is essential to prevent inadvertent extubation, particularly in the first 12 to 18 hours. The criteria for extubation include being afebrile and swallowing comfortably. Repeat examination of the epiglottis and supraglottic structures by direct laryngoscopy or fiberoptic bronchoscopy is not normally necessary.

Until the results of sensitivity tests are known, the child should be treated with a broad-spectrum intravenous antibiotic to cover the majority of possible isolates. Initial treatment is usually a second-generation cephalosporin such as cefuroxime (if meningitis is not present) or a third-generation cephalosporin such as cefotaxime or ceftriaxone. If the isolate is proved to be susceptible, ampicillin, a cheaper agent, may be substituted. If *S. pyogenes* is isolated from the airway, penicillin is the drug of choice. When *S. aureus* is isolated, a semisynthetic penicillinase-resistant penicillin or glycopeptide such as vancomycin should be used depending on sensitivity patterns. Erythromycin should be used for *C. diphtheriae*.

No controlled studies address the duration of antibiotic treatment, but a course of 7 days of intravenous administration (until the child is afebrile for 48 hours) followed by oral

therapy is commonly used. Ceftriaxone in a single daily dose of 100 mg/kg for 5 days is effective.[199]

Although there have been some recommendations to use corticosteroids, no controlled data support their use; in fact, they may be hazardous because of the side effects. Therapy with inhaled epinephrine is of no benefit.

Clinical Course and Prognosis

Complications are uncommon.[200] Evidence of pneumonia or atelectasis is sometimes seen on the chest radiograph. Other findings may include exudative tonsillitis, cervical lymphadenitis, and otitis media. Meningitis, septic arthritis, and pericarditis occurring with epiglottitis are rare; routine lumbar puncture is unnecessary.

In about 10% of children with epiglottitis in whom there is severe airway obstruction, idiopathic pulmonary edema may occur before or after insertion of endotracheal tubes.[176] The hypothetical mechanism is an increased pulmonary blood flow secondary to airway obstruction, causing markedly negative intrapleural pressure with increased venous return to the right side of the heart and decreased left ventricular output. These changes increase the pulmonary microvascular pressure and produce pulmonary hyperemia and edema. Endotoxemia may play a role in altering vascular permeability, but it is not a necessary prerequisite. Continuous positive airway pressure in intubated patients may decrease the occurrence of pulmonary edema.

Complications occurring after extubation include laryngeal edema and subglottic granulations. Long-term complications of nasotracheal intubation are rare. Tracheostomy is lifesaving but has been replaced by safer nasotracheal intubation.

Secondary disease can occur in household contacts of epiglottitis due to Hib. Epiglottitis has also occurred in household contacts of meningitis resulting from Hib. Rifampin (Rifampicin) prophylaxis eradicates nasopharyngeal carriage and is recommended as follows: a dosage of 20 mg/kg/day (600 mg maximum per dose) for 4 days for all members of a patient contact group when the index case has invasive Hib and there is at least one contact who is 4 years of age or younger. For patients younger than 2 years of age, prophylaxis is required for the child and all household contacts.[201]

Prevention of invasive Hib infection is now universally recommended using one of the approved polysaccharide conjugate vaccine regimens for children up to 5 years of age. These vaccines are highly effective in lowering the incidence of invasive epiglottitis resulting from Hib[202,203] (Box 32-21).

BACTERIAL TRACHEITIS

Bacterial tracheitis is uncommon but potentially life threatening. It is characterized by thick membranous tracheal secretions. These do not clear with coughing and can occlude the airway and cause death.[204]

Epidemiology, Risk Factors, and Pathogenesis

The age group most commonly affected is similar to that for viral croup with a mean age of 4 years.[204]

BOX 32-21 Epiglottitis Teaching Points

- Since the introduction of vaccines that protect against *H. influenzae* type B infection, epiglottitis has become a rare disease.
- Most cases now occur in adolescents and adults.
- The onset is typically abrupt, with duration of symptoms before presentation to the hospital usually less than 24 hours.
- Children with epiglottitis are at risk of total airway obstruction and can progress to respiratory obstruction with unexpected suddenness.
- The diagnosis is confirmed under direct visualization. Other investigations are deferred until the airway is secured.

Direct bacterial infection of the tracheal mucosa is caused by the organisms listed in Box 32-22. *S. aureus* is the most common bacteria reported.[205] A significant proportion of infections are polymicrobial.[204] *Moraxella catarrhalis* is described to be more frequent in younger children and to be associated with a more severe course, although this may be due to its association with younger age.[204]

Influenza virus, parainfluenza virus, and enterovirus have been isolated in children with bacterial tracheitis, suggesting that bacterial invasion may occur in an airway already inflamed by viral infection. Bacterial tracheitis is a recognized complication of measles.[206]

The bacterial infection causes a diffuse inflammatory process of the larynx, trachea, and bronchi with mucopurulent exudate and semiadherent "membranes" within the trachea. These membranes contain numerous neutrophils and cellular debris and cause major obstruction.

Clinical Features

In most children, there are prodromal upper respiratory tract symptoms. Bacterial tracheitis usually presents as severe upper airway obstruction, most often in a child who has had viral croup for several days. Not all children present with high fever, systemic toxicity, and severe airway obstruction. In some, particularly those who are older, the illness can remain localized to the trachea.[204]

BOX 32-22 Causes of Bacterial Tracheitis

Common Causes

Haemophilus influenzae type b and nontypable *Haemophilus influenzae*
Klebsiella pneumoniae
Staphylococcus aureus
Streptococcus pneumoniae
Streptococcus pyogenes group A

Rare Causes

Moraxella catarrhalis
Pseudomonas spp.

The differential diagnosis includes severe viral croup, laryngeal or tracheal foreign body aspiration, or epiglottitis. Bacterial tracheitis has a longer duration, a more typical barking cough than epiglottitis, and no drooling. Diphtheria was once a serious consideration as the most common cause of "membranous croup" that produced severe airway obstruction because of adherent membranes that separate from the airway wall with difficulty, causing bleeding.

Diagnosis

The definitive diagnosis requires direct laryngoscopy and tracheoscopy.[207] Bacterial cultures of tracheal secretions are required to isolate causative organisms. The results from blood cultures are usually negative. White blood cell counts may be high or normal.

Endoscopy reveals thick mucopus and sloughed epithelium. The epithelium forms a sheet-like pseudomembrane that separates easily from the airway wall without hemorrhage and sometimes extends from the trachea to the major bronchi.

A lateral neck radiograph shows subglottic narrowing and often reveals findings of radiopaque material in the airway lumen (pseudomembrane) and tracheal irregularities.[204,208] Plain radiographic abnormalities can be confused with those due to a foreign body.

Treatment

Specific diagnosis and treatment are secondary to definitive treatment of impending airway obstruction.[207] In a child suspected of having bacterial tracheitis, management should occur in a pediatric intensive care unit. At least half of children with bacterial tracheitis will need to be intubated.[204] Intermittent positive-pressure breathing is sometimes needed. Repeated suctioning is usually required because of the thick secretions and their tendency to form crusts, with intubation lasting 3 to 11 days. Sometimes, repeat endoscopic removal of the pseudomembrane is required. Occasionally, tracheostomy is needed if endotracheal tube management of secretions proves too difficult.

Empirical antibiotic choice should provide broad-spectrum gram-positive and gram-negative cover. Appropriate first-line choices include amoxicillin/clavulanic acid, cefuroxime, and ampicillin + sulbactam.

Nebulized epinephrine or corticosteroids do not relieve the acute airway obstruction.

Clinical Course and Prognosis

With effective early management, children should make a complete recovery from this severe illness. Reported complications include toxic shock syndrome, septic shock, pulmonary edema, and acute respiratory distress syndrome (Box 32-23).

BOX 32-23 Bacterial Tracheitis Teaching Points

- Bacterial tracheitis is characterized by thick tracheal membranes, which can occlude the airway and cause death.
- It occurs in both the preschool- and school-age groups and can present either with fever and systemic toxicity or as more localized disease.
- Definitive diagnosis requires laryngoscopy and tracheoscopy.
- The etiology can be polymicrobial.
- At least half of children with bacterial tracheitis will need to be intubated.
- Children with this condition should be managed initially in the intensive care unit.
- Broad-spectrum intravenous antibiotics are required.

RECURRENT RESPIRATORY PAPILLOMATOSIS

Juvenile recurrent respiratory papillomatosis (RRP; also known as laryngeal papillomatosis) is a rare condition with benign, wart-like tumors in the respiratory tract, especially the larynx, usually associated with upper airway obstruction, which can become life threatening.[209]

Epidemiology, Risk Factors, and Pathogenesis

The incidence of recurrent respiratory papillomatosis has been estimated as 4.3 per 100,000 children.[210] It occurs at all ages, with about half of all cases appearing in children and the youngest reported patient being 1 month of age.[211]

Human papillomavirus (HPV) types 6 and 11 cause about 90% of cases of recurrent respiratory papillomatosis.[212,213] Type II is more virulent, associated with earlier presentation and more surgical procedures.[212] Occasional coinfection with other viruses has been demonstrated (e.g., herpes simplex, cytomegalovirus, Epstein-Barr virus) and is associated with a more aggressive course.[214] The replicating virus may cause overgrowth of squamous epithelial cells. The papillomata are multiple projections, each with a connective tissue stalk covered by well-differentiated stratified squamous epithelium. The viral antigen is localized in the nuclei of cells in the very superficial layers. Papilloma occur in the larynx, trachea, bronchi, and lung parenchyma.

There is debate about the mechanism of infection with HPV. The same types of HPV that cause perineal condylomata in women also cause juvenile recurrent respiratory papillomatosis. Children can acquire the infection during the birth process from the mother with perineal condylomata.[215-217] However, there are many children in whom there is no evidence of maternal HPV infection in whom the source of infection remains obscure. Host susceptibility has been investigated in a limited number of patients, and only one child has been found to have IgG_2 subclass deficiency.[218]

Clinical Features

In the pediatric age group, about half of patients have symptoms within the first year of life, although clinical recognition of the disease is often delayed. Patients usually come to medical attention late, with respiratory distress due to airway obstruction and stridor, together with hoarseness or a weak cry. Life-threatening upper airway obstruction may occur

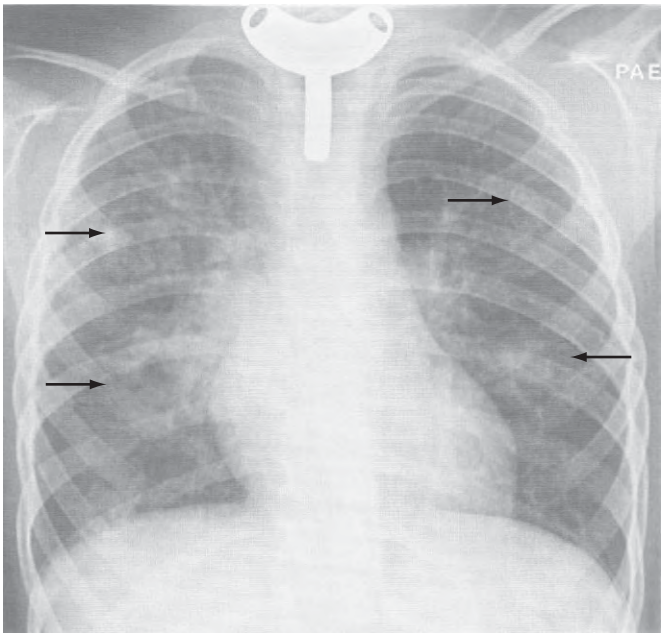

Figure 32-10 In a 13-year-old boy with a tracheostomy tube placed due to laryngeal papillomatosis, chest radiograph shows multiple nodular processes (*arrows*), some of which are cavitating, caused by parenchymal dissemination of the papillomatosis. (From Diagnostic imaging of the respiratory tract. In Chernick V, Boat TF, Wilmott RW, Bush A [eds]: Kendig's Disorders of the Respiratory Tract. Philadelphia, WB Saunders, 2006.)

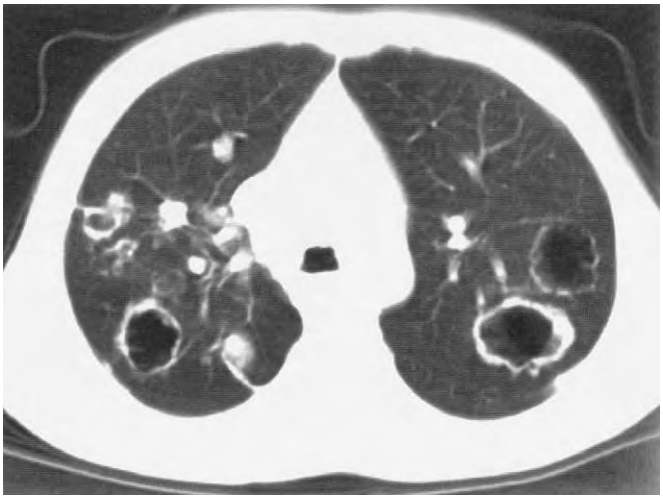

Figure 32-11 Chest computed tomography scan of an 8-year-old girl with laryngotracheal papillomatosis shows multiple peripheral nodules and cavities with posterior dominance, in keeping with pulmonary dissemination. (From Diagnostic imaging of the respiratory tract. In Chernick V, Boat TF, Wilmott RW, Bush A [eds]: Kendig's Disorders of the Respiratory Tract. Philadelphia, WB Saunders, 2006.)

and, less commonly, chronic cough, recurrent pneumonia, failure to thrive, dyspnea, and dysphagia.[209] Although the lesions are usually localized within the larynx, spread to other areas (pharynx, esophagus, trachea, and lung parenchyma) may occur and indicates a more pessimistic outlook.[211] When the lung parenchyma is involved, lung tissue may be destroyed with multiple nodular and cystic lesions (Figs. 32-10 and 32-11). Pneumothorax can occur after the development of cystic pneumatoceles, presumably from the ball-valve effect of a nodular lesion.[219]

The tumors are benign but present obstructive problems because of their localization in the vocal cords or other sites. At presentation, papillomas are usually present on one or both vocal cords with the anterior commissure, supraglottis, or subglottis also commonly affected.

Diagnosis

The condition is diagnosed by inspection of the larynx, either by indirect means such as fiberoptic laryngoscopy or by formal laryngoscopy and bronchoscopy when tissue biopsy samples can be taken for histologic confirmation. The virus signal can be identified in the tissue biopsy, but its intensity does not generally correlate with the clinical behavior of the disease.

Multiple endoscopies are usually required for further investigation and management, and flexible bronchoscopy is the method of choice for surveillance.

A staging system has been developed by Derkay and colleagues[209] with good interobserver reliability.[220] It includes area and severity of involvement, characteristics of voice, and respiratory distress.

Treatment

PREVENTION

Vaccines against HPV types 6, 11, 16, and 18 have been developed to prevent cervical cancer. Vaccination against HPV is likely to be recommended for use in 11- to 12-year-olds.[213] Because of the timing of the vaccination, it is unlikely that it will have an impact on the prevalence of RRP in childhood but could potentially reduce early childhood disease in the next generation.

TREATMENT OF DISEASE

The goals of treatment are to relieve airway obstruction, improve voice quality, and minimize the risk of recurrence. Recurrent respiratory papillomatosis is frustrating to treat because lesions are often recurrent after excision and sometimes locally aggressive. The focus of management is to debulk the papilloma and ensure a safe airway without causing irreversible long-term scarring, especially affecting the voice. Total surgical removal of the disease is impossible in most cases because subclinical viral infection occurs in apparently normal adjacent areas and the degree of destruction necessary to clear the field would require too great a degree of tissue damage.

The carbon dioxide laser is the most widely used surgical tool for removing recurrent respiratory papilloma, vaporizing the papilloma. However, it does not prevent regrowth any better than the older surgical methods, such as direct removal or suction diathermy. Photodynamic therapy has been used, pretreating the patient with a hematoporphyrin derivative and then subjecting the lesion to an argon dye laser beam at a 630-nm wavelength.[221] If possible, tracheotomy should be avoided because of seeding of the disease to the tracheotomy site.

Historically, clinicians have used numerous other therapeutic modalities, including cryotherapy, painting of the

lesions with podophyllin, indole-3-carbinol, photodynamic therapy and antimetabolites, vaccines, and immunotherapy, but the results have been generally poor.

Adjuvant antiviral therapy with acyclovir or ribavirin, or cidovir injected into the lesions has been considered, but there are no controlled clinical trials.[222]

Interferon-α used with surgery has disappointing results. Although most studies have shown a dramatic decrease in the frequency of regrowth immediately after beginning such treatment, regrowth gradually occurs. In one large multicenter, randomized study,[223] interferon was neither of curative nor of substantial value as an adjunctive agent after 1 year of treatment. In another study of 66 patients,[224] there was a 33% sustained complex remission rate, leading the authors to suggest a 6-month trial of interferon-α in children requiring surgery at 2- to 3-month intervals. Although this agent is moderately well tolerated, the almost universal side effects of mild influenza-like symptoms are unpleasant, and the frequent parenteral mode of delivery is disliked, particularly in the younger age group. Interferon therapy may be used in particularly aggressive disease, but it should not be continued beyond 12 months unless the disease responds.[225] In less severe cases, the indication is not absolute.

Clinical Course and Prognosis

The most usual course of the disease is for the papilloma to continue to grow locally despite surgical removal and without significant spread. Over time, the majority of cases in children undergo spontaneous remission (analogous to skin warts). Death is rare. Malignant change to squamous cell carcinoma has been reported in 3% to 5%, mainly in adults.[226] The now-abandoned treatment of these lesions with radiotherapy has been implicated in ensuing malignancies in the pediatric age group (Box 32-24).

BOX 32-24 Recurrent Respiratory Papillomatosis Teaching Points

- Papillomas are projections with squamous epithelium infected with human papillomavirus on a connective tissue stalk.
- They cause airway obstruction, especially around the larynx.
- Diagnosis is often delayed.
- Interferon is considered for aggressive cases.

CHAPTER 33 Viral Infections of the Lower Respiratory Tract

Sean P. Elliott and C. George Ray

TEACHING POINTS

- The majority of all childhood lower respiratory illnesses are caused by viral agents.
- In healthy patients, the course of viral respiratory infections is usually relatively predictable in terms of both the nature of onset and the duration of the acute phase.
- When abrupt deviations in the course of an acute viral illness occur, the possibility of bacterial superinfection must be considered.
- Of the more recently recognized viral agents, human metapneumovirus stands out as an important cause of respiratory syncytial virus–like illness.

Worldwide, it is estimated that 3 to 5 million children die annually as a result of acute respiratory disease. In the United States, respiratory diseases account for 75% to 80% of all acute morbidity. Viral infections are the greatest contributors to this morbidity rate, causing approximately 80% of respiratory illness. Many of these infections produce mild, self-limited symptoms of the upper respiratory tract. Lower respiratory tract illness (LRI), particularly that associated with the presence of crackles or wheezes on physical examination or as parenchymal disease on a chest radiograph, accounts for the majority of severe disease. One third of children develop LRI in the first year of life.[1] Childhood asthma may be initially difficult to discriminate from LRI in some patients; indeed, both conditions can be present simultaneously.

Although 60% or more of LRIs are primarily viral[2] (Table 33-1), the concern often remains as to whether bacterial infection is present, as either a primary problem or a complication of viral infection. Of the bacteria, *Streptococcus pneumoniae* is by far the most common, followed by *Haemophilus influenzae* and *Staphylococcus aureus*. Clinical features that suggest these causes include an abrupt onset or a change in symptoms over a few to several hours, toxicity, and radiographic findings of parenchymal consolidation, pleural effusions, or both. White blood cell counts are of variable help, but extreme leukocytosis (>20,000 cells/mm^3) or increased neutrophil band counts (>1500 cells/mm^3) suggest possible bacterial involvement. However, such findings are not absolute; severe viral infections can produce leukocytosis and variable shifts to the left. Conversely, overwhelming bacterial pneumonia can present with ominous leukopenia. The magnitude of fever is thought by some to be helpful in determining the possible presence of a bacterial infection, but viral LRI can also provoke high fevers, which may persist for several days or longer. Serum levels of procalcitonin and C-reactive protein have shown the most promise to date in distinguishing serious bacterial infection from virus-caused disease, but these findings remain untested in respiratory diseases.[3,4]

Other nonviral agents include *Chlamydia trachomatis*, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, *Mycobacterium tuberculosis*, deep mycoses, and *Pneumocystis jirovecii*. C. *trachomatis* pneumonia is most common among infants between 2 weeks and 6 months. Characteristically, the onset of respiratory symptoms is insidious over several days, the infant is usually afebrile, and air trapping with interstitial infiltrates is often apparent on chest radiographs. Symptomatic *M. pneumoniae* infections are uncommon in children younger than 5 years; however, they frequently cause pneumonia among children in the 5- to 19-year age group.[5] C. *pneumoniae* infections appear to follow clinical and age-specific patterns similar to those of *M. pneumonia* infections, but more data are needed before such a comparison can be confirmed.[6] Tuberculosis and deep mycoses should be considered when the symptoms and radiographic abnormalities insidiously progress over days to weeks. Finally, *P. jirovecii* infections are suggested in patients who have progressive hypoxemia (often without significant hypercarbia), alveolar infiltrates, and significant risk factors such as congenital or acquired immunodeficiency, malignancy, and severe protein malnutrition.

A common clinical dilemma occurs in reliably discerning treatable causes, such as bacteria, from viral agents that may not be susceptible to specific therapies. Often, the choice is made to treat nearly all young patients who have an acute LRI with an antibiotic in case a bacterial agent is involved. Such therapy is useless in viral disease and has not been shown to alter the risk of bacterial superinfection; furthermore, such a practice can result in the selection of more resistant organisms if secondary infection does occur. With the emergence of molecular diagnostic methods, a timely, specific diagnosis of many viral LRIs is possible. In addition, specific antiviral therapy is available for some viral

Table 33-1
Major Causes of Acute Lower Respiratory Tract Illnesses

Syndrome	Viruses	Nonviral Agents	Estimated Percentage Caused by Viruses
Epiglottitis	Rare	*Haemophilus influenzae, Streptococcus pyogenes, Streptococcus pneumoniae, Neisseria meningitidis, Corynebacterium diphtheriae*	5-10
Laryngitis and croup	Parainfluenza viruses, influenza viruses, adenoviruses, respiratory syncytical virus, human metapneumovirus, rhinoviruses, coronaviruses, echoviruses	Rare	90
Laryngotracheitis and laryngotracheobronchitis	Same as for laryngitis and croup	*H. influenzae, Staphylococcus aureus*	90
Bronchitis	Parainfluenza viruses, influenza viruses, respiratory syncytial virus, human metapneumovirus, adenoviruses, coronaviruses	*Bordetella pertussis, Bordetella parapertussis, H. influenzae, Mycoplasma pneumoniae, Chlamydia pneumoniae*	80
Bronchiolitis	Respiratory syncytial virus, parainfluenza viruses, human metapneumovirus, influenza viruses, adenoviruses	*Chlamydia trachomatis, C. pneumoniae, M. pneumoniae*	90
Pneumonia	Same as for bronchiolitis	*M. pneumoniae, C. trachomatis, C. pneumoniae, S. pneumoniae, H. influenzae, S. aureus, Legionella* species, *N. meningitidis,* mixed aerobic and anaerobic flora*	70-80

*Aspiration-related and lung abscess.

infections and may reduce both the morbidity and the mortality rates.

Despite the concern of bacterial coinfection, viral infections remain the most common causes of pediatric LRIs, especially among children younger than 5 years.[7,8] Of these, respiratory syncytial virus (RSV); human metapneumovirus (hMPV); parainfluenza virus types 1, 2, and 3; influenza virus types A and B; and adenoviruses comprise the majority.[7] Rhinoviruses, human coronaviruses (HCVs), influenza virus type C, and parainfluenza virus type 4 are known to have roles in upper respiratory disease, but relatively little is known about their contribution to LRI. Other viruses, such as Epstein-Barr virus (EBV), cytomegalovirus (CMV), and human herpesvirus-6 (HHV-6), have been associated occasionally with LRI, either as primary pathogens or as possible cofactors with other agents. All three increase in overall importance in the setting of immunocompromise; this is especially true for CMV.[9] Measles virus has a long history as a significant cause of LRI. Although eradication of this virus seems possible, it remains a significant problem in underdeveloped nations.

RESPIRATORY SYNCYTIAL VIRUS

RSV is the most common cause of lower respiratory infection in infants and young children, although infants younger than 2 years are most frequently and severely affected. RSV causes a range of illnesses, including croup, tracheobronchitis, bronchiolitis, pneumonia, or some combination thereof, and is associated with such complications as progressive pulmonary failure, cor pulmonale, and a risk of bacterial superinfection. Some evidence suggests there may be a strong association between severe RSV LRI in infancy and asthma or allergic airways disease in childhood. RSV is discussed thoroughly in Chapter 34.

HUMAN METAPNEUMOVIRUS

Human metapneumovirus (hMPV) is an infectious agent that apparently has existed for a long time but only recently (2001) has been recognized as a major cause of LRI. Initially described in patients with LRI in the Netherlands,[10] hMPV has now been identified in pediatric and adult patients with LRI worldwide. hMPV is in the same subfamily of Paramyxoviruses as RSV and displays the same syncytial formation in cell culture. Although comparative prevalence studies are difficult to evaluate due to differences in sensitivity of detection methods, hMPV certainly appears to cause a significant portion of LRI worldwide. In one prospective 25-year study, hMPV prevalence was 12% in nasopharyngeal samples from patients with LRI, compared with 15% RSV, 10% parainfluenza virus, and 5% influenza virus.[11] Infection usually occurs during childhood, causing hMPV seropositivity in up to 52% of 24-month-old infants and 100% of 5-year-old children.[12,13] Like RSV, hMPV has a seasonal pattern, causing its greatest impact in the winter months. Coinfection with hMPV and other respiratory viruses occurs and appears to increase the severity of illness.[14]

Clinically, hMPV infection is similar to RSV disease and includes mild upper respiratory tract disease, influenza-like symptoms (including fever, myalgia, and vomiting), croup, pneumonia, and, most commonly, bronchiolitis.[11,13] Patients typically present with symptoms commonly seen with RSV but, in general, have less severe signs of respiratory distress (Table 33-2). However, patients with immunocompromise or extremes of age are at higher risk for more severe LRI.

Table 33-2
Clinical and Radiologic Findings in Patients with Human Metapneumovirus (hMPV) Compared with Those with Respiratory Syncytial Virus (RSV)

	Percent of Patients with hMPV	Percent of Patients with RSV
Clinical findings		
Cough	72-90	76
Rhinitis	80-88	72
Fever	52-61	48
Retractions	60	64
Hypoxemia	47	82
Anorexia	33-36	76
Wheezing	22-24	32
Chest radiograph findings		
Atelectasis	40	19
Hyperinflation	33	44
Infiltrate	33	31
Bronchial thickening	0	13

Pediatr Infect Dis J 23:1-10, 2004; and van den Hoogen BG, van Doornum GJJ, Fockens JC, et al: Prevalence and clinical symptoms of human metapneumovirus infection in hospitalized patients. J Infect Dis 188:1571-1577, 2003.

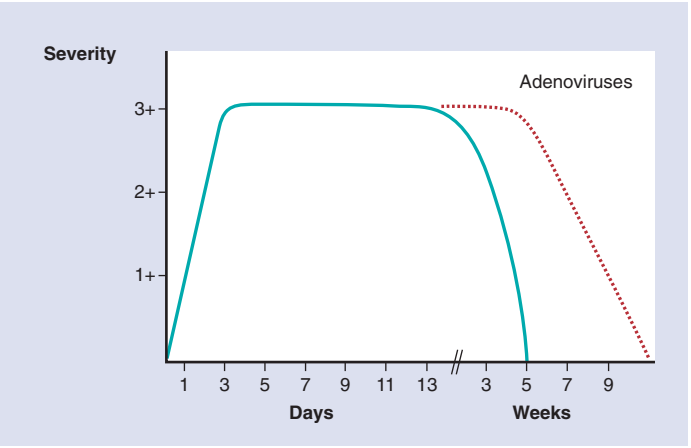

Figure 33-1 Natural history of lower respiratory tract illnesses caused by RSV and parainfluenza viruses, as measured by severity and duration in normal patients (*blue line*). The prodrome with upper respiratory symptoms usually progresses to lower tract involvement over 1 to 3 days. Maximal severity persists as a "plateau" phase for 7 to 21 days (average, 10 days), followed by progressive recovery in the succeeding few weeks. The hatched red line illustrates the similar but more protracted course often seen with severe adenovirus infections.

Patients hospitalized for hMPV-associated LRI require similar length of hospital stays to RSV patients (6 to 7 days[15]). The relationship of hMPV to asthma and reactive airways disease is unclear as studies have demonstrated both positive and negative impacts.

Diagnosis of hMPV is difficult because the virus does not grow readily on routine cell cultures. Reverse transcription–polymerase chain reaction (RT-PCR) assays are the currently available identification methods of choice. Serologic (immunofluorescence and enzyme-linked immunosorbent assays [ELISAs]) testing is not readily available and is compromised by near universal infection in childhood: a ≥4-fold rise in antibody titers must be demonstrated to confirm recent infection.[16] Management of hMPV infection remains supportive, although studies evaluating the effect of ribavirin and intravenous immunoglobulin preparations are in progress. Bronchodilators such as albuterol may benefit those patients with wheezing as part of their symptom complex, but corticosteroids have no demonstrated impact. Prevention of hMPV infection remains the most desirable form of intervention, but no studies on hMPV vaccine products for humans have been reported.[16]

PARAINFLUENZA VIRUSES

The parainfluenza viruses represent the next most common cause of LRI in children younger than 5 years.[8] Parainfluenza virus type 3 is the most common cause of LRI among this group. Such infections can be seen at any time during the year but are most common in the spring and summer.[17] Localized outbreaks of upper respiratory illness, bronchitis, and croup caused by parainfluenza virus types 1 or 2 frequently occur in the autumn and early winter. Parainfluenza virus type 4 is rarely detected and has been associated primarily with upper respiratory symptoms.

The clinical course of parainfluenza virus infection is similar to that described for RSV as depicted in Figure 33-1. Initial symptoms are mild nasal stuffiness and coryza, with variable progression over 1 to 3 days as the infection progresses downward in the respiratory tract causing cough as a predominant manifestation. Parainfluenza 3 often causes bronchitis, pneumonia, and croup in children younger than 1 year. Patients with immunocompromise are at increased risk for serious morbidity and mortality from parainfluenza 3–associated pneumonia.[18] Duration of acute illness can vary from 4 to 21 days but is usually 7 to 10 days.

The basic principles of management for parainfluenza LRIs are the same as those described elsewhere for RSV. When eating and drinking become difficult for the patient, adequate fluids usually need to be provided via an intravenous route. Humidified oxygen is also given when hypoxemia is present, usually beginning at a concentration of 30% to 40%. In severe cases, the oxygen concentration is increased as guided by blood gas determinations. If there is clinical evidence of progressive respiratory failure, endotracheal intubation with mechanical ventilatory assistance is required.

Bronchodilators also may be tried but must be administered cautiously and discontinued if no clear-cut benefit can be demonstrated. Corticosteroids have no demonstrated role in treatment of lower respiratory infection. Their role in upper respiratory infection is discussed elsewhere. Parainfluenza types 1 and 3 are susceptible in vitro to ribavirin, but no controlled clinical trials yet support its use in these infections.

INFLUENZA VIRUSES

The epidemiology of influenza virus types A and B is generally well known: rapidly evolving outbreaks that usually occur during the cooler months of the year. Both types can cause serious, lethal LRI in infants and children.[19] The clinical course contrasts with that of RSV and parainfluenza viruses

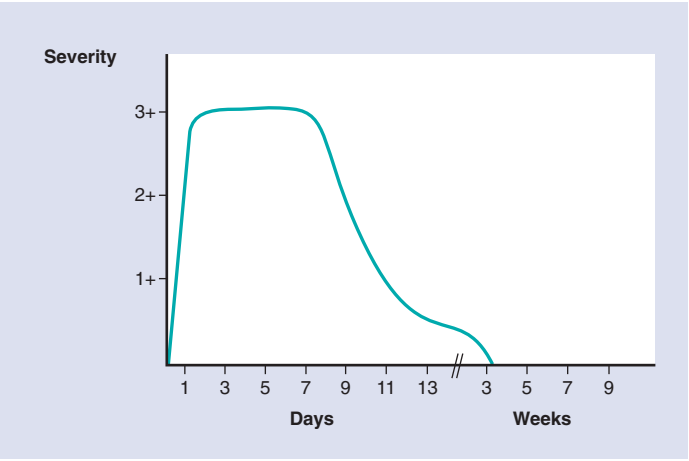

Figure 33-2 Natural history of influenza in normal patients, as measured by severity and duration. Initial symptoms of fever and malaise develop and reach maximal severity over the first 12 to 24 hours and are followed by additional respiratory symptoms. Maximal severity persists for 3 to 7 days (shorter than for RSV and parainfluenza), followed by convalescent period lasting several weeks.

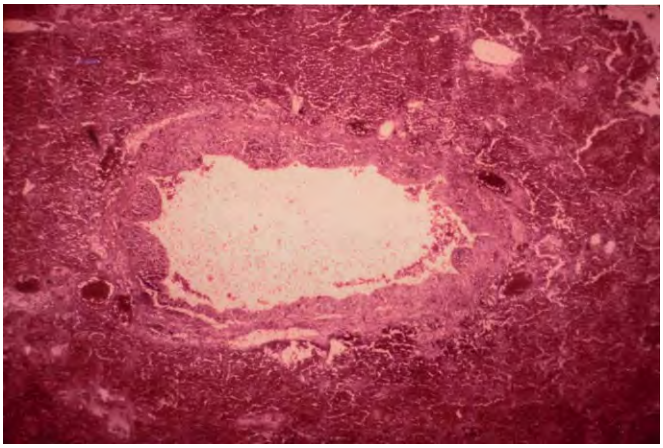

Figure 33-3 Photomicrograph demonstrating bronchiolar necrosis and hemorrhage in a case of overwhelming influenza (original magnification ×100).

in that fever, malaise, and often myalgia usually develop and rapidly become more severe over 12 to 24 hours (Fig. 33-2). Nasal congestion, cough, and subsequent respiratory distress often do not appear until a day or two after the onset of systemic symptoms. Although the mean overall duration of the acute illness (3 to 7 days) is somewhat shorter than with RSV or parainfluenza viruses, the convalescent phase often lasts several weeks, and rapid deterioration as a result of bacterial superinfection can occur at any time in the course. Rarely, patients may develop a rapidly progressive, overwhelming viral pneumonia resulting in death within 2 to 3 days after the initial onset (Fig. 33-3). Pandemic influenza has occurred three times in the past century, causing unusually severe, hemorrhagic pneumonia and millions of deaths. The pathogenicity of these pandemics appears related to a lack of neutralizing serum immunity against the pandemic strain, presumably due to antigenic drift of its hemagglutinin antigen.[20,21]

Diagnosis and basic management are similar to those described for RSV and parainfluenza viruses. Oral amantadine hydrochloride is somewhat effective in treating influenza A but is ineffective against influenza B. If begun within 24 to 48 hours of onset and continued for 5 to 7 days, it may reduce the duration of fever and systemic symptoms and result in a more rapid improvement of peripheral airways function.[22] It also has use as prophylaxis in high-risk children during influenza A outbreaks. A related drug, rimantadine, is also effective and appears to produce fewer adverse effects than amantadine.[22,23] The rapid development of viral resistance to both amantadine and rimantadine has been observed, particularly when either medication is used in households for the simultaneous treatment of symptomatic infection and contact prophylaxis.[24]

The neuraminidase inhibitors (zanamivir and oseltamivir) can also significantly reduce duration and symptom severity of influenza, if begun within 30 hours of onset. Importantly, both agents have efficacy against influenza A and B, are well tolerated, and appear to be associated with viral resistance infrequently.[25]

The combination vaccines for influenza virus types A and B are evaluated annually and reformulated as necessary to antigenically match the strains expected to circulate widely in a subsequent year. Their protective efficacy varies from year to year, ranging between 50% and 95% in immunologically normal individuals older than 6 months. Efficacy in the first 6 months of life is not known, and the influenza vaccine is not recommended for this group; otherwise, annual immunization commencing in the autumn can be used in persons of all ages, except those who have experienced anaphylactic reactions to chickens or eggs. Two doses administered 1 month apart are recommended for children receiving the vaccine for the first time. An intranasal, live attenuated influenza vaccine is also available for children and adults from 5 to 49 years old. This product is highly effective and well tolerated and provides an alternative to further injections. However, it is contraindicated for the high-risk, immunocompromised patient populations, for whom influenza vaccination is recommended.

Children who especially should be immunized annually against influenza include those with chronic pulmonary, cardiac, hematologic, immunologic, and metabolic conditions and those receiving long-term salicylate therapy. In addition, household contacts of these high-risk children and other caregivers (e.g., nurses, physicians, therapists) should be targeted. If an annual immunization is missed and a significant exposure is subsequently suspected (e.g., during a documented outbreak), immunization followed immediately by chemoprophylaxis with amantadine or rimantadine for 2 weeks after the vaccine schedule of one or two doses has been completed can provide "bridging" protection until there is a vaccine response.

Influenza virus type C has been reported to cause outbreaks of febrile respiratory illnesses, especially among pediatric clinic patients and children younger than 3 years. A survey in Los Angeles detected a 64% prevalence of antibodies to this virus among children 5 years and younger.[26] However, longitudinal studies have not supported a significant role for influenza virus type C in LRI, at least among those from birth to 3 years.[17]

Avian influenza A (H5N1) recently has emerged as a highly pathogenic cause of poultry infection in Asian countries that

now has gained the ability to occasionally cause human disease. Influenza A (H5N1) infection in humans is characterized by fever, severe respiratory symptoms, lymphopenia, and a high risk of death.[27] In 2004, at least 44 persons were infected and 32 died; most had direct contact with infected poultry. However, a probable case of person-to-person transmission[28] raises fears of an impending pandemic because few humans will have any immunity against this strain. Chemoprophylaxis with the neuraminidase inhibitors appears to have some benefit, but concerns about emerging viral resistance may limit their use. Thus, such preventive measures as vaccine discovery and prospective poultry screening and culling are critical. Unfortunately, only a few countries have developed influenza pandemic plans and even fewer have the economic and social resources to pursue vaccine development and antiviral stockpiling. Perhaps the greatest impact so far has been the financial reality of domestic poultry destruction in those countries hardest hit by this virus.[29]

ADENOVIRUSES

Adenoviruses are very common causes of fevers, upper respiratory illnesses, and conjunctivitis in young children. Fortunately, they produce LRI only occasionally and sporadically. Adenoviral pneumonia, most commonly caused by types 3, 5, and 7, initially progresses much like the pneumonia described for RSV and parainfluenza viruses (see Fig. 33-1), but the illnesses can be extremely severe and can last for several weeks. Adenovirus types 3 and 7 have been associated with epidemics of LRI.[30] Risk factors for severe, potentially lethal disease include immunocompromise, congenital heart disease, and protein-calorie malnutrition. During the acute phase, chest radiographs often reveal extensive consolidation, particularly in perihilar areas (Fig. 33-4). These findings, along with a frequent occurrence of high fevers, leukocytosis, and multisystem involvement, can make it difficult to discern such infections from bacterial conditions. Other systemic manifestations that sometimes develop are hepatic dysfunction (including Reye's syndrome[31]), encephalopathy, coagulopathies, measles-like exanthems, and diarrhea.[32]

The diagnosis is confirmed best by the detection of the virus in tissues such as lung aspirate or biopsy specimens. Because asymptomatic shedding from the throat or gastrointestinal tract is common in young children, isolation of the virus from the throat must be regarded as diagnostically supportive but not confirmatory, and isolation from stools or rectal swabs needs to be interpreted even more cautiously. Serologic studies of paired acute and convalescent sera obtained at least 2 weeks apart may further aid in confirming the diagnosis. Rapid detection has been used, including immunofluorescence and immunoenzyme assays. Such methods are generally quite specific, but sensitivity ranges between 30% and 60%.

Figure 33-4 Chest radiograph demonstrating extensive perihilar consolidation in a two-year-old patient with adenovirus 3 pneumonia.

Supportive management is all that can be offered at present. These patients must be followed closely because they are at high risk for bacterial superinfection for many weeks. They can also sustain permanent pulmonary sequelae, including pulmonary fibrosis, bronchiolitis obliterans, recurrent wheezing, and bronchiectasis.[33-35] Young age and a previous measles-like illness, as well as nutritional or immunologic deficiencies, have been reported to be risk factors.[34] The persistence of adenoviral antigens and the sustained expression of adenovirus genes in the airway epithelium have been proposed as causes.[35,36]

HUMAN CORONAVIRUSES

Until recently, the role of human coronaviruses (HCoV) in LRIs was not well understood. The two strains most frequently associated with LRI were OC43 and 229E. HCoV OC43 infections produce cough and nasal symptoms in adults and sore throat, cough, coryza, and fever in children.[37] HCoV infections have also been associated with acute attacks of wheezing in children with asthma.[38] In a provocative study of pediatric HCoV LRI,[39] ELISA detected HCoV antigens in 30% of 108 acute respiratory episodes experienced by 30 children younger than 6 years who had a history of at least 10 recurrent respiratory illnesses in the preceding year. In addition, 29% of 51 acute respiratory episodes experienced by the siblings of these patients were also associated with HCoV. Interestingly, 30% of the HCoV infections detected in the former group were associated with LRI symptoms, including wheezy bronchitis, whereas none of the siblings with HCoV had LRI findings. Most infections were due to HCoV 229E, and peaks occurred in the late autumn, early winter, and early summer. Family studies in Seattle have shown that increased levels of antibodies to HCoV strains OC43 and 229E occur more frequently during the winter[40]; children were apparently infected 3 times more often than adults, and serologic evidence suggesting reinfection was frequently observed over 3 years.

Severe Acute Respiratory Syndrome

The 2002 emergence of severe acute respiratory syndrome (SARS) precipitated a new era of international scientific and medical cooperation and led to the discovery of a third coronavirus with human pathogenicity (SARS-CoV).[41,42] The first cases of SARS occurred in China in November 2002 and were followed over the next year by 8098 cases in 26 countries, with 774 deaths.[43] SARS-CoV–like viruses have been detected in raccoon-dogs and Himalayan palm civets in China and also were isolated from such human samples as nasal secretions, serum, feces, and bronchial washings.[42,43] There

is good evidence that bats represent the primary reservoirs of these viruses.[44] Because SARS-CoV has not been demonstrated previously in humans, it appears possible that the virus has crossed the species barrier from animals to humans.[45]

The SARS incubation period ranges from 2 to 10 days, followed by an influenza-like prodrome with such symptoms as fever, myalgias, headache, and watery diarrhea. Respiratory symptoms begin 2 to 7 days after the prodrome and initially include a dry, nonproductive cough and mild dyspnea, accompanied by lung high-resolution CT findings of ground-glass consolidations. Further progression occurs 8 to 12 days later and ranges from a "mild cough variant" with persistent intractable cough to the more common "moderate to severe variant" with hypoxia and dyspnea. Ten percent to 20% of hospitalized patients will require intubation and mechanical ventilation, often heralded by subtle, progressive decreases in oxygen saturation. Recovery begins approximately 14 to 18 days after onset of symptoms.[43,46-48]

Diagnosis of SARS-CoV is available by use of culture and RT-PCR, although the sensitivity of culture is lower than RT-PCR. Specimens obtained 10 days from symptom onset are associated with the highest yield, correlating with the timing of peak virus load. Serologic assays for SARS-CoV include immunofluorescent assays, ELISA, and Western blot assays; however, none is sensitive early enough in the disease course to be useful for rapid diagnosis and thus should be used for paired acute and convalescent-phase serologic diagnosis.[43]

Treatment of SARS remains largely supportive and aimed at those patients who develop respiratory failure. Barotrauma appears to be a frequent complication of SARS-CoV infection, leading to pneumothorax and pneumomediastinum in 20% to 34% of ventilated patients.[49] Thus, a "lung protective" ventilation strategy is recommended for those patients on mechanical ventilation. Other therapeutic interventions have included use of ribavirin, interferon α, lopinavir-ritonavir, and such immunomodulatory therapies as corticosteroids, intravenous immunoglobulin, and plasma exchange.[43] However, no controlled trials have demonstrated benefit in outcome or mortality related to these. Despite the high mortality and devastating impact of SARS-CoV in 2002, the story of its emergence serves to describe a victory due to the worldwide public health measures used successfully to bring the outbreak under control.

A fourth HCoV, NL63, has also been identified and found to cause a significant proportion of acute respiratory disease in humans. Initially described in the Netherlands,[50] HCoV NL63 now has been demonstrated globally, including Australia, Canada, Japan, Belgium, China, Switzerland, and the United States.[51-54] In the United States, the virus currently is named HCoV-New Haven (NH) and most likely represents the same or closely related species as the NL63 described elsewhere. Of 895 children less than 5 years old with acute respiratory illness, 8.8% tested positive for HCoV-NH and negative for other common viral respiratory pathogens.[51] In addition to upper respiratory symptoms, children with HCoV NL63 infection can develop croup, asthma exacerbation, febrile seizures, and such lower respiratory tract findings as tachypnea, abnormal breath sounds, hypoxia, and abnormal chest radiographs.[51,52] HCoV NL63 may demonstrate a variable seasonality, ranging from fall and winter in temperate zones to spring and summer in tropical zones.

Most recently, a fifth HCoV, HKU1, has been described. Initially demonstrated in a 71-year-old man who returned to Hong Kong from an SARS-endemic area of China,[55] a subsequent prospective study of nasopharyngeal aspirates from 418 patients with community-acquired pneumonia demonstrated 10 (2.4%) positive for HCoV-HKU1.[56] All 10 cases occurred in spring and winter; 9 were adults, and 4 had underlying respiratory tract disease. All had symptoms that were indistinguishable from other study participants with community-acquired pneumonia. The global impact of this novel virus remains to be determined.

RHINOVIRUSES

The rhinovirus group is composed of at least 115 unique serotypes that are widely known as the agents responsible for many of the upper respiratory ("common cold") symptoms in adults and older children. Rhinoviruses have been isolated from infants and children hospitalized with LRIs but not at rates that differ significantly from children without respiratory illnesses.[57] The usual incubation period is 2 to 3 days, and the acute symptoms usually last 3 to 7 days. In one retrospective study, the clinical features of 44 rhinovirus culture-positive children with respiratory symptoms, who were either hospitalized or seen in an emergency department, included bronchiolitis or pneumonia; sometimes, both conditions were found (32 patients). The majority of patients were younger than 12 months. Although infrequent, LRIs in children infected with rhinoviruses were indistinguishable from those caused by RSV.[58] Rhinoviruses appears to have a role in triggering episodes of acute asthma.[59,60]

The routine diagnosis of rhinovirus infections depends on tissue culture, although a PCR assay exists that is several times more sensitive than culture. Technical difficulties of identifying rhinoviruses in diagnostic specimens may contribute to an underestimation of their role as causes of LRI. The treatment of rhinovirus infections consists of supportive care; no antiviral medications are recommended at this time. Great attention has been given to possible preventive and therapeutic benefit of such alternatives as zinc and Echinacea, but no controlled studies to date have demonstrated benefit of either.

HERPESVIRUSES

Although uncommon as pulmonary pathogens in healthy children, all members of the herpesvirus family (herpes simplex virus [HSV] types I and II, varicella-zoster virus [VZV], CMV, EBV, HHV-6, HHV-7, and HHV-8) can cause LRI in immunocompromised patients, generally hematogeneously spread as part of a systemic infection. CMV is primarily of concern in the recipients of allogeneic bone marrow transplants, but normal children with lower respiratory tract symptoms can also have positive cultures for CMV. Serologic studies do not generally support a primary role for CMV in LRI among healthy children[17]; however, pneumonia associated with acute, primary, systemic CMV infection in otherwise normal infants has been reported.[61]

CMV pneumonitis in recipients of bone marrow transplantation most frequently results from reactivation of latent virus and less often by transmission via blood products to seronegative patients. Graft-versus-host disease is a significant risk factor for the development of CMV pneumonitis; thus autologous and syngeneic recipients of bone marrow transplant are affected much less often. CMV pneumonitis commonly presents as a primary pulmonary process characterized by fever, tachypnea, and progressive pulmonary distress. Diffuse, bilateral pulmonary infiltrates are generally seen on chest radiographs. The diagnosis can be made by culture of the virus from bronchoalveolar lavage fluid or from lung tissue, although detection of increased viral load by nucleic acid detection methods in the setting of LRI is strongly suggestive. The advent of prophylaxis with intravenous ganciclovir or oral valacyclovir in high-risk patients has greatly reduced the incidence of CMV during the first 3 months after bone marrow transplantation.[62] Ganciclovir is less effective in treating CMV pneumonitis in patients after disease is clinically apparent.

Herpes simplex pneumonitis is most commonly seen as part of perinatally acquired disseminated infections but can also be transmitted during resuscitative efforts. Immunocompromise of any type is also a risk factor for HSV pneumonitis at all ages.

Varicella pneumonitis is a life-threatening complication of primary VZV infection in neonates, immunocompromised patients, and, rarely, healthy children. VZV is spread by aerosolized respiratory secretions, and the initial round of viral replication occurs in the lungs. A primary wave of viremia then occurs and is followed by further viral replication in lymphatic tissue. Characteristic cutaneous lesions erupt after a secondary viremia. Varicella pneumonitis generally develops 2 to 5 days after the outbreak of a rash.[63] The clinical and radiographic manifestations vary. Asymptomatic miliary lung lesions (especially in adult varicella) may later become apparent as calcified foci. In others, a mild interstitial pneumonia is present, which may be overshadowed by a severe bacterial pneumonia caused by such organisms as group A streptococci or *S. aureus*. These are often accompanied by effusions and empyemas and can be extremely difficult to treat. Varicella alone can cause a progressive, lethal pneumonia in immunocompromised patients.

The transmission of VZV to neonates occurs when primary maternal chickenpox occurs within 3 weeks of parturition. Transplacental transfer of maternal antibody specific for VZV is minimal if the onset of illness occurs fewer than 5 days before birth. Thus, if maternal varicella develops within 5 days before to 2 days after delivery, systemic disease and pneumonitis can develop in the neonate, with an estimated case-fatality rate of 5%.[64]

The diagnosis of varicella in normal hosts is generally made by clinical observation. Culture or immunofluorescence staining of vesicular lesions is important in immunocompromised hosts to rule out disseminated herpes simplex infections. Serologic antibody tests are useful for assessing immune status. γ-Globulin preparations containing high titers of anti-VZV activity are effective in preventing varicella if given soon after exposure. Neonates and immunocompromised children are candidates for this treatment.[64] Acyclovir and other related agents are the drugs of choice in treating high-risk patients and reduce the severity of illness if administered within 2 days of the outbreak of a rash. Fortunately, a live VZV vaccine has resulted in a significant reduction of primary varicella and its complications.[65]

Like the other herpesviruses, EBV produces life-long infections and causes a variety of clinical syndromes, including infectious mononucleosis, central nervous system illnesses, malignant lymphoproliferative diseases, and nasopharyngeal carcinoma. Pneumonitis, pneumonia and pleural effusion can occur as part of primary EBV infection but are uncommon, although perhaps underdiagnosed. In a group of 113 normal children with documented EBV-induced mononucleosis, 6 children, all younger than 4 years, developed pneumonia during the illness.[66] Pneumonia was self-limited in all cases. The diagnosis of primary EBV infection is made on clinical grounds in conjunction with serologic tests for heterophil antibody or IgM anti-VCA antibody.

HHV-6, the usual causative agent of roseola infantum, has been suggested as a possible cause of some cases of interstitial pneumonitis in recipients of bone marrow transplants.[67] This virus is one of the most ubiquitous of human viruses: More than 90% of the population becomes infected by 2 years of age. Detection of HHV-6 by culture is not routinely available, but the diagnosis of primary infection can be made by evidence of serologic conversion. Reactivation is difficult to document because a majority of healthy individuals have evidence of continuous viral replication in the salivary glands and blood. HHV-7, more recently described, appears to have similar epidemiology and pathogenicity as HHV-6, whereas HHV-8 has a well-known association with Kaposi sarcoma in immunocompromised and, rarely, immunocompetent patients. Both HHV-7 and HHV-8 appear to cause interstitial pneumonitis in bone marrow transplant patients.[68,69] HHV-6, HHV-7, and HHV-8 are not thought to cause pneumonia in normal persons, and no specific therapy is available.

MEASLES VIRUS

Otitis media and pharyngitis are normal components of the early phase of measles infection. Bronchitis is common, and severe laryngitis may occur occasionally. Pneumonia caused by the measles virus probably occurs in at least 50% of children. In most cases, it is a mild bronchopneumonia and is recognized only by nonspecific lower respiratory signs and hyperinflation on chest radiograph. In other cases the inflammation is more extensive, leading to diffuse infiltrates or even segmental or lobar consolidation on chest radiographs.

Children with measles are prone to secondary bacterial infection with organisms such as pneumococci, *H. influenzae*, *S. aureus*, and *Streptococcus pyogenes*. This is particularly important in developing countries, where infection secondary to measles is a major cause of death in young children. Measles may also have a deleterious effect on the course of tuberculosis in malnourished infants.

The immunodeficient child is prone to develop a progressive and fatal infection that evolves about 3 weeks after exposure. The clinical manifestations start with a fever, and there may be an atypical rash. Nonspecific respiratory symptoms and signs evolve over 2 to 3 days. The chest radiograph generally shows coarse nodular infiltrates, and air leaks are common.

The diagnosis is usually made on culture from nasopharyngeal secretions or bronchoalveolar lavage fluid. Occasionally, a lung biopsy may be necessary. The histopathologic picture is most often that of giant cell pneumonia with inflammatory cell exudate and thickening of the alveolar walls with inflammatory cells. The alveolar lining cells are transformed and contain intranuclear and intracytoplasmic inclusions.[70] Rapid diagnosis by immunofluorescence and serologic diagnosis are also possible.

Treatment of measles involves supportive measures and close observation for signs of bacterial superinfection. Prevention is available via a live, attenuated vaccine that is highly immunogenic but contraindicated in pregnant and immunocompromised individuals. Measles pneumonia can be prevented in the immunodeficient host by active community immunization. Those exposed should have immunoglobulin as soon as possible after exposure.

Modified measles does occur in the partially immune host and presents with fever and an itchy maculopapular rash, particularly over the wrists and ankles. Respiratory involvement is relatively common in this type of measles, presenting with dyspnea and widespread crackles heard on auscultation. The chest radiograph shows hilar adenopathy with nodular infiltrates and frequently a pleural effusion.[71]

HANTAVIRUS

In 1993, an outbreak of acute febrile illness progressing within 3 to 5 days to respiratory failure and shock was noted in the southwestern United States. The hallmark of this syndrome, the hantavirus pulmonary syndrome, is unexplained severe noncardiogenic pulmonary edema occurring in previously healthy persons. Subsequent studies have implicated at least three different hantaviruses, which are primarily maintained as zoonotic agents in rodent reservoirs.[72] As of November 2004, more than 379 cases of hantavirus pulmonary syndrome had been reported from 31 states in the United States, with a case-fatality rate of greater than 50%.[73-75] Hantavirus pulmonary syndrome has also been documented in Canada, Brazil, Argentina, and Paraguay. Few cases have been reported in people 16 years or younger, but the disease spectrum and mortality are similar to those reported in adults.[75,76] The diagnosis can be made by serologic tests, PCR study of frozen tissues, immunochemistry, or paraffin-embedded tissues. No specific therapy has proved efficacious; however, intravenous ribavirin has been suggested based on in vitro data and experience with other hantaviruses.

SIMULTANEOUS INVOLVEMENT BY MULTIPLE PATHOGENS

Other viruses, *C. trachomatis*, *M. pneumoniae*, and *B. pertussis*, can also be detected in a significant number of young children with infections caused by RSV. In the Tucson Childrens' Respiratory Study,[77] 10.9% of previously healthy patients with RSV infection were coinfected with another potential pathogen as documented by culture or antigen detection, and the proportion became even greater when serologic results were also extensively used for diagnosis. The clinical diagnosis and outcomes were no different among patients with RSV alone compared with those already coinfected with additional agents. Routine searches for coinfecting agents when a primary pathogen such as RSV is identified are not recommended for otherwise healthy infants and children. Such extensions of a diagnostic workup are best reserved for patients who are known to have significant underlying illnesses or patients whose clinical course is not congruent with that expected for the pathogen detected.

PROSPECTS FOR PREVENTION AND TREATMENT

Current knowledge concerning the major causes of viral LRIs and their epidemiology and diagnosis has matured remarkably. Exciting advances are now being made in the critical areas of immunopathogenesis, molecular virology, and antiviral therapy. Future discoveries will surely provide even more rational approaches to prevention and treatment, including specifically designed peptide vaccines that can more appropriately recruit specific T-cell populations as allies in long-lasting protection. Other emerging strategies include enhancement of host defenses by cytokine manipulation and novel applications of older concepts, such as specific antibodies for prophylaxis and treatment. There is considerable cause for optimism, in contrast to the state of affairs described by Andrewes more than 4 decades ago, when he suggested that clinicians should perhaps accept these infections as "one of the stimulating risks of being mortal.[78]"

CHAPTER 34 Respiratory Syncytial Virus–Associated Lower Respiratory Tract Disease

Mark L. Everard

TEACHING POINTS

- The respiratory syncytial virus (RSV) causes annual epidemics of respiratory disease that particularly affect infants and the elderly. It remains the most common cause of hospitalization and death among infants outside the neonatal period.
- Phenotypes of lower respiratory tract infection (LRI) caused by the virus in early childhood include acute bronchitis, croup, bronchiolitis, wheeze-associated viral illness (wheezy bronchitis), and virus-induced exacerbations of asthma. The clinical consequences of infection are likely to reflect host factors.
- The only proved therapy for RSV infection in the first 2 years of life is good supportive care including oxygen when patients are hypoxic. Some older subjects with predominant wheeze may respond to bronchodilators. It is likely, but unproved, that these individuals have a viral exacerbation of asthma.
- RSV LRI in early childhood is associated with increased recurrent respiratory morbidity during the first year of life. The patterns of symptoms are likely to be heavily influenced by host factors. Those with "acute bronchiolitis" (characterized by widespread crepitation on auscultation) have relatively mild symptoms most prominent in the first year or two after the initial illness.
- RSV LRI in infancy does not increase the incidence of atopy or atopic asthma.

The respiratory syncytial virus (RSV) is an extraordinarily successful respiratory virus that causes annual epidemics of respiratory disease.[1-7] Although the virus is able to reinfect individuals throughout life, its greatest impact is in the very young[1-7] and the elderly.[8-12] It is the most important infectious agent affecting infants and young children, being responsible for the majority of cases of acute viral bronchiolitis and pneumonia in patients admitted to hospital in this age group. Over the past decade, it has become clear that the virus also has a major impact on the elderly and those with chronic obstructive airways disease. During most years, it rivals influenza in terms of being associated with both the increased respiratory morbidity and mortality in this age group.

The RSV is an RNA virus belonging to the pneumovirus family. It is closely related to the paramyxoviruses but differs in a number of important respects.[13] It is most closely related to the bovine RSV that causes a illness similar to bronchiolitis in young calves. The virus was first isolated from a chimpanzee in 1956 and was originally called the "chimpanzee coryza virus." It was not long before it became clear that this virus was responsible for outbreaks of respiratory disease in infants, and it was renamed because of its predilection for the respiratory system and its tendency to produce syncytia when inoculated into human cell lines.

The virus has been shown to cause respiratory disease in all parts of the world. The virus, without fail, produces yearly outbreaks of respiratory disease. In temperate climates, these commence in late autumn/early winter, rising rapidly to a peak and then falling away by late spring. Isolation of the virus in the summer is uncommon. In tropical and subtropical climates, epidemics tend to occur during the rainy season.[14-17] It is still unclear why the epidemics follow such a regular pattern, and the trigger for each epidemic remains to be defined.[14] It has recently been demonstrated that the virus appears to be able to productively infect human dendritic cells during the RSV season but that out of the season it appears to lie dormant within these cells.[18] Viral replication can be triggered by exogenous nitric oxide (NO),[18] which may be relevant to the seasonality of the epidemics and the observation that the severity of illness is greatest in industrialized areas because NO levels, in contrast to other pollutants, peak in the winter and are highest in industrialized areas. It is also of note that exposure to postnatal cigarette smoke is associated with more severe disease.[19]

The incubation period before the onset of symptoms appears to be in the range of 3 to 8 days. Spread of infection appears to be via large droplets or fomites.[20-23] These droplets are transmitted to hands and fingers, and self-inoculation then occurs with transmission of virus into the eyes or nose, which act as portals to the respiratory tract. Small droplet aerosols appear not to be an important form of transmission. Survival of the virus on hands is variable but generally less than 1 hour. Survival on other surfaces is also generally short, but it can survive for as long as 30 hours on hard, nonporous surfaces in the presence of high humidity. Shedding of virus by hospitalized infants continues even after significant clinical improvement, and the infants generally continue to shed virus for many days after discharge from hospital.[24] Thus, infants, and probably older individuals,

remain a potential source of infection for a period after resolution of the acute symptoms. Within pediatric units, infected members of staff are an important source of nosocomial infection.

During any particular epidemic, a large proportion of the population will develop an RSV respiratory tract infection, but in infancy, the risk of infection is significantly greater, with in excess of 60% of infants being infected.[1,25-27] Almost all infants will have been infected by the virus by the end of their second winter, and half will have experienced two infections during their first two winters. For most infants, symptoms will be relatively mild with upper respiratory tract symptoms alone. However, up to 25% will develop lower respiratory tract symptoms. In most cases, these lower respiratory tract symptoms can be managed in the community, but between 0.5% and 1.5% of all infants are admitted to hospital during the winter epidemic following their birth with RSV lower respiratory tract symptoms. Those aged 1 to 4 months are at particular risk of severe infection and hospitalization. Risk factors for severe disease include postnatal age, preterm birth, chronic lung disease of prematurity, cardiac disease with pulmonary hypertension, neurologic disease, and immunodeficiency.[27-35] Other factors increasing the likelihood of severe disease include attendance at day care, exposure to tobacco smoke, overcrowding, and having older siblings.

RSV infections in infancy are of considerable importance for a number of reasons. Although the mortality rate in hospitalized, previously healthy, infants is very low,[15,16] the acute morbidity is significant. Despite improved outcome with improved supportive care, the virus still poses a threat to those with certain at-risk conditions, which include immunodeficiencies, chronic lung disease of prematurity, and congenital heart disease associated with pulmonary hypertension. However, even in these groups, mortality is low due to advances in supportive care.[31-35] The annual epidemics of RSV lower respiratory tract disease in infancy place great strains on pediatric services every winter. In 2000, it was estimated that in the United States alone, there were approximately 86,000 hospitalizations, 1.7 million office visits, 402,000 emergency department visits, and 236,000 hospital outpatient visits for children younger than 5 years that were attributable to RSV infection. In the United States, total annual direct medical costs for all RSV infection–related illnesses in children less than 5 years of age during 2000 were estimated to be approximately $652 million, with 60% being accounted for by hospitalization and 40% attributable to the medical care of nonhospitalized patients. RSV infection–related hospitalizations increased from 1993 to 2000, but average costs per hospitalization were relatively stable.[36] The trend for increasing admissions has been noted in other countries through the 1980s and 1990s, but more recent data suggest that rates have reached a plateau and indeed are probably falling.

In addition to the acute morbidity, it is clear that RSV LRIs in infancy are associated with an increase in the prevalence of respiratory symptoms in early childhood. This has been observed in cohorts recruited from both hospitalized infants[37-49] and infants managed in the community with RSV LRIs.[50] The nature of these symptoms is unclear but do not appear to be related to an increased prevalence in atopic asthma induced by RSV LRIs. As discussed later, it is likely that it is the host response rather than the virus per se that determines the nature of acute illness and subsequent symptoms. The phenotype of the acute illness probably reflects host factors that impinge on both the acute illness and subsequent symptoms.[51]

The large number of infants being admitted to hospital each winter as a result of RSV infections probably reflects the virus's ability to infect huge numbers of very young infants. This in turn probably reflects poor herd immunity as evidenced by the observation that more than a third of the population are infected every winter. As noted earlier, infection rates in infants are in excess of 60%, and this presumably reflects the ineffectiveness of prenatally acquired passive immunity, a factor that will be even more important in preterm infants. With so many very young infants being infected and having relatively poor protection against extension of virus to the lower respiratory tract, it is inevitable that a significant number will develop respiratory difficulties. Anatomical and physiologic factors such as poor collateral ventilation will further increase the severity of the lower respiratory tract symptoms in those aged less than 6 months. It appears clear that a similar proportion of infants aged 6 to 12 months are infected and probably experience lower respiratory tract symptoms at similar rates, but a far smaller proportion are admitted to hospital because they have the ability to more effectively cope with the effects of airways inflammation.

The poor herd immunity is probably attributable to the ability of the virus to inhibit the production of an effective long-term immune response in infected individuals through direct effects on the immune response or through hiding the important epitopes. Alternatively, antigenic variation may be more important than is currently appreciated.[52-55] If so, this has important implications for the production of vaccines. Unfortunately, there is currently no immediate prospect of preventing these annual epidemics.

PHENOTYPES OF DISEASE

Over the past 30 years, researchers have been trying to identify possible specific immunopathologies that may explain the association of RSV with acute bronchiolitis and/or the association between RSV LRI in early childhood and subsequent respiratory tract infections. As noted, the virus almost certainly influences the host response in order to minimize the effectiveness of memory responses to the virus, and as a consequence, certain aspects of the host viral interaction may differ from that observed with other respiratory viruses. This does not mean that the basic immunopathology is significantly different from that observed with other viruses, and indeed any of the respiratory viruses may induce any of the clinical phenotypes of disease associated with RSV infection.[54] As with other viruses, RSV may cause a simple coryzal illness, acute otitis media, bronchitis, laryngotracheobronchitis, bronchiolitis, pneumonia, virus-associated wheezing, and viral exacerbations of asthma. It is likely that there are differences in both the distribution of virus and host response to the virus in these different phenotypes of disease.

In the past, many studies focused on the presence of RSV itself rather than the phenotype of the illness. More recently, studies have again tended to focus on the phenotype of

disease experienced by an infant rather then the causative organism, and this approach has consistently led to data that suggest that aspects of the host response rather than the particular virus are largely responsible for the phenotype of the acute illness and subsequent respiratory morbidity associated with that phenotype. Lack of precision in defining clinical phenotypes of illness has probably played a major role in perpetuating a number of the controversies that surround this virus.

Acute Bronchiolitis

Surprisingly, despite the frequency and importance of this condition, there are still a number of controversies surrounding the diagnosis and optimal management of infants with "acute bronchiolitis." This appears largely attributable to a failure to agree on the clinical features that characterize patients with acute bronchiolitis. In the United Kingdom, Australia, and parts of Europe, the term *acute bronchiolitis* is limited to infants who present with the following clinical pattern.[58,59] Upper respiratory tract symptoms with coryza and cough precede the relatively abrupt onset of lower respiratory symptoms after 2 to 3 days. Fever is common but frequently settles early in the course of the illness and may be absent when the patient presents to the hospital. The onset of lower respiratory symptoms is frequently acute, and at presentation, the infant is dyspneic with a moist irritating cough. Difficulty feeding and agitation due to hypoxia are not uncommon. Wheeze may be present intermittently but is not characteristic. Tachypnea, hyperinflation of the chest with downward displacement of the liver, and subcostal recession are typically present. However, the defining and characteristic clinical feature is that auscultation reveals widespread bilateral fine inspiratory crackles.

The diagnosis is essentially a clinical diagnosis, and most guidelines recommend that chest radiographs are not indicated unless there are atypical features[60] because clinicians are frequently tempted to use antibiotics when there is evidence of apparent lobar consolidation or bronchopneumonia.[61,62] These radiographic appearances may also encourage clinicians to inappropriately use the term *pneumonia* for such patients even though they have widespread crackles bilaterally. Most infants admitted to hospital with the typical phenotypic illness of acute bronchiolitis characterized by widespread crackles on auscultation will be less than 6 months old. Although older infants will also develop the same clinical picture, far fewer require admission to hospital as hypoxia and significantly impaired fluid intake are less common.

The acute inflammatory response in the airways of infants with this phenotype is dominated by an intense neutrophilia.[63,64] Such a response also characterizes the response to other respiratory viruses such as rhinovirus.[65] Inflammatory mediators such as human neutrophil elastate, myeloperoxidase, and metalloproteases will induce mucus secretion, airways edema, coughing, and sneezing and hence are likely to play a major role in the induction of symptoms and dissemination of the virus.[66,67] Indeed, there is some evidence that the peak of symptoms appears to correlate with the peak in neutrophil numbers, which lags behind the peak in viral titers. The support for the suggestion that neutrophils rather than virus-induced cytopathology are responsible for the generation of symptoms comes from experimental rhinovirus infection in adults in whom symptoms only occurred if there was significant neutrophilia within the airway and did not appear to correlate to evidence of viral replication.[65] If symptoms are peaking as viral titers are falling, then it is perhaps not surprising that antiviral agents have not been shown to have a significant effect in this disease. It is probable that approaches that might reduce the intensity of the neutrophil response may prove to be more effective. There is evidence that neutrophils do have a role in reducing viral titers within the airways, although the mechanism remains to be elucidated.

There are overwhelming data indicating that there is no increase in atopy associated with this phenotype and that the pattern of subsequent respiratory morbidity does not appear to be asthmatic, in that it has yet to be shown that these symptoms respond to inhaled steroids or bronchodilators.[39-42,46-50] The excess of respiratory symptoms experienced by hospitalized infants exhibiting this phenotype is most marked in the preschool years, is associated predominantly with subsequent intercurrent viral infections, and is rarely severe enough to cause further hospitalization.[48] The excess in respiratory morbidity declines rapidly through the early years of life with cohort studies suggesting that this excess has resolved by the beginning of the second decade of life.

Viral Pneumonia

Viral pneumonia in infancy is significantly less common than acute bronchiolitis, although viruses account for the majority of pneumonic illnesses in infancy. Infants with viral pneumonia, including those caused by RSV, typically exhibit a cough, are febrile, and develop significant respiratory distress. They are often more severely affected than those with acute bronchiolitis with a greater need for supportive and intensive care but, somewhat surprisingly, there generally is little to hear on auscultation. Typically, there are widespread nonlobar chest radiograph changes that often change and evolve over relatively short periods of time. There are no specific follow-up data in this group of patients

"Wheeze-Associated Viral Infections" and Exacerbations of Asthma

In much of North America and parts of Europe, the term *acute bronchiolitis* is frequently applied to infants experiencing their first wheezing illness associated with an apparent respiratory viral infection characterized by symptoms such as rhinorrhea and cough.[68] Some would limit the diagnosis to those less than 1 year of age, but many would include children up to 2 years of age or even older. In many countries, including the United Kingdom and Australia, these patients would be described as having "wheezy bronchitis" or an "acute virus-associated wheezing episode." In contrast to those admitted with acute bronchiolitis as defined earlier, those patients admitted to hospital with this phenotype of illness characterized by wheezing without crepitations are generally older than 6 months. Such episodes may recur, and it is likely that this phenotype contains both those with virus-associated wheezing illness (which may be a single episode or

the first of a number of episodes) and those experiencing an early virus-induced exacerbation of asthma.[60,69]

This suggestion has been supported by a number of studies following up infants and young children with virus-associated wheezing episodes attributable to a number of respiratory viruses.[45,70-74] These studies have suggested that wheezing with rhinovirus is more strongly linked with subsequent asthma than is wheezing with RSV. However, even among those with rhinovirus-induced wheeze in early childhood, asthma develops in only a minority. The one study in which patients hospitalized with RSV infection were categorized as "acute bronchiolitis" (based on finding of widespread crepitations) or "wheeze-associated viral illness" at admission[49] found at 3 years of age that there was a predictable increase in cough and wheeze with intercurrent viral infections but no increase in atopy in those admitted with acute bronchiolitis. Despite the increased burden of episodic symptoms, there was no increase in the use of preventive therapy such as inhaled corticosteroids. These findings were in marked contrast to those among the patients with RSV-induced wheezing. In these subjects, there was a significant excess of atopy, and this was accompanied by a significant increase in use of inhaled corticosteroids and health care utilization at 3 years of age, suggesting that the phenotype of the initial illness was associated with different outcomes even though all subjects had been infected with RSV. One recent small study also highlighted the different inflammatory responses in infants with RSV bronchiolitis and those with virus-induced exacerbations of asthma.[75]

Other Presentations

It is well known that the virus can induce severe life-threatening apneas in young infants with or without other evidence of lower respiratory tract involvement.[31,76-81] Apneas are more common in those born preterm and in young infants. The infants infected with the virus can also present with the clinical picture of acute septicemia.

Immunologic Factors

High circulating antibody titers have been shown to be associated with protection from recurrent infection,[82] although it has been claimed that protection correlates more closely with levels of mucosal IgA.[83] High maternal and cord antibody levels are associated with protection against developing bronchiolitis,[84,85] but it is likely that the level of protection is related to the titer of passively acquired neutralizing antibody rather than the total titer of antibodies directed against RSV, because much of this will be nonprotective antibody. These observations led to the development of monoclonal antibodies directed toward conserved epitopes on the relatively stable F surface glycoprotein. It appears clear that the current preparations cannot achieve concentrations sufficient to prevent infection of the upper respiratory tract[85] but are able to provide incomplete protection against significant lower respiratory tract disease.[85-87] The use of an effective monoclonal agent might be expected to result in the emergence of resistant strains,[88] but as yet this does not appear to be a problem in clinical practice. This may well be due to inability of the current preparation to prevent infection of the upper airway, and hence it will exert less evolutionary pressure than a more effective preparation. To date, no other aspect of the host response has been clearly shown to provide protection.

It is clear that elimination of virus is necessary for recovery from infection, but it is of interest that clinical symptoms often peak after the titer of virus starts to fall, suggesting that the host's inflammatory response rather than viral cytopathology is the principal cause of the symptoms.[90] One study has suggested a link between viral titers and disease severity,[89] but if such a link exists, it is unclear whether this reflects infecting load or a relative failure to limit viral replication after inoculation. Immunocompromised patients, especially those with defects of cell-mediated immunity, have difficulty in eliminating the virus and have a high mortality rate.[92-94] Hence, it seems likely that cell-mediated immunity is important in recovery from RSV infections. As noted earlier, antibodies appear to be important in protection from infection, and it is possible that they may have a role in eliminating virus after infection has occurred. Animal[95] and in vitro studies have also suggested that neutrophils play a role in clearing virus from the airway lumen and are not just responsible for generating symptoms, as outlined earlier.

Immunopathology

More than 30 years ago, it was suggested that there may be a specific immunopathology operating in those infants admitted to hospital with RSV bronchiolitis. This was based on the observation that the illness occurred at an age when passively acquired antibody levels are still generally high and on the results of the trials using a formalin-inactivated vaccine in which infants receiving the vaccine had increased morbidity and mortality on subsequent natural exposure to the virus.[96] The first hypothesis proposed that the condition results from an immune complex reaction between nonneutralizing antibody and virus.[97] Subseqeunt theories have included the suggestion that there is a specific IgE response[98] during the acute illness and the suggestions that the pathology is due to excessive cytotoxic[99] T-cell activity, excessive Th2 activity, or impaired macrophage activity due to infection of these cells.[100] Despite intense efforts, it has not been possible to show that any of these proposed mechanisms are fundamental in the causation of the symptoms experienced by infants with RSV-induced lower respiratory tract disease. This is perhaps not surprising when one reflects that identical clinical illnesses can be induced by a wide range of respiratory viruses.

A number of studies have sought to identify genetically determined risk factors such as polymorphisms in certain genes controlling cytokines and Toll receptors. Many potential associations have been reported, but further work is required to determine which, if any, have a significant impact.

Over the past three decades, there have been numerous studies that have used infected rodents such as the cotton rat in an attempt to unravel the immune processes contributing to acute RSV bronchiolitis. The results obtained in such studies must be interpreted with considerable caution because not only have apparently contradictory results been obtained but, perhaps more importantly, these animals are not the natural host for the virus and they do not develop a clinically

significant illness resembling acute bronchiolitis when infected experimentally.[99] Most proposed immunopathologic mechanisms have been supported by at least one rodent model, but these generally involve significant manipulation of the animal model in order to obtain the desired result. Rodent models may prove to be more valuable in assessing the potential role of therapeutic interventions such as immunoglobulin preparations.

A better animal model for determining immunologic responses may prove to be the acute respiratory illness observed in calves and sheep caused by the bovine RSV.[95,102,103] There are a number of similarities in the clinical picture in that they develop upper and lower respiratory signs, the youngest calves experience the most severe illness at a time when passively acquired antibodies are present, and only a small proportion of infected calves experience severe disease. Again, neutrophils are the most prominent inflammatory cell in the airway.

Management of Respiratory Syncytial Virus Infection in Infancy

Although the morbidity associated with RSV infections in infancy is high, the mortality is fortunately low. While the virus is able to cause a variety of phenotypic illnesses, including acute bronchiolitis, pneumonia, and wheeze-associated viral illness, management is essentially the same for each group of patients and has essentially remained unchanged for more than 40 years. Good supportive care remains the cornerstone of therapy, with oxygen being vital in those with hypoxia. There is no convincing evidence that pharmacologic agents have any role in treatment of infants with RSV infection, but despite this, agents such as bronchodilators are still widely used.[104] It is possible that patients less than 2 years of age with an RSV-induced viral exacerbation of asthma will benefit from traditional asthma therapies. However, it is difficult to differentiate those with their first significant exacerbation of asthma from those with wheeze-associated viral illness (bronchiolitis [wheezy bronchitis]) who represent the majority of patients in whom wheeze is a major feature. This difficulty probably underlies some of the apparent discrepancies in outcomes of trials assessing the role of bronchodilators in the treatment of bronchiolitis and is reflected in the American Academy of Pediatric (AAP) bronchiolitis (diagnosis based on presence of wheeze) guidelines,[105] which recommend that bronchodilators not be used routinely in the management of bronchiolitis. They suggest that a carefully monitored trial of α- or β-adrenergic medication is an option, but the inhaled bronchodilators should be continued only if there is a documented positive clinical response to the trial, using an objective means of evaluation.

A small percentage requires more aggressive supportive care, which might include ventilation and even extracorporeal membrane oxygenation (ECMO), but most infants admitted with RSV infections have a brief, self-limiting illness. In North America, the United Kingdom, and northern Europe, the mean duration of hospitalization is 3 days, compared with approximately 9 days in continental Europe.[104] This may reflect differences in severity of patients admitted, differences in criteria for discharge, or availability of hospital beds.

Differential Diagnosis

In the majority of infants admitted with the clinical syndrome of acute bronchiolitis as defined earlier, the causative organism will be the RSV. However, in the midst of an epidemic, it is important to continually consider possible alternative diagnoses that may masquerade as acute bronchiolitis such as cystic fibrosis, recurrent aspiration, congenital lung abnormalities, perinatally acquired *Chlamydia* infection, immunodeficiencies, and congenital heart disease (particularly total anomalous pulmonary venous drainage), all of which can present with many of the features characteristic of acute bronchiolitis. Similarly, disorders such as interstitial pneumonitis and bronchiolitis obliterans due to adenovirus can present with an illness initially suggestive of acute viral bronchiolitis.

Diagnosis

RSV infection and other respiratory viruses can be identified using rapid diagnostic approaches such as immunofluorescent antibody method, enzyme-linked immunosorbent assays (ELISAs), or polymerase chain reaction (PCR). Reliable commercial kits are now readily available and widely used, and indeed some are designed for use by the clinician at the bedside. Samples are generally obtained by means of nasopharyngeal aspirates, nasal lavage, or nasal swabs. A positive result is valuable in supporting the diagnosis and in isolating infants with the virus. However, it should be remembered that all these methods require good-quality samples and a negative result does not exclude RSV infection because the sample may be of poor quality and contain few epithelial cells. Significant rises in RSV antibody titers are uncommon in young infants, and although ELISA techniques appear more sensitive, serologic diagnosis is of little value clinically because convalescent sera are required and hence results are not available for many weeks.

ACUTE BRONCHIOLITIS AND PNEUMONIA

Clinical Assessment

At present, there is no way of predicting which of the many infants presenting with an upper respiratory tract infection during an RSV epidemic will develop acute bronchiolitis. However, as outlined earlier, there are certain groups of children who are at risk of severe disease should they develop bronchiolitis. In previously healthy infants, the peak incidence of admissions is in those aged 1 to 4 months, which is probably due to the low incidence of the condition in younger infants and relatively mild disease in older children, possibly due to growth in the airways and development of collateral ventilation that reduce the impact of occlusion of airways with mucus and secretions. For those admitted to hospital the severity, as judged by the degree of hypoxia, duration of admission, and the need for ventilation are increased in younger and smaller infants.

Certain infants are at increased risk of severe disease, which may lead to respiratory failure, requiring ventilatory support and, in a small proportion, death. This includes those with congenital cardiac disease, particularly those with pulmonary hypertension, chronic lung disease with oxygen

dependency, immunodeficiencies, or cystic fibrosis and those born prematurely. However, the mortality rate even in these groups is now very low.

During RSV respiratory infections in very young infants, the two most serious complications are respiratory failure and apnea. Apnea is most common in the youngest patients, those born preterm, and those with chronic lung disease. Infants may present with apneas and progress to bronchiolitis, show signs of bronchiolitis and develop apneas, or have apnea as the sole sign of RSV infection. Again RSV is not unique in its ability to induce apnea. RSV infection has been implicated in a number of cases of "cot [or crib] death,"[81,106] and its ability to precipitate apnea may be relevant to this observation. A significant proportion of infants with RSV infection requiring assisted ventilation do so because of severe recurrent apneas rather than respiratory failure.[107,108] The mechanisms leading to these apneas are unclear, but they tend to resolve within a few days. The use of apnea monitors is therefore important in young infants, those born preterm, and those with preexisting lung disease.

It is well recognized that the clinical assessment of hypoxia is poor.[109,110] Perhaps the most reliable clinical sign of respiratory failure is agitation, which, if not relieved by supplemental oxygen, can contribute to exhaustion and respiratory failure. Hypercapnia is uncommon in all but the most severely affected infants; hence, with the widespread use of pulse oximetry, blood gas monitoring is rarely required unless mechanical ventilation is being considered. Although these monitors have certain limitations, they play a central role in the assessment of hypoxia and subsequent management of oxygen therapy. Two studies found that an infant's oxygen saturation, as judged by pulse oximetry, was the best objective predictor of disease severity.[111,112]

Decisions regarding hospital admission are therefore based on age, risk factors, clinical assessment, and oxygen saturation. Most infants in at-risk groups will be admitted unless symptoms are very mild, and similarly the threshold for admitting infants less than 6 months of age is relatively low because of the risk of progression to more severe disease and their increased risk of apnea. However, for many infants, the illness is mild and can be managed at home. For those not admitted, it is important to alert parents to signs suggestive of deterioration such as poor feeding and agitation.

During each annual epidemic, it is inevitable that a number of infants will be infected with RSV at the same time as they develop another major problem such as meningitis, osteomyelitis, or urinary tract infection.[113,114] Therefore, every child with evidence of acute bronchiolitis should be thoroughly evaluated to ensure that there is no coexisting acute pathology. However, serious coinfection outside the respiratory tract is uncommon and coexisting bacterial infection of the lower respiratory tract is rare in all but those requiring ventilation.[113,114]

Investigations

Other than obtaining samples for viral identification, no other investigations are required routinely. Chest radiographs are commonly requested, although there is no evidence that they are of any value in most infants admitted with a clinical diagnosis of RSV bronchiolitis and indeed, as noted above, most guidelines state that they should not be obtained unless the child is particularly unwell. It has been suggested that most areas of shadowing suggesting subsegmental consolidation are in fact small areas of collapse, and the authors concluded that this appearance should not alter a pediatrician's decision to withhold antibiotics.[115] A further study found no correlation between the changes on the chest radiograph and clinical severity, leading the authors to suggest that this investigation should be limited to those in whom intensive care was being considered, in those who deteriorate unexpectedly, and in those with an underlying cardiac or pulmonary disorder.[61]

Although inappropriate antidiuretic hormone secretion can occur,[116,117] electrolyte disturbances are uncommon except in the most severely ill babies, and hence there is no indication for the routine assessment of serum electrolytes. Neutrophilia with an excess of immature neutrophils is a frequent finding during RSV infections,[117] and full blood counts are also of little value.

Management

Careful monitoring and good supportive care remain the cornerstones of management. For those without an underlying immunodeficiency, RSV infections are self-limiting, and management is aimed at providing adequate support until the illness resolves. Monitoring is principally directed toward the detection of apnea, hypoxia, and exhaustion. Supportive care is directed at alleviating hypoxia, providing adequate fluids, and preventing exhaustion by relieving hypoxia and minimal handling.

OXYGEN

In the early 1960s, Reynolds and Cook noted that "oxygen is vitally important in bronchiolitis and there is little evidence that any other treatment is useful,"[119] and this is essentially true today with improved supportive care allowing correction of hypoxia in those in whom supplemental oxygen alone is not sufficient. Hypoxia due to ventilation-perfusion mismatch is frequent,[120] although, as noted earlier, it is difficult to detect clinically. Oxygen at 30% to 40%, warmed and humidified and delivered via a headbox or nasal cannula, is sufficient to correct the hypoxia in most cases and rapidly relieves the distress and agitation observed in hypoxic infants. The AAP guidelines recommend the use of supplemental oxygen for those infants whose saturation falls below 90%,[105] although some centers would commence supplemental oxygen at higher levels.

FLUIDS

If uncorrected, the poor intake of fluid due to the respiratory distress and cough can lead to dehydration, and this tendency may be compounded by vomiting associated with the bouts of coughing. Hyponatremia due to inappropriate antidiuretic hormone can occur,[116,117] and hence it is sensible to restrict fluids to about two thirds of maintenance.

The route of administration varies between units. Some argue that the risks and disadvantages associated with nasogastric feeding are such that any infant requiring supplemen-

tal oxygen requires intravenous fluids. The potential problems include increased work of breathing due to obstruction of the upper airway, increased work of breathing due to fluid within the stomach, and an increased risk of gastroesophageal reflux and aspiration. Other units find that those with mild to moderate illness tolerate a nasogastric tube very well and appear more comfortable with frequent small-volume feeds. However, intravenous fluids are recommended in those more severely affected. Occasionally, infants suddenly deteriorate due to aspiration.

ANTIVIRAL AGENTS

Ribavirin is a broad-spectrum virustatic drug first synthesized in 1972 whose exact mode of action is unclear. Since the initial enthusiasm that greeted its launch in 1986, concerns have been raised about its cost, safety, and efficacy. A systematic review[121] concluded that further large studies were required if a role for the drug were to be established. Most studies are now almost 20 years old, contained very few subjects, and had remarkably high death rates compared with current practice. The drug is administered as an aerosol generated by a small-particle aerosol generator (SPAG). The aerosol is usually delivered into a headbox for 12 to 18 hours. No study to date has clearly demonstrated a significant impact on the course of the disease, and few units currently use the drug in previously healthy individuals or indeed those at risk of severe disease such as those with cardiac or pulmonary disease. Anecdotal reports suggest it is valuable in treating those with immunodeficiencies.[122]

ANTIBIOTICS

Secondary bacterial infection appears uncommon in infants with RSV bronchiolitis,[113,114,123] and hence antibiotics are rarely indicated even in those with patchy changes suggesting pneumonia. The clinical picture together with the rapid confirmation of RSV infection provides reassurance in most mild to moderately unwell infants. A large prospective study, covering a period of 9 years, found that secondary bacterial infection was more common in those given antibiotics than in those who did not receive them.[113] However, dual infections with viruses and bacteria do occur, and it is not unreasonable to start antibiotics in those who are particularly ill or in those with atypical features, and possibly in some disadvantaged populations. Even in those ventilated, bacterial coinfection is relatively uncommon but is probably sufficiently frequent to justify the use of antibiotics in those requiring ventilatory support while awaiting the results of bacterial cultures on samples obtained from the lower airway.[124,125]

Although uncommon, it is also important to bear in mind that coincidental infections, such as urinary tract infections or meningitis, do occur in infants with RSV infections including bronchiolitis.

BRONCHODILATORS

One of the greatest areas for contention in the management of acute bronchiolitis is in the role of bronchodilators. This probably stems in part from the desire of clinicians to have some form of therapy that they can offer beyond simple supportive therapy. Some of the differences may also be influenced by the types of clinical illness included in studies under the label of acute bronchiolitis. Published data suggest that bronchodilators such as selective β–agonists and nonselective agents such as epinephrine and theophylline are widely used, particularly in North America,[104] but to date there is no evidence that any of these interventions has a significant impact in those with acute bronchiolitis.[105,126,127] These findings are perhaps not surprising in view of the marked mucus production and mucosal inflammation that are contributing to the airways obstruction. It should be borne in mind that one potential problem with studies in the age group is that it is extremely difficult to assess symptomatic improvement. For example, it would be inappropriate to assess the impact of a bronchodilator on a child with moderately severe exacerbation of asthma by recording the time to discharge. The modest symptomatic relief obtained while awaiting the impact of systemic steroids clearly needs to be assessed using a different outcome measure. In infants, it is more difficult to objectively document symptomatic benefit as the patient cannot give his or her opinion.

OTHER THERAPIES

Published studies have consistently failed to show any benefit from the use of systemic[128] or inhaled corticosteroids. Despite this, steroids are used extensively in North America to treat these patients. There is also no evidence that mist therapy or physiotherapy has any role in the treatment of acute bronchiolitis,[129] and indeed the excessive handling associated with physiotherapy can be detrimental.

MORE INTENSIVE SUPPORTIVE CARE

Although the number of infants with acute bronchiolitis requiring ventilation can be minimized by good supportive care, a small proportion of infants admitted to the hospital may require ventilation for either recurrent apnea or respiratory failure. The majority of those admitted to intensive care are previously healthy individuals.[130] Indications for intubation vary from unit to unit, but in general, infants are intubated for either recurrent apnea with significant oxygen desaturations or respiratory failure with persistent acidosis or hypoxia despite high oxygen requirements. Rising CO_2 levels of greater than 7 to 8 kPa would be viewed by some as an indication for intubation, but others would tolerate significantly higher levels in the absence of overt exhaustion, acidosis, or uncorrected hypoxia. Patients should be weaned from the ventilator as rapidly as possible. Occasionally, these infants develop a picture consistent with adult respiratory distress syndrome.

A number of units have reported a reduction in the need for assisted ventilation following the introduction of nasal continuous pressure ventilation (CPAP). Some infants who continued to deteriorate despite mechanical ventilation have been treated with extracorporeal membrane oxygenation (ECMO) and preliminary reports are encouraging. The role of NO, high-frequency ventilation, heliox, and other agents such as surfactant continue to be debated, and the role of these interventions has still to be clearly determined.

Advances in supportive care have ensured that the prognosis for the vast majority of infants who develop acute bronchiolitis is very good, with an overall mortality rate significantly less than 1%.[131,132] Mortality in previously well

infants is extremely low, but the mortality rates in high-risk groups has historically been much higher with figures as high as 37% reported in infants with congenital heart disease.[133] With improved supportive care, the mortality in infants from high-risk groups who develop severe bronchiolitis is now generally below 4%

Post Bronchiolitic Symptoms

As noted earlier, there is increased respiratory morbidity in subsequent years among infants admitted to the hospital with RSV bronchiolitis, the nature of which has not been fully explained. It is possible that it reflects a preexisting predisposition to experience significant LRIs when infected with a virus.[134] It may also be attributable to changes induced in the airways by the intense inflammation during the acute event. This may be due to an increase in airways responsiveness or structural changes such as mucus gland and goblet cell hyperplasia, either of which may be responsible for heightened symptoms during subsequent viral infections. The evidence to date would argue strongly that neither inhaled[135,136] nor oral steroids administered during or immediately after the acute illness significantly alter the frequency or severity of such symptoms, although the topic remains a subject of debate, with a minority of studies suggesting that there may be some benefit from the use of inhaled steroids during and/or immediately after the acute illness.[137]

In addition to these symptoms, it is clear that infants can experience ongoing symptoms in the weeks immediately following the acute illness and discharge from hospital. One pilot study has suggested that a leukotriene antagonist administered after discharge does have an impact on the level of morbidity in the weeks immediately after the acute illness,[138] but no such benefits were identified in a second study.[139] The results of a much larger study are awaited, but interpretation of the results may be difficult if RSV infection in those under the age of 2 years is used as the criterion for entry, as patients experiencing a number of phenotypes of disease will be included.

WHEEZING ASSOCIATED WITH RESPIRATORY SYNCYTIAL VIRUS INFECTION

As noted, many of those admitted to the hospital with an acute LRI during the later part of the first year of life will have this phenotype of illness. Within this group, the majority are likely to have a pattern of illness variously labeled as "wheezy bronchitis" or "wheeze-associated viral illness" (or "acute bronchiolitis" in North America and parts of Europe if it is the first episode) and will likely outgrow this tendency to wheeze with viruses in the preschool years. A minority will be experiencing their first episode of asthma, but clearly it is very difficult to distinguish these two entities on clinical grounds. In those with true asthma, that is a condition defined by a clear and unequivocal response to asthma therapy; there may be benefit from using inhaled β-agonists and indeed oral steroids, but at present, we are unable to reliably identify those who will respond to therapy. As a result of this inability, there is ongoing debate as to the value of conventional therapy in those with an apparent viral infection and wheeze.[105,140-142] This may be resolved only if a definitive test for "asthma" (other than response to therapy) is devised.

Prevention

Attempts to produce an effective vaccine have continued for more than four decades without success. As yet, the only widely applicable effective measures available are those designed to prevent nosocomial spread within pediatric wards.

Cross-Infection

It has been known for many years that the virus rapidly spreads through infants on pediatric wards if precautions are not taken,[143-147] and fatalities among infants acquiring the virus while they are inpatients are well recorded. Inhalation of small-droplet aerosols generated by coughing and sneezing does not appear to be an important method of transmission. Infection of staff is common through self-inoculation of virus from hands into eyes or the nose[18]; indeed, infection in members of staff appears to be a major source of nosocomial spread. The virus is transmitted to infants on the hands of attendant staff or relatives, and hence simply isolating infants is inadequate in preventing spread. Careful attention to hand washing appears to be the most important aspect in the prevention[143,144] of cross-infection because it will help to reduce both self-inoculation of staff and transmission of virus directly to other patients. More extensive precautions have been advocated by some authors who argue that simple isolation and hand washing are ineffective; these include the use of gowns, gloves, and even goggles. Most of these measures will serve principally to reduce the infection rate among staff and so prevent them from passing it on to other children, but they will also heighten appreciation of the need for infection control measures.

Although severe disease is unusual in neonatal units, it is still very important to try to prevent nosocomial spread in these units, as the virus can cause significant respiratory disease, can mimic other forms of sepsis with nonspecific symptoms, and may induce significant apneas.[146] During epidemics, it is important to devise strategies designed specifically to avoid spread to inpatients at highest risk.[145]

Vaccines

For over two decades, much effort has been devoted to producing a vaccine able to prevent much of the respiratory morbidity associated with RSV bronchiolitis. The 1960s trials of a formalin-inactivated alum precipitated vaccine produced alarming results in that not only did the vaccine fail to protect infants but also there was excess morbidity and mortality in the immunized children when they subsequently were infected with the virus. Whether the enhanced disease severity noted on subsequent exposure to the virus was due to an abnormal response or represented an exaggeration of the natural response is unclear, although animal data suggest an aberrant response was induced.

Subsequent approaches have been to try to develop live attenuated strains, the generation of subunit vaccine, expression of viral glycoprotein genes on the surface of carrier viruses using recombinant gene technology, and the use of purified F protein obtained from tissue cultures.[147,148] Debate continues as to whether injection, inoculation into the respiratory tract to produce local immunity, or even administra-

tion to the mother[149] would be the most appropriate route if an effective vaccine could be developed.

Specific Immunoglobulin

Studies have demonstrated that a humanized synthetic anti-F antibody preparation (Palivizumab) administered intramuscularly at monthly intervals does reduce hospitalization in certain at-risk groups, including preterm infants, those with chronic lung disease,[87,150] and those with hemodynamically important cardiac disease.[88] The protection is incomplete, and despite large numbers of subjects, the use of this preparation was not shown to have an impact on intensive care unit days or mortality, which is low even in these high-risk groups due to improved supportive care. As noted earlier, these high-risk groups represent a minority of those reaching the intensive care unit, and therefore this approach is unlikely to have a major impact on the workload of pediatric units during the winter. The cost effectiveness of this approach is the subject of considerable debate in many countries.[150-153] Work is ongoing to produce better preparations while other non-vaccine approaches to preventing infection are also being pursued.

CONCLUSIONS

The prevention of acute RSV bronchiolitis in infancy remains a major challenge. The morbidity associated with this condition is considerable, and the financial strain placed on health services is enormous. With improved supportive care, the mortality is now low even in at-risk groups, but the condition still poses a major threat to the health of infants with underlying disease. A phenotypic approach to the management of infants infected with the virus appears to be important both clinically and when assessing the outcomes in clinical trials. The basis of treatment for those with acute bronchiolitis remains good supportive care.

Despite an enormous amount of work aimed at preventing the annual influx of infants with acute bronchiolitis, it seems likely that the annual epidemics of RSV will continue to be the cause of season-affective disorder among pediatricians for the foreseeable future.

CHAPTER 35 Bacterial Pneumonia, Lung Abscess, and Empyema

Susan E. Crawford and Robert S. Daum

TEACHING POINTS

- The etiology of pneumonia varies based on patient age, vaccination status, relevant exposures, immunologic status, and clinical setting in which the causative agent was acquired.
- Determining the etiology of pneumonia is difficult and the choice of antimicrobial therapy is often empirical.
- *Streptococcus pneumoniae* is the most common bacterial etiology of community-acquired pneumonia in all age groups including children.
- Immunization practices have influenced the incidence of *Haemophilus influenzae* type b and *S. pneumoniae* pneumonia.
- The incidence of pneumonia with empyema appears to be increasing in many geographic locales across the world; the optimal treatment strategies remain to be defined.

GENERAL ASPECTS OF BACTERIAL PNEUMONIA

History

The importance of pneumonia has been known at least since the time of Hippocrates, who described *peripneumony* as an acute, febrile illness characterized by unilateral or bilateral pain, painful breathing, cough, scanty "high-colored" urine, and improvement usually by about the seventh day. It was not until around 200 AD, however, that Aretaeus provided a clinical description of this syndrome. In the early 1700s, De Konilfeld offered the first distinction between pleurisy and pneumonia. Later, in 1728, Boerhaave distinguished lobar pneumonia from other syndromes. After the introduction of percussion by Auenbrugger in 1761, Laennec described the signs and symptoms of pleurisy and pneumonia in 1819 and, further, detailed the histopathologic changes for the first time. In 1837, Seiffert introduced the term *bronchopneumonia*, and in 1850, Barthez and Rilliet called attention to the fact that this syndrome also occurred in children.

The modern era of clinical observation regarding pneumonia began in 1880 when Sternberg recognized *Pneumococcus* organisms in the saliva of healthy adults and continued in 1881 with Pasteur's observation of *Pneumococcus* organisms in the saliva of a child with pneumonia. However, not until 1884 did Fraenkel suggest that the organism found by Sternberg and Pasteur (known as the *coccus of sputum septicemia*) was the most common cause of pneumonia. In the early twentieth century, the term *Captain of the Men of Death* was applied to bacterial pneumonia in recognition of its high mortality rate, the term having originally been coined by Bunyan in reference to tuberculosis.[1]

Epidemiology

The World Health Organization (WHO) estimated that in 2000 to 2003, pneumonia was responsible for 2 million deaths each year, or 19% of the 10.6 million yearly deaths in children younger than 5 years of age.[2] Results from several studies in the United States indicated that children younger than 5 years of age have an incidence rate of three to four lower respiratory tract infections per 100 children per year.[3,4] Overall, the highest rates of pneumonia have been documented in young children; the rates gradually decline with increasing age, a trend continuing until adolescence.[5,6] Most mortality occurs in developing countries, where a child younger than 5 years of age dies every 7 seconds of an acute respiratory infection. The WHO reports that 46% of worldwide pneumonia deaths occur in Africa, where undernutrition is a large contributor to this mortality rate. Even in developed countries, however, childhood pneumonia is an important cause of morbidity and remains an important reason for the hospitalization of young children.[7,8]

Thus lower respiratory tract infections, particularly pneumonia, constitute a major health problem throughout the world. Bacterial pneumonias make up only a small number of lower respiratory tract infections but have the highest mortality rates. Overall, the mortality rate from bacterial pneumonia is 2.7 times higher than that from presumed viral pneumonia.[9]

Several factors have been associated with an increased incidence or severity of pneumonia, particularly in developing countries.[10] These include young age, increasing birth order, low birth weight,[11,12] young maternal age, limited parental education, day-care attendance, exposure to passive tobacco smoke,[13] industrial pollution,[14] urban residence,[15] previous history of pneumonia, chronic heart and lung disease, male gender,[4] and asthma.

In addition, malnutrition has been identified as a risk factor for the incidence and severity of pneumonia. The results of one study found that although the incidence of

respiratory infections was similar in nourished and malnourished Costa Rican children, the likelihood of pneumonia was 12 times higher in the malnourished group.[16] A possible explanation for this predisposition is vitamin A deficiency.[17] However, data conflict on this point.[18]

Environmental factors may also affect the incidence of pneumonia. For example, up to 30% of urban households in developing countries use biomass fuels, such as wood, agricultural waste, and manure for cooking and heating, and, although a resulting increase in bacterial pneumonia has not been documented, their use has the potential to disrupt physiologic protective mechanisms of the lung. Household crowding may also be a risk factor, presumably because it facilitates the spread of droplets containing relevant pathogens.[19]

Many pathogens that cause bacterial pneumonia, such as *S. pneumoniae*, *H. influenzae* type b, and, occasionally, *S. aureus*, can be transmitted from person to person by the spread of contaminated droplets during breathing, coughing, or sneezing. Contaminated water and aerosols have been implicated in the spread of some pathogenic bacteria, such as *Legionella pneumophila*. In hospitals and other health care facilities, contaminated equipment used for respiratory support may be involved in outbreaks of nosocomial pneumonia caused by pathogens such as *Klebsiella pneumoniae* or *Pseudomonas aeruginosa*. Some pathogens associated with bacterial pneumonia in children, such as *Francisella tularensis* and *Yersinia pestis*, are zoonoses, animal pathogens that occasionally infect humans.

On contact with a pathogenic organism, many individuals become asymptomatic carriers, whereas others become ill, some in a very short time. Similarly, the time of communicability of the offending pathogen after antibacterial therapy has been initiated is uncertain; this is probably pathogen specific and aided by case-specific clinical features, such as the presence of cough. As a rule of thumb, many experts consider that communicability is greatly decreased 24 hours after the initiation of therapy, although few explicit data support this view.

Cases of bacterial pneumonia are sporadic and may occur any time throughout the year. However, most studies indicate a peak incidence in winter, which may extend into early spring.[5] This seasonal distribution may partly reflect an association between bacterial pneumonia and certain preceding viral illnesses that have a peak winter incidence. For example, *S. aureus* pneumonia has been associated with influenza epidemics.

Epidemics of community-acquired bacterial pneumonia are relatively unusual. In nosocomial settings, such as intensive care units or nurseries, outbreaks of pneumonia caused by *K. pneumoniae*,[20,21] *P. aeruginosa*,[22] and other microorganisms have been described. Typically, the spread of the organism in these settings has implicated contaminated health care delivery materials or local environmental contaminations.

Many cases of bacterial pneumonia in children are preventable by the current universal vaccination programs. For example, invasive *H. influenzae* type b infection, including pneumonia, has decreased by more than 95% with the implementation of universal immunization programs in infants. Additionally, a 7-valent protein-polysaccharide pneumococcal conjugate vaccine licensed for use in infants and young children in the United States in 2000 has decreased the incidence of pneumococcal pneumonia.[23,24] Importantly, deploying these vaccines in developing countries has been problematic because of their high cost.

Certain underlying conditions render a host more susceptible to bacterial pneumonia (Box 35-1).[25,26] These may be divided into those likely to produce pneumonia in a single region of the lung and those likely to produce diffuse or multifocal pneumonia.

Etiology

The etiology of any pneumonia (Box 35-2), including that caused by bacteria, differs according to age of the patient, the clinical setting in which the pneumonia was acquired (e.g., community versus hospital), relevant local epidemiology (e.g., annual respiratory syncytial virus epidemics and influenza activity), the vaccination status of the child (e.g., *H. influenzae* type b), relevant exposures (e.g., to contaminated water or infected animals), host factors (e.g., the presence of underlying diseases that predispose to pneumonia), and immunologic status. Even with all relevant clinical information, determining the etiology of uncomplicated pneumonia is difficult and infrequently attempted in practice; with the exception of blood cultures, culture material suitable for definitive diagnosis requires invasive procedures not justifiable for mild to moderately ill children. Thus, in most cases, the precise etiology is never determined, and the therapeutic approach to the patient is based on generalizations regarding etiology in the relevant clinical setting.[4,27,28] This is particularly true for community-acquired pneumonias, many of which are self-limited diseases for which no specific therapy is available or needed.

In the neonate, the most common causes of bacterial pneumonia are the group B β-hemolytic streptococci (GBS) and gram-negative enteric bacilli, such as *E. coli* and *K. pneumoniae*, the same organisms that cause bacteremia and sepsis. Less frequent etiologic agents include *S. aureus*, *P. aeruginosa*, *H. influenzae* (often not serotype b), *S. marcescens*, and *Flavobacterium* species.

In children past the neonatal period, viruses are the most frequent etiologic agents in community-acquired pneumonia, although a viral and bacterial etiology may occur concomitantly.[29-31] In addition, *Chlamydia trachomatis* is an important pathogen in infants who are 3 to 19 weeks of age.

Among the bacterial etiologies, *S. pneumoniae* is most frequent.[30,32,33] *H. influenzae* type b was an important cause in the prevaccination era but is now rare. *S. aureus* pneumonia is also infrequent but requires special consideration because it may rapidly progress and because the usually prescribed antimicrobial therapies may not provide satisfactory coverage against this pathogen. The group A β-hemolytic streptococci are an uncommon cause of pneumonia, although their necrotizing nature may prolong its course. In children who chronically aspirate, anaerobic bacteria are important pathogens implicated in pulmonary infections.[34]

Viruses are also the most common etiologic agents in school-age children and adolescents. Bacterial causes are similar to those causing disease among preschoolers. *S. pneumoniae* is the most frequent cause. *S. aureus*, *H. influenzae*, and *Neisseria meningitidis* are rare causes. *Mycoplasma pneumoniae* is an important etiologic consideration among school age children.

BOX 35-1 Conditions Predisposing to Bacterial Pneumonia

Abnormalities Usually Resulting in Pneumonia in a Single Lung Region

- Abnormalities within the airway lumen
  - Foreign body
  - Bronchial tumor
    - Adenomas
    - Mucoepithelial dysplasia
    - Lipoma
    - Papilloma
  - Broncholithiasis
- Abnormalities producing external compression of the airway
  - Lymphadenopathy associated with infections
    - Tuberculosis
    - Histoplasmosis
    - Coccidioidomycosis
    - Blastomycosis
    - Other conditions
  - Lymphadenopathy associated with tumors
  - Structural abnormalities that cause decreased mucus clearance
    - Tracheal bronchus
    - Bronchial stenosis or atresia
    - Localized bronchiectasis
- Right middle lobe syndrome associated with asthma
- Bronchogenic cyst
- Pulmonary sequestration syndrome

Abnormalities Usually Resulting in Pneumonia in One or More Contiguous Lung Regions

- Microaspiration
  - Impaired swallowing
    - Cranial nerve injury
    - Drug-induced injury
    - Seizures
    - Cricopharyngeal incoordination
      - Maturational incoordination
      - Familial dysautonomia
      - Myasthenia gravis
      - Sydenham's chorea
      - Multiple sclerosis
    - Neuromuscular disorders
      - Idiopathic cricopharyngeal achalasia
      - Myotonic dystrophy
      - Muscular dystrophy
      - Other conditions
  - Laryngeal cleft
  - Submucosal cleft
  - Obstructive lesions of the tongue or larynx
  - Esophageal obstruction or dysmotility
    - Vascular rings
    - Mediastinal cysts
    - Enteric duplications
    - Esophageal web
    - Esophageal stricture
    - Achalasia
    - Tracheoesophageal fistula before and after repair
  - Gastroesophageal reflux
- Asthma
- Immunodeficiency syndromes
  - Severe combined immunodeficiencies
  - Immunoglobulin deficiencies
  - Wiskott-Aldrich syndrome
  - Ataxia-telangiectasia
  - DiGeorge syndrome
  - Immunodeficiency secondary to other diseases or cytotoxic treatment
  - Complement deficiencies
  - Phagocyte defects
- Acquired immunodeficiency syndrome (AIDS)
- Mucociliary dysfunction
  - Cystic fibrosis
  - Ciliary dyskinesias
  - Tracheobronchomegaly
  - Cartilage deficiency

In hospital-acquired pneumonia, consideration of the possible etiology requires knowledge of the institution-specific epidemiology of nosocomial infections.[35] Most published data defining the etiology of nosocomially acquired bacterial pneumonia have been gathered from adult populations, and it is likely that the etiologies in children are similar.[36] Gram-negative organisms, such as *K. pneumoniae*, *Pseudomonas* and *Serratia* species, and gram-positive organisms such as *S. aureus*, occur most frequently. Water-associated organisms such as *Acinetobacter* and *Flavobacterium* species, are occasionally implicated as well. Nosocomially acquired *Legionella* pneumonia is rare in pediatric populations[37] and has been linked to contaminated aerosols, typically from the water supply or air-conditioning cooling towers.[38]

In developing countries, the bacterial agents frequently responsible for community-acquired pneumonia are not unlike those causing similar disease in developed countries.[39] Exceptions include the important role ascribed to nontypeable and non-type b *H. influenzae* isolates in Papua New Guinea, The Gambia, and Pakistan as well as an observation of uncertain importance regarding the serologic diagnosis of

‡Pertussis is discussed in Chapter 38.

putative *Moraxella catarrhalis* infection in children with pneumonia in The Gambia.[40,41]

Pathophysiology

Most bacterial pneumonia results from inhalation of contaminated air. Bacteria, including pulmonary pathogens, can be found in ambient air. Droplets can be transmitted from person to person, and pharyngeal secretions may contain up to 10^8 bacteria per milliliter of saliva. Bacteria may gain access to the respiratory tract by inhalation or microaspiration, events occurring daily even in normal children.[42] Whether pneumonia results from such bacterial entry depends on the outcome of interactions between the bacterium and the host respiratory defense system (Fig. 35-1).

Droplet size plays a major role in determining the level of the respiratory system reached by inhaled bacteria. Most inhaled bacteria are enveloped in moisture and therefore acquire aerodynamic and dimensional characteristics that determine their destination. For example, particles larger than 10 μ do not usually traverse the pharynx, whereas those 3 to 10 μ may lodge in the larger airways, and those 0.5 to 3 μ can reach the alveolar surface.[43]

Certain medical interventions or anatomic abnormalities can facilitate bacterial transit toward the alveolus. Examples include tracheostomy, endotracheal intubation, and respiratory therapy. Similarly, direct extension to the pulmonary parenchyma through a bronchopleural fistula also facilitates bacterial access to the alveolar epithelial surfaces.[44] Bacteria may also reach the lungs via metastatic hematogenous spread from a distant site.

Because the usual interaction between bacteria and the host limits bacterial access to the lowest regions of the respiratory tract, it is generally believed that the respiratory tract below the major bronchi is sterile or nearly so. However, when a bacterium does gain access to the alveolus, additional host defense mechanisms are called into action. The bacterium makes initial contact with the alveolar wall and is enmeshed in the epithelial lining fluid that contains opsonins and, depending on the immunologic experience of the host, specific immunoglobulin G (IgG) antibody. The usual outcome of this interaction is ingestion by alveolar macrophages (alveolar type II cells); an alternative, less common outcome is complement-mediated bacterial lysis. The former mechanism is especially important in dealing with encapsulated bacteria such as *S. pneumoniae*. The process is rapid; in an animal exposed to a bacterial inoculum, whether aerosolized or instilled onto the alveolar surface, bacteria remain free for only 30 minutes before being internalized by a macrophage.[45,46]

When these mechanisms fail to destroy alveolar bacteria, polymorphonuclear leukocytes with their phagocytic capability are recruited, and an inflammatory response, presumably mediated by cytokine release, occurs. If continued, this process results in pneumonia with attendant vascular congestion and exuberant edema, best characterized for pneumonia caused by pneumococci. In this instance, sheets of pneumococci ride waves of edematous fluid from alveolus to alveolus through the pores of Kohn. This edematous zone of engorgement progresses centrifugally and leaves behind clusters of erythrocytes and purulent exudate consisting of fibrin, polymorphonuclear leukocytes, and bacteria. This stage is histologically termed *red hepatization*. The pneumococcal cell wall is probably the bacterial component that initiates these events.[47] Pneumococci do not produce a known toxin, and it is thought that bacterial growth and the exudative response to their presence cause consolidation.[47]

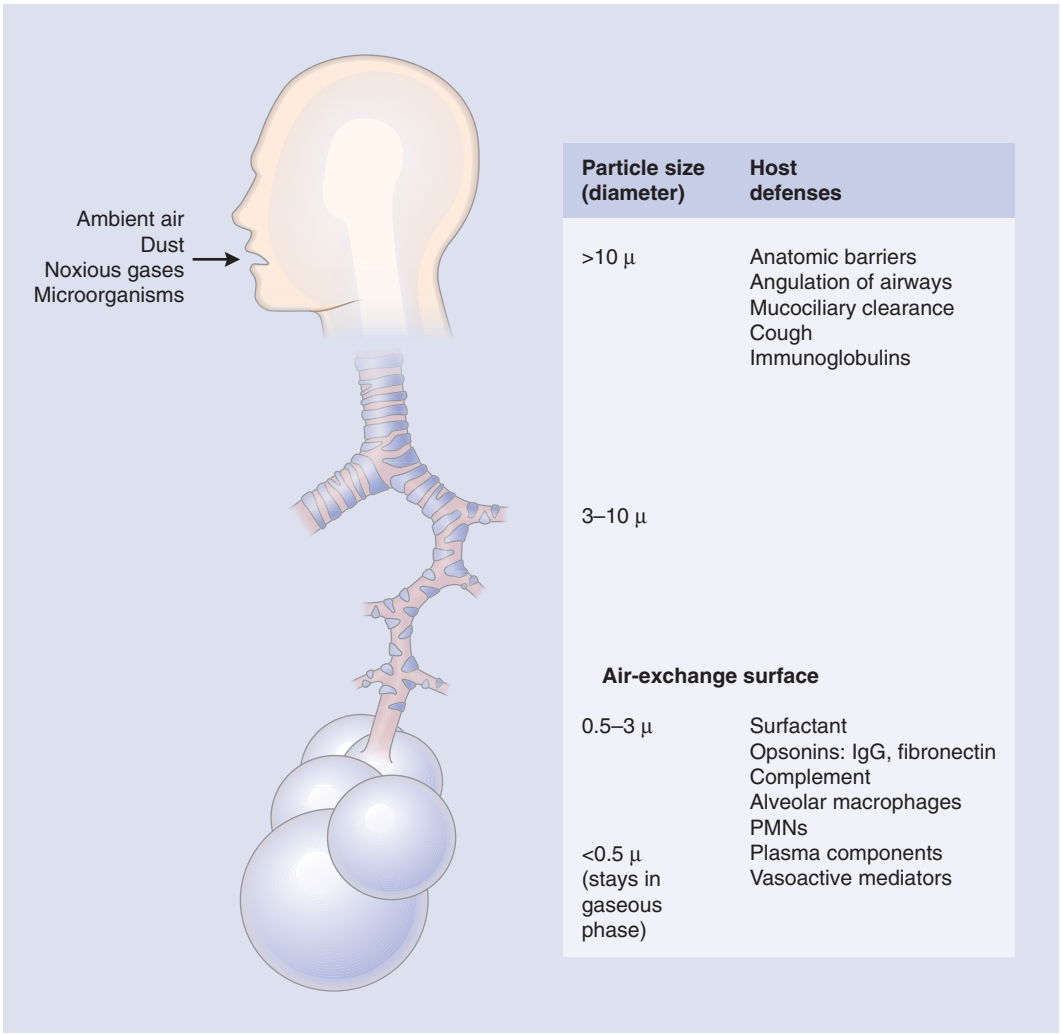

Figure 35-1 Lung defense system. IgG, immunoglobulin G; PMNs, polymorphonuclear neutrophils [leukocytes].

The next stage in pathogenesis is termed *gray hepatization*. Events characterizing this stage include the active phagocytosis of pneumococci by polymorphonuclear leukocytes. The release of bacterial cell wall components and pneumolysin by enzymatic degradation leads to increased inflammation and cytotoxic effects on all pulmonary cells. The result is the blurring of cellular elements and the loss of cellular architecture.

Resolution of pneumonic consolidation begins when anticapsular antibody appears. Polymorphonuclear leukocytes continue to phagocytose the pneumococci; monocytic cells clean up the debris. The term *zone of resolution* is sometimes applied to such an area. As long as the reticular structure of the lung remains intact (i.e., involvement of the interstitium is absent), complete parenchymal restoration and healing of the alveolar epithelium occur after successful treatment. Scarring is minimal.[47,48]

Death from bacterial pneumonia is due to respiratory failure, which occurs when the airspaces are filled with edematous fluid or exudate. The residual volume of the lung is markedly expanded by this fluid, which precludes air exchange at the alveolar level. The clinical picture of sepsis may be concomitant; shock may further complicate end-organ perfusion, and a mixed metabolic and respiratory acidosis therefore typically precedes death.[48] The pathogenesis of pneumonia caused by other bacteria may vary. For example, tissue necrosis and rapid bacterial spread throughout the alveolar spaces characterize pneumonia caused by *S. aureus* and make full recovery less likely when extensive necrosis occurs.

Clinical Manifestations

In children who are no longer neonates and who have acute pneumonia, no reliable clinical symptoms or signs distinguish the pneumonia caused by bacteria from that caused by other infectious agents. Children with bacterial pneumonia are more likely to appear ill, anxious, or distressed; have a higher incidence of and more severe fever; and have physical signs attributable to respiratory tract infection. However, there is sufficient overlap in the clinical picture to recommend caution in inferring etiology. For bacterial pneumonia of any etiology, cough is usual but not invariable. Sputum production by children younger than about 8 years of age is rare because any sputum produced is swallowed. Abdominal pain and emesis are variable complaints and may be sufficiently severe

to misdirect the diagnostic evaluation toward an acute abdominal condition.

Signs localized to the respiratory tract may provide important clues to the diagnosis. Audible expiratory noise or grunting may be present in young children or infants. Cyanosis and hypoxia, flaring of the alae nasi, subcostal and intercostal retractions, and nonspecific signs of dyspnea may also be present. Shallow breathing, splinting, and tachypnea (≥50 to 60 breaths/min in children younger than 12 months of age and ≥40 breaths/min in older children) suggest pneumonia. Pain during respiration, often called *pleuritic pain,* may be present, as may pain appearing to originate from an abdominal process. On auscultation, crackles, evidence of pulmonary consolidation, decreased breath sounds, bronchophony, increased fremitus, and dullness to percussion are often present. A friction rub suggests pleuritis, a common concomitant condition of bacterial pneumonia.

In the neonate, the clinical picture of bacterial pneumonia may resemble that found in the older child. However, apnea and signs suggestive of generalized sepsis may be the dominant clinical features instead. Auscultation of the chest may produce normal results; fever and cough are usually absent.

Diagnosis

Guidelines for the diagnosis of pediatric pneumonia were formulated by a group of Canadian pediatricians.[49] Most pediatric patients who are no longer neonates and who have bacterial pneumonia have symptoms and signs suggesting an abnormality of the respiratory system; in their absence, bacterial pneumonia is an unlikely diagnostic consideration. An exception may be some children with very high temperature (≥41.1° C) who may have radiographic evidence of pneumonia in the absence of findings attributable to respiratory system infection.[50] In developing countries, where sophisticated diagnostic tools may not be available, it has been suggested by the World Health Organization that tachypnea with indrawing of the respiratory muscles should alert the clinician to a presumptive diagnosis of pneumonia. Although the reliability of this superficial approach is obviously less than optimal, respiratory rates higher than 50 and 40 breaths/min have been used as diagnostic criteria in children younger than 12 months and between 13 months and 5 years of age, respectively,[51-55] particularly when more sophisticated tests are unavailable.

Once a determination is made that pneumonia is likely, defining its etiology poses a clinical challenge. Indeed, for many children with pneumonia, particularly when it is community acquired and mild, clinicians often take an empirical approach and perform little more than a blood culture in the way of investigation. Occasionally, there is no investigation at all; this approach is justified because the procedure required to obtain a specimen is invasive and examination of the specimen is unlikely to accurately provide the etiology. A result of this clinical dilemma is that more than 80% of patients who have "nonbacterial" pneumonia may receive antimicrobial therapy.[56]

In cases of suspected bacterial pneumonia in which precise microbiological diagnosis is deemed clinically important, a variety of techniques are available to sample respiratory secretions at various levels of the respiratory tract. Many of these procedures use instrumentation, such as a bronchoscope or another suction device, that traverses the pharynx or upper airway.[57] Generally, the easier the specimen is to obtain, the less likely it is useful in providing diagnostic help.

Moffet[58] has divided acute pneumonia culture sources in children into the following categories: conclusive, occasionally conclusive, and dubious. Examples of conclusive culture sources include blood, pleural fluid, and material obtained by open lung biopsy or lung puncture. Occasionally conclusive sources include cultures obtained at bronchoscopy, cultures of tracheostomy secretions, and, in older children, cultures of fluid obtained by transtracheal aspiration. Cultures of dubious importance for bacterial pneumonia include nasotracheal aspirates and throat cultures. Potential pathogens may be present as flora at these sites, which may create ambiguity in interpretation. For example, the leading cause of bacterial pneumonia, *S. pneumoniae,* may colonize the nasopharynx in up to 40% of healthy children in the winter.[56]

Therefore the clinician must consider which various diagnostic tests should be used in the evaluation of a patient in whom bacterial pneumonia is likely. Consideration is given as to how the microorganisms obtained from a given site may reflect the theoretical gold standard, the demonstration of etiologic bacterium in the infected lung.[59]

In a patient presumed to have pneumonia, isolation of a bacterium from the blood,[60] pleural fluid, or lung tissue is considered etiologic. However, bacteremia occurs in only 3% to 12% of cases[56] of presumed bacterial pneumonia, and at least 1 day is required to obtain results from tests. Because phlebotomy is relatively noninvasive and inexpensive, a blood culture is recommended for routine performance when the clinician is evaluating children for possible bacterial pneumonia. When pleural fluid is present, whether ascertained by physical examination or radiography of the chest, sampling it (e.g., by ultrasound-guided needle aspiration) provides a valuable specimen for Gram staining and culture. Depending on the clinical situation, culture for *Mycobacteria* species, fungi, or bacteria requiring special media may also be relevant. Additional studies commonly performed in the evaluation of such pleural effusions include a leukocyte count (including cytologic analysis when relevant) and measurement of the pH, protein, glucose, and lactate dehydrogenase concentrations. Attempted detection of relevant bacterial antigens (e.g., by latex agglutination) is sometimes performed. In practice, diagnostic pleurocentesis is performed in patients sufficiently ill to require hospitalization for putative bacterial pneumonia, in patients who nosocomially acquire presumed bacterial pneumonia (particularly during a course of antiinfective therapy), or in patients with presumed bacterial pneumonia and pleural effusion who do not respond to initial, empirically chosen therapy.

In children, the examination of sputum by Gram stain and culture is limited by the difficulty in obtaining a satisfactory specimen, especially in children younger than 8 years of age. The quality of the specimen can be inferred from a paucity of epithelial cells. Material that is produced by cough and that contains excess squamous rather than epithelial cells testifies to an upper tract origin. Clinical laboratories generally do not process specimens submitted as "sputum" with more than 25 squamous cells per low-power field on micro-

scopic examination. Other useful parameters are the presence of polymorphonuclear leukocytes and a monotonous or relatively monotonous morphology of the bacteria in the specimen. (Upper respiratory tract flora consists of bacteria of diverse morphologic structure.)

Even if a satisfactory specimen can be obtained, its usefulness in the diagnosis of bacterial pneumonia is questionable. Although once considered helpful in defining the etiology, it is now widely accepted that the diagnosis made from organisms recovered from sputum correlates poorly with that made from organisms recovered from more reliable sites, such as blood or pleural fluid, because of contamination of the sputum by the flora in the upper respiratory tract. In adults, these secretions may contain 10^8 to 10^9 bacteria per milliliter. Nevertheless, in the presence of many polymorphonuclear leukocytes and bacteria of a single morphology, Gram stain and culture of properly collected sputum may provide useful information regarding the etiology of bacterial pneumonia.[61] Identification of acid-fast bacilli or fungi by examination of sputum provides valuable diagnostic information because such microbes are infrequent constituents of the normal flora.

A variety of clinical situations require a more aggressive approach for defining the etiology of a putative bacterial pneumonia. Examples include acute pneumonia when a patient is severely ill or has respiratory failure, the condition fails to respond to therapy, the condition worsens despite initial empirical antimicrobial therapy, or it occurs in a patient with compromised immunologic integrity. In these instances, determining the etiology may be necessary so that more precise therapy can be prescribed and the toxicity of unnecessary agents can be avoided.

Bronchoscopic techniques are sometimes used in the diagnosis of bacterial pneumonia, particularly when there is local expertise in performing the procedure and when the child is sufficiently stable to allow the 1- to 2-day interval required for specimen handling. Bronchoalveolar lavage (BAL) fluid obtained during bronchoscopy should be submitted to the appropriate laboratories for histopathologic and microbiologic evaluation. Interpretation of the data is limited by the nonspecificity of the inflammatory cells present (even in large quantities) and the uncertainty regarding the importance of bacteria and yeast present in the specimen, which may represent airway flora or organisms infecting the lung. Aubas and coworkers[62] suggested that two indexes, the simplified bacterial index and the predominant species index obtained from quantitative BAL fluid cultures, were useful in defining the presence and etiology of bacterial pneumonia in adults. However, these indexes are not widely used, and the observations have not yet been extended to children.

To solve the problem of airway contamination, clinicians have used devices such as a protected catheter brush or a telescope-plugged catheter. Cultures obtained by the brush technique correlated well with the isolate obtained from blood in a small number of bacteremic adults with pneumonia.[63] However, the telescope-plugged catheter does not add much to the results obtained from lavage.[64] Few assessments of these bronchoscopy-based techniques have been performed in children, but the available data in adults suggest that quantitative BAL bacterial culture may help in the accurate diagnosis of bacterial pneumonia, particularly when a single or limited number of bacterial species is present in excess of 10^3 colony-forming units per milliliter.

Transtracheal aspirations are generally not performed in young children because of the high rate of complications, particularly in small infants, uncooperative children, and children with bleeding diatheses, severe coughing, severe hypoxemia, and dyspnea. It is uncertain whether the procedure is useful in the accurate diagnosis of bacterial pneumonia.[65] The correlation with organisms obtained by lung puncture[66] is only fair.

Obtaining lung tissue for culture can be accomplished by percutaneous lung puncture,[66] transthoracic needle aspiration biopsy (TNAB),[67-69] or open lung biopsy.[70] These procedures are normally considered in an immunocompromised host and in patients with severe pneumonia, particularly when the condition is nosocomially acquired or when empirical therapy has not produced a clinical response. They are more likely to yield important information regarding etiology when performed early in the clinical course. Percutaneous lung puncture and TNAB are usually performed under radiologic guidance[68] and should be done by an experienced person.[66] In both procedures, the pleural space is aspirated to detect an inapparent effusion before entry of the parenchyma proper. The clinician may choose not to continue into the parenchyma when pleural fluid is encountered, reasoning that the pleural fluid may provide sufficient opportunity to recover the pathogen without the increased morbidity of the lung puncture itself. Important complications of these two procedures are hemoptysis and pneumothorax,[66] although a review of 32 lung puncture studies reported in the last 70 years found that treatment for a complication was needed in less than 0.5% of cases.[67] TNAB has the advantage of providing a core of tissue for histologic examination when a large-bore needle is used, although the results may occasionally be misleading.[71] Dorca and associates[68] compared the results of TNAB performed with an ultrathin needle to other microbiologic and serologic criteria frequently used in the diagnosis of nosocomial pneumonia in adults. TNAB results were specific and had a high positive predictive value in this population. However, the relatively low sensitivity (60.9%) and low negative predictive value precluded reliance on this single diagnostic modality.[68] Vuori-Holopainen and colleagues[69] also compared the results of TNAB with microbiologic criteria used in the diagnosis of community acquired pneumonia in children; they found a similar sensitivity rate of 59% in determining the etiology of pneumonia.

Open lung biopsy is often considered the standard but requires general anesthesia and a skilled support staff. It is usually performed when a variety of microbiologic diagnoses are being considered but seldom performed when bacterial pneumonia is the most likely consideration. Pneumothorax may complicate the postoperative recovery and prolong the ventilator-dependent recovery phase.

A variety of nonspecific laboratory evaluations have been used to support the likelihood of bacterial pneumonia; these include an increased serum concentration of C-reactive protein, an increased erythrocyte sedimentation rate, and an increased blood leukocyte count with a predominance of polymorphonuclear leukocytes.[56] However, all these techniques suffer from poor sensitivity and positive predictive value.[32,72,73]

Bacterial antigen detection in blood and urine has a limited role in the diagnosis of bacterial pneumonia. Several available techniques include counterimmunoelectrophoresis, latex particle agglutination, and staphylococcal coagglutination; the last two are more widely used. Only a limited number of bacterial antigens theoretically useful for the diagnosis of bacterial pneumonia (e.g., *S. pneumoniae*, *H. influenzae* type b, *N. meningitidis*, group B streptococci) can be detected by commercially available methods; however, false-positive and false-negative results are frequent.[30,32,56,74,75] Furthermore, the meaning of *antigenemia* or *antigenuria* may be difficult to interpret because the patient may have an infection such as pneumonia, be an asymptomatic carrier of an organism such as a pneumococcus, or be colonized by a "cross-reacting" microorganism, such as *S. pneumoniae* type 14, which cross reacts with *H. influenzae* type b. Bacterial antigen detection in pleural effusions was recently evaluated and found to have a sensitivity of 90% and specificity of 95% when compared with the test standard of culture or polymerase chain reaction (PCR).[76]

The serologic diagnosis of bacterial pneumonia has received some attention, but is rarely used in clinical practice. Reasons include the delayed time frame inherent in the process of gathering sera and performing assays, the paucity of bacterial agents for which reliable antibody assays are available, and the immature immune response often present at the time of infection (e.g., with *H. influenzae* type b) that results in a modest or absent antibody response to infection. Investigators from Finland claimed success in diagnosing pneumonia by performing enzyme immunoassays on "convalescent" sera (obtained as early as 5 days after hospitalization) to detect antibodies directed against *S. pneumoniae* (pneumolysin), *H. influenzae* type b (whole cell), *M. catarrhalis* (whole cell), and *M. pneumoniae* (whole cell).[73] For the reasons already noted, it seems unlikely that this approach will become a widely available, clinically useful tool.

Highly sensitive techniques that detect bacterial nucleic acid sequences, such as in situ hybridization, PCR, and ligation-mediated PCR, have shown some promise in determining the etiology of bacterial pneumonia. Their value will likely be limited when performed on specimens such as sputum, in which discrimination between a colonizing and an infecting isolate has proved problematic. However, PCR may be a useful diagnostic tool when performed on a normally sterile fluid, such as blood or pleural fluid. For example, streptococcal sequences from the autolysin gene *lyt* were found in the blood of patients with presumed pneumococcal pneumonia in The Gambia.[77] Perhaps the greatest promise of these techniques lies in the relatively rapid diagnosis of infections caused by *Chlamydia*, *Mycoplasma* and *Mycobacterium* species, *Bordetella pertussis*, and a variety of viruses. In many of these instances, PCR may be useful on specimens obtained from airway secretions because these microorganisms are not typically among the denizens of the respiratory tract, and culturing them requires extra effort and time.

Many patients require evaluation for a variety of pathogens not amenable to detection by standard culture techniques. For example, evaluation of a patient, particularly when severely ill or immunocompromised, includes tests for important viral pathogens. It is important to remember that multiple pathogens may be responsible for pneumonia in a given instance (e.g., when influenza is complicated by bacterial pneumonia). In addition, evaluation of a patient with pneumonia may involve an etiologic search for fungi, *P. jiroveci*, mycobacteria, and *Chlamydia* and *Mycoplasma* species.

Imaging Modalities

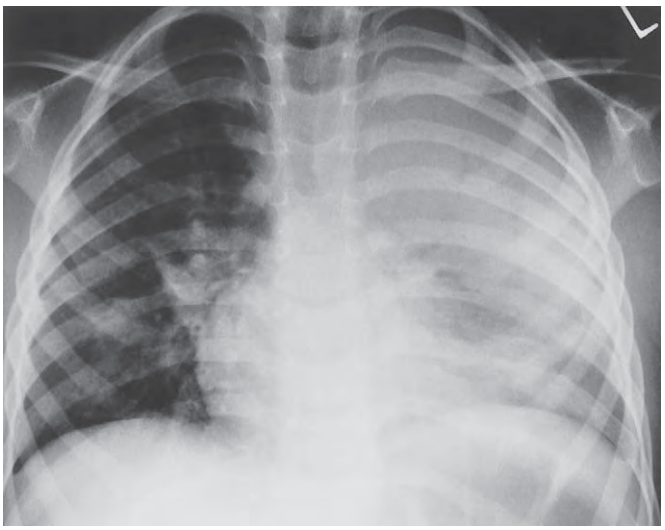
In the absence of respiratory signs, the detection of pneumonia by radiography in otherwise healthy young children is unlikely[78]; thus, the use of a radiograph as a screening tool should generally be avoided and carefully individualized. In older children, a chest radiograph is usually not indicated in the absence of respiratory signs except as part of an evaluation for prolonged, unexplained fever.

Interpretation of a chest radiograph is seldom performed without clinical data regarding the patient's illness. Even experienced radiologists are biased by this clinical information and incorporate it into the assessment of a radiograph.[79] Indeed, the rate of pneumonia diagnosed when radiologists were aware of the clinical impression was higher than that when radiologists were unaware of the clinical data.[79] Thus, despite a tendency to accord a standard to the chest radiograph, this potential for "overcall" bias should be kept in mind. Conversely, a negative radiograph does not exclude the diagnosis of bacterial pneumonia, particularly when the illness has been of short duration.

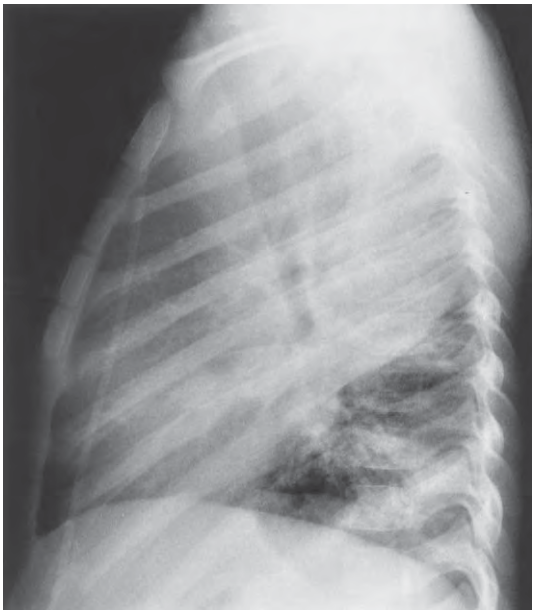
Despite these concerns, the radiograph of the chest remains an important diagnostic tool in the evaluation of a child for bacterial pneumonia.[80] The frontal posteroanterior upright chest view is generally preferred to an anteroposterior view to minimize the cardiac shadow, except in the young child in whom there is no difference in the cardiothoracic ratio between the two positions.[81] In this instance, an anteroposterior supine film is preferred because of the increased likelihood of better inspiration and ease of immobilization. It has been suggested that the frontal posteroanterior chest view (anteroposterior in young children) may often suffice for initial radiographic evaluation. However, the possibility that pneumonia may "hide" behind the dome of the diaphragm or the cardiac silhouette has resulted in the lateral film being routinely obtained at the initial evaluation.

Radiographic findings in children with pneumonia are traditionally divided into interstitial and alveolar/airspace patterns. Bacterial pneumonias are usually alveolar/airspace processes, and interstitial patterns usually reflect other etiologies; however, there is substantial overlap as well as the possibility that one pattern may progress to the other with ongoing disease.[56] Highly suggestive of bacterial pneumonia are a large lobar or diffuse consolidation, a bulging fissure (Fig. 35-2) implying extensive exudate or occult abscess in a lobar pneumonia, and associated pleural effusion[56] in the setting of a clinical pneumonia. Such pleural effusions may occur in about 20%, 40%, and 60% to 80% of children with pneumonia caused by *S. pneumoniae*, *H. influenzae* type b, and *S. aureus*, respectively.

Swischuk and Hayden[82] suggested that several radiologic patterns help differentiate among possible etiologies of an infective pulmonary infiltrate. A so-called *lobar consolidation*, whether homogeneous or fluffy, suggests a bacterial or *M. pneumoniae* pneumonia. A diffuse, bilateral, fluffy infiltrate extending into the periphery suggests a bacterial process,



A



B

Figure 35-2 Bulging fissure in a 3-year-old boy with group A streptococcal pneumonia. The chest radiograph demonstrates consolidation in the left upper lobe with expansion of the lobe. The increased volume is manifested as a larger-than-expected infiltrate in the anteroposterior view **(A)** and posterior bulging of the upper portion of the oblique fissure on the lateral view **(B).** Sonography of the same patient on the same day demonstrated areas of early cavitation.

A

B

Figure 35-3 Alveolar pneumonia in the left lower lobe in a 16-year-old boy with fever, chest pain, and cough. Posteroanterior **(A)** and lateral **(B)** radiographs demonstrate the typical characteristics of an alveolar process involving the left lower lobe. The infiltrate stands out against the preserved left cardiac silhouette in the posteroanterior projection. (It is posterior to the heart.) It silhouettes the diaphragm in both the posteroanterior and lateral views.

whereas a central peribronchial infiltrate with or without atelectasis suggests a viral or *Mycoplasma* infection. A peribronchial infiltrate with peripheral consolidation suggests a viral process but is not inconsistent with a superimposed bacterial infection; a reticulonodular infiltrate restricted to one lobe suggests *Mycoplasma* pneumonia.[82] Although these criteria are helpful in distinguishing bacterial from viral and mycoplasmal pneumonia, the etiology cannot be inferred solely from the chest radiograph because substantial overlap among the observed patterns exists.[56,79,83,84]

Bacterial pneumonia is commonly manifested radiographically as an alveolar consolidation whose pattern corresponds to its pathologic characteristics. The basic radiographic unit of the alveolar consolidation is the acinar shadow, which corresponds to a secondary pulmonary lobule in which the air is replaced by fluid. It is 2 to 5 mm in size with an ill-defined margin caused by extension of the exudate into adjacent acini via the canals of Lambert and pores of Kohn. When confluent, acinar nodules produce the typical continuous, homogeneous alveolar infiltrate. The borders are unclear at the interface with uninvolved lung; however, the margins are sharp at the interface with pleural surfaces, such as interlobar fissures. When an alveolar process abuts an adjacent organ (e.g., the heart, another mediastinal structure, the diaphragm), the loss of definition of the margin is called the *silhouette sign* (Fig. 35-3). The larger bronchi frequently remain aerated when

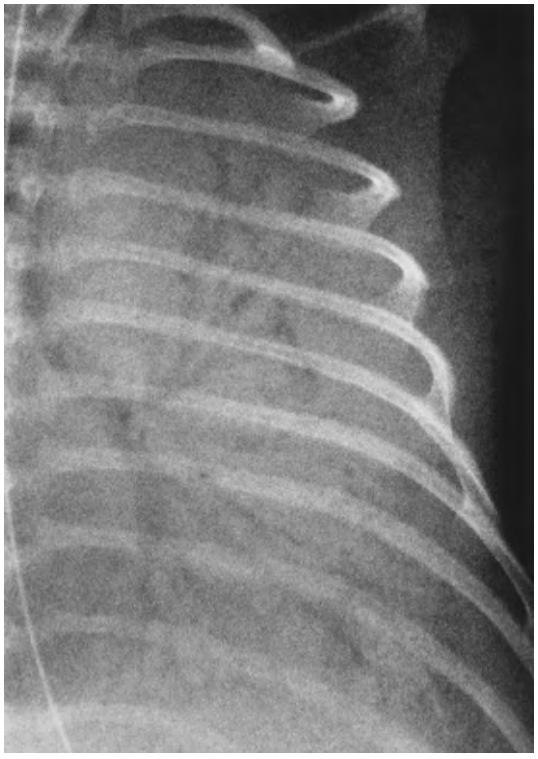


Figure 35-4 Air bronchogram. The air-filled bronchial tree stands out against the background of consolidated lung in fatal staphylococcal pneumonia in a 1-month-old infant. Rapid evolution of complete pulmonary consolidation within a few hours caused the entire bronchial tree to be visible on this plain radiograph of the left hemithorax.

the surrounding pulmonary lobules are consolidated. Those bronchi stand out against the opaque background, producing an air bronchogram (Fig. 35-4).

Alveolar consolidative pneumonias have been subclassified into two groups—airspace pneumonia and bronchopneumonia—according to the pattern of distribution of the infiltrate at diagnosis; however, the distinction between them may blur if the process is extensive. Airspace pneumonia is acquired by the inhalation of small particles and starts in the peripheral parenchyma. Typical examples are *S. pneumoniae*, *Legionella*, and *K. pneumoniae* pneumonia. Consolidation spreads concentrically because of the production of exudate and typically results in a spherical infiltrate (so-called *round pneumonia* [Fig. 35-5]), the most common "mass" lesion of the lung in children. In most patients, this kind of infiltrate has a single focus; however, multiple or bilateral foci also occur, particularly in children with predisposition to pneumococcal infection, such as patients with sickle cell disease. The round configuration may rapidly form a more extensive alveolar infiltrate.

Because bronchopneumonia (Fig. 35-6) is acquired by the aspiration of infective particles, it tends to start adjacent to centrally located bronchi. The multiple central segmental infiltrates that are typically produced may become confluent and diffuse. This sequence is typical of pneumonia caused by *Streptococcus aureus*, *Streptococcus pyogenes*, *H. influenzae*, and enteric gram-negative bacilli. Pathogens associated with bronchopneumonia are more commonly associated with lung necrosis, cavitation, pneumatoceles, and abscesses than those producing airspace pneumonia.

Figure 35-5 *Streptococcus pneumoniae* pneumonia in a 6-year-old boy. A round, mass-like infiltrate is present in the right upper lobe. It disappeared at follow-up after treatment.

Certain situations (e.g., complete opacification of a hemithorax, differentiation of pleural and parenchymal components of a complex suppurative process) may require resolution between pulmonary and other intrathoracic processes and may exceed the resolution capabilities of a chest radiograph. In these instances, other cross-sectional modalities such as computed tomography (CT) and sonography are useful.

CT has the advantage of imaging all of the chest anatomic structures, including aerated lung and bony elements. It is not as operator-dependent as ultrasound but is better than other modalities at depicting an associated pneumothorax or osteomyelitis of the rib. It is particularly helpful when there are multiple superimposed chest abnormalities involving large areas and more than one anatomic site, such as the lung parenchyma, pleura, and mediastinum. Air bronchograms are more readily seen in pulmonary opacities by CT than in plain radiographs, an observation enabling more confident differentiation of consolidation associated with bacterial pneumonia or any kind of airspace process from other chest opacities. With the administration of intravenous contrast material, the branching pulmonary blood vessels may be visualized within consolidations; this observation may aid in differentiating consolidation associated with bacterial pneumonia from other pulmonary opacities when an air bronchogram is absent.[85]

The value of ultrasonography of the chest varies with the experience of the operator. Modern sonographic equipment has the advantage of superior tissue characterization, real-time acquisition that permits evaluation of tissue motion and adherence, spectral and color Doppler that allows identification of the blood supply, and portability that allows rapid evaluation of critically ill patients in an intensive care unit or emergency department without the need for sedation.[86] This modality is helpful in identifying early cavitation (Fig. 35-7) and in distinguishing a pneumonic process from other intrathoracic events, such as avascular cavities and fluid collections from vascular consolidations. Ultrasonography of the chest requires an acoustic window. Because bone and air interfere with the sound beam, sonography is optimal for lesions that

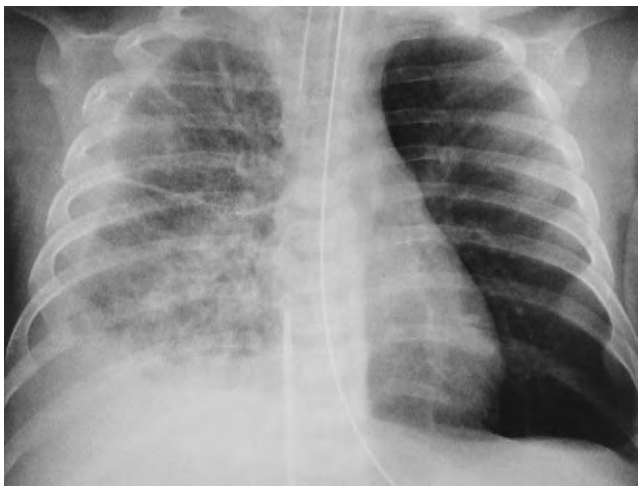

Figure 35-6 Bronchopneumonia. In this 3-month-old girl, *Streptococcus pneumoniae* pneumonia evolves as a typical bronchopneumonia with multiple central patches of segmental and confluent alveolar infiltrates accompanied by a parapneumonic pleural effusion.

are peripheral without intervening aerated lung (i.e., for processes that abut the chest wall, diaphragm, or both structures). With this modality, the consolidated lung has a liver-like architecture; air bronchograms appear as branching, highly echogenic structures.[87,88] A fluid bronchogram may be seen by sonography but not by CT.[89] In a patient with peripheral lesions, ultrasonography allows differentiation between pulmonary and pleural involvement[90,91] and is also useful for guiding needle aspiration, biopsy, or drainage. Magnetic resonance imaging adds little benefit over CT in the diagnosis of pneumonia and, in young children, requires sedation.

Management

The approach to management is greatly influenced by the age of the child,[56] the clinical setting in which the illness is acquired (e.g., community or nosocomial), and the immunologic status of the host. For community-acquired pneumonia suspected to be bacterial, hospitalization is the rule for children younger than about 4 to 6 months of age. For older children, the decision to hospitalize should depend on the severity of the clinical picture.

The choice of the antimicrobial regimen for childhood pneumonia is often empirical because of the difficulty in defining the etiology. General guidelines for the initiation of therapy in commonly encountered clinical situations may be found in Table 35-1. These recommendations have been affected by changes in the prevalence of β-lactam resistance in *S. pneumoniae* and *S. aureus* and ampicillin resistance in *H. influenzae*.

For nosocomially acquired pneumonia suspected to be bacterial, empirical therapy is guided by knowledge of the clinical setting and the underlying disease prompting the hospitalization. Also, the consideration of possible etiologic agents differs from that of community-acquired pneumonias. For example, gram-negative bacilli and *S. aureus* are important causes of nosocomial pneumonia in infants and children, whereas gram-negative bacilli are not an important consideration if the infection is community-acquired. In community-

Figure 35-7 Pneumonia with an opaque chest. This 4-year-old girl with fever, cough, and shortness of breath had group A streptococcal pneumonia. **A,** Chest radiograph demonstrates an opaque left hemithorax with a mediastinal shift to the right. **B,** Sonography of the chest demonstrates a large pleural effusion with sediment in the fluid. The underlying lung is consolidated with an area of impending cavity. **C,** CT 1 week later demonstrates pulmonary consolidation with multiple cavities—some containing fluid and some containing air. A typical crescent empyema has evolved posterolaterally.

Table 35-1
Approach to Antimicrobial Therapy for Bacterial Pneumonia in Immunocompetent Children

Age	Regimen	
	Inpatient	Outpatient
Birth-4 wk	Ampicillin and gentamicin*†‡	Not applicable
>4-8 wk	ESC and ampicillin§	Not applicable
>8 wk-1 yr	ESC*‡§	Amoxicillin§
>1 yr	ESC*¶	Amoxicillin¶

*Add oxacillin, clindamycin, or vancomycin as appropriate if *Staphylococcus aureus* is suspected.
†ESC (extended-spectrum cephalosporin) and gentamicin if *Klebsiella pneumoniae* or another ampicillin-resistant gram-negative bacillus is suspected.
‡Use erythromycin or another macrolide if *Bordetella pertussis* is suspected.
§Use erythromycin if *Chlamydia trachomatis* is suspected.
¶Use erythromycin or another macrolide if *Mycoplasma pneumoniae* is suspected.

acquired or nosocomially acquired pneumonia, antimicrobial therapy is targeted toward the specific bacterium when the etiology is identified. Guidelines for therapy in this instance are detailed in Table 35-2.

Few data exist regarding the optimal duration of antimicrobial therapy for bacterial pneumonia. A 7-day course is usually sufficient for uncomplicated, community-acquired pneumonia in children who are no longer newborns. Pneumonia in the neonate is typically treated for 14 days by the parenteral route. For nosocomial bacterial pneumonia, the duration of therapy (typically 10 to 14 days) is guided by the clinical course and knowledge of the likely causative microorganism. Staphylococcal pneumonia may require extended treatment.

Guidelines from the World Health Organization for the therapy of children with pneumonia in developing countries reflect uncertainty regarding the etiology of pneumonia in a given child, the increased likelihood that a clinically relevant pneumonia is bacterial, the cost of antimicrobial agents, the necessity for reliance on clinical signs (e.g., tachypnea) to diagnose pneumonia, and the relatively high mortality rate associated with pneumonia. For outpatient therapy of children with nonsevere pneumonia, a 5-day course of cotrimoxazole or amoxicillin, has been recommended. In severe cases of pneumonia, chloramphenicol is often used prior to referral to an inpatient setting. It may be given intramuscularly prior to hospitalization or if hospitalization is not possible, intramuscular injections may be given twice daily for 5 days followed by oral therapy for 5 additional days.[92] Inpatient treatment of pneumonia includes administration of ampicillin or penicillin. For infants younger than 2 months of age, penicillin or ampicillin plus gentamicin may be used; oxacillin may be substituted for penicillin when staphylococcal pneumonia is suspected. These antibiotic regimens may all be given intramuscularly.[31] The increasing recognition of antimicrobial resistance of *S. pneumoniae*, *S. aureus*, and *H. influenzae* will prompt ongoing evaluation of these guidelines that will vary according to local resistance patterns and resources available for the purchase of antimicrobials.

Adjuncts to antibiotic therapy for the child with bacterial pneumonia include supplemental oxygen, if needed, and provision of maintenance fluids. Chest physiotherapy has been widely used; however, the modern view is that its efficacy is poor and that it does not hasten resolution.[93] Vitamin A supplementation has not proved to be definitely efficacious.[94]

Long-Term Management and Prognosis

In uncomplicated, community-acquired pneumonia, documentation of a normal chest radiograph is unnecessary.[95]

Table 35-2
Antimicrobial Therapy When the Etiology is Known

Organism	Regimen of Choice	Alternative Regimens
Streptococcus pneumoniae	Penicillin*	ESC Macrolide† TMP/SMX
Haemophilus influenzae	Ampicillin/amoxicillin*	ESC Doxycycline (for children >8 yr) Chloramphenicol TMP/SMX
Staphylococcus aureus	Oxacillin/nafcillin for MSSA Clindamycin for MRSA	Cefazolin for MSSA Vancomycin, linezolid, or daptomycin for MRSA
Group A streptococci	Penicillin	Macrolide†
Moraxella catarrhalis	ESC	Macrolide† TMP/SMX
Gram-negative enteric bacilli	ESC with or without aminoglycoside	ESC
Pseudomonas aeruginosa	Anti-pseudomonal β-lactam (e.g., ticarcillin/clavulanate, piperacillin/tazobactam) and aminoglycoside	Ceftazidime
Anaerobes	Clindamycin	Metronidazole Chloramphenicol

*When susceptible.
†Erythromycin or azithromycin, for example.
MRSA, methicillin-resistant *Staphylococcus aureus;* MSSA, methicillin-susceptible *Staphylococcus aureus;* TMP/SMX, trimethoprim-sulfamethoxazole.

Indications for serial radiography include neonatal pneumonia, severe symptomatology, suspicion of a complication (such as a lung abscess), pleural involvement (such as an effusion or empyema), or an unsatisfactory response to treatment.

The traditional view is that timely administration of antimicrobial therapy renders an excellent outcome in bacterial pneumonia. In developed countries, the mortality rate from uncomplicated cases of pneumonia is less than 1%; lung structure and tissue almost always return to normal—even in patients with empyema or a lung abscess. Some caution regarding this generally bright outlook has come from a recent study, which suggested that a relation might exist between pneumonia in children younger than 2 years of age and the occurrence of chronic obstructive lung disease later in life[96]; however, no data support this association with bacterial pneumonia.

Recurrent pneumonia, defined as at least two episodes in 1 year or three or more episodes at any age with radiographic clearing between episodes, should prompt further patient evaluation.[26] Components of such an evaluation may be found in Box 35-3, but the evaluation of each patient must be individualized. Many of the disorders listed in Box 35-1 are associated with recurrent bacterial pneumonia in children and young adults and should be considered as predisposing to pneumonia in such a patient. These disorders include cystic fibrosis (CF), pulmonary sequestration, bronchiectasis, disorders of normal pulmonary physiology (e.g., immotile cilia syndrome), and a variety of congenital (e.g., severe combined immunodeficiency, immunoglobulin deficiency disorders, Job's syndrome) and acquired (e.g., human immunodeficiency virus [HIV]) immunodeficiency disorders.

Complications and Outcome

Pneumothorax is an uncommon complication of pneumonia and is usually associated with *S. aureus* pneumonia. An intraparenchymal cavity containing air may sometimes be associated with bacterial pneumonia. This may represent a pneumatocele, a cavitation, an abscess (see separate section), or rarely, a sequela of massive lung necrosis. A pneumatocele, recognized most commonly in staphylococcal pneumonia, is a thin-walled air collection that can become large and occasionally cause a clinically important mass effect. Its pathogenesis remains controversial. Some argue that a pneumatocele is an enlarged airspace whose walls ruptured after air trapping distal to a bronchus that was occluded by inflammatory exudate and mucosal edema. However, others have invoked thin-walled, subpleural interstitial blebs that occasionally coalesce and appear radiographically as a pneumatocele.[97] Although a pneumatocele contains no fluid when it is first formed, an air-fluid level may develop. When this occurs, it may be difficult to differentiate it from a cavity or an abscess, particularly if a surrounding infiltrate prevents accurate evaluation of the lesion wall. A pneumatocele typically appears during convalescence and may either resolve spontaneously within weeks or linger for months before it gradually diminishes and disappears.[98] The earliest radiographic sign of a cavity may be visualized by sonography, before demonstration by CT or plain radiography, as an echolucent focus within the pulmonary consolidation at the hepatization phase. Later, bronchial communication results in air entering the cavities,

BOX 35-3 Evaluation of Children with Recurrent Bacterial Pneumonia

General

A history should be taken, with special attention to high-risk situations for foreign body aspiration, stools consistent with malabsorption, sinusitis, otitis, asthma and atopy, severe pulmonary disease, environmental exposure, prematurity, oxygen exposure, and early deaths in family members.

A physical examination should be done, with special attention to nutritional state, anatomic structures of the upper airway, muscular strength, neurologic functions (such as swallowing and gag reflexes), resting respiratory rate, accessory muscle use, inspiratory to expiratory ratio, wheezes, crackles, and cardiovascular system for suggestion of congenital anomalies of the heart or great vessels and the presence of heart failure.

Specific

- The chest radiograph should be reviewed by a radiologist.
- A complete blood count with differential should be obtained.
- A blood culture should be done.
- Sputum should be examined for a cell morphologic study if the patient is old enough to comply—Gram's stain, fungal smear, acid-fast smear, and culture for aerobes, fungi, and *Mycobacterium* species.
- Fiberoptic bronchoscopy may be needed in some cases to obtain sputum.
- Bronchoalveolar lavage (BAL) fluid should be examined by silver methenamine stain for *Pneumocystis jiroveci,* fungi, *Mycobacterium* species, and cellular elements (e.g., eosinophils, erythrocytes).
- Alveolar macrophages can be stained for hemosiderin for the diagnosis of recurrent pulmonary hemorrhage.
- Purified protein derivative analysis should be done.
- A sweat chloride test should be obtained.
- *Further evaluation should be performed as appropriate:*
  - Chest CT
  - Airway fluoroscopy
  - Laryngoscopy
  - Bronchoscopy
  - Endoscopy
  - Barium swallow
  - Mediastinal magnetic resonance imaging to evaluate vascular structures
  - Lung biopsy
  - Quantitative serum immunoglobulin assay
  - Neutrophil function studies
  - T and B cell enumeration, quantitative of subsets' function
  - Nasal turbinate or tracheal biopsy for electron microscopy for cilia ultrastructure and phase microscopy for function
  - Spirometry without and with β_2-agonist inhalation challenge

rendering them visible first by CT and later by plain radiograph.

Pneumonia in the First Month of Life

Despite having many features in common with pneumonia in older children, certain unique aspects of bacterial pneumonia in the first month of life warrant special consideration. It has been convenient to subdivide neonatal bacterial pneumonia according to the acquisition time of the etiologic microorganism and the onset of clinical manifestations. A classification scheme similar to that proposed by Marks and Klein[99] provides a useful framework. In this scheme, pneumonia occurring in the first month of life is subdivided into congenital or intrauterine pneumonia and neonatal pneumonia.

The term *congenital* or *intrauterine pneumonia* is applied when the bacteria are acquired transplacentally or in utero by the ascending route; the source of the etiologic organism is most often the maternal genitourinary tract. Infants with congenital or intrauterine pneumonia are stillborn or die shortly after birth, usually within 24 hours. The pathogenesis is not completely understood. Identified risk factors, such as prematurity, prolonged rupture of membranes, intrauterine asphyxia, and infection of nonrespiratory tract sites, are similar to those predisposing to neonatal bacteremia. Microorganisms from the maternal genitourinary tract may contaminate the maternal membranes, amniotic fluid, and periumbilical vascular tissues by ascending to them through small, unrecognized defects in the decidua or after premature membrane rupture.

The pulmonary pathology (as defined at autopsy) reflects an inflammatory reaction. Polymorphonuclear leukocytes are evident and are often accompanied by vernix and squamous cells. The interstitial tissue of small bronchioles and the interalveolar septa may be infiltrated by lymphocytes.[100] Alveolar macrophages may also be present and tend to increase in number with the duration of the postnatal illness.[101] The distribution of inflammation is characteristically diffuse. Interestingly, certain features of bacterial pneumonia acquired after birth, such as pleural reaction, alveolar fibrinous exudate, and infiltration or destruction of the bronchopulmonary tissue, rarely occur in congenital or intrauterine pneumonia.

The term *neonatal pneumonia* is used to describe pneumonia in which bacterial acquisition occurs during passage through the maternal genital tract or shortly thereafter; the clinical features are manifested in the first few days to the first month of life.[99] The portal of entry for the etiologic agent may be the lung after the aspiration of infected amniotic fluid and may therefore be a consequence of contact with vaginal or uterine secretions in the birth canal, contaminated water or medical equipment, or contact with caregivers.

The pulmonary pathology in neonatal bacterial pneumonia is similar to that in older children and adults. The lungs may contain regions of exudate with hemorrhage, congestion, and necrosis.[99] Bacteria are often seen in lung sections—a finding absent in the histology of congenital or intrauterine pneumonia. The histopathology depends in part on the microbial etiology. For example, *S. aureus* and *K. pneumoniae* typically cause necrosis of lung tissue, empyema, or microabscesses.[102-104] *S. aureus*, *E. coli*, and *K. pneumoniae* may be associated with pneumatocele formation.[105] GBS pneumonia has been associated with intra-alveolar hyaline membranes in which microorganisms may be visualized.[106] Similar hyaline changes have also been noted with neonatal pneumonia caused by *H. influenzae* and gram-negative enteric bacteria.[107]

The incidence of neonatal pneumonia is difficult to determine because of uncertainty regarding case definitions, rate differences in patient populations, and ascertainment bias. In a study of consecutive live births at a tertiary care center in Oxford, England, pneumonia was defined as respiratory distress associated with changes on the chest radiograph that persisted for more than 48 hours. Early onset pneumonia, which occurs in children younger than 48 hours of age, was found in 1.8 per 1000 live births, whereas late-onset pneumonia, which occurs in children older than 48 hours of age (mean, 35 days of age), was found at a rate of 2.0 per 1000 live births.[108] In a review of nine studies describing autopsy findings in stillborn and live-born neonates, the incidence of pneumonia was 15% to 38% and 20% to 32%, respectively.[99]

Neonates born into low-income families have a significantly greater incidence of pneumonia than those from higher-income families. At comparable economic levels, however, African-American infants have a higher incidence of newborn pneumonia than do Hispanic or white infants, although this racial/ethnicity difference has not yet been reasonably explained.[109,110] Pneumonia in newborns is also found at much higher rates in developing countries.

Epidemics of neonatal pneumonia have occurred. The outbreak is often caused by a single source of infection (e.g., a nursery worker, contaminated equipment or solutions used for patient care). In the 1950s and early 1960s, many nurseries in the United States experienced epidemic *S. aureus* pneumonia. The identification of infants colonized with virulent *S. aureus* phage 80/81 was often accompanied by a sharp increase in the incidence of *S. aureus* neonatal pneumonia. For unclear reasons, the frequency of epidemic *S. aureus* pneumonia has greatly decreased since that time, but sporadic cases still occur.[103]

Recent reports of clusters of methicillin-resistant *S. aureus* (MRSA) skin infections in neonates has again prompted further examination of hygiene and infection control practices in nurseries.[104] Other bacteria, such as *Pseudomonas* species, *Flavobacterium* species, and *S. marcescens*, have also been responsible for nursery epidemics.[99]

When the pathogen is acquired in the maternal genital tract, the most common causes of pneumonia are group B streptococci and gram-negative enteric organisms such as *E. coli*, *K. pneumoniae*, and *Proteus* and *Enterobacter* species. *Chlamydia* organisms are also believed to be acquired in this manner. Occasionally, pathogens normally associated with respiratory tract spread, such as group A streptococci, *H. influenzae*, *S. aureus* and *N. meningitidis*, are found in the maternal genital tract and transmitted vertically to neonates.

After birth, bacteria causing pneumonia are usually acquired from parents, caregivers, or environmental sources. These include *S. aureus* (30% of all cases caused by this organism occur in children younger than 3 months of age)[111] and gram-negative bacilli, such as *Pseudomonas* and *Flavobacterium* species, *Citrobacter diversus*,[112] and *S. marcescens*.

H. influenzae, *M. catarrhalis*, *L. pneumophila*, and *Bacillus cereus*[113] are infrequently recognized etiologic agents. *S. pneumoniae*[114] pneumonia is infrequent in this age group. It usually manifests shortly after birth and has a high mortality rate.

The diagnosis of neonatal pneumonia is usually based on clinical, microbiologic, and diagnostic imaging data. Because the clinical manifestations are usually nonspecific, especially at the onset, the birth history may provide important clues. Important risk factors in neonates are prolonged rupture of the maternal membranes (particularly longer than 24 hours), prolonged maternal labor, the identification of meconium-stained or malodorous amniotic fluid, and meconium-stained laryngeal or tracheal secretions.

If not stillborn, infants with congenital or intrauterine pneumonia are often very ill at birth. There are usually signs of asphyxia, including the presence of meconium, nuchal cord, apnea, and depressed respirations; the mortality rate within the first 24 hours of life is high. Pneumonia occurring during or shortly after birth is manifested by lethargy and anorexia, both of which are nonspecific signs of a generalized illness. Fever is commonly absent. Signs attributable to the respiratory tract, such as dyspnea, tachypnea, grunting, nasal flaring, coughing, cyanosis, and retractions, either may be initially evident or may develop later. The presence of auscultatory findings of crackles and diminished breath sounds also varies.

The most helpful aid in diagnosing neonatal bacterial pneumonia is a chest radiograph. The typical findings include diffuse or patchy bilateral alveolar infiltrates, streaky densities, confluent opacities, and peribronchial thickening. The presence of these findings is inconsistent, however, and the radiologic diagnosis of pneumonia in the newborn may, therefore, be difficult.[115] Other causes of respiratory distress in the newborn, such as hyaline membrane disease, retention of fetal fluid, and pulmonary edema, may also be associated with diffuse, bilateral radiographic opacities. Conversely, the chest radiographs may be normal in some infants with pathologically proven bacterial pneumonia.[116] Further complicating this conundrum are the variable radiographic findings when pneumonia is the certain diagnosis. For example, among infants with histologic evidence of pneumonia at autopsy, 77% had diffuse or patchy bilateral alveolar infiltrates. In 17%, however, the radiograph suggested retained fetal fluid consistent with transient tachypnea of the newborn. In 13%, the radiographic picture closely resembled hyaline membrane disease.[116] Indeed, the radiographic picture of this disease may mimic that of pneumonia, particularly when group B streptococcus is the pathogen (Fig. 35-8). The presence of a pleural effusion may aid in differentiation because this finding is not observed in hyaline membrane disease.

The diagnosis of pneumonia in a neonate in intensive care with underlying chronic lung disease is especially difficult. Infection is suspected in the presence of a suggestive clinical picture (i.e., a sudden increase in the severity of pulmonary abnormalities or another clinical deterioration and a new pleural effusion or an opaque chest radiograph). Pneumonia with pneumatoceles or cavitation may mimic congenital diaphragmatic hernia or a cystic adenomatoid malformation.

CT of the chest with infusion of contrast material is less helpful in the neonate than in the older child but may be of use in localizing a lesion, especially in distinguishing among an abscess, empyema, pneumatoceles, or a bronchopleural fistula. Ultrasonography has been useful in assessing pleural effusions for the presence of loculation or debris, differentiating empyema from lung abscess, and clarifying the components of an opaque chest radiograph. It has also been used to diagnose a case of pneumonia in utero in a fetus of 32 weeks' gestation.[117]

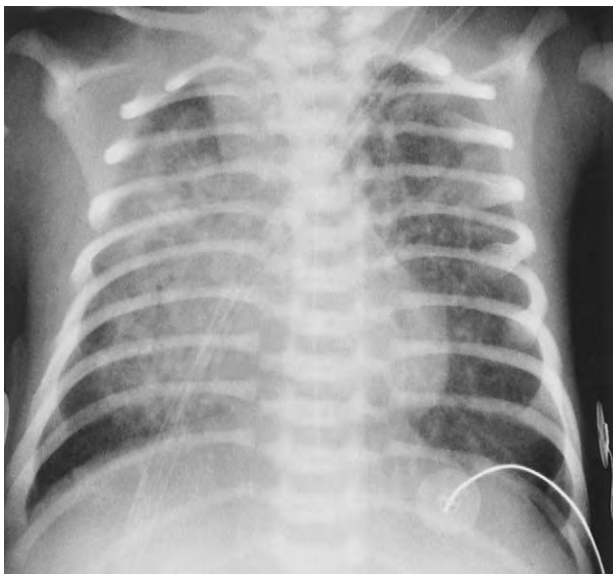

Figure 35-8 Group B streptococcal pneumonia in a neonate. A full-term male newborn with diffuse bilateral infiltrates, both reticular-linear and confluent.

Aspirating pulmonary exudate under radiologic guidance can provide unequivocal information about the causative agent. Bronchoscopy may also be helpful. In addition, open lung biopsy has been useful in newborns when other diagnostic techniques have failed to provide precise information in infants with respiratory failure.[118]

The evaluation of an infant in the first month of life for suspected pneumonia is usually performed in the context of evaluation for a possible systemic infection. Thus, many infants with suspected neonatal pneumonia undergo blood, urine, and cerebrospinal fluid (CSF) cultures at the time of initial evaluation. Because viruses, such as herpes simplex virus and cytomegalovirus, may be responsible for pneumonia and even a clinical picture resembling a systemic infectious illness, evaluation of an infant in the first month of life may include consideration of these nonbacterial agents.

A bacterium recovered from blood, urine, or CSF often provides a valuable clue to the etiology of suspected pneumonia. Some researchers have suggested that a tracheal aspirate performed during the first few hours of life may also provide a clue as to the etiology of pneumonia.[119] Antigen-detection techniques such as latex particle agglutination may also provide clues; however, in the neonate, these are limited to detection of group B streptococcal antigens, which have been found in the serum and urine of patients with group B streptococcal pneumonia.

The selection of antimicrobials for the therapy of neonatal pneumonia is also performed in the context of a possible systemic bacterial infection (see Table 35-1). An empirical

regimen that includes a β-lactam, such as ampicillin, and an aminoglycoside, such as gentamicin, often constitute initial therapy. Once a bacterium is identified, the regimen may be targeted toward it (see Table 35-2). Few explicit data are available to guide the duration of antimicrobial therapy. The decision regarding length of therapy is often guided by treatment response and by the etiology, if identified. For example, a 14-day course may suffice when the clinical response has been prompt; however, a course of at least 21 days is often used for pneumonia caused by gram-positive organisms such as *S. aureus* and group B streptococci or pneumonia of any other etiology when the response has been slow.

Supportive care includes the provision of oxygen and mechanical ventilation (when appropriate), maintenance of fluid, electrolyte, and metabolic balance; and drainage of appropriate pleural effusion or abscesses. Such care is essential to optimize chances for a good outcome.

The outcome of therapy depends on many factors. The availability of state-of-the-art neonatal intensive care greatly improves the likelihood of a good outcome; the mortality rates in developing countries lacking these facilities are often high.[120,121] In developed countries, prematurity, underlying diseases, the host response, the aggressiveness and appropriateness of antimicrobial therapy, and supportive care measures all have a great impact on the mortality rates and prognosis.

SPECIFIC CAUSES OF PEDIATRIC PNEUMONIA

Causes of Frequent Clinical Concern

STREPTOCOCCUS PNEUMONIAE, PNEUMOCOCCUS

The pneumococcus is the most common cause of bacterial pneumonia in children.[32,122] The observation by Pasteur[123] and Pasteur and colleagues[124] that lancet-shaped pairs of cocci found in human saliva could cause disease in rabbits provided the first notion that these bacteria were important human pathogens. In 1886, Fraenkel[125] named these bacteria *pneumococci* because of their tendency to cause pneumonia, but in 1920, the Society of American Bacteriologists assigned the name *Diplococcus pneumoniae*.[126] However, because pneumococci form chains in liquid media, the name *S. pneumoniae* was assigned to the species in 1974.[127]

The organism is a gram-positive coccus that was among the first bacteria described by the then fledgling technique developed by Gram in 1884.[128] The classic Gram stain morphology is so-called lancet-shaped, gram-positive diplococci. The organism grows easily in fresh beef heart infusion broth with whole blood or serum, which provides catalase to break down the accumulating hydrogen peroxide. Incubation at 35° to 37° C and an atmosphere containing 5% carbon dioxide improve growth.

In the United States the epidemiology of pneumococcal disease has been greatly influenced by the introduction of the heptavalent pneumococcal conjugate vaccine in 2000 (Prevnar, Wyeth-Lederle, Madison, NJ). High cost has limited its use in developing countries. Prevnar was licensed for use after it had been demonstrated to have an efficacy of 97.4% against invasive pneumococcal disease caused by serotypes contained in the vaccine in infants and children attending Kaiser Permanente Clinics in Northern California.[129] The vaccine contains purified capsular polysaccharide from serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F linked to a nontoxic mutant of diphtheria toxin (CRM_{197}). The serotypes included in the vaccine accounted for about 84% of cases of invasive disease in United States children.

In the prevaccine era, the incidence (number of children per 100,000 per year) of invasive pneumococcal infections in Northern California peaked at 241 per 100,000 per year in children 12 to 17 months. This compares to an incidence of 150 per 100,000 per year for invasive *H. influenzae* type b disease in the same population in infants younger than 12 months of age and 63 per 100,000 per year in toddlers before the introduction of vaccination. The decline in overall pneumococcal disease after introduction of vaccination has been 69% among those younger than 2 years and 59% among those younger than 5 years.[130] Invasive disease caused by vaccine and vaccine-related serotypes declined by more than 75% in controlled clinical trials done in the United States.[129-131] Disease rates among adults have also declined, presumably reflecting decreased transmission from children to adults.[132] Rates of antibiotic-resistant invasive pneumococcal infections have also decreased by 57% since introduction of the conjugate vaccine, presumably because 5 of 7 serotypes in the vaccine were responsible for most penicillin-resistant infections.[133]

The effectiveness of the pneumococcal conjugate vaccine in prevention of pneumonia has also been evaluated. Rates of clinically diagnosed pneumonia and of pneumonia with a positive radiograph were compared between 37,868 children stratified into vaccinated and nonvaccinated groups. In recipients of the pneumococcal vaccine, first episodes of clinically diagnosed pneumonia declined by 4.3% but all episodes with a positive radiograph decreased by 20%, $P = .02$.[134] When the radiographs were subjected to analysis using World Health Organization standardized interpretive criteria, the efficacy of the vaccine against a first episode of radiograph-confirmed pneumonia was 30%.[135] Ten of the 11 cases of pneumococcal pneumonia with a positive blood culture were in the nonvaccinated group, suggesting greater efficacy for the vaccine against bacteremic pneumonia. Additionally, a Texas study evaluating the epidemiology of pleural empyema in children found that the number of children hospitalized with empyema steadily increased from 1992 through 2000 but then decreased from 2000 to 2002 after introduction of universal Prevnar immunization.[136]

The difficulty in establishing a definite etiology of pneumonia and discrepancies in interpreting chest radiographs complicate the evaluation of vaccine impact on pneumonia. Nonvaccine serotypes may also be responsible for a large proportion of nonbacteremic or noninvasive pneumonia and, therefore, pneumonia caused by these serotypes may be un-affected by the current vaccine. Additionally, serotypes not included in the vaccine (serotype 1) were responsible for increasing cases of pneumonia complicated by empyema in certain geographic locales after introduction of the vaccine.[137] Continued surveillance and serotyping strains isolated in cases of pneumonia will help further clarify these issues.

The species *S. pneumoniae* is subdivided into 90 immunologically distinct serotypes. There are two numbering systems:

the American system, which numbers serotypes in numerical sequence, and, in wider use, the Danish system, which groups antigens according to immunologic similarity.

The distribution of serotypes responsible for invasive infections has varied with geographic locale, age of the patient (child versus adult), clinical syndrome (invasive disease versus otitis media), and immunization status.[138,139] For example, in children in Northern California, types 6B, 14, 18C, 19F, and 23F accounted for 95% of all invasive pneumococcal infections in the prevaccine era. In Connecticut, the same serotypes caused 68.5% of invasive disease in children; the inclusion of types 4, 6A, 9V and 19A encompassed an additional 20% of cases.[140] The two most common serotypes among Israeli children, types 1 and 5, are rare in Western Europe and North America.[139] Thus, the currently formulated pneumococcal conjugate vaccine may have different efficacy in different populations.

Asymptomatic nasopharyngeal colonization by the pneumococcus is common; 20% to 40% of healthy children are colonized at any given time.[141] The rate of isolation of pneumococcus from asymptomatic children is also higher in institutional settings. Virtually all infants are carriers at least once when followed longitudinally.[142] Pneumococcal carriage is infrequent in the first 6 months of life, increases thereafter to reach its peak rate among preschool children, and then declines slowly to a nadir among adolescents. The highest rates of colonization have been found from December to April, although carriers can be detected throughout the year among healthy children.[142] In an unimmunized population the serotypes most commonly associated with asymptomatic carriage—types 6, 14, 19, and 23—are similar to those causing disease. In immunized infants and children, nonvaccine serotypes appear to have replaced vaccine serotypes among nasal carriage strains.[143,144]

With respect to invasive disease, male patients are affected more often than are female patients. Statistically significant risk factors for invasive disease include attendance at day-care, frequent episodes of otitis media (more than three episodes in 6 months), frequent upper respiratory tract infections (at least three episodes in 6 months), premature birth, and previous hospitalization for respiratory disease. Insignificant trends for increased risk included anemia, asthma, and previous insertion of polyethylene tubes into the tympanic membrane.

Certain populations, such as Alaskan,[145] Apache,[146] and Navajo[147] children, were at higher risk for invasive disease prior to introduction of the heptavalent vaccine. Indeed, the incidence of pneumococcal infection among the White Mountain Apache population (156 per 100,000 population [1988 U.S. population]) has been the highest reported; the peak incidence was in children 1 to 2 years of age (2396 per 100,000). Some 79% of these invasive pneumococcal infections were pneumonia.[146] Other individuals at increased risk for invasive pneumococcal disease include those with asplenia, those with congenital or acquired immunodeficiency, recipients of cytoreduction or other immunosuppressive therapies, those who have undergone bone marrow transplantation, and those with cerebrospinal fluid (CSF) leaks, chronic pulmonary or renal disease, congestive heart failure, Hodgkin disease, complement deficiencies, nephrotic syndrome, sickle cell disease, or systemic lupus erythematosus.

In addition to their increased risk attributable to sickle cell anemia or low socioeconomic status, African-Americans may generally be at higher risk for invasive disease. Vaccination has reduced but not eliminated this disparity.[148,149] A series of observations early in the twentieth century established the capsule as the critical virulence determinant of pneumococci. After the recognition that the soluble substance found in serum and urine in patients with lobar pneumonia reacts with specific antiserum to pneumococci of identical serotype and that the capsular polysaccharide is the cell wall component responsible for this reaction, Dubos and Avery[150] demonstrated that pneumococci with enzymatically removed capsules were relatively avirulent in mice. Until this time, only proteins were believed to be immunogenic; this was the first demonstration that the immunogenicity of the capsular polysaccharide in mice protected against subsequent pneumococcal challenge.

The mechanism by which the capsule imparts virulence to the pneumococcus is incompletely understood. The capsular polysaccharide itself is not toxic, but the quantity of elaborated capsular polysaccharide may explain some intraserotypic differences in virulence.[150] Most investigators implicate impaired antibody-mediated, complement-dependent phagocytosis of pneumococci to the capsule to explain its role in virulence, but this traditional explanation may not be sufficient. For example, a clear relation between in vitro opsonophagocytosis and protection in an experimental mouse model of pneumococcal disease for serotype 3 exists, but it has not been possible to establish a similar relation for serotype 1 isolates.[151]

Host defense mechanisms that deal with pneumococcal infection include local respiratory defenses, such as ciliary action, the cough reflex, and the production of mucus. Phagocytosis and the presence of type-specific anticapsule antibody also play crucial roles. The incubation period varies but can be as short as 1 to 3 days. When invasive disease occurs, it is usually shortly after a new serotype is acquired in the upper respiratory tract. An organism associated with prolonged carriage is an unlikely cause of invasive illness.

Factors influencing transmission of the pneumococcus organism from person to person have not been thoroughly studied. The recent application of molecular techniques should result in an improved understanding of this problem. For example, despite few reports of clusters of invasive disease in young children, it is now clear that *S. pneumoniae* may occasionally be readily transmitted from child to child in the day-care setting.[152]

The onset of pneumococcal pneumonia may be preceded by a mild upper respiratory tract infection, purulent unilateral conjunctivitis, or otitis media. The clinical manifestations vary somewhat with age. In infants, a sudden rise in temperature may be accompanied by a seizure, and diarrhea or vomiting may be among the earliest manifestations. Restlessness, apprehension, nasal flaring, rapid and shallow respirations, grunting, abdominal distention, perioral cyanosis, tachycardia, and unilateral diminished respiratory excursion (splinting) may variably ensue. Cough may be absent.

In the older child and the adolescent, the clinical features more closely resemble those in adults. Onset is typically abrupt. The patient may appear ill with shaking chills or rigors, fever, headache, dyspnea, pleuritic pain, and cough.[153]

Sputum production may be apparent in children older than about 8 to 10 years of age. If a viral illness was the predisposing factor, the onset may be more insidious, with coryza and low-grade fever preceding higher fever and possibly sputum production.[154] Pleuritic chest pain reflecting involvement of the visceral pleura may occur. Occasionally, signs and symptoms suggesting bacterial pneumonia may be absent; fever may be the only sign.

Physical examination consists of the features noted earlier in the general section on clinical manifestations of pneumonia.[154] Many patients with pneumococcal pneumonia may have leukocytosis. However, the sensitivity and specificity of the leukocyte count are sufficiently low to preclude reliance on its presence for diagnosis.

As noted earlier, the usefulness of sputum as a diagnostic tool in pneumococcal pneumonia falls between "conclusive" and "occasionally conclusive" in terms of clinical importance in properly collected specimens that contain large numbers of polymorphonuclear leukocytes and typical lancet-shaped gram-positive cocci or that yield *S. pneumoniae* on culture. Antigen-detection techniques have been used in the diagnosis of pneumococcal pneumonia. A blood culture may yield the causative pathogen and should, therefore, be performed during the initial evaluation.

The radiographic changes of acute pneumococcal pneumonia are not pathognomonic. However, pneumococcal pneumonia is frequently associated with the radiographically "classic" acute airspace pneumonia that starts peripherally in the lower lobes or posterior segments of the upper lobes.[154] It then spreads concentrically with no respect for segmental boundaries, unlike bronchopneumonia. This characteristic picture may result in a mass-like round infiltrate, the most common pulmonary mass lesion in children. Alternatively, pneumococcal pneumonia may appear radiographically as a patchy or even linear ("interstitial") infiltrate. A radiographically visible pleural effusion occurs in a small percentage of cases and is more common in young children than in adults. In infants and young children, pneumococcal pneumonia may occasionally be complicated by pneumatoceles, abscess, and empyema.[155] The resolution of radiographic abnormalities may occur 10 to 14 days after appropriate therapy is initiated but more commonly may persist for weeks or even months after recovery.

Once the diagnosis is suspected, antimicrobial therapy should be started. Characteristically, the fever decreases a few hours later, if the isolate is susceptible. Penicillin has been the drug of choice for pneumococcal infections. Until the late 1970s, penicillin resistance was recognized in only a few, sporadic isolates. An outbreak of disease in South African children in 1978 as a result of penicillin-resistant pneumococci signaled that *S. pneumoniae* would henceforth require routine susceptibility testing by microbiology laboratories. These resistant isolates have now been found in many parts of the world, including the United States.

Penicillin-nonsusceptible pneumococci may be of intermediate susceptibility (minimum inhibitory concentration of penicillin = 0.1 to 1.0 μg penicillin/mL) or of absolute resistance (minimum inhibitory concentration ≥2.0 μg/mL). Resistance is mediated by the production of one or more penicillin-binding proteins with altered affinity for penicillin. In some areas of the United States more than 40% of isolates from sterile body sites were nonsusceptible to penicillin and as many as 50% of these isolates were of absolute resistance to penicillin.[156,157] Susceptibility to extended-spectrum (third generation) cephalosporins has been assumed until recently, even among penicillin-resistant isolates. However, extended-spectrum cephalosporin resistance has now been documented in association with treatment failure in patients with pneumococcal meningitis.[158] Moreover, these penicillin-resistant pneumococcal isolates are frequently resistant to multiple antibiotics including macrolides, clindamycin, and trimethoprim-sulfamethoxazole—a fact that further complicates treatment. Serotypes 6B, 9V, 14, 19A, 19F, and 23F are most frequently associated with penicillin resistance.

Pneumonia caused by strains with intermediate resistance to penicillin usually responds to high-dose penicillin or to extended-spectrum cephalosporin therapy.[159] Pneumonia caused by absolutely resistant isolates may also respond to high-dose penicillin or extended-spectrum cephalosporin therapy; however, if the isolate is nonsusceptible to penicillin, treatment with clindamycin (9% of isolates are resistant) or vancomycin may provide greater clinical comfort to the clinician. These compounds may also be appropriate if the child is allergic to penicillin.

Aside from antimicrobial therapy, oxygen and ventilatory support may be necessary. Intensive care may be required, particularly if hypotension is present or hypoxia is severe. Hyponatremia may be present secondary to inappropriate secretion of antidiuretic hormone and may require fluid restriction. Complications of pneumococcal pneumonia may be "local" (i.e., secondary to the pneumonia itself) or "distant" as a result of a concurrent bacteremia. Empyema is the most common local complication[154] and probably arises when bacteria seed a parapneumonic pleural effusion. Adult respiratory distress syndrome (ARDS) does not commonly occur. Most cases of ARDS actually occur in children; leukopenia during acute pneumonia may be a risk factor.[160] Distant complications may include purpura fulminans, meningitis, endocarditis, peritonitis, septic arthritis, and pericarditis.[161]

Clinical features associated with increased morbidity include multilobar involvement, hypoxemia, leukopenia with overwhelming sepsis, bacteremia, and infection caused by serotype 3. Permanent pulmonary sequelae of uncomplicated pneumococcal pneumonia are extremely rare. Slow clinical resolution is usually due to an underlying problem, a mistaken diagnosis, or a superinfection. The mortality rate in those with pneumococcal pneumonia and ARDS may be as high as 50%. Before the introduction of antibiotics, the mortality rate in infants was 20% to 30%; now it is less than 5% in both infants and older children.

In addition to the heptavalent conjugate vaccine, a 23-valent capsular polysaccharide pneumococcal vaccine is recommended for select groups. The antigens in the 23-valent vaccines represent the serotypes causing nearly 100% of bacteremia and meningitis cases in children. However, the polysaccharides have limited immunogenicity in children younger than 2 years of age; hence, the vaccine is not recommended for use in children younger than age 2. The Committee on Infectious Diseases of the American Academy of Pediatrics[162] currently recommends the 23-valent vaccine for children older than 2 years of age who have conditions predisposing them to an increased risk of pneumococcal infection. Exam-

ples of this are sickle cell disease, functional and anatomic asplenia, nephrotic syndrome, chronic renal failure, conditions associated with immunosuppression, refractory HIV infection and other immunodeficient states, or anatomic CSF leaks. Revaccination after 3 to 5 years should be considered for children remaining in a high-risk group. Passive immunization with intravenous immunoglobulin is recommended for preventing pneumococcal pneumonia in children with certain congenital or acquired immunodeficient states predisposing them to *S. pneumoniae* infection.[162-165]

STAPHYLOCOCCUS AUREUS

S. aureus and the coagulase-negative species *Staphylococcus epidermidis* are two important human pathogens that may cause pneumonia in children. Pneumonia caused by *S. aureus* is uncommon but may be increasing in frequency in certain geographic locales. The emergence of MRSA has dramatically changed the importance of this pathogen. *S. aureus* pneumonia may be associated with a rapidly progressive course, particularly in children younger than 1 year of age, and antimicrobial regimens commonly used for the therapy of bacterial pneumonia may not provide optimal *S. aureus* coverage. Pneumonia caused by *S. epidermidis* is rare and occurs almost exclusively in neonates and immunocompromised individuals.

The detection of coagulase and protein A, bacterial products produced exclusively by *S. aureus*, is used as the basis of laboratory tests that distinguish the important pathogen *S. aureus* from other so-called *coagulase-negative* staphylococcal species such as *S. epidermidis*. Morphologically, all staphylococci are gram-positive cocci that resemble clusters of grapes when viewed under the light microscope.[166]

Staphylococcal cell walls are composed of teichoic acid, a ribitol phosphate polymer, and peptidoglycan. The cell wall of *S. aureus* also contains protein A, which binds the Fc fragment of IgG and fixes complement in the process. It has been noted that most pathogenic strains of *S. aureus* have a polysaccharide capsule; four types of capsular polysaccharides have been identified in *S. aureus* isolates.[167] Surveillance in industrialized countries revealed that capsular polysaccharide types 5 and 8 were identified in 80% of adults with bacteremia. These data seem to suggest that these capsules play an important role in the pathogenesis of *S. aureus* invasive infections.[168]

A variety of extracellular factors play a role in the virulence and pathogenesis of *S. aureus* infection. Coagulase clots animal plasma and was once thought to be the determinant of virulence. However, *S. aureus* isolates that do not have free or bound coagulase retain their virulence in animal models. Neither does coagulase inhibit polymorphonuclear cell phagocytosis in vivo, nor is there a correlation between circulating anticoagulase antibody and protection from *S. aureus* infection.[169] Other factors produced by *S. aureus* strains that affect virulence include the α-, β-, γ-, and δ-hemolysins.

Recently there has been renewed interest in the Panton-Valentine leukocidin (PVL) toxin. PVL is found in the majority of community-acquired methicillin-susceptible *S. aureus* (MSSA) and (MRSA) isolates responsible for skin and soft tissue disease, necrotizing pneumonia, pneumonia with empyema, necrotizing fasciitis, and severe sepsis syndrome. PVL is not a newly identified virulence factor, but the epidemiology of *S. aureus* isolates carrying the PVL genes has changed.[170,171] The genes encoding PVL were found in only about 1% to 2% of unselected MSSA isolates.[172,173] However, when examining disease-causing MSSA isolates, the genes encoding PVL were found in 93% of isolates obtained from patients with furunculosis and 85% of isolates from patients with community-acquired pneumonia.[174,175] In contrast, *S. aureus* isolates obtained from the blood rarely contain the PVL genes.[172] PVL genes are also associated with necrotizing pneumonia. In a case-control study of MSSA and MRSA isolates causing community-acquired pneumonia, those containing the PVL genes caused more severe disease characterized by hemoptysis, tissue necrosis, and higher morbidity and mortality than isolates that lacked the genes.[176]

S. aureus pneumonia may be increasing in prevalence as a result of a worldwide increase in community-acquired MRSA infections. Community-acquired *S. aureus* pneumonia typically occurs in very young infants: 30% of cases occur in children younger than 3 months of age, and 70% occur in those younger than 1 year of age. Most cases occur in the colder months, and boys are more frequently affected than are girls. A history of an antecedent viral upper respiratory infection, particularly influenza, is common. In years with influenza epidemics, *S. aureus* pneumonia may occur more frequently.[177-180] The interval between the apparent viral illness and the onset of *S. aureus* pneumonia may be brief.

S. aureus may also cause pneumonia in the nosocomial setting. In fact, epidemics often associated with isolates of phage type 80/81 once plagued neonatal nurseries, but then largely disappeared for unexplained reasons. Descendants of phage type 80/81 that are now methicillin-resistant have re-emerged in the United Kingdom and other countries in the past few years.[181]

S. aureus pneumonia usually follows inhalation of the infecting organism. *S. aureus* pneumonia may also result from seeding of the lung during bacteremia.[182] Predisposing illnesses in this regard include infections of the venous system, intravenous substance abuse, or chronic vascular catheterization for hemodialysis or other purposes. Lung abscesses and pneumonia secondary to septic emboli have been found in patients with deep vein thromboses and bone, joint, or muscle staphylococcal disease in the pelvis or lower extremities.[183] In this instance, the radiographic picture may be that of multiple small, discrete pulmonary infiltrates that may become cavitary within a few days.

There are important differences in the pathology of *S. aureus* pneumonia that depend on the age of the patient and the clinical presentation. In rapidly progressive cases, the large bronchial epithelium may be inflamed, covered with a fibrinous pseudomembrane, or extensively destroyed by infiltration of the underlying walls by polymorphonuclear leukocytes. Necrosis of smaller bronchi leads to pulmonary artery branch thrombosis with septic embolization to the lung parenchyma. The alveoli fill with edematous fluid and contain extravasated blood, polymorphonuclear leukocytes, and hyaline membranes. Destruction of alveoli may lead to the formation of a pneumatocele or tension pneumothorax; unable to escape through a necrosed bronchus, air becomes trapped in an area of necrosed alveoli. A pneumatocele formed in this manner may rupture and produce a pneumo-

thorax or a pyopneumothorax. The pneumatoceles may disappear when the surrounding pneumonia resolves and the trapped area finds an avenue for escape.

In less rapidly progressive cases, the lungs are firm and consolidated beneath the pleural surface; involvement is more patchy and mainly affects the segments of the posterior lower lobe. These segments may coalesce and form small abscess cavities that may communicate with small bronchi and fill them with pus. In the neonate, the pathology of *S. aureus* pneumonia may resemble both these processes. Alternatively, there may be a more diffuse, non-necrotizing picture consisting of lobular or lobar areas of hemorrhagic consolidation with a well-structured fibrinous layer that may overlie the pleural surface. Abscess cavities are more common and may also be diffusely distributed.

The severity of the clinical picture varies. Typically, a mild upper respiratory tract infection is followed by fever, cough, grunting, and tachypnea.[184] Occasionally, prostration, cyanosis, dyspnea, shock, or even the toxic shock syndrome[185] or severe sepsis syndrome[186] may be present. In neonates, the clinical course of staphylococcal pneumonia is often fulminating and is associated with a high mortality rate shortly after the onset of symptoms. Fever may be absent.

A greatly increased leukocyte count, sometimes called a *leukemoid response*, is said to be classic for *S. aureus* pneumonia but is variably present and nonspecific.[182] Leukopenia may also be an ominous sign and has been hypothesized to result from the cytotoxic effects of the PVL toxin. Some patients are bacteremic, but the proportion is unknown.

At the onset of clinically manifested *S. aureus* pneumonia, the chest radiograph may be normal.[187] However, the radiographic picture of staphylococcal pneumonia is more commonly bronchopneumonia with a patchy, central alveolar infiltrate. Multiple areas may be involved, but the process is generally unilateral. The infiltrates tend to coalesce rapidly and form large consolidations; cavitations may be present within the infiltrate (Fig. 35-9). Indeed, the rapidity of the radiographic progression to a virtual "whiteout" of the lung may be striking and should raise the possibility of *S. aureus* pneumonia when it occurs. In many patients, a pleural effusion is not visible on the first radiograph, but an effusion and empyema develops in about 90% of patients. The pleural effusion may be large and, therefore, may mask the underlying consolidation—the effect being that of an opaque chest. Spontaneous pneumothorax and pyopneumothorax occur in about 25% to 50% of cases. Pneumatoceles occur in more than 50% of cases (Fig. 35-10; see also Fig. 35-9) and may change hourly in number and size during the acute phase. Occasionally, they are sufficiently large to mimic a tension pneumothorax or to cause mediastinal shift. They may also contain fluid. The finding of a pneumatocele strongly suggests the diagnosis of *S. aureus* pneumonia. The radiographic picture of staphylococcal pneumonia, however, is not pathognomonic. Similar findings, including pneumatoceles, may occur with pneumonia caused by *E. coli*, *Pseudomonas* or *Klebsiella* species, other gram-negative bacteria, group A streptococci, and occasionally, pneumococci.

Staphylococcal pneumonia should be suspected in hospitalized infants, particularly those in intensive care units, who develop new pleural parenchymal abnormalities or an unexplained opaque chest without volume loss. In the perinatal

Figure 35-9 Staphylococcal pneumonia with cavitation. An 11-month-old boy with staphylococcal pneumonia in the left upper lobe. Both radiographs demonstrate the expanded, consolidated left upper lobe, which contains multiple air- and fluid-filled cavities. **A,** Supine anteroposterior chest radiograph. **B,** Supine horizontal beam lateral chest radiograph. At 14 years of age, this boy manifests a hyperlucent, hypoperfused left upper lobe with thin-walled clear cavities.

Figure 35-10 Pneumatocele. Staphylococcal pneumonia in this 17-year-old girl resulted in a very large upper right pneumatocele that imitated a pneumothorax. A multiloculated pyopneumothorax with multiple air-fluid levels was also present.

period, staphylococcal pneumonia with cavities or pneumatoceles may radiographically mimic congenital diaphragmatic hernia or cystic adenomatoid malformation.

When used for empirical coverage, extended-spectrum cephalosporins provide some coverage against methicillin-susceptible *S. aureus*. Reliance on these agents, however, is suboptimal when *S. aureus* pneumonia is suspected based on clinical evidence. The production of β-lactamase by nearly all *S. aureus* isolates has rendered ineffective any therapy using compounds hydrolyzed by this enzyme. Thus, for many years, the first-line therapy for suspected *S. aureus* infections, including pneumonia, has been the so-called *β-lactamase-resistant penicillins*, such as methicillin. Although methicillin itself is no longer in use, its modern analogmes (i.e., oxacillin, cloxacillin, flucloxacillin, nafcillin) or first-generation cephalosporins (e.g., cefazolin) are available. The recognition of *S. aureus* isolates resistant to these agents, generically termed *methicillin-resistant S. aureus* (MRSA), has posed a therapeutic dilemma. By definition, MRSA isolates are considered resistant to all β-lactam antimicrobials, including all cephalosporin compounds. MRSA infections that are nosocomially acquired tend to be multiply resistant and have forced reliance on the glycopeptide vancomycin as the agent of choice for serious MRSA infections. Furthermore, community-associated MRSA infections, including pneumonia, have recently become an increasing problem and now account for up to 70% to 78% of *S. aureus* clinically significant infections in certain geographic locales.[187-189] Unlike their nosocomially acquired counterparts, community-acquired MRSA isolates are less likely to be multiply resistant. Clindamycin has been an effective alternative for *S. aureus* infections when the isolate is susceptible. The duration of antibiotic treatment is usually 2 to 3 weeks unless complications arise, although some would recommend up to 6 weeks to minimize the risk of recrudescence or relapse. Supportive therapy should include oxygen administration, maintenance of hemoglobin levels, and fluid and electrolyte maintenance as indicated. Pneumatoceles may persist for many weeks and require no special therapy.

The most important complications of *S. aureus* pneumonia are empyema and lung abscess.[190] *S. aureus* pneumonia may rarely result in the formation of a bronchopleural fistula, which in turn may lead to the formation of tension pneumothoraces that are occasionally bilateral. In adults, these have been managed with synchronous independent lung ventilation.[191] Aortobronchial fistulae have also been reported.[192] In adults, *S. aureus* pneumonia has also been associated with Pancoast syndrome.[193]

The prognosis is variable. Mutisystem dysfunction and death have resulted from MSSA and MRSA primary pneumonia, even when appropriate antibiotics and supportive therapy were provided. Recovery is eventually complete in those with disease limited to lungs and pleura when appropriate therapy is instituted and when complications are identified and treated promptly.

HAEMOPHILUS INFLUENZAE *TYPE B*

Before the introduction of a vaccine, *H. influenzae* type b was an important cause of childhood pneumonia. In many countries where universal immunization is not practiced, it remains an important cause of pneumonia. A precise estimate of its incidence has not been available, mainly because of diagnostic difficulties in identifying the etiologic agent, but one study concluded that *H. influenzae* type b was responsible for 5% to 18% of cases of bacterial pneumonia.[49] The advent of immunization against this important pediatric pathogen has decreased the occurrence of all invasive *H. influenzae* type b syndromes by more than 95% in many developed countries; presumably this includes pneumonia. The importance of *H. influenzae* type b as a cause of pneumonia was emphasized by a vaccine trial completed in The Gambia, which suggested that *H. influenzae* type b pneumonia was an important clinical syndrome and accounted for a substantial proportion of presumed bacterial lower respiratory tract infections in children in developing countries.[194]

The realization that *H. influenzae* was the cause of several important infectious syndromes in childhood, including pneumonia, and not the cause of influenza came from the work of Margaret Pittman; in 1931, she also recognized that the serotype b capsule was the major virulence factor among isolates causing invasive disease.[195,196] Subsequent investigations determined that antibody to polyribosylribitol phosphate (PRP), the serotype b capsular polysaccharide, could protect against invasive disease.[197] This observation spawned efforts to develop immunity by active immunization.

H. influenzae is a fastidious, gram-negative, pleomorphic coccobacillus that requires factors X (hematin, heat stable) and V (phosphopyridine nucleotide, heat labile) for growth. These factors are present within erythrocytes, and the demonstration of their requirement for growth is the basis for speciating *H. influenzae* in the laboratory.

Some *H. influenzae* isolates are surrounded by a polysaccharide capsule. Such isolates can be serotyped into six antigenically and biochemically distinct types, designated *a* to *f*. The most virulent isolates belong to serotype b. Before the introduction of immunization, these were responsible for almost all *H. influenzae* invasive infections in children, including meningitis, cellulitis, epiglottitis, septic arthritis, osteomyelitis, pericarditis, bacteremia without focality, and a variety of other rare syndromes. Disease caused by other capsular serotypes of *H. influenzae*, such as types a and f, was rare[198] but is now proportionally more frequent. Nonencapsulated (nontypable) *H. influenzae* isolates can cause invasive disease in neonates,[199] immunocompromised children,[200] children in certain developing countries,[201] and rarely, children in the United States.[198] Nontypable isolates are common etiologic agents in certain mucosal infections, such as otitis media and sinusitis.[202,203] They have also been associated with chronic obstructive pulmonary disease in adults. Other *Haemophilus* species are occasional causes of invasive disease, including pneumonia. For example, *Haemophilus parainfluenzae* may cause pneumonia with empyema. Humans are the only natural hosts for *H. influenzae*. It is not widely appreciated that this species is a constituent of the normal respiratory flora in 60% to 90% of healthy children and is a frequent isolate from the oropharynx.

Before the introduction of vaccine, a striking feature of the epidemiology of invasive *H. influenzae* type b infections was its age distribution. In the United States, more than 90% of all infections occurred in children 5 years of age or younger, although a few occurred in older children and adults. Most studies showed a predominance among male patients.[203-205]

In the prevaccine era, the annual attack rate of invasive disease was estimated to be 33 to 129 cases per 100,000 children (younger than 5 years of age) per year.[206] In Finland, the reported annual incidence was 41 cases per 100,000 children in the prevaccine era; 40% occurred in children older than 2 years of age.[207] Populations identified as having an increased incidence of invasive disease include Alaskan Inuit, Apache and Navajo Native Americans, and African Americans.[208] In these populations, the number of cases of invasive disease in children younger than 12 months of age was relatively high. People known to be at an increased risk for invasive disease included those with sickle cell disease, asplenia, congenital and acquired immunodeficiencies, and malignancies.

The most common mode of *H. influenzae* transmission is by direct contact or by inhalation of contaminated respiratory tract droplets. The incubation period for invasive disease is variable, and the exact period of communicability is unknown. Among age-susceptible household contacts who have been exposed to a case of invasive *H. influenzae* type b disease, there is a substantial risk of developing "secondary" invasive disease in the first 30 days (estimated at 0.26%). The attack rate for such disease in household contacts is highest in susceptible children younger than 24 months of age (3.2%) and rare in contacts older than 47 months of age (<0.1%). Unlike in the general population, asymptomatic carriage of *H. influenzae* type b is frequent in household contacts of patients with disease. More than 75% of families have at least one colonized household member in addition to the index patient.[209,210]

The precise mechanisms that facilitate colonization of the respiratory epithelium have yet to be identified. In an organ culture of human nasopharyngeal tissue, both type b and non-b strains of *H. influenzae* organisms attach to nonciliated columnar epithelial cells and subsequently can be seen within those cells and in the intercellular spaces.[211-213]

Noninvasive *H. influenzae* infections, such as otitis media, sinusitis, and bronchitis, which are usually caused by nontypable strains, probably gain access to sites such as the middle ear or sinus cavity by direct extension from the pharynx. Serotype b organisms are infrequent causes of these noninvasive infections but probably cause disease by the same mechanism. Antibody directed against the type b capsular polysaccharide, PRP, is acquired in an age-related fashion and facilitates clearance of *H. influenzae* type b from blood in experimental animal models[214,215]; its presence was correlated with protection in several clinical trials that used both active and passive immunization.[197,216]

Before the introduction of vaccination and then later among recipients of unconjugated PRP vaccines, protection from *H. influenzae* type b infection was presumed to be directly correlated with the concentration of circulating anti-PRP antibody at the time of exposure. Most infants had a low or absent level of anti-PRP antibody and were thus susceptible to disease on exposure to *H. influenzae* type b.

Unlike the PRP unconjugated vaccine, the conjugate vaccines behaved as thymus-dependent antigens with the exception of a PRP–*N. meningitidis* type B outer membrane protein complex vaccine (PedvaxHib, Merck), which also has thymus-independent type I properties. The conjugate vaccines elicit serum antibody responses in young infants, although multiple doses may be required, and they prime for memory antibody responses on subsequent encounters with PRP.[217,218] More importantly, the concentration of circulating anti-PRP antibody in a child whose immune system has been primed by a conjugate vaccine may not correlate precisely with protection because a memory response may occur rapidly on exposure to PRP and provide protection.[219]

The signs and symptoms of pneumonia caused by *H. influenzae* type b cannot be distinguished from those caused by pneumonia resulting from many other microorganisms. Associated infectious foci, such as meningitis, are common; pneumonia is frequent in children with acute epiglottitis.[220]

The radiographic manifestations of *H. influenzae* pneumonia vary from a bronchiolitic type of image with central linear infiltrates and overinflation to bronchopneumonia with patchy consolidation and no lobar predilection. Pleural effusion is present in about one third of patients with *H. influenzae;* less commonly, a pericardial effusion may be present. Pneumatoceles are rare but have been reported.[221]

The techniques used in the detection of PRP in CSF, serum, urine, or other relevant body fluids have included counter-immunoelectrophoresis, latex agglutination, staphylococcal protein A coagglutination, and enzyme immunoassay.[222] Latex agglutination is perhaps the most sensitive, versatile, and accessible method for the direct detection of PRP[222] when the results of culture are not revealing.

Children younger than 12 months of age suspected of having *H. influenzae* pneumonia should promptly receive parenteral antimicrobial therapy because of the increased risk for bacteremia and its complications. Older children who do not appear severely ill and are, therefore, unlikely to be bacteremic may be treated with an orally administered antimicrobial; customarily a 7- to 10-day course of parenteral, oral, or combined parenteral-oral therapy is completed.

Before 1974, all *H. influenzae* isolates were presumed to be susceptible to ampicillin. Subsequently as the prevalence of β-lactamase-positive isolates increased, chloramphenicol became the agent of choice for therapy against invasive *H. influenzae* type b disease. Advantages of chloramphenicol have included low cost, good penetration into CSF, and its effectiveness against most isolates of *H. influenzae* type b irrespective of β-lactamase production. The disadvantages of chloramphenicol include the necessity for monitoring serum levels and often emotionally held views regarding the rare occurrence of idiosyncratic aplastic anemia. Chloramphenicol-resistant isolates of *H. influenzae* type b have been identified but have remained relatively infrequent in the United States and worldwide; however, they are more common in a few locales such as Barcelona and Taiwan. Use of chloramphenicol has waned in developed countries, whereas it remains a first line agent in developing countries.

Isolates resistant to both chloramphenicol and ampicillin have rarely been identified. In the United States, less than 1% of isolates were resistant to both compounds. Among antimicrobials used for oral therapy of mild *H. influenzae* infections, resistance to amoxicillin/clavulanate and azithromycin occurred in less than 10% of clinical isolates in a recent survey of isolate susceptibility spanning 13 countries in 1999 to 2000. More than 20% were resistant to trimethoprim-sulfamethoxazole (TMP/SMX) or amoxicillin.

The initial antibiotic therapy of invasive infections possibly caused by *H. influenzae* type b should be a parenterally administered antimicrobial agent effective in sterilizing all foci of infection. Such therapy should also be effective against ampicillin-resistant strains. Extended-spectrum cephalosporins, such as cefotaxime or ceftriaxone, have achieved popularity because of their relative lack of serious adverse effects and ease of administration. To date, resistance to extended-spectrum cephalosporins has not been documented. Alternatively, chloramphenicol can be used with ampicillin. Once the antimicrobial susceptibility of the isolate has been determined, an appropriate agent can be selected to complete the therapy. Oral antimicrobial agents are sometimes used to complete a course of therapy initiated by the parenteral route and even as initial therapy for older children with pneumonia who are not very ill. The principles of therapy are the same: when the isolate is susceptible to ampicillin, it or amoxicillin is the compound of choice. When the isolate is resistant to ampicillin, cefixime or amoxicillin/clavulanate may be used. Chloramphenicol is another option.

In households where one or more children younger than 48 months of age are not fully immunized, approximately 4 days of rifampin prophylaxis is indicated for all members of the household contact group in whom a case of *H. influenzae* type b disease occurs.[209] This recommendation includes the index patient. Relevant definitions and dosing recommendations have been found in the Report of the Committee on Infectious Diseases of the American Academy of Pediatrics.[162] There are no data to address whether a similar approach to non-serotype b disease is appropriate.

With the development of conjugate vaccines that have proved highly immunogenic in young children, PRP vaccine has been replaced by several licensed *H. influenzae* type b conjugate vaccines that differ in the carrier protein used, the saccharide molecular size, and the method of conjugating the saccharide to the protein.[223] The introduction of effective immunization against *H. influenzae* type b with the use of the conjugate vaccines has greatly decreased the occurrence of *H. influenzae* type b infections.[224-226]

STREPTOCOCCUS AGALACTIAE

The designation *group B β-hemolytic streptococci* (GBS) was first applied by Lancefield in 1933[227] to *Streptococcus agalactiae*, an important cause of bovine mastitis known to infect cows as early as the 1800s.[228] In the 1960s, GBS became increasingly recognized as a cause of neonatal infection, including pneumonia. Today, GBS are common causes of pneumonia and other invasive infections in neonates. The incidence of neonatal pneumonia has greatly decreased with the implementation of maternal antibiotic prophylaxis for GBS carriers at the time of delivery.

Group B is distinguished from other streptococcal groups by its distinctive carbohydrate antigen, which is bound to the bacterial cell wall; L-rhamnose is the major antigenic determinant. Nine serotypes have been described; serotypes Ia, Ib, II, III, and V are responsible for approximately 95% of cases in the United States.[229]

GBS infections are often classified by the onset time of clinical manifestations. Although this distinction is somewhat artifactual and there is substantial overlap in the clinical features of so-called *early-onset* and *late-onset* disease, differences in pathogenesis, clinical syndromes, and the responsible serotypes have made separation of these syndromes of some use. Early onset disease is manifested in the first week of life, often on the first day. Serotypes Ia, II, III, and V are most commonly responsible for this syndrome. Transmission of GBS most likely occurs a short time before or during birth. Risk factors for early-onset disease include prematurity, prolonged rupture of the chorioamnionic membranes before birth, or maternal infection. Late-onset disease is manifested after the first week of life, with most cases occurring in children younger than 1 month of age. GBS disease is extremely rare in toddlers and older children; occasionally, very late-onset GBS disease occurring in older children may be an early manifestation of untreated HIV infection.[230] In late-onset disease, serotype III organisms are almost exclusively responsible for infection, but serotype Ia has also been implicated. The transmission of GBS to patients with late-onset disease is believed to occur after birth, either during or after the hospital stay. Carriage, once acquired, may persist for many months.

Antibiotic administration is now routinely used to interrupt the transmission of GBS from mother to neonate at the time of birth. Antenatal antimicrobial treatment of colonized women aimed at eradicating carriage has not been effective.[231] Moreover, Siegel and colleagues[232] administered penicillin to unselected neonates at birth as prophylaxis against GBS disease but found no associated decrease in mortality rates, an increase in the recovery of penicillin-resistant organisms of other genera, and increased mortality from infections caused by these penicillin-resistant isolates. However, intrapartum ampicillin decreased the maternal-fetal transmission of GBS.[233,234] This observation led to recommendations from the Centers for Disease Control and Prevention (CDC)[235] to screen all pregnant women for GBS vaginal and rectal colonization at 35 to 37 weeks' gestation and to manage those with a positive screen with intrapartum chemoprophylaxis. Any woman who had GBS bacteriuria during the current pregnancy or who had a previous infant with invasive GBS disease should also receive prophylaxis during labor and delivery. If a woman's GBS status is unknown at the time of delivery, a risk-based approach is used and intrapartum prophylaxis should be administered to women with pregnancy less than 37 weeks' gestation, prolonged rupture of membranes, or intrapartum fever.

Early-onset disease was more frequent than late-onset disease prior to the introduction of targeted maternal intrapartum antibiotic prophylaxis. Since antibiotic prophylaxis policies have been incorporated, the incidence of early onset disease decreased by 81% to approximately 0.3 cases per 1000 live births and is now equal to the incidence of late-onset disease. Intrapartum antibiotics have not been shown to prevent late-onset disease.

For early-onset disease, the clinical picture is one of sepsis.[236,237] The features may include onset within hours of birth, tachypnea, apnea, and a generally ill appearance. Pneumonia is almost always present. The pulmonary clinical picture may be indistinguishable from respiratory distress syndrome of prematurity.[238,239]

Late-onset disease is more indolent in its presentation. Fever, bacteremia, and meningitis are commonly, but not universally, present. GBS with late presentation is not usually

associated with pneumonia.[240] If present, the clinical features are characteristic of pneumonia caused by other bacteria. Indeed, an identifiable infectious focus may not be evident. In one series, about one third of infants with GBS disease, most of whom had late-onset disease, did not appear ill or irritable, and about one third had no fever.[240] Occasionally, the clinical picture of early onset disease may be evident, and the chest radiograph may resemble that caused by respiratory distress syndrome.

The diagnosis is made by recovery of the organism from blood or another normally sterile body fluid, such as pleural fluid, CSF, urine, or synovial fluid. Detection of the group B carbohydrate antigen in blood or CSF (e.g., by latex agglutination)[241] is useful but requires careful interpretation and should not be relied on as the sole method of bacterial detection. Urine testing in particular has been prone to false-positive and false-negative findings; because of this, in 1997, the Food and Drug Administration advised against using latex agglutination methods in testing of urine specimens.

The treatment for GBS pneumonia in the absence of meningitis involves 200,000 units/kg/day of penicillin intravenously in three divided doses in the first week of life and 300,000 units/kg/day intravenously in four divided doses thereafter. A 14-day course is usually administered for pneumonia. Higher doses and a 21-day course are often used when meningitis is present. Initial therapy with a β-lactam and an aminoglycoside results in more rapid killing in vitro and may be a useful clinical adjunct.[242] When used, the aminoglycoside is usually discontinued after about 5 days and the course completed with the β-lactam. Other options include ampicillin or ceftriaxone. Intravenously administered immune globulin has been used as adjunctive therapy, but data establishing its effectiveness are lacking.

Empyema may complicate group B streptococcal pneumonia. The associations with group B streptococcal pneumonia, group B streptococcal bacteremia, a generalized septic picture, and distant metastatic infectious foci (such as meningitis and skeletal infections) are well described. It is probable that group B streptococcal pneumonia seldom occurs in an infant who is not systemically ill.

Even when appropriate antimicrobial and supportive therapy are initiated in a timely way, the mortality rate from early onset GBS disease is high (about 14%), particularly in cases occurring in the immediate perinatal period and those in small premature infants.[243] Many authors believe that this rate represents a decline from higher rates,[244] possibly as a result of improved supportive care. The mortality rate from late-onset disease is much lower (about 2% to 6%).[240,245]

Some have advocated intravenously administered immune globulin to prevent GBS infections. However, in a prospective trial of 2416 very low birth weight newborns who were randomized to receive either placebo or intravenously administered immune globulin every 2 weeks until the infant weighed 1800 g, no difference was identified in the incidence of GBS infection, length of hospitalization, or mortality rates.[246]

Efforts to prevent GBS disease by vaccination are ongoing. Many investigators have advocated immunizing pregnant women in the hope of transferring antibody produced by immunization to the fetus in utero, thereby offering protection in the neonatal period. A tetravalent polysaccharide vaccine produced only a modest response in healthy adults.[247] Conjugate vaccines consisting of the capsular polysaccharide covalently linked to tetanus toxoid have been shown to be safe in adults and to elicit a good antibody response.[247] It is presumed that immunization of pregnant women would result in passive antibody transfer to the fetus and later protection of neonatal and infant GBS disease. Licensure of such a vaccine will depend on documentation of the efficacy in pregnant women.

Causes of Less Frequent Clinical Concern

ACINETOBACTER *SPECIES*

Members of the genus *Acinetobacter*[248] are gram-negative bacilli with variable morphologic pictures depending on the phase of growth in broth culture and environmental conditions. The organism is a strict aerobe that is ubiquitous in water, sewage, and soil. Several species have been described. From clinical specimens, the most common isolates belong to the *Acinetobacter baumanii*, *A. calcoaceticus* complex, and *A. lwoffi*. *Acinetobacter* species are not members of the resident skin flora but may transiently colonize skin, saliva, or other body secretions. Most often, the organism is a commensal. Invasive infection is associated with a stay in an intensive care unit, immune deficiency, antimicrobial treatment, invasive use of instruments, and prolonged venous catheterization.

Pneumonia caused by *Acinetobacter* species is rare, particularly in children; it has been described only in those with impaired immunity. In adults, *Acinetobacter* pneumonia is usually sporadic, although outbreaks have been described. For example, an outbreak of pneumonia occurred in foundry workers who were presumably exposed to infected metallic dust.[248] Members of *Acinetobacter* species survive well in water; thus the use of respiratory therapy equipment, particularly endotracheal intubation and aerosols, are risk factors for *Acinetobacter* infections. Cases of *Acinetobacter* pneumonia occur more often in the summer than in other seasons.

No unique pathologic or clinical features distinguish *Acinetobacter* pneumonia from other bacterial pneumonias. More than one lobe is involved in most reported cases. Empyema and the formation of intrapulmonary cavitations have been described. Because this species may colonize asymptomatically, isolation of the organism from pharyngeal secretions is not helpful in the diagnosis of *Acinetobacter* pneumonia. Definitive diagnosis is based on lung aspirate or biopsy or isolation of the organism from blood in the presence of a clinical picture compatible with pneumonia.

Susceptibility testing of clinically relevant isolates aid in antibiotic selection. *Acinetobacter* species are variably susceptible to cephalosporins and aminoglycosides. Carbapenems (meropenem, imipenem, or ertapenem) are effective in approximately 90% of cases in the United States and are now often used to treat *Acinetobacter* infectons. Multidrug resistance among *Acinetobacter* strains is an emerging problem and cases of carbapenem-resistant *A. baumannii* are increasing worldwide. Colistin and tigecycline have been successful in treating some multidrug-resistant infections.

ACTINOMYCES *SPECIES*

The term *actinomycosis* was first used in 1877 by Bollinger to describe sarcoma-like masses in the jaws of cattle.[249] Acti-

nomycosis is uncommon in children.[250] About 10% of all cases occur in children younger than 18 years of age.[251,252] It is more common in immunocompromised children and in those with poor oral hygiene. Distribution is worldwide; there is no racial or occupational predisposition. A male predilection has been noted in adults, but studies in children suggest no gender differences.[253] Actinomycosis is not believed to be contagious, and the causative organisms have been isolated only from humans.[251]

Trauma and a favorable anaerobic milieu are important factors in the predisposition to clinical disease.[254] *Actinomyces* species are saprophytic inhabitants of the normal oral cavity and nasopharynx, particularly at the gum margins and in the presence of dental caries. The organism has also been found in tonsillar crypts, periodontal tissue, paranasal sinuses,[255] and gastric and bronchial secretions.[256] Because the onset of the disease can occur at any time after colonization is initiated, the incubation time varies from days to years after initial contact with the organism.[257]

Infection occurs by direct tissue invasion[253] without regard for tissue planes.[258] *Actinomyces* organisms are readily phagocytized by host defense cells but, like mycobacteria, are often not killed after the ingestion.[259] Actinomycosis is classified into the following syndromes: cervicofacial, abdominal, and thoracic. (The last includes pulmonary and extrapulmonary intrathoracic disease.) Overall, about 15% to 20% of patients with actinomycosis have pneumonia.[256] Most have primary pulmonary involvement.[255] Among 48 adults and children with actinomycosis pneumonia, 8 had evidence of bacteremic seeding of the lung or extension from an extrapulmonary site, whereas 40 had lung involvement that was considered to be primary.[251] In this instance, infection usually arises from aspiration of infected material from the oropharynx[251] and rarely arises after esophageal disruption secondary to nonpenetrating trauma or surgery. Previous lung injury increases the likelihood of disease when aspiration or inhalation occurs.

Pulmonary actinomycosis is a chronic, localized inflammatory process.[251] Histologic features include a thick, fibrous wall without necrosis in loculated regions. The finding of so-called *sulfur granules* (small, lobulated, grainy microcolonies of bacteria 1 to 2 mm in size that are cemented together by a protein-polysaccharide capsular complex) is virtually pathognomonic for actinomycotic infection; the granule may be mineralized with calcium phosphate and may sometimes be visible macroscopically.[260] Necrosis rarely occurs,[251] although focal liquefaction without fibrosis is occasionally present.[251] Large macrophages with foamy cytoplasm accumulate around the purulent center. These may be absent in acute lesions, in which mostly fibrin is found.[252]

Symptoms of pulmonary involvement include low-grade fever and cough productive of purulent or blood-streaked material. Sputum, if present, is usually not malodorous. Dyspnea and orthopnea have been noted.[251] Other symptoms may include malaise, anorexia, weight loss, and localized chest pain.[258] Nonspecific laboratory findings may include moderate leukocytosis and anemia, particularly in more chronic cases.

Physical examination may reveal asymmetrical crackles and dullness on percussion. Signs suggesting the presence of a pleural effusion may be apparent. There may be subcutaneous abscesses over the chest wall. Examination of the abdomen may be abnormal and reflect extension of the infectious process through the diaphragm.

A delay in diagnosis is common.[261] The median number of weeks between presentation and diagnosis is 3 to 5 and ranges up to 24 weeks.[261] The initial diagnosis in many cases is malignancy. The presence of chest pain, which is common in actinomycosis but less so in malignancy, may help distinguish this condition from others.[261] Another reason for delay is the lack of a typical picture. Children may be asymptomatic despite the presence of a large pulmonary mass.[255]

The distinctive radiographic characteristics of actinomycosis involving the lung are secondary to its lack of respect for the anatomic boundaries of the chest compartments. Pulmonary actinomycosis may appear radiographically as an infiltrate with associated soft tissue, rib, and pleural involvement. Primary pulmonary involvement may start as a patchy, peripheral, airspace infiltrate similar to that occurring in pneumococcal pneumonia and may resolve completely if treated; basal lobe involvement is frequent. If untreated, however, intrapulmonary cavitation or mass lesions may be present; the process may extend peripherally to cause empyema, rib osteomyelitis with the pathognomonic contiguous dense periosteal reaction[249,255] in multiple ribs, or a chest wall abscess.[262] The radiographic classic triad of actinomycosis, lung infiltrate, and rib or chest wall involvement, as well as empyema,[263] is useful in suggesting the correct diagnosis but is infrequently present.[261,262] Occasionally, there is vertebral destruction.[249,263] Parasitization of the blood supply by these lesions from the chest wall circulation may result in systemic to pulmonary shunting.[115]

As with any other complex thoracic process that involves the chest wall as well as intrathoracic structures, CT, preferably contrast enhanced, is the imaging modality of choice. CT is used when chest radiographs do not clarify the findings[264] or when the suspicion of a malignancy is high.

The differential diagnosis includes other infectious processes that tend to disregard tissue boundaries, such as blastomycosis, cryptococcosis, tuberculosis, and rarely, aspergillosis. Rib destruction associated with intrathoracic opacities may be present with pyogenic osteomyelitis, chest wall tumors (particularly Ewing sarcoma), and primitive neuroectodermal tumors.

Definitive diagnosis is by histopathologic examination.[260] The diagnosis is suggested by the finding of beaded, branched, gram-positive bacilli in pus, and it is strongly endorsed by isolation of the organism; the visualization of typical gram-positive, branching bacilli in histologic sections; or the presence of sulfur granules.

The organism may be isolated from tissue obtained by local resection, lobectomy, transthoracic needle aspiration,[261] or pleural fluid.[265] Resection is most commonly performed because malignancy is incorrectly suspected.[266] *Actinomyces israelii*, the most frequent isolate, grows anaerobically, and usually requires 4 to 8 days for incubation. *Actinomyces meyeri* is occasionally the isolate and has a predilection for the apical region.[267]

Actinomyces species is usually not isolated in pure culture.[255] In about two thirds of cases, another bacterium, often *Actinobacillus actinomycetemcomitans*, was isolated.[254,256] Some have theorized that the presence of an

aerobic bacillus lowers the redox potential of the tissue and thereby promotes the growth of *Actinomyces* species[255] by improving the anaerobic growth conditions.

Both the dosage and duration of penicillin therapy have not been critically evaluated, and clinical experience is, therefore, anecdotal.[249,255] Most experts recommend an initial course of intravenous penicillin at high dosage (e.g., 250,000 units/kg/day) for 2 to 6 weeks and then oral penicillin (e.g., 125 mg/kg/day) for several months thereafter. *Actinomyces* species is susceptible to penicillin, but prolonged therapy for thoracic actinomycosis is necessary to prevent relapse. Some[268] have exclusively advocated oral penicillin V therapy (e.g., 125 mg/kg/day) with reportedly good results. Irrespective of the therapeutic regimen used, the dose and length of penicillin treatment should be related to the amount of induration and fibrosis and the extent of infection at the time of diagnosis.[253,255] Separate therapy directed against concomitantly isolated organisms, such as *A. actinomycetemcomitans*, is traditionally said not to be necessary. Clindamycin, erythromycin, chloramphenicol, and tetracycline (for children 9 years of age and older) are alternative treatment choices.[265] Serial radiography of the chest is useful in documenting the adequacy of therapy.[258]

The main role of surgery is to drain any abscesses or empyema that may be present. Surgery was once believed necessary to cure actinomycosis. Radical surgery is still sometimes performed, particularly in the presence of extensive fibrosis, or unwittingly as a treatment for a commonly presumed diagnosis of carcinoma.[269] Management in the modern antibiotic era must be individualized; even in the presence of extensive disease, it is reasonable to consider that medical therapy alone warrants consideration.

The mortality rate in untreated or inadequately treated cases has been about 90%.[249,255] Conversely, about 90% of those treated recover. Complications of actinomycosis pneumonia include the development of parenchymal abscesses or empyema and the formation of draining sinuses. In one review, such sinuses were present in 25% of patients with thoracic actinomycosis.[251] They may connect with the trachea, esophagus, pericardium, heart, or skin.[270] Rib and vertebral destruction may occur by direct extension.[270] Disseminated disease, although rare in children,[271] may complicate thoracic actinomycosis[254,255,271] and may be fatal despite accurate diagnosis and treatment.[251] Good oral hygiene is the best available prevention against actinomycosis.

Anaerobes

Guillemot and colleagues[272] first reported in 1904 that empyema could be caused by bacteria that did not grow under standard, aerobic conditions. It was realized that because similar organisms were also found in the oral cavity, an aspiration event and pneumonia probably preceded the empyema.[273] Subsequently, more than 2000 cases of anaerobic empyema were reported in the preantibiotic era.[274] With the advent of antibiotics, however, interest in anaerobic pneumonias decreased until the 1970s, when a resurgence of interest occurred because of improved techniques for anaerobic culture, organization of anaerobic taxonomy (to lessen confusion), and trials of therapeutic agents that required bacteriologic confirmation.[273]

It is believed that a major role should be ascribed to anaerobic bacteria as a cause of aspiration pneumonia. It follows that patients predisposed to aspiration, such as children with dysphagia, seizures, neurologic disorders (including cerebral palsy), general anesthesia, drug use, gastroesophageal reflux, or compromised consciousness, are at risk. If aspiration occurs when the child is in the upright position, the basal segments of the lower lobes are the most common sites of pneumonia, whereas if the child is recumbent, the posterior segments of the upper lobes or the superior segments of the lower lobes are more likely locations of pneumonia.[273,275]

In the absence of such a predisposition, the role of anaerobes in uncomplicated pneumonia remains uncertain, particularly in children. In adults, some[276,277] have suggested that pneumonitis caused by anaerobes cannot be distinguished from other bacterial pneumonias, and because the microbiologic evaluation of any pneumonia is often difficult and anaerobic cultures are seldom performed, any existing role for anaerobes in uncomplicated pneumonia may not be adequately appreciated.

Few data exist regarding the specific anaerobic organisms that might cause pneumonia in children. Experience in adults suggests that the most frequent isolates are anaerobic streptococci, such as *Peptostreptococcus* species; microaerophilic anaerobic streptococci such as *Streptococcus intermedius*, *Streptococcus parvulus*, *Streptococcus constellatus*, *Streptococcus morbillorum* (now reclassified as *Gemella morbillorum*); and other anaerobic organisms such as *Bacteroides melaninogenicus* (now referred to as *Prevotella*), *Porphyromonas* species, and *Fusobacterium nucleatum*.[275] The *Bacteroides fragilis* group includes most of the pathogenic anaerobic organisms.[278]

Treatment of pulmonary infections involving anaerobes usually involves one of three strategies. *Bacteroides* species are usually susceptible to penicillin G, ampicillin, and broad-spectrum penicillins. Some authors believe that penicillin G is the drug of choice for anaerobic pneumonia,[279] whereas others favor clindamycin because it is active against almost all mouth and respiratory tract *Bacteroides* isolates.[162,276] β-Lactamase production has been identified in many non-*B. fragilis* species and in fusobacteria.[278] Susceptibility of non-*B. fragilis* isolates was recently surveyed at 28 U.S. centers, and it was found that 64.7% of *Bacteroides* species and 41.1% of fusobacteria elaborated β-lactamase.[278] Anaerobic susceptibility testing is technically difficult, particularly for slow-growing and fastidious organisms such as *Fusobacteria* and non-*B. fragilis* species.[278] Thus, the clinical laboratory seldom provides meaningful guidance in this area. Complications of anaerobic pneumonia include lung abscess and empyema,[275] entities that are dealt with separately in this chapter.

ARCANOBACTERIUM HAEMOLYTICUM

Arcanobacterium haemolyticum[280,281] is a rare cause of pneumonia in children. The organism is a gram-positive bacillus, with humans as the primary reservoir. The incubation period is unknown, although long-term pharyngeal carriage has been identified. The usual manifestation is a skin infection or pharyngitis. However, when this pathogen causes pneumonia, respiratory signs and symptoms, such as tachypnea, fever, and coughing, may be present.

The organism may be isolated from a blood culture. Although serologic antibody tests for *A. haemolyticum* exist, none has been standardized or is commercially available. The organism is susceptible to penicillin, erythromycin, clindamycin, chloramphenicol, and tetracycline. All these agents appear appropriate for therapy.

BACILLUS ANTHRACIS

Anthrax is usually a disease of livestock caused by *Bacillus anthracis*, which are large, aerobic, spore-forming, gram-positive, rod-shaped bacteria. It is found in cattle, sheep, and goats.[282] In the United States, it is endemic in the states where livestock is concentrated.[282] Naturally acquired human infection has all but vanished in the United States. When it occurs, it is acquired via the lungs or skin after contact with hides, furs, wool, or other spore-contaminated animal products.[282] However, intentional contamination of the U.S. mail with *B. anthracis* in 2001 resulted in 22 cases of anthrax, of which 5 cases resulted in death. Its potential use as a biological weapon has renewed interest in *B. anthracis* as a cause of pneumonia. The virulence of *B. anthracis* is due to its weakly antigenic, antiphagocytic, poly-D-glutamic acid capsule and the production of three exotoxins called *edema factor, lethal factor,* and *protective antigen.* The capsule and toxin genes have been localized to plasmids routinely found in virulent isolates.[283]

There are three clinical forms of anthrax. The majority of cases involve characteristic skin lesions and regional lymphadenopathy. Pulmonary involvement (the so-called *inhalational form*) is initiated by inhalation.[283] After inhalation, the spores are transported by lung macrophages to mediastinal and hilar nodes.[282,284] Either during transport or on arrival at the lymph node, the spore germinates, a process that may result in severe, hemorrhagic lymphangitis with marked adenopathy.[282] The bacilli may then enter the bloodstream and disseminate.[282] The lung may be seeded during this bacteremic phase. Rarely, a patient with anthrax may have clinical features of gastroenteritis.

The hallmark of pulmonary involvement is hemorrhagic edema. Microscopically, there is massive hemorrhage and edema fluid in all involved airspaces. A serofibrinous exudate with many large bacilli and an absence of polymorphonuclear leukocytes is typical. In patients who have survived for a prolonged time, the septa become necrosed, and fibrin thrombi obliterate the pulmonary capillaries.

Clinically, the onset of systemic anthrax is insidious, with malaise, a nonproductive cough lasting many days, and low-grade fever. Stridor may also be present secondary to mediastinal nodal compression of the trachea.[282] When bloodstream invasion occurs, there may be a sudden onset of high fever and shock accompanied by dyspnea and cyanosis. These events usually lead to death within 24 hours.[282]

Obtaining a history of exposure to the infectious agent is important; few cases occur in which such an exposure cannot be identified. Because anthrax is rare in the United States and may herald the onset of biological attack, any case should be reported immediately to the local or state health department. The diagnosis of *B. anthracis* infection is made by visualization of the organism after Gram stain of material obtained from a lesion or discharge, growth in culture, or direct immunofluorescence of tissue or culture material. An enzyme immunoassay that measures IgG antibodies against protective antigen can be used for diagnosis but requires a convalescent serum specimen. PCR and a now commercially available QuickELISA Anthrax-PA Kit (Immunetics Inc) are rapid diagnostic tools useful as screening tests.

In anthrax pneumonia, the chest radiograph usually demonstrates marked widening of the mediastinum associated with mediastinal and hilar lymphadenopathy, patchy or diffuse confluent infiltrates, and consolidations seen with hemorrhagic pneumonia. Pleural effusions are common, and areas of localized pulmonary edema secondary to lymphatic blockage may occur either unilaterally or bilaterally.[282]

A high index of suspicion and rapid administration of effective antibiotics are essential for effective treatment of anthrax. Death from the cutaneous form of anthrax is rare. However, the prognosis is poor for inhalation of anthrax. Ciprofloxacin or doxycycline are recommended as part of the multidrug treatment of inhalational anthrax until susceptibility results are known. Both drugs are rarely used in children because of safety and side effect concerns, but should be used in treatment of life-threatening infections. Penicillin, ampicillin, clindamycin, and clarithromycin are other drugs suggested for use in conjunction with ciprofloxacin or doxycycline. Penicillin is the drug of choice when the isolate is susceptible. Treatment of inhalational anthrax should continue for at least 60 days. Complications of respiratory anthrax include meningitis and gastrointestinal tract involvement. Necrotic intestinal lesions have been found at autopsy.[282]

Patients with anthrax should be isolated until antibiotics have been administered for 72 hours. BioThrax (manufactured by BioPort, Rockville, MD) is a cell-free culture filtrate vaccine recommended for use in individuals at ongoing risk of acquiring anthrax, including certain laboratory workers and military personnel. The efficacy of this vaccine has been established in adults. However, no data are available in children, and the vaccine is, therefore, not licensed for use in them. Development of improved component vaccines is underway.[285]

OTHER BACILLUS *SPECIES*

Bacillus species are members of the family Bacillaceae, a group of aerobic, saprophytic, sporulating organisms commonly isolated from dust, soil, air, and water. Although they frequently contaminate clinical specimens, members of the genus may cause endophthalmitis, meningitis, and endocarditis; may contaminate hemodialysis equipment; and may cause food poisoning. As a pulmonary pathogen, the species *B. cereus* has received recent attention in immunocompromised hosts[286] and at least occasionally in patients with normal immune systems. Two premature infants who died with evidence of necrotizing pneumonia with *B. cereus* as the causative agent were recently described.[287] At autopsy, one had scattered "tan" areas with well-demarcated areas of necrosis and large numbers of visualized gram-positive rods, and the other had pneumonitis with well-defined areas of necrosis not associated with substantial inflammatory cellular infiltrates. Acquisition of the organism was believed to be nosocomial. Other *Bacillus* species have been implicated even less frequently; pneumonia and empyema were found to be caused by a *Bacillus* species that resembled *Bacillus*

alvei,[288] and an adult with chronic asthma had a gelatinous pseudotumor of the lung caused by *Bacillus sphaericus*.[289]

Antimicrobial therapy for infections caused by *B. cereus* is complicated by the realization that members of the species are generally resistant to β-lactams and cephalosporins. However, clindamycin, imipenem, vancomycin, erythromycin, chloramphenicol, and aminoglycosides have been highly active. Other *Bacillus* species are usually susceptible to β-lactams and cephalosporins.[290]

BARTONELLA HENSELAE

Cat-scratch disease (CSD) was first described in 1950 by Debre and coworkers[291] It has now been recognized that the causative organism is *B. henselae*, a fastidious, slow-growing, gram-negative bacterium. Pneumonia associated with CSD is exceedingly rare and has been described in only a few children.[292] CSD is a common infection in children[293]; 80% of cases occur in those younger than 20 years of age. Transmission is via contact with a cat or kitten; more than 90% of patients with CSD have a history of feline exposure.

Patients with CSD usually have self-limited regional lymphadenopathy after contact with a cat or more commonly, a kitten.[294] Constitutional symptoms occur in 50% to 70% of cases and are usually limited to fever and, less frequently, emesis, seizures, and respiratory distress.[292,295] Only five cases of pneumonia and pleural effusion were identified in a recent review[292,295]; all had multisystem involvement. The pathogenesis of CSD pneumonia is uncertain; hematogenous seeding of the lung during bacteremia has been proposed.[292,295] Pleural effusion is usually present. The diagnosis of CSD is usually made serologically. An indirect immunofluorescent assay for serum antibodies to *Bartonella* species antigens performed by many commercial laboratories, state public health departments, and the CDC[296] has been the standard. A newer ELISA assay[297] is less sensitive than the immunofluorescent assay performed by the CDC.[298]

Detection of *B. henselae* nucleic acid sequences by PCR is now available in some commercial and research laboratories.[299,300] Identification of the distinctive morphology of *B. henselae* by Warthin-Starry silver impregnation stain is useful if tissue is available. Culturing *B. henselae* has remained problematic; successful cultivation has been largely limited to the CDC laboratory and is performed there by heart infusion agar with defibrinated rabbit blood in the presence of 5% carbon dioxide for 7 to 14 days at 35° C.[301] Administration of antimicrobials diminishes the likelihood of successfully cultivating the organism or visualizing it by Warthin-Starry staining.

No controlled trials of antimicrobial therapy have been performed for the treatment of CSD, and the few cases of pneumonia described in children provide little help. Clearly, CSD even with pneumonia is a self-limited illness. Thus, antibiotics might shorten the clinical course but are unlikely to improve the long-term outcome, which is generally excellent. The choice of antimicrobial agents is another area of uncertainty.[300] Azithromycin, erythromycin, and TMP/SMX have been advocated for severe CSD, as has ciprofloxacin alone or in combination with gentamicin, but no data from controlled trials exist. Adults with severe *Bartonella* infection have responded to azithromycin, erythromycin, doxycycline alone or in combination with rifampin, or rifampin and gentamicin. Patients with bacillary angiomatosis or parenchymal peliosis, which are unusual and severe manifestations of *Bartonella* infection in patients with HIV infection, have responded to erythromycin, doxycycline, and clarithromycin. The development of feline vaccines against *B. henselae* might be useful in decreasing the incidence of transmission and infection in human hosts.[302]

BRUCELLA *SPECIES*

Brucellosis is a rare human disease that may be caused by one of several small, gram-negative rods in the genus *Brucella*, including *B. melitensis*, *B. abortus*, and *B. suis*.[303] Human infection is caused by direct contact, usually via ingestion of unpasteurized dairy products, accidental laboratory exposure, or contact with diseased swine, cattle, or wild animals (e.g., moose).[282,303] Specific to each organism, *B. melitensis* may be transmitted from goats, their carcasses, or their secretions. *B. abortus* may be transmitted by direct contact with cows, their carcasses, or their secretions, including milk. Pasteurization of milk and milk products is especially important in the prevention of disease in children. Humans are also accidental hosts for *B. suis* and contract disease by direct contact with pigs, their carcasses, or their secretions. Rarely has human transmission been thought to occur in family clusters.[303] Infection may also be transmitted by the inhalation of contaminated aerosols. The incubation period varies from less than 1 week to several months; most children are ill within 3 to 4 weeks of exposure.

Brucellosis pneumonia is rare. Histologically, there are fibrinous pleuritis and proliferation of pleural endothelial cells found with a round cell interstitial infiltration. Nodules that resemble a tuberculous granuloma may be found.

Particularly with *B. melitensis*, which is the endemic species, disease can be severe with either an acute or an insidious onset. Although fever is usually present, there are no unique clinical findings, which makes the diagnosis difficult. It has been termed *a disease of mistakes*.[303] Nonspecific complaints, including sweats, weakness, malaise, anorexia, weight loss, arthralgias, myalgias, and backache, abound. Findings on physical examination may include lymphadenopathy and rarely hepatosplenomegaly. Cough is variably present. Chest radiographic findings may include bronchopneumonia, single or multiple nodules, and hilar adenopathy.[282]

Diagnosis is based on the isolation of excised, caseous nodules from the lung. Isolation of the causative organism from the blood is possible, but the yield is low.[304] The laboratory should be alerted that this diagnosis is being considered because the incubation time may be long and the organism may be misidentified by automated identification systems. Serologic testing has been the hallmark of diagnosis. A presumptive diagnosis may be made by showing a high (≥1:160) or rising serum titer of specific antibodies in a child with symptoms consistent with brucellosis. The serum agglutination test is most commonly used and detects antibody to *B. abortus*, *B. melitensis*, and *B. suis* but not *B. canis*. False-negative results may be related to the prozone effect. Newer serologic tests, including an ELISA for antibodies, are under evaluation but are not yet widely available.[304] Recently, the diagnosis of brucellosis has been accomplished by PCR using primers directed at a 31-kD protein from *B. abortus*.[305]

The standard antigen cross-reacts with all *Brucella* species except *B. canis* but may also react with *Yersinia enterocolitica, Vibrio cholerae,* and *F. tularensis*.[303] When brucellosis is being considered, the laboratory should be notified so that multiple serial dilutions of serum can be performed to exclude the prozone effect.[306] Treatment is with tetracycline, 30 to 40 mg/kg/day in four doses daily (if more than 9 years of age), or oral doxycycline, 2 to 4 mg/kg/day in one or two divided doses, both for 4 to 6 weeks. If the clinical symptoms are severe, streptomycin or gentamicin, in addition to doxycycline or tetracycline, may be administered for the first 7 to 14 days of therapy.[303] In small children, TMP/SMX is usually used.[306] The conditions of most children receiving the appropriate antibiotics respond to treatment.[306] Complications include lung abscess, pleural effusion, empyema, and atelectasis secondary to large hilar nodes pressing on a bronchus.[282]

BURKHOLDERIA (PSEUDOMONAS) CEPACIA

Burkholderia cepacia is an increasingly recognized cause of nosocomial pneumonia, particularly in children with immunodeficiency. The organism was first described in 1950 as causing a "soft rot" in onions.[307] It is closely related to *Pseudomonas mallei, P. pseudomallei, P. pickettii,* and other *Pseudomonas* species that are plant pathogens. It is only distantly related to *P. aeruginosa*.[307]

The organism is ubiquitous and versatile; it seems to thrive under adverse conditions and can even use penicillin for its food supply.[307] The organism is durable and resistant to many disinfectants, antiseptics, and preservatives. Children are thought to acquire the organism in the hospital or via contact with colonized siblings.[307] Strain-specific properties are now being identified that may, in part, determine which strains are efficient colonizers of susceptible patients, such as those with cystic fibrosis (CF).[308]

The organism is virtually nonpathogenic in the healthy child or adult. In less than 2% of healthy adults the pharynx is colonized.[309] In patients with altered host defenses,[310,311] such as children with CF, burns, and indwelling catheters or other medical devices, serious infection, including pneumonia, endocarditis, meningitis, bacteremia, peritonitis, postoperative and burn wound infections, skeletal infections, and lung abscess, may occur. *B. cepacia* infection may be the first manifestation of chronic granulomatous disease. Children with CF whose respiratory secretions are colonized with *B. cepacia* tend to have more serious lung disease and poorer pulmonary function than those who are not colonized with this organism.

Virulence factors[312] include an extracellular protease,[313] lipase, and siderophore. The genetic regulation of these exoproducts has been the subject of recent attention[314]; extracellular material from broth cultures of *P. aeruginosa* increase the production of protease, lipase, and siderophore in *B. cepacia.* Such interspecies signaling might allow insight into certain bacterial interactions in the lungs of patients with CF.

Histopathologic examination of lungs infected with *B. cepacia* revealed several disease patterns that included severe necrotizing pneumonia[307] and atypical granulomatous lesions in a patient with chronic granulomatous disease. In patients with *B. cepacia* colonization and CF, lobar and peribronchial pneumonia with neutrophilic infiltrates and microabscess formation occurs most commonly without necrotizing pneumonia or vasculitis.[315] A more chronic inflammatory infiltrate with interstitial pneumonitis in the presence of macrophages, lymphocytes, and plasma cells has also been described.

In adults with CF who are colonized with *B. cepacia,* the following clinical patterns have been observed: (1) chronic asymptomatic carriage, (2) progressive deterioration over many months with recurring fever and weight loss, and (3) rapid, usually fatal, deterioration.[316] In other patients, the clinical picture may resemble that of other bacterial pneumonias.

Diagnosis is by isolation of the organism from blood or sputum. Isolation from the latter may pose a problem for the clinical laboratory because other bacteria are likely to be present in the secretions of patients with CF; selective media, such as PC agar or an oxidation-fermentation base, contain antibiotics and other ingredients aimed at suppressing other flora, thereby aiding in the diagnosis.

B. cepacia is resistant to multiple antimicrobials; thus, treatment poses a challenge. Previously, the most effective antibiotics were chloramphenicol and TMP/SMX. The child with CF, however, is often resistant to these agents. Meropenem is the most active agent against the majority of *B. cepacia* complex isolates.[317] In vitro susceptibilities may guide the choice of compounds, although ceftazidime has been associated with clinical failure despite in vitro susceptibility.[307] High-dose[318] therapy with the chosen antibiotic may be necessary because the pharmacokinetics of many antibiotics are altered in patients with CF.

There are no definitive measures to prevent *B. cepacia* infections. Cohorting of colonized individuals, education regarding optimal infection-control practices, and careful handwashing all decreased colonization of *B. cepacia* in one large CF center; these measures have been widely adopted.[319]

BURKHOLDERIA PSEUDOMALLEI

Burkholderia pseudomallei[320] is a rare but serious cause of pneumonia. The first cases of human infection were identified in 1910 by Whitmore and Krishnaswami[321] in Rangoon. The etiologic agent is *B. pseudomallei,* a short, gram-negative,[322] aerobic,[323] bipolar-staining bacillus.[322] The organism can grow on MacConkey agar, Sabouraud dextrose medium, or eosin-methylene blue; rough, characteristically wrinkled colonies are usually visible after a 72-hour incubation.[324,325] The organism is a free-living bacterium that is found in surface water and in soil; transmission to humans is thought to be via contaminated food,[322] inhalation, or contamination of wounds.[325]

Acquisition of the causative organism in cases of pneumonia probably results from inhalation of contaminated dust[326] or infected laboratory materials.[327] Although animals (especially sheep and swine) may acquire the causative agent of melioidosis, direct transmission from animal to humans has never been reported.[326]

The endemic region lies in a narrow belt in the tropics within 20 degrees north and south latitude.[323] Subclinical infection is common; 29% of healthy Thai adults had detectable hemagglutinating antibody to *B. pseudomallei*[328]; in Thai

children, a trend toward an increasing prevalence of hemagglutinating antibody with increasing age was apparent.

Histologically, the lesions found in pulmonary melioidosis, as well as in infection elsewhere, begin as a collection of neutrophils surrounded by a zone of congestion, and they progress to disseminated, sharply defined, small, pus-filled abscesses with granulomatous margins and are associated with local necrosis. The necrotic regions coalesce with adjacent areas to form a honeycombed lesion.[320] In chronic infections, epithelioid histiocytes, lymphocytes, and multinucleated giant cells surround the abscess, and the lesion becomes granulomatous. Granulomas may become scarred with deposition of dense fibrin; central necrosis of these granulomas may resemble the caseating granulomas found in tuberculosis.[323]

The two clinical patterns are chronic and acute.[329,330] In both, the lung is the most commonly affected organ.[331] The indolent nature of the pulmonary involvement may simulate a mycotic infection or tuberculosis.[325]

Signs and symptoms of chronic pulmonary melioidosis may be minimal or absent[325] and may render the infection subclinical. Alternatively, fever, malaise, dry cough,[322] weight loss, chest pain, or hemoptysis may be present.[323] The white blood cell count is variable,[320,322,323,325] and neutrophilia is uncommon.[323] Nodular infiltrates, often with cavitation, are common findings on the chest radiograph.[325] Some 95% of adults with chronic pulmonary melioidosis have upper lobe involvement, either with infiltrates alone or with cavities, usually single, that vary in size.[323] Chronic pulmonary melioidosis may spontaneously resolve without treatment or advance to fulminant sepsis.[331]

The second pattern of melioidosis is more severe. The clinical picture is of generalized sepsis; skin sores resembling boils are widespread, and abscesses are commonly found in the lung, liver, spleen, and bone marrow at autopsy.[322,325] Most cases are accompanied by malnutrition and debilitation. The clinical course may deteriorate quickly[331]; the mortality rate is 60% to 95%.[331]

The most important factor in establishing the diagnosis is a high index of suspicion. For example, melioidosis should be considered[326] in a child who has a travel history or prior or current residence in Southeast Asia and who has a fever and a localized suppurative process. The diagnosis may be confirmed by isolating *B. pseudomallei* from blood or lung tissue obtained by lung aspiration.[325,326] The laboratory should be notified that *B. pseudomallei* is a consideration because the organism may be misidentified as *P. aeruginosa*, *Klebsiella*, or *Enterobacter* species, or another gram-negative bacterium.[331] Several serologic tests, including hemagglutination and complement fixation test, are useful diagnostic tools.[331] The demonstration of a fourfold or higher rise in paired sera is most helpful. Interpretation of a single titer is more difficult. A hemagglutination titer higher than 1:40 or a complement fixation titer higher than 1:8 had 97% sensitivity in culture-proven cases.[332]

The rapid institution of aggressive antibiotic therapy is important—even when clinical evidence of pulmonary disease is absent—because dissemination and overwhelming sepsis may occur quickly.[325] Combination therapy is preferred, with the theoretical goal of minimizing the development of antimicrobial resistance. Antibiotic courses of short duration and the severity of illness at presentation have both been associated with a high rate of relapse after the cessation of therapy.[333] The antibiotic regimen of choice for patients who appear ill (septic form) is ceftazidime, imipenem or meropenem, and TMP/SMX.[334] A 2- to 4-week course of parenteral antibiotics, followed by a prolonged course (e.g., 6 months) of oral antimicrobial therapy, is recommended.[326,335] For patients who do not appear ill, amoxicillin/clavulanate[336] or tetracycline and chloramphenicol[325] have been used, the last two often given in combination with TMP/SMX.[326] A 30-day course is typical.

Until recently, the mortality rate from melioidosis was as high as 95%,[322,326] especially in patients with the septic form of disease, despite prompt antibiotic therapy. The use of ceftazidime has greatly decreased the mortality rate in adults,[335] although specific data in children are lacking.

CITROBACTER *SPECIES*

Citrobacter species are most often associated with neonatal sepsis and meningitis; species members are rare causes of sporadic pneumonia, which occurs almost exclusively in neonates and immunocompromised individuals. *Citrobacter* organisms were first isolated in 1932 by Werkman and Gillen,[337] who proposed the generic term *Citrobacter* and described seven species. A bewildering array of taxonomic changes[338] ended in 1977, when Brenner and associates[339] designated the following species: *C. freundii*, *C. amalonaticus*, and *C. diversus*. *Citrobacter* organisms are enteric gram-negative rods that are closely related to *Salmonella* organisms. In humans, *Citrobacter* species are most often reported as a cause of meningitis in the neonate.

Most cases are sporadic, although outbreaks have been described. Once introduced into the nursery, *Citrobacter* species colonization may become prevalent. One study in a neonatal nursery identified 11 of 128 infants colonized with *C. diversus*.[340] The umbilicus was the most frequent site of colonization.

The diagnosis is made by identifying the causative bacterium in blood, CSF, or in an older child, in sputum. Treatment is with an aminoglycoside or an extended-spectrum cephalosporin. Almost all isolates are ampicillin resistant.

The fatality rate for *Citrobacter* infections in newborns and older immunocompromised patients with *Citrobacter* pneumonia has been said to be high.[338,341] Recent data defining these rates more precisely are not available.

The complications of *Citrobacter* pneumonia include associated bacteremia with metastatic foci, particularly meningitis. *C. diversus* pneumonia may also be associated with abscess formation in the lung[346] and with empyema.

CORYNEBACTERIUM *SPECIES*

Members of *Corynebacterium* species are gram-positive bacilli that have rarely been implicated as a cause of pneumonia in either immunologically normal or abnormal hosts. Examples are *C. xerosis*,[343] *C. pseudodiphtheriticum*,[344] and *C. jeikeium*.[345] Most patients have an underlying disorder. Fever is often absent. In vitro, *C. pseudodiphtheriticum* isolates were susceptible to ampicillin and other β-lactams but were often resistant to clindamycin and erythromycin. A report from Spain describing a patient with empyema fluid from which *Corynebacterium* species was isolated suggests

that empyema may complicate *Corynebacterium* species pneumonia.[346] This patient was managed with imipenem and clindamycin.

COXIELLA BURNETII

In 1935, the disease caused by the organism *Coxiella burnetii* was given the name Q *fever* by Dr. E. H. Derrick of the Queensland Health Department in Australia because he was unable to diagnose the disease and, therefore, referred to it as Q for "query" fever. The organism was later named *C. burnetii* for Drs. Cox and Burnet, who were instrumental in isolating the organism.[347] The first cases of *C. burnetii* pneumonia were identified in 15 of 153 employees who had contracted the illness in one building of the National Institutes of Health in 1940.[348]

C. burnetii is a gram-negative, pleomorphic, intracellular coccobacillus. The organism is able to form spores, which allows it to survive for more than 40 months in skim milk at room temperature and more than 1 month on or in meat in cold storage.[347] *C. burnetii* infects many different animal species. Sheep, cattle, and goats are the traditional animal reservoirs, although horses, pigs, cats, and dogs may also be infected.[347] Once infected, animals may shed the organism for several months. For example, cows may shed *C. burnetii* in milk for up to 32 months; after birth, sheep may shed it in feces for 11 to 18 days.[349]

Humans are the only animal in which *C. burnetii* infection usually proceeds to illness. The usual route of infection is by dose-dependent aerosol aspiration.[350] Human-to-human transmission is rare.[347]

Initial infections are often asymptomatic and disease attributable to Q fever occurs in acute and chronic forms. Pneumonia develops in 20% to 40% of patients but varies by geographic region, possibly reflecting strain-specific properties.[347]

The clinical features of Q fever have included fever, fatigue, chills, myalgias, nausea, vomiting, pleuritic chest pain, and cough. Headache may be severe and retro-orbital. Signs of Q fever pneumonia vary; clinical evidence of respiratory tract involvement may be absent, despite radiographic evidence of pneumonia. Alternatively, a dry, nonproductive cough may be present. Occasionally, the course is rapidly progressive. Physical examination of the chest of the patient with Q fever pneumonia may be normal; alternatively, inspiratory crackles may be present. Some 5% of patients with Q fever pneumonia have splenomegaly.[347]

The radiographic picture of patients with Q fever pneumonia is variable and includes nonsegmental and segmental pleural-based opacities. A pleural effusion is present in about one third of patients. Atelectasis and hilar adenopathy are infrequent findings.

Most laboratories do not have the facilities necessary for the isolation of Q fever. Serologic diagnosis may be made by the detection of antibodies with a variety of techniques, including complement fixation microagglutination, microimmunofluorescence, and ELISA. A fourfold rise in serum antibody titer between the acute and convalescent phases is considered diagnostic.[347]

Acute Q fever is generally a self-limited illness but treatment may shorten the duration of symptoms. The best therapy for Q fever pneumonia is doxycycline.[347] Fluoroquinolones or chloramphenicol are alternatives. Most cases of pneumonia resolve, although death has been reported in one adult.[347]

An inactivated whole-cell Q fever vaccine has been developed but is not yet available.[351] It would presumably be used for high-risk populations, such as animal handlers and those working in abattoirs.

ESCHERICHIA COLI

Escherichia coli is an extremely rare cause of childhood pneumonia except in neonates or in those with an underlying disease. *E. coli*, the "colon bacillus," was first isolated in 1885 by T. Escherich from the feces of breastfed infants.[352] It is a gram-negative, nonencapsulated bacillus that may be either motile or nonmotile. Typing of strains is based on the following antigens: flagellar (H), somatic (O), and capsular (K or B). The ability of *E. coli* to bind to host tissue via specific fimbriae is an important first step in infection. Hemolysin is another virulence-associated characteristic of severe *E. coli* infections in children.[353]

E. coli is an important cause of neonatal pneumonia when the causative organism is acquired either shortly before or during delivery.[354] The source of the organism is usually the maternal gastrointestinal tract or aspirated amniotic fluid. The incubation period is variable and ranges from birth to several weeks of age. A study of 34 infants with late neonatal pneumonia (onset of symptoms more than 48 hours after birth) suggested that *E. coli* was the probable etiology in 6%; coliforms accounted for 44% of the episodes.[355] *E. coli* strains with K1 capsular polysaccharide antigen are the most common causes of neonatal *E. coli* meningitis and bacteremia and of the less frequent invasive infections that occur in infants. In children older than 2 years of age, the importance of K1 is diminished[356] because invasive *E. coli* infections usually occur only in association with underlying disease.

Nosocomial acquisition of *E. coli* from nursery personnel and equipment has also been documented. Others at increased risk for *E. coli* infections may include neonates with immunologic defects, breakdowns in skin integrity, or asplenia.

E. coli may occur more frequently in malnourished older children in developing countries. In contrast to its rare occurrence in children beyond the neonatal age group in developed countries, a study in Nigeria identified *E. coli* pneumonia by lung aspiration in 8.8% of 99 malnourished children (age, 9 months to 5 years); this organism was the third leading cause of pneumonia in these children.[357] Similarly, 5.3% of malnourished children in Zaire had *E. coli* pneumonia.[358]

E. coli pneumonia may be acquired via inhalation or may result from bacteremic seeding of the lung. The organism is not a usual constituent of normal pharyngeal flora but may be found in the pharynx of ill children or adults, particularly among hospitalized patients. Spread in the hospital is facilitated by hand-to-mouth contact, often with fecal contamination, and by fomites such as contaminated respiratory equipment.

A study of autopsy findings in neonates with *E. coli* pneumonia identified diffuse inflammation as the most common pathologic finding.[359] In contrast, diffuse bilateral lower lobe bronchopneumonia was found with occasional abscess formation in adults at autopsy. The alveoli were typically filled with fluid in the presence of mononuclear cells. The alveolar cells

exhibited cuboidal metaplastic changes with thickened, edematous septa.

The clinical findings of *E. coli* pneumonia are nonspecific[359] and are similar to those of bacterial pneumonia of any etiology in the respective age group. The diagnosis is usually based on recovery of the causative organism from the blood.

A pneumatocele has been reported in a neonate with *E. coli* pneumonia[360]; lung abscesses are rare. In general, if the correct diagnosis is made and appropriate treatment is instituted, recovery usually occurs.

Childhood *E. coli* pneumonia is usually treated with an aminoglycoside, an extended-spectrum cephalosporin, or the two in combination. Although combination therapy is preferred, few explicit data document its superiority. Ampicillin may be substituted for the cephalosporin when the isolate is susceptible. Amikacin may be substituted for gentamicin if the isolate is resistant. At the University of Chicago Hospitals in 1996, 98% and 99% of *E. coli* isolates were susceptible to gentamicin and extended-spectrum cephalosporins, respectively.

FRANCISELLA TULARENSIS

The bacterium *Franciscella tularensis* was first identified in 1910 by McCoy and Chapin in Tulare County, California, as the microorganism responsible for the plague-like disease in ground squirrels in that area.[361] The organism in culture is a fastidious, gram-negative coccobacillus.[362] In nature, however, it is a hardy organism that may survive for several weeks in water and mud, particularly around aquatic mammal dwellings.[363] Although it does not form spores, it resists drying and cold and, thus, may be transmitted as a fomite.[363]

Tularemia is endemic throughout the United States, with the highest number of cases occurring in Arkansas, Missouri, Montana, Oklahoma, Tennessee, Texas, Utah, and Wyoming.[363] Each year, 150 to 300 cases are reported.[364] Tularemia is also endemic throughout Europe and Asia.[282] Male patients in rural areas are most commonly infected,[363] although infections are also well documented in urban environments.[365] Some 6% to 30% of cases of tularemia occur in children,[366] mostly in the second decade of life.

Tularemia is primarily a disease of wild animals; human infection is incidental[367] and can be initiated in several ways, including direct contact with or ingestion of infected animals or animal tissues; bites from ticks, flies, or other arthropods; inhalation of dust from contaminated environments[366]; and consumption of contaminated water. There have been no reports of person-to-person spread.

The causative bacterium has been reported in more than 100 species of wild or domestic mammals, birds, fish, and amphibians. It has been estimated that 15% to 30% of wild rabbits in the United States serve as a natural reservoir for tularemia.[366] Tularemia occurring after bites by ticks represents the third most common tick-borne disease in the United States.[368] Tick bites account for about 50% of all cases of tularemia.[364,369]

Tularemia has traditionally been classified by its *form*, a term referring to a constellation of the clinical features that are initially recognized. The ulceroglandular form accounts for about 80% of reported cases. This disease is characterized by an erythematous, punched-out, indurated skin ulcer and tender, localized lymphadenopathy. Glandular, oculoglandular, oropharyngeal, typhoidal, intestinal, and pneumonic forms also occur. The pneumonic form is said to occur after direct inhalation of infected particles from an animal carcass,[366] a laboratory specimen, or contaminated dust.[363]

Primary tularemia pneumonia can begin after the inhalation of infected particles. Pneumonia may also occur as a consequence of hematogenous spread.[282] After inoculation, lymphatic spread ensues with the development of acute local inflammation, nodal swelling, necrosis, and caseation. The organisms may enter the bloodstream from the lymphatic system and become disseminated. Spontaneous resolution is unlikely once this occurs because *F. tularensis* is able to survive intracellularly, even when entrapped by the reticuloendothelial system.[370] Symptomatic bacteremic seeding of the lungs is manifested as a multifocal lobular or even lobar pneumonia with interstitial involvement. The process may be unilateral or bilateral with segmental, lobar, or patchy infiltrates. Less common manifestations include the formation of multiple small abscesses, cavitation, residual cysts, and a miliary pattern.[282] Microscopically, in patients who die of tularemia with pulmonary involvement, mononuclear cells are found in fibrin-rich alveolar exudate. Thrombosis and necrosis of small- and medium-sized arteries and veins are common. A child with tularemic pneumonia and unrecognized chronic granulomatous disease was found to have discrete, round, nodular, well-localized areas of granulomatous inflammation in a subpleural and parenchymal distribution.[371]

Patients who survive infection are immune. Antibodies do not appear until 1 to 2 weeks after the onset of symptoms.[372] Passively transferred antibody can confer protection on recipient mice,[373] and specific antibody enhances the rate of clearance of *F. tularensis* from blood.[374]

Tularemic pneumonia may pose a considerable diagnostic dilemma, especially when the portal of infection is not obvious. A thorough clinical history, particularly with inquiries about contact with rabbits or other wild animals, provides an aid to diagnosis.[375]

Prodromal symptoms may include malaise, cough, and chest tightness lasting 10 days to 3 weeks. The onset is usually less abrupt than that of pneumococcal pneumonia and may be difficult to pinpoint with certainty. Chills and fever are usual. In Arkansas, 87% of children with pulmonary tularemia had fever.[376] A relative bradycardia may be present; peripheral vascular collapse is rare.

Few laboratory tests contribute valuable diagnostic information. In particular, the leukocyte and platelet count, erythrocyte sedimentation rate, and urinalysis were not found to be helpful.[376]

There is a dissociation between clinical manifestations attributable to pneumonia, which may be minimal or absent, and the chest radiograph, which may be markedly abnormal.[377] This effect may be dramatic when systemic manifestations of tularemia, such as headache, myalgia, and high fever, are apparent.

Hilar adenopathy occurs in about one third to one half of cases and pleural effusion in 25% to 30%[378] Radiographs become positive as early as the second day after the onset of symptoms. Most patients have a distinctive pattern of a single (occasionally multiple) oval consolidation that is frequently

juxtahilar. Early radiographic changes include peribronchial infiltration with a bronchopneumonia pattern; hilar adenopathy is evident in 32% to 64% of cases[378] and may represent an important clue to the diagnosis. Cavitary pneumonia is unusual.[379] Fibrosis and calcification changes may occur late.[282]

Care should be taken when cultivation of *F. tularensis* is attempted because inhalation or inoculation with as few as 10 to 50 organisms can produce pneumonia. Many hospital laboratories refer specimens to a reference laboratory or to the CDC for processing.[380] The organism is fastidious but can be recovered on commercially available chocolate agar and from most automated blood culture systems. The laboratory should be notified that *F. tularensis* is suspected because prolonged incubation may be required. Presumptive isolates are identified by agglutination with commercially available antiserum.[362]

Serologic diagnosis remains the diagnostic gold standard. The commercially available tube agglutination test is most frequently used. Growth on culture may be identified by direct fluorescent antibody, PCR, or rapid slide agglutination tests. Prompt initiation of antibiotics in patients with tularemic pneumonia (often before agglutinating antibody titer is detectable) may be lifesaving, particularly when the clinical course is severe. Streptomycin, gentamicin, or amikacin are recommended for the treatment of tularemia.

Lung abscess formation is rare[381] but may be multiple. Pleural effusion, characteristically exudative, is present in tularemic pneumonia[382] in up to 50% of cases.[383] Pericarditis is a rare complication of tularemia. Meningitis has rarely been identified in patients with tularemic pneumonia.[372] Nonspecific features of severe tularemic pneumonia have included ARDS requiring positive end-expiratory pressure,[384] acute renal insufficiency, neuropathy,[384,385] and encephalopathy.

Handling of wild animal carcasses while wearing rubber gloves, masks, and protective glasses and taking appropriate precautions to prevent tick bites may decrease exposure to the causative organism. Postexposure chemoprophylaxis has not been recommended.[364] Tularemia is reportable to state or local boards of health.[363] For laboratory workers anticipating exposure, a vaccine is available from U.S. Army Medical Research and Development Command at Fort Detrick, Maryland.

KINGELLA *SPECIES*

Although rarely reported outside of Israel, *Kingella kingae* infections have been identified as a cause of childhood pneumonia, especially in the very young. The organism, a member of the so-called HACEK group, is a gram-negative coccus with morphologic characteristics similar to those of *Moraxella* species. In a 5-year observational study in Israel, the incidence of invasive *K. kingae* infection was 31.9 per 100,000 children younger than 12 months of age, 27.4 per 100,000 children younger than 2 years of age, and 14.3 per 100,000 children younger than 4 years of age.[386] Of those with invasive disease, 2 of 25 had a lower respiratory infection, and one had a pulmonary infiltrate; both children with respiratory infections recovered fully after antibiotic treatment with ampicillin or cefuroxime.[386]

Empyema with *Kingella* species has also been described. One article described an adult with empyema from which *K. kingae* and *Coccidioides immitis* were isolated from the pleural fluid; the latter organism had previously been isolated from fluid obtained by bronchoscopy performed for the evaluation of a pulmonary nodule.[387] *Kingella denitrificans* was isolated with *Peptostreptococcus* species from the pleural fluid of another adult with bronchogenic carcinoma and empyema.[388]

KLEBSIELLA PNEUMONIAE

Despite its name, *Klebsiella pneumoniae* is a rare cause of pneumonia in children. The organism was first identified in 1882 by Carl Friedländer, who recognized it as a cause of lobar pneumonia but incorrectly believed that it was a major cause.[389-391] Most cases occur in the neonate or immunocompromised host. In the latter group, it is often nosocomially acquired.

The genus *Klebsiella* is one of four genera in the tribe Klebsielleae of the family Enterobacteriaceae. There are four species, but *K. pneumoniae*, a gram-negative, encapsulated bacillus, is the most important.[392-394] Many different capsular serotypes can cause human disease, and a capsular polysaccharide-based vaccine will need to be multivalent.[395]

Infection with *Klebsiella* can be sporadic and occasionally epidemic in several clinical situations. Community-acquired *Klebsiella* pneumonia in children is infrequent. Among 102 children hospitalized for community-acquired pneumonia, *K. pneumoniae* was isolated from a tracheal aspirate of a single child who also had evidence of infection with respiratory syncytial virus.[30] Among adults, the incidence of community-acquired *K. pneumoniae* pneumonia is also low, with less than three bacteremic cases per year at large municipal hospitals.[396] *K. pneumoniae* bacteremia is more common than pneumonia. Most children with *K. pneumoniae* bacteremia acquire infection nosocomially and are young; only a small number have pneumonia.

Data to define the incidence of *K. pneumoniae* pneumonia in the neonate are not available; inference is made from data regarding the occurrence of *K. pneumoniae* bacteremia. At Yale from 1966 to 1978, *K. pneumoniae* was responsible for 14% of cases of neonatal bacteremia, the third leading cause after *E. coli* and group B streptococci.[397] Risk factors for *K. pneumoniae* neonatal bacteremia included a prior operative procedure, tracheostomy, infected venous cutdown site, and multiple exchange transfusions.[398,399]

In the hospital, *K. pneumoniae* invasive infection, including pneumonia, has been related to prior colonization,[400] which in turn is related to prior antimicrobial therapy. The rates are high in hospitalized patients, particularly those in postoperative situations or intensive care units. Spread of the organism is facilitated by hand-to-patient contact, and hospital staff can be facilitators.[401,402] Patients receiving immunosuppressive therapy also constitute a group at increased risk,[400] especially in the nosocomial setting.

K. pneumoniae probably reaches the lung most commonly by inhalation. Bacteremic seeding of the pulmonary parenchyma may also occur but has been difficult to document with certainty. Among adults, alcoholics are said to be at high risk; presumably the organism is aspirated during binge drinking.

K. pneumoniae pneumonia may occur anywhere in the pulmonary parenchyma; multiple lobe involvement is

common. In adults in whom alcoholism is the predisposing condition and infection is acquired by aspiration, the most common involvement occurs in the upper lobes, particularly on the right side.[403] The capsular polysaccharide of *K. pneumoniae* plays an important role in pathogenesis[404] by interfering with opsonization or by preventing complement activation.

Most information regarding the pathology of *K. pneumoniae* pneumonia comes from postmortem data that often predate the antibiotic era and represent observations from patients with severe disease. No single feature histologically distinguishes *K. pneumoniae* pneumonia. As with pneumococcal pneumonia, the stages of red hepatization, gray hepatization, and resolution may occur. Thrombosis and circulatory impairment follow and terminate in necrosis with sloughing, hemorrhage, and the potential for cavity and abscess formation.[405] Abscesses may be multiple and small, solitary and large, or intermediate between these designations.

The clinical features of *Klebsiella* pneumonia depend on the setting. In the neonate and older child, the clinical features resemble those of bacterial pneumonia of any etiology in the respective age group. Chest pain or discomfort with or without dyspnea may be evident, although the clinical picture in an immunocompromised child may not suggest clear-cut localization to the respiratory tract. *K. pneumoniae* pneumonia may occur with pneumococcal pneumonia, a possibility that should be considered, particularly in an immunocompromised child with an abscess who does not respond to therapy directed against *S. pneumoniae*.[406]

The diagnosis depends on identifying the causative organism in a clinically relevant setting. Sputum, when available (e.g., from older children), may be blood tinged, or "rusty," although this sign was only present in about one third of adults with *Klebsiella* pneumonia. Because asymptomatic colonization may occur, sputum analysis may be misleading,[407] although suspicion should be raised in the presence of monotonous gram-negative rods, a pure or nearly pure culture, or both results.[396]

Isolation of *K. pneumoniae* from the blood during an episode of acute pneumonia is usually accorded diagnostic importance, as is isolation of the organism from pleural fluid.[396] Radiographic findings in adult *K. pneumoniae* pneumonia include a bulging fissure of the involved lobe margin, a sharp infiltrative margin of the pulmonary infiltrate (both occur in about 64% of patients),[408] and a predilection for upper lobes and abscess with cavitation. More importantly, any or all of these "classic" features may be absent, and the radiographic appearance may not be distinct from that of other airspace pneumonias.[409] Lesions consistent with the radiologic appearance of a pneumatocele in patients with *Klebsiella* pneumonia have also been described.

The treatment of *K. pneumoniae* pneumonia in children usually involves an aminoglycoside, an extended-spectrum cephalosporin, or the two in combination. Combination therapy is preferred, although few explicit data document its superiority. Resistance may be a particular problem during nosocomial outbreaks.[410] Lung abscess is a frequent complication in children and adults and may occur in one third to one half of cases.[408] Surgical treatment may be necessary if medical intervention fails. Percutaneous drainage is usually sufficient.[411] Massive pulmonary gangrene, the rapid total destruction of part of the lung, is an extremely rare complication of *K. pneumoniae* pneumonia. Some have suggested that this entity may represent a synergistic infection caused by *K. pneumoniae* and an undetected anaerobe.[396] The process may resemble a lung abscess initially but reveals itself by its rapid, destructive course; fewer than 20 cases have been reported.[396] Other intrathoracic complications include empyema with residual pleural thickening[390,396] and pneumopericarditis.[412]

"Chronic" *K. pneumoniae* pneumonia, which by definition persists longer than 1 month, is an entity described only in adults, primarily in the older literature. Cavitation may be present, and the clinical picture may resemble that of tuberculosis. Some have suggested that chronic *K. pneumoniae* pneumonia, like massive pulmonary gangrene, may reflect a synergistic infection between *K. pneumoniae* and an anaerobic species.[396]

The mortality rate of *K. pneumoniae* bacteremia in the neonatal period is very high[400] despite appropriate antibiotic therapy. Few specific data exist for older children with uncomplicated *K. pneumoniae* pneumonia and intact host response capability. However, recovery is the rule, providing that appropriate antimicrobial therapy is administered and relevant foci are drained.

To date, a polyvalent polysaccharide vaccine prepared from 24 *Klebsiella* serotypes has been well tolerated and immunogenic among the more than 2000 adults to whom it has been administered. More recently, a vaccine based on O side chains has been evaluated; this approach may prove simpler to implement because a vaccine containing 3 to 7 O serotypes could prevent 60% to 90% of disease in patients.[413,414]

LEPTOSPIRA *SPECIES*

Leptospirosis is a rare cause of childhood pneumonia. The clinical illness was first described by Weil in 1886, and the organism was first seen in 1907. The rat was considered the only animal host until the 1940s, when it became evident that leptospirosis was a zoonosis of worldwide distribution that affected many species of wild and domestic mammals. Worldwide, the rat is the most common source of human infection. In the United States, dogs, livestock, cats, rodents, and wild mammals are the most common sources.

The cause is *Leptospira interrogans*, which is a spirochete. *L. interrogans* is further classified into serogroups and serovars (serotypes). About 19 serogroups and 250 serovars have been recognized. In the United States, disease is caused by more than 10 serovars, most commonly *icterohaemorrhagiae* and *canicola*. *L. interrogans* is pathogenic for both animals and humans.

Transmission of leptospires to humans follows contact with the tissues or body fluid of infected animals or exposure to an environment contaminated by leptospires. The occurrence of flooding (e.g., after a heavy rainfall) facilitates spread of the organism. In 1972, an outbreak of leptospirosis in Missouri was traced to contaminated soil in suburban lawns. Dogs have become an increasingly recognized vector and reservoir of this disease in the United States.[415] In urban environments, rats have been increasingly implicated in the maintenance of the *L. interrogans* reservoir.[416] After penetration of the skin or mucous membranes, the organisms invade the bloodstream and are spread throughout the body.

Although presumed to be present, leptospires were not demonstrable in the lungs until recently.[417]

Pulmonary lesions are usually the result of hemorrhage secondary to the vasculitis that characterizes disseminated leptospirosis rather than acute inflammation. Localized or confluent hemorrhagic pneumonitis may be evident. In addition, petechial and ecchymotic hemorrhages may be found throughout the lungs, pleura, and tracheobronchial tree.[417]

Leptospirosis is usually separated clinically into anicteric and icteric (Weil's syndrome) disease. About 90% of patients have anicteric disease. The traditional view has been that pulmonary manifestations are usually mild and of little clinical importance. A dry, hacking cough, occasionally with blood-stained sputum, may be present. A chest radiograph may show infiltrates that may be diffuse, bilateral, and patchy. Rarely, chest pain, hemoptysis, respiratory distress, and cyanosis may be present.[418] Hemoptysis, if present, usually clears by day 5. Physical examination may reveal crackles on auscultation or a friction rub. In light of reports of severe pulmonary symptoms and pulmonary hemorrhage during outbreaks of leptospirosis in Korea, China, and Nicaragua,[419] the disease spectrum of pulmonary leptospirosis may require expansion.

A blood or CSF culture obtained in the first 7 to 10 days of the illness and plated on special media, such as Fletcher, EMJH, and Tween 80-albumin media, may lead to the diagnosis. The organism may also be isolated from the urine if the specimen has been obtained after about the 10th day of illness. Investigators have suggested that it may be possible to diagnose leptospirosis by using dark-field microscopy to examine BAL specimens.[420] Previously, it was widely held that direct dark-field fluid examination was not recommended because the organisms were present in small numbers and perhaps difficult to distinguish from fibrin filaments.

Several serologic strategies for diagnosis have been used. The microscopic agglutination test is the current standard for the serologic diagnosis of leptospirosis and can be arranged at the CDC through referral by state health departments. Indirect hemagglutination, indirect immunofluorescence,[421] ELISA,[422] and dot-ELISA tests have been used well in various circumstances. PCR is available only in research laboratories.[423,424]

Treatment is with high-dose intravenous penicillin, typically given for 7 days. Although endotoxin has not been demonstrated in the causative bacterium, Jarisch-Herxheimer reactions have been described,[425] as has ARDS. Death from leptospirosis is usually associated with severe jaundice, severe oliguric renal failure, and the recently recognized associated pulmonary hemorrhage. Amoxicillin and doxycycline are alternative treatments.

Leptospirosis is a disease that must be reported to state and local health authorities. While the child is in the hospital, strict universal precautions should be followed. Public health measures include controlling rodents, preventing contact with animal urine, wearing protective clothing when exposure is likely, and avoiding contact with potentially contaminated water. Adult prophylaxis is effective with 200 mg of oral doxycycline once a week in those with occupational exposure. There are no current recommendations for prophylaxis in children.

LISTERIA *SPECIES*

Listeria monocytogenes is a gram-positive, facultatively anaerobic rod. It was first recognized as a human pathogen in 1929 and was named after Lord Lister, the British surgeon who developed the technique of antiseptic surgery.[426] The first documentation of infection in infants was published by Burn in the 1930s.[427]

L. monocytogenes accounts for almost all listerial infections in humans, although infections with *L. ivanovii*, *L. seeligeri*, and *L. welshimeri* have rarely been reported. It is an uncommon cause of neonatal pneumonia.[428] Human groups at risk for infection include pregnant women, immunocompromised patients, and neonates.

Human infection is acquired by contact with domestic or wild birds and animals, meat, milk, vegetables, or contaminated soil.[282] The organism has also been found in the gastrointestinal tract in 1% to 5% of asymptomatic individuals. Neonates may acquire infection transplacentally during passage through an infected birth canal or from maternal bacteremic seeding.[429] Some reports have suggested cross-infection in neonatal nurseries. The organism is distributed worldwide,[282] and although there was a suggestion of geographic differences associated with perinatal listeriosis, surveillance conducted by the CDC did not document a geographic or seasonal pattern.[429]

The pathogenesis of listeriosis involves a complex interaction among the organism, the host immunologic response, and the amount of organism present. Both humoral and cell-mediated immunity are important. Efficient opsonization of *Listeria* species is mediated by IgM and complement, which are at physiologically low concentrations in the neonate; it has been suggested that these physiologic nadirs are what place neonates at particular risk.[430] Remarkably, *Listeria* organisms can mobilize actin filaments and usurp the contractile system of the host cell, which allows cell-to-cell spread. This property accounts for its virulence in individuals with defective cell-mediated immunity; it also accounts for the ability of the organism to invade the gastrointestinal tract without erosive lesions and to invade the placenta and fetus during maternal bacteremia.[431]

Early onset neonatal listeria infections are usually manifested as pneumonia or sepsis.[432] Tachypnea, respiratory distress, or apnea may be present. Others have identified heart failure, cyanosis, seizures, and emesis. Some note the presence of roseoles, or tiny focal cutaneous granulomas. These "listeriomas" are usually present in the posterior pharyngeal wall if dissemination has taken place. In the older literature, a septic-like clinical picture with diffuse granulomas was termed *granulomatosis infantiseptica*. Transmission of the organism is thought to be from mother to infant, with high concordance of recovery of an organism of identical serotype from mothers of infected infants. For late-onset disease, meningitis is more frequent, and there is less likelihood of recovering the infecting organism from the mother.[432]

Careful bacteriologic evaluation of a patient with possible listeriosis is essential because the organism may be mistakenly identified as a *Corynebacterium* species contaminant on Gram stain. Certainty regarding the diagnosis involves isolation of the organism from a normally sterile site (e.g., blood). The organism will usually grow in culture within 36 hours. Serologic testing is not helpful. PCR coupled with fluorescent

antibody reagents and DNA probes may be helpful in the diagnosis, especially when the organism is in a nonsterile environment where isolation from culture may be difficult. Radiographically, *L. monocytogenes* pneumonia may produce diffuse, bilateral infiltrates that may be miliary, patchy, or interstitial.[282]

The most commonly recommended medication for the therapy of listeriosis is ampicillin, either alone or with the addition of an aminoglycoside, such as gentamicin, for synergy. Treatment failures are common with cephalosporins, so their use should be avoided. The optimum length of treatment has not been fully established, but most clinicians treat neonates for 2 to 3 weeks.

The risk of food-borne listeriosis may be decreased if pregnant women and immunosuppressed or immunodeficient patients avoid raw vegetables, unpasteurized dairy products (especially soft cheeses), undercooked meats, or ready-to-eat foods left standing at temperatures at which bacteria may survive and grow. Other measures include avoidance of bovine or ovine contamination of foods meant for human consumption and antimicrobial management of listerial infections diagnosed during pregnancy. Mortality rates depend on the clinical syndrome. Early onset neonatal infection, especially granulomatosis infantiseptica and listeriosis in immunocompromised hosts, are risk factors for high mortality.

MORAXELLA CATARRHALIS

M. catarrhalis is a gram-negative diplococcus morphologically similar to *Neisseria* species. It was first identified by Frosch and Kolle in 1896 and was given the name *Mikrokokkus catarrhalis;* it was placed in the genus *Neisseria.* In the early 1970s, however, its taxonomy was reconsidered on the basis of DNA base content, fatty acid composition, and genetic transformation, and the organism was then placed in the genus *Branhamella* (named in honor of Dr. Sarah Branham, a *Neisseria* researcher).[433] The correct taxonomic designation for this and related organisms is the subject of current debate,[434,435] but most clinicians have adopted the name *Moraxella catarrhalis*.

It was thought for many years that *M. catarrhalis* was a nonpathogenic inhabitant of the respiratory tract.[436] In Sweden, 17% to 36% of healthy preschool children were found to harbor *M. catarrhalis* in the nasopharynx.[437] It is now clear, however, that this organism is an important cause of otitis media and sinusitis. In addition, it may rarely cause pneumonia[436,437] and a variety of other infections in children.[438]

Establishing a role for *M. catarrhalis* as a pulmonary pathogen has been a complex task because of the frequency with which this organism colonizes the respiratory tract.[438] The following lines of evidence suggest a strong likelihood that *M. catarrhalis* is at least an occasional cause of bacterial pneumonia:

1. It has been occasionally isolated from the pleural fluid of patients with empyema.[438]
2. It was isolated from the lung of a few patients who died from bronchopneumonia.[438]
3. Serologic methods have identified a subset of patients with pneumonia who have increased antibody to *M. catarrhalis* on convalescence.[437]
4. A few children and adults with underlying illnesses have been described with a clinical illness consistent with pneumonia and *M. catarrhalis* bacteremia.[439]

The peak incidence of *M. catarrhalis* infection is believed to occur in the winter.[438] Transmission of the organism may be via person-to-person spread; nosocomial spread in a pediatric intensive care unit may play a role as well.[440] The role of environmental spread remains to be defined, although the organism survives in sputum for weeks.[438] The clinical features of *M. catarrhalis* pneumonia are not specific and resemble pneumonia caused by other bacteria. The diagnosis is made by isolating the organism from a normally sterile site such as blood in a relevant clinical situation. Serologic diagnosis has not been reliable.[441]

Because most strains of *M. catarrhalis* produce β-lactamase, antibiotics useful in the therapy of *M. catarrhalis* infections include amoxicillin/clavulanic acid, erythromycin and other macrolides, TMP/SMX, and extended-spectrum cephalosporins. It has been suggested that the presence of β-lactamase producing *M. catarrhalis* strains may confound the treatment of pneumonia caused by other β-lactam susceptible bacteria. For example, in a mouse model of pneumococcal pneumonia, animals inoculated with *S. pneumoniae* and β-lactamase producing *M. catarrhalis* had a poor outcome when treated with penicillin compared with mice inoculated with *S. pneumoniae* and β-lactamase–negative *M. catarrhalis;* clavulanate therapy ablated this difference.[442]

NEISSERIA MENINGITIDIS

Meningococcal pneumonia is rare, especially in children.[443] The organism *N. meningitidis* is a gram-negative diplococcus. Members of the species usually produce one of several antigenically and immunologically distinct capsular polysaccharides that are designated *A, B, C, X, Y, Z, 29E, W135, H, I, K,* and *L*.[444] The organism was first identified in 1886 by Anton Weichselbaum in the CSF of a patient who died of purulent meningitis. Meningococcal pneumonia was first recognized by Holm and Davison during the influenza epidemic in 1918 and 1919.

The initial colonization of meningococci is through adherence to the microvilli of nonciliated epithelial cells that line the respiratory mucosa. The mucosal barrier is breached by first entering the apical side of epithelial cells by a process that involves host actin. The bacteria then transcytose through the cell and exocytose at the basolateral side. Once the pathogens are in the subepithelial space, invasion of the bloodstream is likely achieved by entry through endothelial cells lining the blood vessels. M cells in the tonsillar sites of the nasopharynx might also be a portal of entry for invasion. Once bacteremia occurs, overt signs of disease are often present, and meningococci may be spread to target sites for metastatic infection.[445,446] The integrity of the mucosal barrier is the first line of defense against meningococcal infection. Serum specific antibody against meningococcal proteins and capsular polysaccharide causes lysis of bacteria, enhances phagocytosis by monocytes and polymorphonuclear neutrophils, and neutralizes endotoxin. Underscoring the importance of complement in the defense against meningococcal bloodstream invasion is the observation that people with deficiencies in certain complement components, such as C5, C6, C7, C8,

and properdin, are more prone to meningococcemia, despite the presence of protective antibody. Mucosal IgA may be important in mucosal defense against meningococci.

Infection with the meningococcus results in several clinical entities. The most common is asymptomatic carriage, which results in natural immunity. Humans are the only known reservoirs for transmission.[447] Meningococcemia is a rapidly progressive syndrome with an aggressive, downhill course and high mortality. Meningococcal meningitis is a more indolent disease with meningitis clinically resembling that caused by other bacteria. Chronic meningococcemia is a low-grade febrile illness frequently associated with arthritis and rash.

Meningococcal pneumonia may occur as a part of disseminated meningococcal infection variably accompanied by meningitis, arthritis, myocarditis, pericarditis, or endophthalmitis. Systemic illness may be mild.[448] Meningococcal pneumonia also occurs in the absence of the clinical picture of sepsis. Primary pneumonia is rare in children and adolescents. An association with antecedent viral pneumonia, particularly that caused by influenza and adenovirus, has been described.[449] However, the studies have been small, and the nature of the relationship has been unclear. Others have described a similar association between viral or *M. pneumoniae* infections and bacterial meningitis, but this relationship also requires further study.[447]

The presumed pathogenesis of meningococcal pneumonia begins with inhalation of the organism. Attack rates are highest in infants 6 to 12 months of age. The serotypes of *N. meningitidis* that have been described to cause pneumonia differ from those usually responsible for invasive disease. For example, serotype Y has repeatedly been cited as an important cause of primary meningococcal pneumonia despite its relatively minor role as a cause of septicemia.[450] Serotype W135 has been similarly implicated.[451] The incubation period is 1 to 10 days but is usually less than 4 days. Most cases of *N. meningitidis* pneumonia have been presumed to be community acquired. However, nosocomial pneumonia has also been described.[452]

Macroscopically, meningococcal pneumonia is lobular and rarely, lobar. The pleura is seldom involved. Histologically, affected bronchioles and alveoli are filled with polymorphonuclear cells that contain gram-negative intracellular diplococci.

No distinct clinical features distinguish meningococcal pneumonia from pneumonia caused by other bacteria[453]; adults usually have cough, fever, chest pain, and dyspnea.[282] The diagnosis is based on isolation of the causative microorganism from blood, sputum (when available), or both fluids. Bacteremia is infrequently reported in primary pneumonia but commonly found when pneumonia is part of generalized sepsis. Group-specific meningococcal antigen can sometimes be detected in CSF, serum, and urine, which allows for the possibility of rapid diagnosis; however, false-negative results commonly occur. This diagnostic tool may be particularly helpful if antibiotics have been administered. Detection of a meningococcal insertion sequence IS1106 and ribosomal RNA genes[454] by PCR in CSF is currently available only on a limited basis.[455] Radiographically, patchy or confluent densities in one or both lungs may be present with occasional cavities. A pleural effusion may sometimes be evident.[282]

Meningococcal pneumonia is treated with parenteral penicillin G. Isolates have generally remained susceptible to penicillin. Recently, relatively resistant isolates (minimum inhibitory concentration, 0.1 to 1.28 μg/mL of penicillin) have been reported from several countries.[447,456] Susceptibility testing is infrequently performed but guidelines may soon change. In a recent case report, a patient with meningococcal sepsis developed pneumonia and empyema while receiving treatment with penicillin; the meningococcal isolate was found to have intermediate susceptibility to penicillin.[456] In the presence of meningococcemia, meningococcal meningitis, or both conditions, the dosage of penicillin should be high (e.g., 300,000 units/kg/day; maximum, 24 million units/day) and divided into 4 to 6 daily doses. In uncomplicated meningococcal pneumonia, a lower dosage (e.g., 100,000 units/kg/day) will probably suffice. Extended-spectrum cephalosporins such as cefotaxime and ceftriaxone are alternatives but are more expensive. Chloramphenicol remains an excellent alternative and is useful for the child allergic to penicillin. Although specific data are lacking regarding duration of therapy, a 7-day course is usually sufficient.

There are few complications of meningococcal pneumonia when the infection is not disseminated. Empyema may occasionally complicate meningococcal pneumonia.[456,457]

Respiratory isolation is indicated for 24 hours after the initiation of effective therapy. Control measures also include careful observation of exposed school, household, or child care contacts. If a febrile illness develops in a contact, the person should receive prompt medical evaluation, and if indicated, antimicrobial therapy should be started. Antimicrobial prophylaxis is indicated within 24 hours of illness in the index case for all contacts, including those normally residing in the household of the index patient and day-care and nursery school contacts. Respiratory tract cultures are not helpful in decisions regarding prophylaxis. Rifampin or ceftriaxone are appropriate drugs for chemoprophylaxis in children; ciprofloxacin is an alternative for adults.

In the United States, Canada, and many European countries, a serotype-specific quadrivalent conjugate meningococcal vaccine is available against groups A, C, Y, and W135 *N. meningitidis*. The duration of protection is expected to be longer than that conferred by the polysaccharide vaccine. The vaccine is recommended for universal administration to young adolescents, patients who are anatomically asplenic, those with terminal complement component deficiencies, military recruits, or to those traveling to countries with hyperendemic or epidemic *N. meningitidis* disease. The meningococcal polysaccharide quadrivalent vaccine is recommended for use in those between ages 2 and 11 as well as those older than age 55, for whom the conjugate vaccine is currently not recommended.

NOCARDIA *SPECIES*

The first known recognition of nocardiosis occurred in 1888 when Nocard identified a disease that resembled glanders in cattle on Guadeloupe.[458] The first case in a patient was described in 1890 by Eppinger, who visualized the organism in pus from a brain abscess. In 1904, Stokes recognized that *Nocardia* species could cause pneumonia in children when he reported a case occurring in a 28-day-old infant.

In 1889, it was suggested that the organism be designated *Nocardia*, although it was not until a better classification system for the order Actinomycetales was derived in 1943 that the term was widely used. *Actinomyces* species and *Nocardia* species are microbiologically similar and cause diseases with overlapping clinical and radiographic findings, although the treatments differ.[459]

Nocardia species are bacteria that are distinguished by their filamentous growth with true branching. Members of the genus are acid-fast, gram-positive organisms found in parasitized soil and dust. They are rarely commensals in humans or animals. The most common species causing disease in humans is *N. asteroides;* other human pathogens include *N. brasiliensis*, *N. otitidis-cavarum (N. caviae)*, and *N. farcinica.*

The most frequently isolated pathogen, *N. asteroides*, is found worldwide. Infection caused by this organism has been reported in patients 4 weeks to 70 years of age.[460] A higher percentage of cases occur in male patients.[461] There are no seasonal predilections. *N. asteroides* pneumonia in children is rare[460,462,463] and usually occurs among immunocompromised patients, especially those with HIV infection,[464] chronic granulomatous disease, or other impairments of cell-mediated immunity.[465] Among adults and children, only 500 to 1000 cases were reported in the United States in 1974[466]; 75% were immunocompromised.[461]

The lung is the usual portal of entry; infection begins with inhalation of the organism. The inflammatory response is suppurative and necrotizing with the formation of abscesses filled with neutrophils and inflammatory debris. In chronic infection, the abscesses may be multiple and separated by fibrotic areas. The process is similar to that found in actinomycosis except that the abscesses are less well defined and the fibrinous reaction is sparse.[467] There may be coalescence with cavity formation. A granulomatous reaction that surrounds a central area of caseous necrosis[467] and that forms a nodule similar to the one found in tuberculosis has been described, but sometimes it may represent concomitant tuberculosis.

The clinical presentation is not specific. The child with pulmonary nocardiosis may have fever, cough, anorexia, weight loss, night sweats, fatigue, malaise, chest pain, and dyspnea.[460] Leukocytosis is usual (≤50,000 leukocytes/mm^3).[460] Disease progression may be acute, subacute, or chronic; remissions and exacerbations may occur.[468,469]

The radiographic findings are also not specific.[464] There may be evidence of segmental infiltrates or large lobar consolidations. Pleural involvement is variable. The lower lobes are more frequently affected.[458] One or more lesions typical of a lung abscess may be present, as may small or large cavities with thin walls. Hilar involvement is unusual; bronchiolitis obliterans has been described.[470]

The diagnosis is made by the identification of typical beaded, branched, weakly gram-positive rods in sputum or pus. The organism grows slowly; cultures should be maintained for 7 to 10 days or longer. Although rarely isolated in the absence of infection, recovery of *N. asteroides* from an immunocompromised child should be regarded as proof of active infection until it is proved otherwise.[469,471] Demonstration of *Nocardia* species in tissue is best done by Brown and Brenn stain or Gomori methenamine silver stain. The clinical and radiographic picture of pulmonary nocardiosis may mimic malignancy[472] or tuberculosis.

Treatment is with a sulfonamide, usually in combination with TMP.[473] Immunocompetent children are usually treated for 6 to 12 weeks, whereas immunocompromised children or those with hematogenous spread are treated for 6 to 12 months,[474] and those with AIDS may require an even longer course.[475] Treatment failures have been reported.[476] When a patient's condition fails to improve, assessing compliance, measuring serum sulfonamide levels, performing susceptibility tests on the isolate, and draining the abscess may be appropriate. Alternative therapy in this instance may consist of increasing the dose of TMP/SMX; when TMP/SMX is contraindicated, treatment may consist of an alternative agent, such as ampicillin, erythromycin, amikacin, or minocycline. Cefotaxime and ceftriaxone have good in vitro activity, but there has been little clinical experience.[477]

Lung abscess and cavity formation may complicate *Nocardia* pneumonia; multiple draining sinus tracts and empyema may be present.[478] Hematogenous spread to the liver, brain, kidney, and other organs occurs in about 30% of cases.[460,467] The central nervous system is the most commonly seeded distant site.[479] Brain abscesses are usually surgically drained. Relapse has been reported years after therapy.[474]

Most children with *Nocardia* pneumonia recover after TMP/SMX therapy. Concomitant corticosteroid or antineoplastic chemotherapy and disseminated disease are associated with increased mortality rates, even when prompt, appropriate treatment is provided.[460,474,480]

PASTEURELLA *SPECIES*

The genus *Pasteurella* consists of eight species of small coccobacilli that are animal pathogens. One of these, *Pasteurella multocida*, is further divided into the following subspecies: *multocida*, *septica*, and *gallicida.* Human infections, rarely including pneumonia, are usually caused by *P. multocida* subspecies *multocida* and subspecies *septica.* Other genus members, *P. canis*, *P. stomatis*, and *P. dagmatis*, are rarely responsible for infections in humans.

P. multocida is a short, ovoid, gram-negative bacillus that may vary to a coccobacillary shape with convex sides and rounded ends. It may appear in pairs, chains, or clusters or may appear as a single organism. It may exhibit bipolar staining and may become increasingly pleomorphic on subculture. Distinguishing *P. multocida* from *H. influenzae* on morphologic grounds is sometimes difficult, but the former does not require X or V factors for growth. The virulence of the organism is believed to be partly related to the presence of a capsule.[481]

P. multocida is found in the oropharyngeal flora of 70% to 90% of cats and 25% to 50% of dogs and in the pharynx and gastrointestinal tract of many other mammals and birds. Human *P. multocida* infections follow dog or, more typically, cat bites or scratches, although infections have been reported with no identifiable animal contact.[482-484] Respiratory spread from animals to humans also may occur. Human-to-human spread has not been documented. One study identified a dog bite–related seasonal variation in human infection, with the highest incidence occurring in the autumn and winter,[485] although others showed no seasonal differences. There is no

gender difference in attack rates. The incubation period is usually less than 24 hours.

Patterns of infection in humans with *P. multocida* include local soft tissue infection, chronic respiratory tract infection, and bacteremia.[486-488] Local disease usually occurs within 24 to 48 hours of the animal bite or scratch and may include swelling, tenderness, erythema, and serous or sanguinopurulent discharge. Osteomyelitis and septic arthritis may reflect direct inoculation of the bacterium into a bone or joint. Regional lymphadenopathy, chills, and fever may occur. Pneumonia is most often associated with chronic upper respiratory tract colonization or bacteremia.[489] The former may continue for an undetermined interval before bloodstream invasion or organism spread to contiguous structures (e.g., middle ear, mastoid bone, sinuses, epiglottis, lung) occurs. The bacteremic pattern may be associated with pneumonia, empyema, or septic arthritis. The diagnosis of *P. multocida* pneumonia can be made definitively by recovering the causative organism from relevant sites. These sites include sputum, pleural fluid, and blood.

The antimicrobial therapy of choice is penicillin, ampicillin, or amoxicillin. These agents in combination with clavulanic acid are often used empirically to manage dog and cat bites in which *P. multocida* and *S. aureus* are potential pathogens. In children allergic to penicillin, appropriate alternatives are TMP/SMX, chloramphenicol, and tetracycline. More important, oral cephalosporins (such as cephalexin), semisynthetic β-lactams (such as oxacillin or nafcillin), and the macrolide erythromycin are unlikely to be effective. The duration of therapy is measured against the clinical course; useful guidelines are 7 to 10 days for local infection and 10 to 14 days for invasive infections.

Reported complications of *P. multocida* pneumonia include several cases of lung abscess,[490] pleural effusion, and empyema.[491]

PROTEUS *SPECIES*

Infections by *Proteus* species in children are infrequent and are most often associated with neonatal sepsis and meningitis and with childhood urinary tract infection. Pneumonia has also been described.[492]

Members of the genus *Proteus* are motile, gram-negative, enteric bacilli; the most commonly isolated species is *Proteus mirabilis*. The organism is found in soil, sewage, and manure. Epidemic spread in a newborn nursery has been described, with multiple cases of invasive *Proteus* infections occurring in a span of several years.

There are no pathognomonic features of *Proteus* pneumonia. In the neonate, the signs and symptoms are the same as those of other causes of neonatal bacterial pneumonia or sepsis. In the older child, the clinical features of *Proteus* pneumonia are also typical of those of any bacterial pneumonia and include fever, chills, chest pain, dyspnea, and cough.

The diagnosis is usually made after isolation of the causative organism from infected pleural fluid, lung abscess material, blood, or another normally sterile site. Radiographic findings of consolidation are common and usually involve an upper lobe (posterior segment) or the superior segment of the right lower lobe.

Most *P. mirabilis* isolates are susceptible to ampicillin; thus this compound is usually the mainstay of treatment. For invasive infections such as pneumonia or meningitis, empirical combination therapy with an aminoglycoside is often used. An extended-spectrum cephalosporin provides an acceptable alternative.

The complications of *Proteus* pneumonia include associated bacteremia with metastatic foci, particularly meningitis. *Proteus* species pneumonia may also be associated with abscess formation in the lung and with empyema.

PSEUDOMONAS AERUGINOSA

Pseudomonas aeruginosa is a rare, opportunistic cause of community-acquired pneumonia and an occasional cause of nosocomial pneumonia in children. Infection in immunocompetent hosts is unusual. This bacterium is a special problem for patients with CF.

The organism is a usually motile, gram-negative bacillus that lives in soil and water and grows easily on most media. Most strains have a polar flagellum and fimbriae or pili on the cell surface. More than 90% of strains produce the blue-green pigments pyocyanin and pyoverdin. For epidemiologic distinction, strains are sometimes differentiated by serotyping on the basis of immunochemical distinctions of lipopolysaccharides, phage typing, and typing of pyocyanin, a bacteriocin elaborated by many clinical isolates.

P. aeruginosa isolates elaborate a variety of virulence factors,[493,494] including adhesins, elastases, and proteases. *P. aeruginosa* can be part of the transient flora of the skin or the gastrointestinal tract. Hospitalization may lead to high rates of colonization on the skin of patients with burns, in the respiratory tract of patients receiving mechanical ventilation, in the gastrointestinal tract of patients receiving cytoreductive chemotherapy, or at any site in people receiving antibiotics. Because it has few nutritional requirements, the organism can be found in swimming pools, hot tubs, contact lens solutions, mop water, and dilute disinfectant solutions.[493]

Childhood infections with *P. aeruginosa* usually occur in patients with neutropenia resulting from chemotherapy for cancer and are associated with prior hospitalization, the receipt of previous antibiotic therapy, disruption of mucocutaneous barriers, and the presence of indwelling central lines. The bacterium may reach the lung by aspiration or by bacteremic seeding. The latter mechanism occurs mainly in patients with malignancies or those who are neutropenic because of chemotherapy for their malignancies. Children and adults with HIV may also have serious *P. aeruginosa* infections, which include pneumonia[495] in the absence of neutropenia or prior hospitalization.[496] *P. aeruginosa* is also an important pathogen in the neonate, who may acquire the bacterium in utero[497] or during passage through the maternal genital tract with associated early onset septicemia. *P. aeruginosa* pneumonia in healthy children is rare.

Children with CF constitute a population at unique risk for *P. aeruginosa* lower respiratory infections. The rate of *P. aeruginosa* colonization in patients with CF is related to age. About one fifth of patients are colonized in the first year of life, whereas older patients (in their late twenties) have rates exceeding 80%.[498] The bacteria are present in large numbers in the thick mucus that occupies the intra-airway space. The bacteria (mucoid) are often coated with a thick, alginate polysaccharide capsule, which is rarely seen in patients with

other disorders.[499] The observation that patients with CF rarely develop *P. aeruginosa* bacteremia suggests that these organisms are uniquely adapted for parasitism of the respiratory tract of patients with CF and less effective at survival elsewhere.

P. aeruginosa colonization of the respiratory tracts of patients with CF is also positively correlated with clinical score, extent of pulmonary disease, severity of radiographic changes, and serum immunoglobulin concentrations.[500] Similarly, *P. aeruginosa* has been associated with acute exacerbations and chronic progression of disease. Moreover, there is growing recognition of inflammatory airway disease, the presence of neutrophils, and progressive airway disease in association with the presence of *P. aeruginosa*. These views have caused reassessment of the once-prevalent view that *P. aeruginosa* colonizations in the lungs of CF patients were harmless commensals.

The persistence of *P. aeruginosa* in the lungs of children with CF has been related to the presence of one or more sputum factors that interfere with bactericidal activity. Blocking IgG antibodies stops the normal bactericidal IgM activity of human sera.[501] During chronic infection with *P. aeruginosa* in the CF population, there may be conversion of the mucoid colony morphology and rough lipopolysaccharide; these mutations occur in global regulators (i.e., alternative σ factors and their accessory elements).[502]

In addition to its important role in the pathogenesis of CF lung disease, *P. aeruginosa* can cause pneumonia in other patients. When pneumonia occurs in this context, it is usually secondary to aspiration of the infecting organism. There are microabscess formation, necrosis of the alveolar septa, and focal hemorrhage. When it results from seeding of the lung during bacteremia, the lesion begins as a small area of necrosis around a medium-sized pulmonary artery; poorly defined hemorrhagic nodular areas that are frequently subpleural may surround the infected vessel. Alveolar necrosis may be present. Because this histopathologic picture usually occurs in severely immunocompromised patients, substantial inflammatory response may be minimal or even absent.[503] Alternatively, a lesion resembling the one caused by intraparenchymal ecthyma gangrenosum may be present. In this instance, bacteria can be seen to invade small muscular arteries and veins with adjacent small, firm, yellow-brown nodules and hemorrhage into the lung parenchyma; microabscess formation may be present with leukocytes and liquefaction necrosis.

P. aeruginosa is an important cause of so-called *ventilator-associated pneumonia* (VAP),[504,505] defined as bacterial pneumonia occurring more than 24 hours after the initiation of mechanical ventilation. VAP is the result of the microaspiration of oropharyngeal bacteria, which occurs in up to 35% of patients whose lungs are mechanically ventilated.[506] The oropharynx of a critically ill patient is often colonized with aerobic gram-negative bacilli, including *P. aeruginosa*,[507] which may originate from contaminated respiratory therapy equipment or the stomach of an ill patient with diminished production of gastric acid.[508]

The clinical features of *P. aeruginosa* pneumonia resemble the age-specific features of other bacterial pneumonias. In the immunocompromised or chronically hospitalized child, signs may include chills, systemic toxicity, apprehension, confusion, and severe dyspnea with progressive cyanosis.

The findings on physical examination of the chest are nonspecific. The chest radiograph may show bilateral bronchopneumonic infiltrates, more often in the lower lobe with a distinctive nodular pattern. The picture of lobar consolidation is unusual. An interstitial pattern may also be present. Small pleural effusions are common; empyema is rare.

P. aeruginosa isolates are often resistant to a variety of antimicrobial agents; thus susceptibility testing of available isolates may be helpful in planning appropriate antimicrobial therapy for suspected or proven *P. aeruginosa* pneumonia. An extended-spectrum cephalosporin with antipseudomonal activity, such as ceftazidime, or an antipseudomonal penicillin, such as mezlocillin, ticarcillin, or piperacillin, is often used with an aminoglycoside, such as gentamicin or tobramycin. Whether such cephalosporin/aminoglycoside or antipseudomonal β-lactam/aminoglycoside combination therapy improves the outcome compared with ceftazidime alone is the subject of some controversy. The preponderance of evidence suggests that routine use of combination therapy is warranted[509] because *P. aeruginosa* pneumonia is often a severe infection and occurs in the clinical setting of an immunocompromised host. Antipseudomonal penicillins should not be used as the sole therapy for *P. aeruginosa* pneumonia; they have not been shown to be effective in this regard, and they may be too vulnerable to hydrolysis by the *P. aeruginosa* β-lactamases for effective therapy. β-lactamase inhibitors, such as clavulanate, do not inhibit *P. aeruginosa* β-lactamases, and thus fixed combinations, such as ticarcillin/clavulanate (Timentin), offer no advantage over, for example, ticarcillin alone. Ciprofloxacin, a quinolone antibiotic, offers good activity against many isolates of *P. aeruginosa*. Although there is concern regarding arthropathies occurring in growing children who receive this antibiotic, accumulating evidence suggests that this concern may be more theoretical than real.[510] Resistance may develop quite rapidly.

High doses of antimicrobials may be needed to achieve a therapeutic effect in patients with CF. Increased nonrenal clearance, decreased tubular reabsorption, and increased renal tubular secretion all play a role in this regard.[511] Thus serum aminoglycoside levels should be monitored to ensure that therapeutic levels of these compounds are achieved.[512] Some investigators have used aerosolized antibiotics with intravenous antibiotics as suppressive therapy in an outpatient setting in patients with CF who are chronically colonized with *P. aeruginosa*. In this regard, therapy with aerosolized aminoglycosides, antipseudomonal penicillins, and ceftazidime has been attempted with some success as measured by improved pulmonary function and decreased need for hospitalization.

The prognosis depends largely on the underlying disease process. Most deaths in children with CF are from progressive pulmonary insufficiency; in almost all of these patients, *P. aeruginosa* is recoverable from the lungs. In other patients, *P. aeruginosa* pneumonia in association with bacteremia may follow an aggressive clinical course, with death ensuing shortly after onset.

In cases of ventilator-associated pneumonia in which *P. aeruginosa* is the major cause, the duration of intubation has increased the risk by a mean threefold; ventilator-associated pneumonia contributes to 60% of infection-related hospital

deaths.[504] Reported mortality rates from *P. aeruginosa* pneumonia have varied widely but may be as high as 90%.[513]

SALMONELLA *SPECIES*

Bacteria of the genus *Salmonella* are gram-negative, aerobic, enteric organisms. Numerous attempts have been made to order the complex taxonomy of *Salmonella* species. More than 2460 *Salmonella* serotypes exist. It is still useful to divide *Salmonella* on clinical grounds into typhoidal and nontyphoidal strains. Typhoid fever continues to be a global health problem, although great progress has been made in controlling this problem in the United States and many other countries. In contrast, the incidence of invasive nontyphoidal *Salmonella* infections is on the increase in the United States. Transmission to humans from contaminated food, either from animal colonization or during processing, continues to be the most important mode of spread. In addition, the severity of *Salmonella* infections in adults and children with impaired immune systems, particularly as a consequence of HIV infection,[514,515] has been increasing.

Despite the importance of typhoid fever as a childhood health problem in developing countries, *Salmonella typhi* is seldom implicated as a cause of pneumonia,[516] even though a dry cough occurs in many patients with typhoid fever. Indeed, when a pulmonary infiltrate is recognized during the course of typhoid fever, another, supervening bacterium is most often the etiologic factor.[517] Nontyphoidal *Salmonella* species rarely cause childhood pneumonia; the pathogenesis is most often believed to be a consequence of seeding of the lung during bacteremia. Gastroenteritis may be absent.[518] No particular *Salmonella* serotype has been implicated in *Salmonella* pneumonia; many, including *S. choleraesuis*, *S. typhimurium*, *S. oranienburg*, *S. paratyphi*, *S. stanley*, and *S. suipestifer*, have been isolated from lungs and empyema fluid.[283]

Pulmonary involvement by nontyphoidal *Salmonella* species has been manifested as several infectious syndromes. Radiographically, bronchopneumonia, lobar consolidation, miliary lesions, pleural effusion (empyema),[283] lung abscess, and bronchopleural fistula have all been reported.[519] Pulmonary involvement by *Salmonella* species may also reflect transdiaphragmatic spread from a splenic abscess. Pericarditis has also been reported as a complication.[283]

The treatment of *Salmonella* infection, typhoidal and nontyphoidal, has been a subject of controversy. Currently, antimicrobials are not routinely recommended in instances of uncomplicated *Salmonella* gastroenteritis because the disease is self-limited; therapy does not shorten the course, and antimicrobial use may encourage resistance. A possible exception is in young infants, in whom extraintestinal complications are relatively common. Antimicrobial therapy is always indicated for typhoid fever or when extraintestinal infection is suspected or proved. Antimicrobial resistance has been a major problem that reflects in part the human-to-animal transmission of many *Salmonella* strains and the use of antibiotics in livestock feed as well as injudicious antibiotic use by physicians and patients. In addition, some compounds to which *Salmonella* species are often susceptible in vitro (such as aminoglycosides) may not perform well in vivo, perhaps because the organisms are pathogens that gain access to the intracellular milieu as an early step in the pathogenesis. Thus, selection of an antimicrobial involves a decision as to whether any treatment is necessary as well as knowledge regarding the susceptibility of the infecting isolate. Useful compounds with good therapeutic effectiveness when the isolate is susceptible include ampicillin, chloramphenicol, and extended-spectrum cephalosporins such as ceftriaxone and cefotaxime. A 14-day course is sufficient to manage uncomplicated pneumonia, but empyema and lung abscess may require a longer course.

SERRATIA MARCESCENS

The genus *Serratia* contains many named species, but only one, *Serratia marcescens*, is associated with human disease. The organism is a gram-negative aerobe and may cause childhood pneumonia, particularly in patients with compromised immunologic integrity in the nosocomial setting.[520,521] *Serratia* organisms are now recognized as important but relatively infrequent causes of hospital-acquired infections, including pneumonia, bacteremia, urinary tract infections, and surgical wound infections. Most are associated with intravenous, intraperitoneal, or urinary tract catheterization and instrumentation of the urinary or respiratory tracts.

The clinical features of *Serratia* pneumonia are not specific. Exceptions are pseudohemoptysis and red sputum secondary to the production of prodigiosin (a red pigment made by some *S. marcescens* strains). This is a dramatic clinical sign but in the authors' experience is seldom present. Radiographically, *S. marcescens* typically appears as confluent or patchy infiltrates; cavitation is usual, and a pleural effusion may be present.[282,520]

S. marcescens may be resistant to a variety of antimicrobials, perhaps because of its hospital habitat. Extended-spectrum cephalosporins (ceftriaxone or cefotaxime) may be useful; these are typically combined with an aminoglycoside.

Local complications include empyema and lung abscess. Concomitant pneumonia and bacteremia caused by *S. marcescens* may lead to distant, infectious complications.

SPIRILLUM MINUS *AND* STREPTOBACILLUS MONILIFORMIS *(RAT-BITE FEVER)*

Rat-bite fever, a rare, febrile illness, follows a bite from a rat or another small rodent.[522] Although rat-bite fever has been recognized for many centuries, Wilcox[523] published the first account of it in 1839.

Streptobacillus moniliformis is a microaerophilic, gram-negative pleomorphic bacillus transmitted by a bite or scratch from rodents (such as rats, mice, or squirrels) or carnivores that prey on them (such as dogs, pigs, ferrets, cats, or weasels). Oral ingestion by drinking of milk or eating of food products contaminated by an infected animal has been associated with erythema arthriticum epidemicum (Haverhill fever), an illness resembling rat-bite fever. The incubation period ranges from 1 to 22 days but usually lasts less than 10 days.

Clinical manifestations include the bite (which heals quickly), fever, vomiting, severe headache, and chills. A blotchy, irregular, maculopapular rash usually occurs 1 to 8 days after the onset of the fever and can be found over the extensor and lateral surfaces, most prominently over the joints. The rash may last from 1 to 21 days; it may become purpuric and, ultimately desquamate. Migratory arthritis and arthralgias are common. Polyarthritis or true septic arthritis

may ensue. The fever spontaneously subsides but may relapse for weeks or months; arthritis may persist for up to 2 years. Focal infections may be manifested as endocarditis, pericarditis, and meningitis.[524,525] Pneumonia is rarely recognized in children or adults, although an interstitial pneumonitis was appreciated at the postmortem examination of a 2-year-old child who died of *S. moniliformis* infection.

Diagnosis is aided by a history of animal contact or other close-contact cases. Direct visualization of typical pleomorphic bacilli by material from an infectious site that is stained with Gram or Giemsa stain may provide a diagnostic clue. *S. moniliformis* may be isolated by the culture of blood or wound lesion material. Because the organism is fastidious, the laboratory should be notified that *S. moniliformis* is suspected. Rapid identification is possible by gas-liquid chromatography of washed growth from 24-hour broth cultures.[526] Specific agglutinins appear within 10 days of the onset of clinical symptoms and persist for several months. A fourfold rise in the titer or a single titer higher than 1:80 is considered diagnostic. False-positive, nontreponemal tests for syphilis have been described in patients with rat-bite fever.[527]

Treatment is with intravenous penicillin G. A 7- to 14-day course is typical. The last 5 to 7 days can be completed with oral phenoxymethyl penicillin. For penicillin-allergic patients, erythromycin, chloramphenicol, or streptomycin may be substituted. Tetracycline is another alternative for children older than 9 years of age.

Before the advent of penicillin treatment, the mortality rate for *S. moniliformis* rate-bite fever was about 10%. Death is still a possible outcome, particularly if the diagnosis is not considered as a cause of the pneumonia.

STREPTOCOCCUS PYOGENES *(GROUP A STREPTOCOCCI)*

Despite its continued importance as the major cause of bacterial pharyngitis and many other infectious syndromes in children, *Streptococcus pyogenes* is a rare cause of pneumonia. When it does occur, however, the necrotizing nature of pneumonia caused by this organism often makes the clinical course rapidly progressive, severe, and protracted—even when antimicrobial therapy is promptly initiated.

The organism, group A β-hemolytic streptococcus, also called *S. pyogenes*, is gram-positive and has a slimy, hyaluronic acid capsule. Among the determinants of virulence are M protein, pyrogenic exotoxins, C5a peptidase, hyaluronidase, streptolysins S and O, and streptokinase. M protein is a major virulence factor, partly because of its antiphagocytic activity. Anti-M antibody is opsonic and contributes to the bactericidal activity of blood. There are more than 80 distinct antigenic M protein types[528]; three types—1, 3, and 18—are more likely to be associated with invasive disease.[529] Lipoteichoic acid is the basic chemical component of hairlike fimbriae that protrude through the hyaluronic acid capsule and mediate the adherence of group A streptococci to epithelial cells.[530]

S. pyogenes makes many extracellular products that are important to its virulence. One such product is streptolysin O, an oxygen-labile hemolysin that targets bronchiolar macrophages and is useful in the diagnosis of group A streptococcal infection because of its immunogenicity. Streptolysin S is a hemolysin that injures the cell membranes of a variety of cells (including those of the myocardium),[531] but it is not immunogenic. In addition, four deoxyribonucleases (DNAses)—A, B, C, and D—are elaborated; hyaluronidase, streptokinase, proteinases, amylases; esterases are also produced. These last products facilitate the liquidation of pus and the spread of streptococcus through tissues. In addition, considerable attention has recently been given to a family of molecules produced by group A streptococci called *streptococcal pyrogenic exotoxins*. In the older literature, these have been called *erythrogenic* and *scarlet fever toxins*. Streptococcal pyrogenic exotoxin-A can maximally stimulate the production of tumor necrosis factor-α by peripheral monocytes, which with interleukin-1β, contributes to the pathogenesis of shock and tissue injury.

Before the advent of antibiotics, group A streptococcal pneumonia accounted for 3% to 25% of childhood bacterial pneumonia and had a mortality rate of 75% to 90%.[532] Epidemic pneumonia occurred in military adolescents in the early part of the century[533] and in the 1960s.[534] Many believe that certain antecedent viral illnesses predispose to group A streptococcal pneumonia.[535] Few specific data have been gathered by modern epidemiologic techniques, but the recognition that epidemics of influenza, measles, and varicella have occurred with group A streptococcal outbreaks would seem to support this anecdotal association.[535] The incidence of streptococcal pneumonia increases after 5 years of age into adolescence.[535] The peak incidence is in winter; most cases occur from late autumn through early spring.

Streptococcal pneumonia is usually acquired by the inhalational route but may also arise from secondary seeding from a bacteremic focus.[536] There are two distribution patterns: Most patients have a patchy, interstitial bronchopneumonia, whereas about one fourth have a lobar pattern.[533] Histologically, the lungs have thickened bronchiolar walls, necrosis of the mucosal lining[535] with formation of ragged ulcers, purulent engorgement of the lymphatic system, and microabscesses that can rupture into the pleura. Pleural effusion is usually present; it is serous initially but may become serosanguineous with rapid progression to fibrinopurulence.

Most children are ill for 2 to 3 days before experiencing an abrupt progression of the symptoms associated with respiratory compromise. Fever, chills, lethargy, myalgia, dyspnea, cough, pleuritic chest pain, and hemoptysis are common presenting complaints.[535] Weight loss is typical and may be profound. About one third of children have an associated streptococcal pharyngitis. Rarely, group A streptococcal pneumonia may be associated with purpura fulminans[537] or streptococcal toxic shock syndrome.[538]

The diagnosis is made by recovery of the causative organism from the lung, pleural fluid, or blood. Suggestive evidence allowing a presumptive diagnosis includes recovery of the organism from the oropharynx or sputum. Serologic diagnosis includes demonstration of a rising titer against a relevant streptococcal antigen. Included in this regard are antistreptolysin-O, antihyaluronidase, and anti-DNAse B. The detection of antibody to streptokinase and anti-DNAase A may also be of use, but these tests are not performed by many laboratories. The Streptozyme test may also be useful for detecting antibodies to streptococcal "extracellular products," but it is less specific. Leukocytosis is variably present; mild to moderate anemia may reflect intrapleural blood

loss. Radiographically, group A streptococcal pneumonia is manifested as a patchy bronchopneumonia or lobar pattern with frequent cavitation, parapneumonic effusion, and empyema.[537]

Treatment consists of intravenous penicillin G at a high dose. Resistance has not yet been recognized. A 2- to 4-week course is usual, and the medication may be given orally after satisfactory clinical improvement. Despite the susceptibility of the causative organism to penicillin, the resolution of pneumonia may be slow; fever and pleuritic chest pain may persist for 8 to 10 days.[535]

Pulmonary complications include pneumothorax, pneumatocele, bronchiectasis, persistent atelectasis, and bronchopulmonary fistula.[536] Pleural effusions may be copious in volume and average 100 to 150 mL/day in infants and considerably more in adults.[535] Empyema occurs in a high number of cases.[537] The fluid may be tenacious, and drainage may be difficult[535]; thus, surgical drainage or decortication may be required.[539] Pericarditis has been reported in about 10% of children.[535]

Other Streptococcal Species

Pneumonia may occasionally be caused by viridans streptococci, nutritionally deficient streptococci, the *S. intermedius* or *Streptococcus milleri* group, or β-hemolytic streptococci groups C and G. The taxonomy of these organisms has been imprecise and controversial. Viridans streptococci possess general characteristics of all streptococci. When cultivated on blood agar, they characteristically produce a zone of greening, so-called *α-hemolysis*, which is a phenomenon reflecting partial hemolysis. They are distinguished from pneumococci, many enterococci, and nonenterococcal group D streptococci by their resistance to optochin and inhibition of growth in 6.5% sodium chloride. Some viridans streptococci react with Lancefield grouping antisera, but many isolates cannot be grouped. Clinically important species belonging to the viridans group include *Streptococcus anginosus*, *S. constellatus*, *S. crista*, *S. gordonii*, *S. mitis*, *S. mutans*, *S. oralis*, *S. parasanguis*, *S. salivarius*, *S. sanguis*, *S. sobrinus*, and *S. vestibularis*.

The viridans streptococci (including the nutritionally deficient streptococci) and the *S. intermedius/S. milleri* group are endogenous flora and are normally carried in the upper respiratory tract, particularly the oropharynx (gingival crevices, dental plaque, teeth surfaces), intestinal tract, female genital tract, and skin. Groups C and G streptococci have been identified as constituents of the normal flora of the nasopharynx, skin, and genital tract. Group C organisms have also been isolated from the umbilical surface of healthy newborns and from vaginal cultures of puerperal women. Group G organisms have also been found in the intestinal tract.

Viridans streptococci are rarely proved to be the cause of pneumonia in adults and children. In a few adults[540-542] and children,[543] they have been isolated from the blood during a clinical illness consistent with bacterial pneumonia. In a Canadian study of 1118 patients with pneumonia, 76 of whom were bacteremic, 7 (9%) of the 76 bacteremic patients had viridans streptococci isolated from the blood.[544] Some of these isolates may, of course, have represented procedural contaminants. More commonly, invasive viridans group infection results in bacteremia or endocarditis. Nongroup D α-hemolytic organisms have been implicated as a cause of neonatal sepsis.[545] Identifying viridans streptococci as a more frequent cause of pneumonia has been difficult, partly because of their presence among the normal flora and because of their susceptibility to many antimicrobials used to treat presumed bacterial pneumonias. It is possible that they have a greater role in the pathogenesis of pneumonias associated with aspiration, but even in this situation, they are usually recovered with other microorganisms, particularly anaerobes. This fact further complicates the understanding of their role. It has even been suggested that the pathogenicity of the *S. intermedius/S. milleri* group in the lung might be related to synergy with an anaerobic organism.[546]

Members of the *S. intermedius/S. milleri* group are also infrequently implicated as etiologic agents in patients with pneumonia. In a review of *S. milleri* infections in 51 adults, no cases of pneumonia were identified, although 8 cases of pleural empyema occurred.[547] Among 186 patients with *S. milleri* infection in New Zealand, 12% of the infections were of pleuropulmonary origin.[548] *S. milleri* has also been reported as a cause of neonatal sepsis.[549,550] In this instance, the organism may be acquired antenatally from the maternal vaginal tract or during the birthing process.[551]

Group C streptococcus is an uncommon cause of pneumonia, but the clinical picture may be severe and may resemble that of pneumonia caused by group A streptococci.[552] The pneumonia is usually lobar, with associated bacteremia occurring in most cases. Group G streptococcus is also a rare cause of pneumonia that occurs in both immunologically normal and immunocompromised patients.

The diagnosis is usually based on recovery of the organism from a culture of blood, sputum, abscess, or pleural fluid. In one review of viridans pneumonia in adults, the chest radiographs were not distinctive: A segmental alveolar opacity was the most common abnormal finding.[180] In a separate report, radiographs of four cases of community-acquired viridans pneumonia in South Africa demonstrated a segmental or subsegmental consolidation, which appeared "mass-like" in two of four patients.[553]

The organisms are usually susceptible to many antibiotics, including penicillins, cephalosporins, clindamycin, and vancomycin. In the neonate, ampicillin and gentamicin are effective. In the child allergic to penicillin, erythromycin may be used.[554] Group C streptococcal pneumonia has been treated with penicillin G; however, because few cases have been well documented, information about the performance of other compounds is limited.

Empyema and lung abscess are common with viridans pneumonia and may require drainage for effective treatment. Complications of group C streptococcal infection include metastatic infectious foci, empyema, and intraparenchymal cavitation.

In adults, the mortality rate reported was 28% in one study[180] and 26% in another.[555] In neonates, the mortality rate from viridans streptococci infection appears to be lower than that from GBS infection.

YERSINIA *SPECIES*

Several species of *Yersinia* organisms—*Yersinia enterocolitica*, *Y. pseudotuberculosis*, and *Y. pestis*—can cause disease in humans. The most important species, particularly regarding

pneumonia, is *Y. pestis*, the cause of plague. The organism, a gram-negative, nonmotile coccobacillus,[363] was first identified in 1894 by Alexandre Yersin during an epidemic in Hong Kong[556] and was named *Pasteurella pestis* to honor his teacher, Louis Pasteur; it was subsequently renamed *Y. pestis* to honor Dr. Yersin. The disease has played a prominent role in world history since the start of civilization. In the United States, however, cases in crowded, urban settings have disappeared, with the last known urban plague occurring in Los Angeles between 1924 and 1925.[363,557]

Plague occurs worldwide. It has been suggested that there is a decreased incidence of human plague in the past several years.[558] Most human cases have been reported in developing countries, especially in South America, Asia, and Africa.

In the United States, human plague is infrequent but more than one half of the cases occur in children.[559] Most cases occur in the southwestern states.[559-562] Plague is maintained in well-established foci among the wild rodent population.[363] Worldwide, more than 200 species of mammals and 80 species of fleas have been implicated in keeping *Y. pestis* in enzootic foci.[563]

Y. pestis multiplies in the esophagus of the flea and is regurgitated when the flea sucks blood. Once it gains access to the human host, the bacterium may multiply intracellularly and spread from the lesion to the regional lymph nodes, with bacteremia following 5 to 10 days later.

Plague has been classified clinically into the following syndromes: bubonic, septicemic, pneumonic, and meningitic. The term *pneumonic plague* indicates the presence of pneumonitis. The lung may become infected by two routes. Inhalation of the organism from an infected person or animal, such as a cat,[564,565] produces primary pneumonia, which is rare. Secondary pneumonic plague, in which the lung is seeded during bacteremia, is more frequent; it usually represents bloodstream invasion from an infected lymph node or bubo.[566]

Primary pneumonic plague has a short incubation period (≤3 days). Clinical features include cough, chest pain, bloody sputum, high fever, and chills.[567] In addition, nausea, vomiting, diarrhea, and abdominal pain may be present. In children, encephalopathy may be present and is characterized by lethargy, ataxia, and confusion.[566] The course may be fulminant.

The diagnosis is suggested by the demonstration of typical, gram-negative, bipolar, safety pin–shaped coccobacilli in the sputum. When available, sputum is the specimen of highest yield.[558] A smear and culture of a bubo aspirate or other relevant body fluid and a blood culture may be useful. A fluorescent antibody test is available in some laboratories[363] and can be performed directly on clinical specimens. Confirmation by culture should be obtained, but definitive identification may require input from the Plague Branch of the CDC in Fort Collins, Colorado, where a passive hemagglutination serology test is available; a fourfold rise or a single titer higher than 1:16 is diagnostic.[567]

The antimicrobial agent of choice is streptomycin. Other aminoglycosides said to be effective include gentamicin and kanamycin.[363] Tetracycline, doxycycline, chloramphenicol, trimethoprim-sulfamethoxazole, and ciprofloxacin are effective alternatives.[363] TMP/SMX is less effective than streptomycin.[568] Chloramphenicol should be used when meningitis or endophthalmitis is present.

A child with plague should be placed into respiratory isolation. If pulmonary involvement is documented, precautions may be discontinued when 48 hours of antibiotic therapy have been administered.[363,559,567]

If the condition is untreated, the mortality rate in patients with pulmonary plague is 100%.[567] Survival is rare when treatment is not initiated within 18 to 24 hours after the onset of clinical symptoms. However, with appropriate and timely antibiotic therapy, the condition usually improves within 24 to 48 hours. In reviewed cases of pneumonic plague from 1970 to 1995, the case fatality rate was 40%.

A formalin-killed vaccine is available in the United States and is recommended for laboratory personnel working with *Y. pestis*, people who are exposed to materials or animals with possible infection, isolated park or forest rangers, or wildlife workers. In addition, people traveling to epidemic or hyperendemic areas are possible candidates for immunization.[363] Vaccine-induced immunity is short-lived and probably wanes after 6 months, so reinoculation is recommended.[569,570] There are no recommendations for the use of this vaccine in children.

Prophylactic agents should be given to people exposed to a patient who has pneumonic plague.[363] For children younger than 8 years of age, TMP/SMX is usually recommended.[567] For older people, doxycycline or ciprofloxacin is recommended.

Y. enterocolitica is widely distributed in nature and is isolated from animals, particularly pigs, horses, and dogs. It typically causes acute gastroenteritis and enterocolitis[282] and is a rare cause of pneumonia in both immunocompetent and immunocompromised patients.[571] Its epidemiology is obscure. Radiographically, hilar adenopathy may be the only finding,[282] although fluffy infiltrates, consolidations, or nodules may be evident. The organism is susceptible to streptomycin, chloramphenicol, tetracycline,[282] TMP/SMX, aminoglycosides, extended-spectrum cephalosporins, and quinolones.[572] There is no clear therapy of choice. Necrotizing *Y. enterocolitica* pneumonia in an immunocompromised adult was successfully treated with an extended-spectrum cephalosporin for 6 weeks,[573] and a child was treated with cefuroxime followed by TMP/SMX.[572] Complications of *Y. enterocolitica* pneumonia have included lung abscess, empyema,[572] and erythema nodosum as part of a sarcoid-like syndrome with hilar adenopathy.[282]

LUNG ABSCESS

A lung abscess is an accumulation of inflammatory cells, especially polymorphonuclear leukocytes, accompanied by tissue destruction or necrosis that produces one or more large cavities in the lung. It is probably arbitrary to designate larger cavities by the term *lung abscesses*, and smaller, multiple cavities with similar histologic appearance by the term *necrotizing pneumonia*. However, because a lung abscess has distinctive pathophysiologic and clinical features, it will be considered separately here.

Lung abscess is unusual in children. Among 230,325 consecutive admissions to Children's Memorial Hospital in

Chicago from 1985 to 1990, only 28 children had a discharge diagnosis of lung abscess—a rate of 1 case per 8226 admissions.[574]

Some authors classify a lung abscess according to whether it occurred in a patient with no underlying disorder (primary) or in a patient with an underlying or predisposing condition (secondary).[575-577] We have not found this distinction clinically helpful. Rather, consideration of the relevant pathogenesis of a lung abscess provides a more useful consideration for the approach to diagnosis and therapy.

Pathophysiology

Aspiration is the most important factor predisposing a child to lung abscess. Therefore children who have relevant conditions (e.g., achalasia, chronic neurologic conditions) are at increased risk. Aspiration alone, however, is not sufficient to cause lung abscess because all children and adults aspirate daily to some degree. It is likely that the number of aspirations, the volume of the aspirated material, and any impairment of normal respiratory tract clearance mechanisms of aspirated material contribute to the likelihood of abscess formation. The most common sites of lung abscess formation are the most frequent destinations of aspirated material (i.e., those most dependent in the recumbent position: the right and left upper lobes and the apical segments of both lower lobes). If periodontal disease is present, the potential for lower respiratory tract infections with aspiration is increased because these children have more oropharyngeal organisms.

After a known aspiration event has occurred, it takes several days for an abscess to develop and for signs and symptoms to occur.[578] The localized inflammatory process that constitutes the host response to the aspirated material may paradoxically induce a delay in healing by mechanically obstructing the vascular supply to the area. The result may, therefore, be an inability to physiologically drain the affected area and to transport other defense mediators to the region. Tissue necrosis may ensue, with the dead tissue forming a spherical cavity bounded by a fibrous wall. Such a walled-off cavity may then lead to a large solitary lung abscess or small regions of necrosis with or without air-fluid levels.

A single abscess is clinically recognized more frequently than multiple abscesses. An abscess may vary from a few millimeters to 5 to 6 cm in diameter. After cavitation has occurred, a putrid oral discharge may be noted in more than 50% of children. This discharge is often copious, fetid, and green-black (hence the name *gangrene of the lung*).[579]

Other predisposing factors may also place a patient at risk for lung abscess. For example, a lung abscess may evolve from untreated pneumonia that progresses to abscess formation or from antecedent bronchiectasis; alternatively, a subdiaphragmatic, intra-abdominal infection may extend into the lung or pleural space via the lymphatic system.[578] Recently, epidemic community-associated MRSA disease including pneumonia with multiple pneumatoceles or abscesses has been described in pediatric patients.[183] A lung abscess may also result from airway obstruction by a foreign body, an enlarged mediastinal lymph node, or a neoplastic mass. It may occur with infection in a congenitally abnormal lung (e.g., sequestration, lung cysts). Although rare in children, a lung abscess may result from extension of a parapharyngeal abscess. Seeding of the lung by a septic embolus from bacterial endocarditis (usually right sided in origin), a distant suppurative thrombophlebitis as has occurred in some community-associated MRSA infections, or seeding of the lung during any bacteremia may also occur. In these instances, multiple small abscesses or cavities may be present in the lung, even though the initial lesion may appear to involve only a single lobe. Seeding of other lobes may have occurred but may not become clinically apparent until later.[578]

Clinical Features

The clinical spectrum of illness in children with lung abscess is variable and often indistinct from related pulmonary infectious syndromes such as pneumonia. Tan and coworkers[575] summarized the symptoms and signs of 45 children with lung abscess of varying pathogeneses; only fever (84%) and cough (53%) occurred in the majority of the patients. Other symptoms and signs included dyspnea (35%), chest pain (24%), anorexia (20%), production of "purulent" sputum (18%), rhinorrhea (16%), and malaise and lethargy (11%). Infrequently, diarrhea, vomiting, or irritability may be present. Minor hemoptysis is common in adults but may be life-threatening in children.[580] The course of a lung abscess before medical intervention may be surprisingly indolent and may last several weeks. Weight loss may occur. Conversely, the clinical course is occasionally more aggressive; apnea and hypotension may be present.[578]

The physical findings in children with lung abscess resemble those found in early pneumonia and include tachypnea and audible crackles on auscultation. If the abscess persisted for a time before medical intervention, amphoric or cavernous breath sounds may be evident. Digital clubbing is rare.[581]

Laboratory findings are not specific. White blood cell counts range from 14,000 to 23,000/mm^3.[575] Mild anemia may be present.

The diagnosis of lung abscess is often suggested by a chest radiograph in which an abscess appears as a thick-walled cavity with an air-fluid level (Fig. 35-11). Initially, however, the lung abscess appears as a solid lesion within the parenchyma, most often surrounded by an alveolar infiltrate. At this stage, the chest radiograph may be misleading (Fig. 35-12) because the abscess may appear as a solid mass and may be indistinguishable from the surrounding infiltrate or from a concomitant pleural effusion or an empyema; gas may be absent. Particularly at this stage, an abscess must be distinguished from a loculated empyema and a pneumatocele. The latter have thin walls and do not contain air-fluid levels.[582] Suspicion of an abscess may arise when the "consolidation" is unusually persistent, when "pneumonia" remains persistently round or mass-like, or when a bulging fissure representing increased volume of the involved lobe is present.[583]

Gas may be present in an abscess as a result of bacterial metabolism by gas-forming organisms or as a result of a communication with a bronchus. Once gas is present within the abscess cavity, its appearance by radiography is characterized

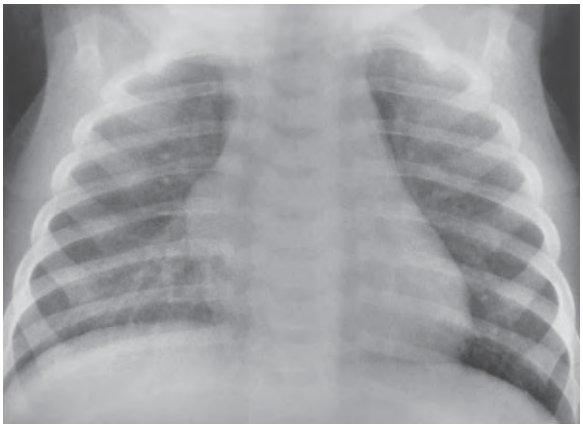
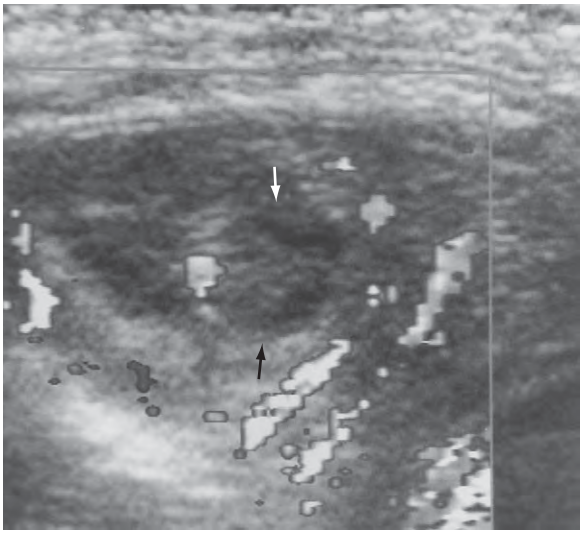
Figure 35-11 Lung abscess in a 2-week-old boy with a cavitary lesion in the left side of the chest. A, Supine anteroposterior chest radiograph demonstrates a large cavity in the left lower lobe, causing a mediastinal shift to the right. **B,** Left side-down decubitus film shows a large air-filled level within the cavity.



A



B

Figure 35-12 Occult lung abscess. Pneumonia in the right middle lobe in an 18-month-old boy did not respond to antibiotic therapy as expected. **A,** Chest radiograph demonstrates a straightforward pleuropneumonia in the right middle lobe without volume expansion or an air-containing cavity. **B,** Sonography demonstrates a mostly avascular hypoechoic lesion within the consolidation (*arrows*). Black-and-white rendering of a color Doppler examination of the infiltrate demonstrates pulmonary vessels supplying the lung around the abscess and a still-vascular nodule within the abscess.

by irregular, thick walls; air-fluid levels may be multiple and are optimally demonstrated when the radiographs are taken with a horizontal beam (upright or decubitus cross-table). Mediastinal adenopathy sometimes accompanies the parenchymal infection and may also be evident on the chest radiograph.[584]

Lung abscesses may occur at any site. A review of several series of children with lung abscesses suggested that occurrence in the right lung was more frequent (about 70%) and that although any lobe may be involved, the upper, middle, and lower lobes accounted for about 40%, 20%, and 40%, respectively, of right-sided lung abscess in children.[574,575,577] As noted, the location of a lung abscess may provide a clue as to pathogenesis. For example, abscesses resulting from septic embolic events tend to be multiple and more diffusely situated than the solitary abscess secondary to aspiration, which is often situated in the right upper or lower lobe.

Diagnosis

Contrast-enhanced CT may aid the clinician in localizing an abscess and in distinguishing it from empyema, pneumatocele, bronchopleural fistula, congenital anomalies (such as bronchogenic and duplication cysts), pulmonary sequestration, or rarely, persistent pneumonia (Fig. 35-13).[583] CT is also used to guide diagnostic and therapeutic drainage procedures.[583] The classic findings of a lung abscess by this modality include a thick, ragged wall; central fluid; acute angle with the chest wall; and surrounding parenchymal consolidation. An air-fluid level may be seen even when it is not apparent on the plain radiograph. Helpful features that distinguish abscess from other entities include the well-marginated nature of the abscess mass, distinction between it and the pleura, greater density of the abscess than of water, and contrast enhancement in adjacent tissues. Bolus contrast injection may demonstrate pulmonary vascular branches in

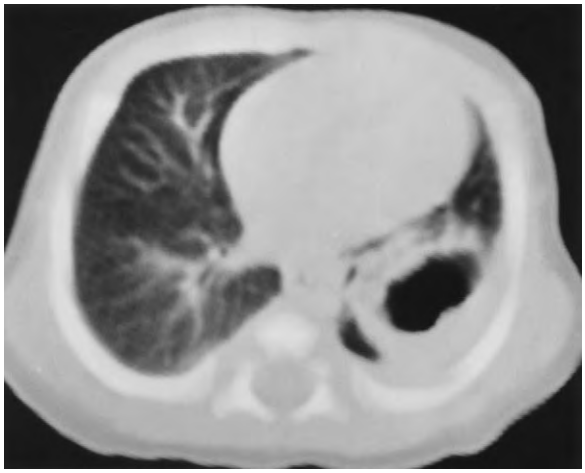


Figure 35-13 CT scan of a lung abscess. The cavity has thick, irregular walls and an acute angle with the chest wall—features typical of a lung abscess. A sonographically-guided fluid aspiration yielded pus. The lesion healed without further intervention.

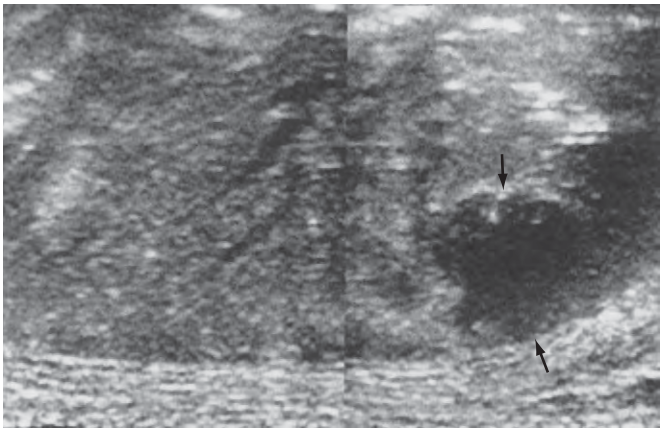

Figure 35-14 Sonography of lung abscess. An irregular cavity (*arrows*) with irregular walls, an acute angle with the chest wall, a hypoechoic center, and an absence of separation of pleural layers characterize this lung abscess in a 3-year-old girl who developed fever, cough, and a persistent infiltrate in the left lower lobe after trauma.

the territory of an equivocal lesion and thereby reveals its pulmonary rather than its pleural origins.[85] Occasionally, an abscess may rupture into the pleural cavity and result in a combined lesion with CT features of both pleural and pulmonary pathology.

Sonography is also a valuable tool, particularly in patients in emergency situations and in critically ill patients in whom the abscess abuts the chest wall, diaphragm, or mediastinum and thereby provides an acoustic window. With this technique, a lung abscess has a thick, irregular wall with a blurred outer margin and an oval or round shape. It forms an acute angle with the chest wall, and pleural layers are absent.[585] Color and spectral Doppler may allow demonstration of the abscess within the territory supplied by the pulmonary artery. However, any long-standing inflammatory process in the lung, including an abscess, may parasitize the blood supply from the chest wall; thus, the abscess may be supplied by the intercostal and bronchial arteries. A lung abscess may possess an avascular hypoechoic center even before it contains air. If the abscess is adherent to the chest wall, real-time sonography shows absence of gliding against the chest wall (Fig. 35-14). A lung abscess was identified by technetium-99m white blood cell scintigraphy[582] in a patient in whom this diagnosis was not suspected.

Defining the bacteriologic diagnosis of a lung abscess in children poses some practical problems; bacteremia is infrequent.[586] Material for culture from the abscess cavity itself is usually not obtained because of the procedure's invasive nature. Sputum cannot usually be obtained from young children, and even when available, sputum culture may reflect pharyngeal flora. Diagnostic evaluation of a concomitant pleural effusion associated with a lung abscess may provide an opportunity to isolate the causative organism.

Diagnostic needle aspiration of a lung abscess depends on accessibility of the abscess and a size sufficient to allow procurement of an adequate specimen. It is often performed with ultrasound or CT guidance. Both the sensitivity and the specificity of this procedure are high, although the procedure is not without risk.[587] Among six studies using needle aspiration for diagnosis, 24 complications occurred among 800 children, 2 of which were serious (pneumothorax).[588]

Useful information may be obtained from needle aspiration of a lung abscess when it is performed in appropriately selected cases. Among 35 consecutive patients in Taiwan with lung abscess (31 adults, 3 adolescents, and 1 child), needle aspiration was successfully performed in 33.[589] Two patients developed a pneumothorax of minor clinical importance. One or more microorganisms were recovered from 31 of the 33 patients, many of whom were receiving antibiotics. In contrast, the offending pathogen was recovered from only 3% of blood cultures, 11% of sputum cultures, and 3.1% of alveolar lavage fluid cultures.

Transtracheal aspiration, a procedure once commonly used to obtain material in adults for the etiologic diagnosis of lung abscess, is unsuitable in small children for technical reasons and may not yield the offending pathogens. BAL in adults has compared favorably with transtracheal aspiration for identifying aerobic and anaerobic organisms.[590] However, no data are available regarding this modality in the diagnosis of lung abscess in children.

Etiology

Because the techniques required to obtain material for culture are often invasive, only a subset of patients with lung abscesses are subjected to such procedures; therefore, published information regarding the etiology may reflect selection bias. Nevertheless, it seems reasonable to conclude that the organisms causing lung abscess secondary to aspiration are generally those normally inhabiting the upper respiratory tract. Thus, anaerobes are often implicated in the etiology of lung abscess. Important clues that suggest anaerobic lung infection are observed aspiration, disease in a dependent segment, cavitation or abscess formation with or without empyema, and foul-smelling sputum. Anaerobes, either alone or with aerobes, have been recovered from about 30% of adults with lung abscesses.[591] In one study of children with lung abscess, anaerobes were identified by transtracheal aspiration in all

10.[592] The most common anaerobic isolates were gram-positive cocci, pigmented *Prevotella* species, members of the *Porphyromonas* group, and *Fusobacterium* species. The predominant aerobic bacterial isolates were α-hemolytic streptococci, *E. coli*, *K. pneumoniae*, *S. pyogenes*, *P. aeruginosa*, and *S. pneumoniae*. *S. aureus* has also been implicated as a cause of lung abscesses, especially when they are multiple or believed to occur as an embolic complication of an intravascular infection, such as endocarditis or septic thrombophlebitis. In addition, many other bacterial species have occasionally been isolated from lung abscesses. *Mycobacterium fortuitum* may cause lung abscess.[593] *Arcanobacterium hemolyticum* was identified as a cause of lung abscess in a child, and it was also isolated from expectorated sputum and from material obtained from bronchoscopy in an otherwise healthy, immunologically normal adolescent.[594] In immunodeficient patients or those receiving immunosuppressive therapy, *Alcaligenes xylosoxidans*[595] and *Pseudallescheria boydii*[596] have been isolated. *Selenomonas artemidis*[597] was isolated from a patient with lung abscess and tuberculosis. Community-acquired *Lactobacillus casei (L. rhamnosus)* has been reported as a cause of lung abscess,[598] and botryomycosis abscess has been reported as a presentation of chronic granulomatous disease.[599] *Salmonella* species have been associated with lung abscess—rarely in healthy patients but in a patient with Wegener granulomatosis.[600]

Lung abscess is rare in neonates[601]; six were found in a review of medical records spanning 20 years at Parkland Memorial Hospital and Children's Medical Center in Dallas. Predisposing factors may include congenital lung cysts or pneumonia. At one time, *S. aureus* pneumonia was an important predisposing factor and recent increases in MRSA disease may impact the epidemiology of lung abscesses again.[602] Lung abscess in this age group may also be caused by GBS, *E. coli*, and *K. pneumoniae*.[603]

Treatment

Antibiotic therapy is the mainstay of treatment; the length of therapy depends on the rate of abscess resolution, the extent of the abscess, and the severity of illness at presentation. On average, parenteral antibiotic therapy is provided for 2 to 3 weeks. Oral therapy may then be administered for 4 to 8 weeks.[575] Neonates should receive the entire course parenterally.

For the therapy of lung abscess that results from the introduction of pharyngeal flora into the lung (e.g., aspiration), penicillin has long been the front-line agent. However, presumably because of β-lactamase-producing anaerobes, some clinicians have preferred metronidazole or clindamycin in addition to penicillin in patients with lung abscesses who are critically ill.[604] Others have suggested ticarcillin or ampicillin/clavulanic acid or piperacillin/tazobactam. Care should be taken to ensure that the chosen antimicrobial regimen includes optimal coverage for *S. aureus* (both MRSA and MSSA) when a lung abscess appears to complicate a preexisting pneumonia or there is metastatic seeding from a distant focus (e.g., endocarditis, distant bone/joint disease, or intravascular focus in the pelvis). In addition to antimicrobials, physiotherapy, particularly postural drainage, is an important mainstay of therapy.

The success of medical treatment with antimicrobials and physiotherapy is related to age. The prognosis for resolution is better in children older than 10 years of age because the child may have a productive cough; thus the abscess can be physiologically drained through the larger airways.

Sometimes surgical intervention is required to provide adequate drainage for a child with a lung abscess. Indications include failure to respond to antimicrobial therapy, especially in neonates, and severity of illness (e.g., critically ill patients).[605] Newer, invasive radiologic techniques aimed at providing drainage generally approach the abscess percutaneously with the guidance of CT, ultrasonography,[583,606,607] or fluoroscopy.[608] Drainage procedures have included needle aspiration or the insertion of small-bore or Malecot or "pigtail" catheters. In many instances, these techniques have replaced more traditional, more invasive procedures. Occasionally, however, the necessity for drainage may still require operative catheter insertion or wedge resection.[609] The need for definitive lobectomy should be infrequent, although in the presence of an underlying immunodeficiency (such as Job syndrome), elective resection may be the procedure of choice[610] because the involved area may be a nidus for recurring abscesses.

Complications

A lung abscess may rupture into adjacent tissue compartments, an important complication occurring most frequently in abscesses caused by *S. aureus*. Rupture into the pleural space leads to empyema, pyothorax, or pneumothorax. Empyema may sometimes be accompanied by the formation of a bronchopleural fistula. Localized bronchiectasis may also occur as a complication. If the pathogenesis of the lung abscess was associated with bacteremia, distant metastatic foci may also be present.

Prognosis

The prognosis is good if effective therapy and close follow-up are provided and the predisposing causes can be eliminated. Asher and colleagues[577] reported that 9 of 11 patients with "primary" lung abscess (no underlying condition) had normal pulmonary function when assessed approximately 9 years after diagnosis. All these children were growing normally. Radiologic resolution may be delayed and may require more than 6 months for complete resolution.[577]

PLEURAL EMPYEMA

A pleural empyema is the presence of purulent material usually consisting of polymorphonuclear leukocytes and fibrin, in the pleural space. The pleural space is normally a theoretical one between the visceral and parietal pleura—the former covering the lung parenchyma and the latter lining the interior of the thoracic cavity. The parietal pleura is sometimes said to consist of *costal, mediastinal, and diaphragmatic* parts, descriptive terms referring to the relevant, adjacent anatomic regions.[611]

Normally, a small amount of fluid is evenly distributed in the pleural space and lubricates the movement of the visceral pleura on the parietal pleura during respiration. It was believed that this physiologic pleural fluid was a passive trans-

udate from blood; however, important differences between the composition of serum and pleural fluid suggests that this is not the case. Cells (1500 to 2400 cells/mm^3) are normally present in pleural fluid in experimental animals; the majority are mesothelial or mononuclear cells, but neutrophils may constitute 2% of the resident leukocyte population.[612]

The lymphatic vessels of the costal pleura drain ventrally to nodes along the internal thoracic artery and dorsally toward the internal intercostal lymph nodes near the insertion of the ribs. The lymphatic system of the mediastinal pleura drains to the tracheobronchial and mediastinal nodes; drainage of the diaphragmatic parietal pleura is to the parasternal, middle phrenic, and posterior mediastinal nodes. The lymphatic vessels communicate with the pleural space by means of stomas [2 to 6 nm in diameter] that are found on the mediastinal pleura and intercostal aspects of the costal pleura.

Pathophysiology

Pleural empyema is usually secondary to an infection at another site, most often pulmonary. Indeed, it occurs most commonly after infection of a parapneumonic pleural effusion, commonly present in bacterial pneumonia. Progression of such an effusion to empyema is said to have a three-stage evolution. The first stage is exudative. Antimicrobial therapy for "pneumonia" is often initiated at this stage and may abort disease progression.

The second stage is termed fibrinopurulent and is heralded by the arrival of bacteria, most often by pleural invasion from the contiguous pneumonic process. Progression occurs with neutrophil accumulation and fibrin deposition; frank pus is present, membrane formation occurs, and the developing empyema may become compartmentalized or loculated. With time, the pleural fluid pH and glucose concentration decrease, and the concentration of lactic acid dehydrogenase may increase.

The third stage is characterized by organization; fibroblasts grow into the exudate from the visceral and parietal pleural surfaces. An inelastic membrane called the *pleural peel* is formed and may encase the lung, with the potential to restrict respiration. The thick exudate may drain spontaneously through the chest wall or into the lung and produce either a pleurocutaneous or a bronchopleural fistula.

Less frequently, an empyema may occur in the absence of a parapneumonic process. For example, empyema may complicate a thoracic surgical procedure, especially pneumonectomy.[613] After the pneumonectomy, the space vacated by the procedure fills with serosanguinous fluid. By 2 weeks after surgery the pleural space is about 80% to 90% filled with fluid, and by 2 to 4 months the space is completely filled. As fluid accumulates, the mediastinum also shifts ipsilaterally to fill the vacated space. Failure of this shift to occur or a return to symmetry of the mediastinum should prompt consideration that empyema is present. The infecting bacterium may be introduced during the surgical procedure or may seed the collected fluid during a bacteremia that may be clinically inapparent. The time from surgery to identification of the empyema ranges from 8 days to 7 years, although most cases are evident within 1 month. Empyema may complicate any invasive intrathoracic procedure, such as thoracentesis, thoracotomy, or esophageal perforation.

Empyema may also be found in association with a bronchopleural fistula. The presence of such a fistula should be suspected when a child with a collection of pleural fluid produces "sputum" only when lying in one position. By radiography, a bronchopleural fistula usually has an air-fluid level in the pleural space in the upright position; CT is valuable in making this diagnosis.

Empyema may also reflect the spread of infection from an adjacent site. Such direct extension was the predisposing factor in 10% of the cases of empyema in one study.[614] Implicated in this regard were periodontal, retropharyngeal, peritonsillar, and subdiaphragmatic abscesses—as well as subcutaneous abscesses of the neck.

Clinical Features

The diagnosis of empyema may pose a clinical challenge because the clinical features of empyema (classically heralded by tachypnea, tachycardia, dyspnea, cough, irregular breathing, pleuritic chest pain, and possibly cyanosis) resemble those of uncomplicated pneumonia or pneumonia in the presence of an uninfected parapneumonic pleural effusion.[611] Inflammation of the parietal pleura, which has pain fibers, leads to the so-called *pleuritic chest pain*. Some children with pleural effusion have a dull, aching chest pain rather than pleuritic pain,[615] especially if the underlying process directly involves the parietal pleura (e.g., with a lung abscess). Pleuritic pain that is simultaneously perceived in the ipsilateral shoulder and in the lower chest is highly suggestive of a paradiaphragmatic pleural effusion.

A dry, nonproductive cough may be present. Dyspnea may be associated with a pleural effusion of any etiology. The degree of dyspnea may be out of proportion to the size of the pleural effusion and may reflect splinting caused by pleuritic chest pain. Fever, anorexia, malaise, headache, nausea, vomiting, and prostration are variably present in patients with empyema. In a very young child, signs and symptoms pointing toward an abdominal process may dominate the clinical picture; abdominal distention may be present. The absence of fever and symptomatology involving the chest does not exclude the presence of empyema, especially if the patient is debilitated or receiving immunosuppressive therapy.

The findings on physical examination may reflect the presence of empyema or any pleural effusion and include decreased chest movement, scoliosis or splinting toward the affected side, flushed face, nasal flaring, and sternal retractions. On inspection of the chest, a discrepancy in the size of the hemithorax may indicate ipsilateral increased pleural pressure on the larger side. Bulging of the intercostal spaces may be present. Conversely, a relatively small hemithorax may indicate decreased pleural pressure on the same side of the effusion. In this situation, the size of the intercostal spaces may be exaggerated and may retract with inspiratory efforts. Scoliosis may be present; in 44% of children with empyema the curvature of the spine was greater than 5 degrees.[616] Splinting may occur in an attempt to reduce tension on the inflamed pleura or as a result of contraction of the pleural lining on the affected side.

In children with pleural effusion, palpation of the chest may be helpful in determining the extent of the effusion.

Tactile fremitus is absent or attenuated in areas of the chest where the pleural fluid separates the chest wall from the lung because the fluid absorbs the lung vibrations. This sign is more reliable than percussion in identifying the upper border of the pleural fluid and the proper location for thoracentesis. Palpation may also be useful in determining whether the cardiac point of maximal impulse is shifted. The trachea should also be palpated because its location indicates the relationship between the pleural pressures in the hemithoraxes.

Percussion over a pleural effusion is flat or dull and maximal at the base of the lung where the fluid is the thickest. If only a thin rim of fluid is present, however, there may be no change in dullness. On auscultation, breath sounds are decreased or absent over the empyema. Paradoxically, breath sounds may be increased near the upper border of the fluid because of increased sound conductance in the partly atelectatic area under the fluid. A rub may also be present, especially if the effusion is diminishing in size, and may be associated with localized pain on breathing.

Empyema may also become apparent during the resolution of seemingly uncomplicated bacterial pneumonia; thus an apparent "relapse" of bacterial pneumonia should prompt a search for empyema. An empyema may occasionally be chronic; in this instance, symptoms involving the chest may be absent, and therefore only constitutional abnormalities, such as low-grade fever or weight loss, may provide a clinical clue.

Epidemiology

Historically, the rate of occurrence of empyema has been expressed as a percentage of children hospitalized with pneumonia. In the preantibiotic era, 10% of hospitalized children with pneumonia had empyema; *S. pneumoniae* was the most common pathogen. With the availability of sulfonamide antibiotics, the percentage of hospitalized children with pneumonia diminished greatly but surged in the 1950s to 14% of children hospitalized with pneumonia, with *S. aureus* accounting for 92% of the cases. In the 1970s, the percentage of children hospitalized with pneumonia who had empyema decreased to about 2%.[617]

Recently, studies have suggested that the worldwide incidence of empyema is increasing.[618-623] The reasons for this increase are unclear, but may be due to the emergence of more virulent pneumococcal and community-associated MRSA strains. In Salt Lake City, Utah, the percentage of children hospitalized between 1993 and 1999 with community-acquired pneumonia that had empyema was 28.3%, with 5 cases per 100,000 children in 1999.[618] The majority of pneumococcal empyema was caused by serotype 1. A retrospective review of patients discharged from a large tertiary care children's hospital in Texas from 1993 to 2002 found that the discharge diagnosis of empyema increased from 1993 to 2000 when it peaked at 23 cases per 10,000 admissions. In England, investigators analyzed the number of admissions under the International Classification of Diseases code "pyothorax" between 1995 and 2003 and found that the rate of admissions increased from 14 per million in 1995/1996 to 26 per million people in 2002/2003.[623]

Etiology

S. pneumoniae and *S. aureus* are the most common etiologic agents.[615] *H. influenzae* type b was an important cause[624] in the prevaccination era but is now rare. Group A streptococcus and *N. meningitidis* are infrequent causes of empyema.

The introduction of the pneumococcal conjugate vaccine has had a variable impact on the incidence of empyema with pneumococcal pneumonia. Overall, the incidence of pneumococcal pneumonia has decreased. However, the incidence of pneumococcal empyema caused by serotypes not included in the vaccine has increased in some geographic locales. In contrast, a decrease in the prevalence of pneumococcal empyema was documented in other locales after the introduction of the vaccine in 2000 with a corresponding increase in empyema due to community-associated MRSA.[625]

Brook[626] called attention to the role of anaerobes in empyemas occurring in children. Anaerobic bacteria (*Bacteroides* species, *Fusobacterium* species, *Peptostreptococcus* species, *Veillonella* species, *Propionibacterium acnes*, and *Clostridium perfringens*) were isolated from blood or pleural fluid in pure culture from 24% of the children studied and in combination with an aerobe in an additional 10%.[626] Foul-smelling pleural fluid was not always present when an anaerobe was isolated.[627] Presumably, anaerobic bacteria associated with empyema originate from a pulmonary process such as pneumonia or a lung abscess, or an extrapulmonary process such as a retropharyngeal or lymph node abscess or a paravertebral abscess.

When empyema occurs as a result of external introduction of organisms related to trauma, surgery, or thoracentesis, important causes include *S. aureus* or aerobic gram-negative bacilli.[614] Anaerobes should also be considered in this instance.

Empyema may also complicate a subdiaphragmatic abscess; in this instance, the flora may be mixed and may include enteric gram-negative bacilli, other aerobic intestinal flora, or anaerobes. Other causes of empyema are extremely infrequent. However, it is probable that any bacterium capable of infecting the lung can also be associated with a parapneumonic pleural empyema.

Diagnosis

A parapneumonic pleural effusion and empyema should be considered in the evaluation of any patient for bacterial pneumonia. The presence of an effusion is usually demonstrated by radiography of the chest. However, because uninfected parapneumonic effusions resolve with the resolution of the pneumonia, distinguishing such an uninfected effusion from empyema is of clinical importance and may be challenging. Several distinguishing features may be useful. For example, the rapid loculation of an empyema results in an inability to shift the pleural effusion. Thus demonstration of "layering," a shift in the location of the effusion with change of patient position, suggests that empyema is absent. In practice, this distinction is often made on the basis of lateral decubitus radiographs. Furthermore, a fusiform, pleural-based shadow may be present and is sometimes large enough to obliterate the entire chest and shift the mediastinum contralaterally. Empyema is also more likely when a pulmonary alveolar

consolidation is adjacent or when a lung abscess or cavitary pneumonia is present.[628,629] Such an associated cavitation may have eroded into the pleural space.

The occasional complication of a bronchopleural fistula may result in a pyopneumothorax that is manifested radiographically as an air-fluid level within the pleural effusion. Unlike a pulmonary abscess, which has similar length in different projections because of its round nature, the flat geometry of empyema results in an air-fluid level that is long in one projection and much shorter in the perpendicular plane.

CT provides an excellent global view of the abnormality and enables evaluation of the extent of pleural involvement (Fig. 35-15). CT has not been helpful in distinguishing between empyema and parapneumonic effusion but CT with contrast can be helpful in identifying loculated pleural fluid. With this modality, an empyema appears with a lentiform shape at an obtuse angle with the chest wall, separation of the two pleural layers, compression of the adjacent lung, and uniform chest wall width with a sharp interface with the lung.[630,631] Contrast enhancement may demonstrate an unexpectedly thick, enhancing rind surrounding an empyema that may fail to resolve after therapy with drainage and antibiotics. Such thick, enhancing walled empyemas may be caused by *S. aureus* or other pathogens[632] and often require surgical decortication. Radiation exposure from a CT can be high.

Sonographic characteristics of pleural empyema are similar to those described for CT (Fig. 35-16). Sonography has the superior ability to assess the quality of the fluid within the pleural space and can differentiate free from loculated pleural fluid. Doppler sonography may aid in the differentiation of pulmonary and pleural lesions by demonstrating intercostal artery enlargement and increased flow velocities associated with an adjacent empyema.[633] Ultrasound can be used to guide chest tube insertion and can be conveniently used at the bedside.

Ultimately, diagnostic thoracentesis is necessary to obtain the information that allows distinction between uninfected

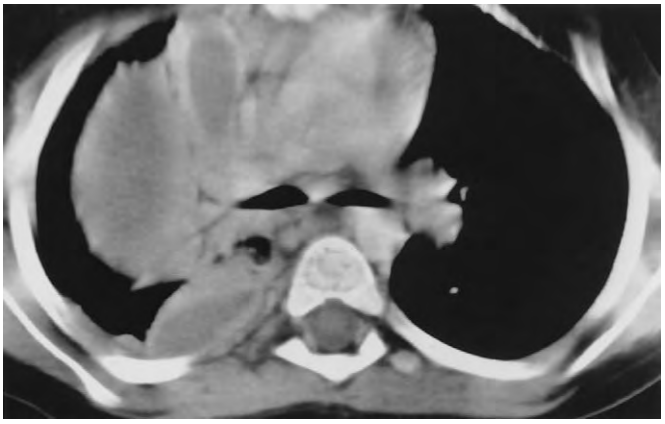

Figure 35-15 CT scan of pleural empyema in a 5-year-old boy with extensive right pleuropneumonia (*Streptococcus pneumoniae*). CT was performed to clarify the various components of a complex chest radiograph with diffuse opacities. An apical, complex empyema demonstrates the classic characteristics: fusiform shape; smooth, uniform walls; an obtuse angle with the chest wall; and peripheral location (along the mediastinal, apical, and posterior pleural surface).

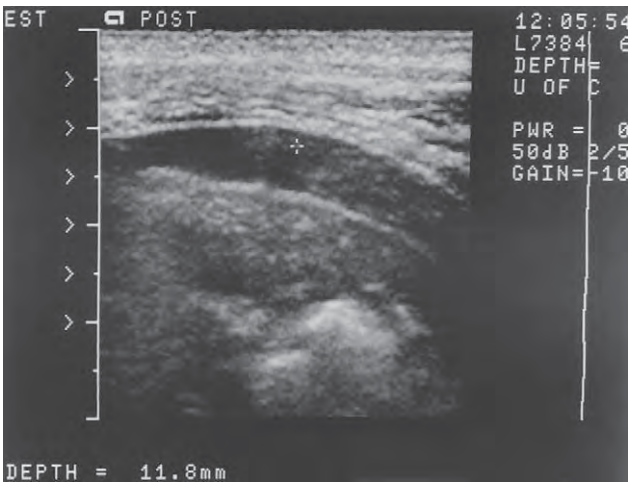
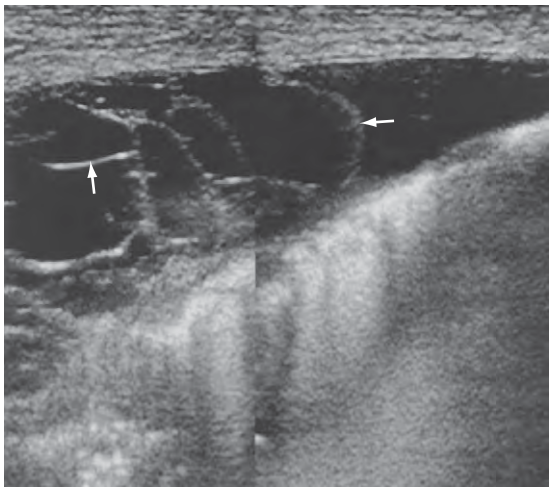
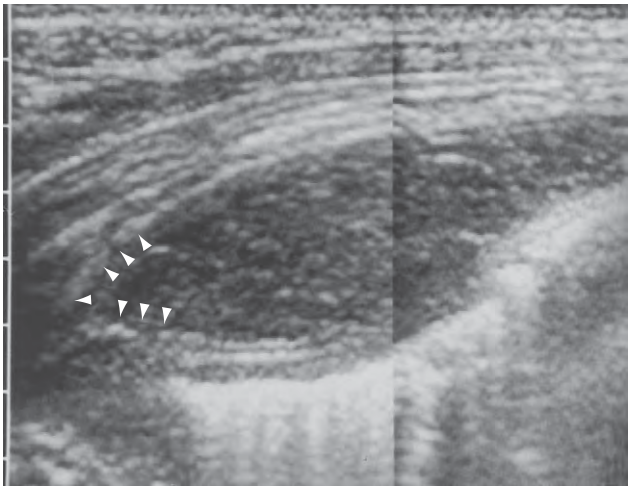


A



B



C

Figure 35-16 Sonography of pleural empyema in three patients. **A,** In a 3-year-old boy with group A streptococcal pneumonia, an empyema with fluid containing debris (+) separates the chest wall from the consolidated lung. **B,** Empyema with multiple septations in a boy 3 years and 10 months old who has pleuropneumonia (*arrows*). **C,** Typical mature empyema: fusiform shape; thickened, separated pleural layers; uniform wall width; echogenic fluid within the empyema; and obtuse angle with the chest wall (*arrowheads*).

parapneumonic effusions and empyema. The decision to perform this procedure must be individualized; all parapneumonic pleural effusions do not require diagnostic thoracentesis. However, because the presence of empyema usually necessitates drainage of the infected material, most often via the insertion of a chest tube, thoracentesis should be performed when empyema is suspected.

The diagnosis of empyema is strongly supported by the presence of thick pus, bacteria demonstrable when the fluid is subjected to Gram stain, a pH less than 7.3, or a glucose concentration less than 60 mg/dl. In exudative pleural effusions, the protein concentration is rarely less than 3.0 g/dl, and the lactate dehydrogenase concentration is high. The average white blood cell count in empyema fluid is 19,000 cells/mm^3 but may be somewhat lower (about 11,000 cells/mm^3) in a patient with chronic empyema. Culture of the pleural fluid should include procedures appropriate for the growth of aerobic and anaerobic bacteria, fungi, and mycobacteria. Importantly, these findings may be variably present and must be interpreted in their clinical context.

Detection of bacterial antigens in pleural fluid is potentially useful in the diagnosis of empyema.[634] The advantages are the rapidity with which the test can be performed and the possibility that antigen may be present (despite the presence of too few organisms to allow their visualization by Gram stain or despite a pleural fluid culture rendered sterile by prior antimicrobial therapy). The disadvantages of antigen detection tests lie in the limited availability of reagents for antigen detection for the organisms that commonly cause empyema (among the common causes, only *S. pneumoniae* capsular polysaccharide can be detected with commercially available reagents) and the imperfect sensitivity and specificity of the available tests.

Treatment

The mainstay of therapy in empyema consists of antimicrobial therapy[635] and adequate drainage of infected material in the pleural space. The choice of medications depends on the knowledge of the likely causative microorganisms. An appropriate empirical regimen for empyema presumptively caused by aerobic bacteria usually includes coverage for *S. aureus* and *S. pneumoniae*. In regions that have not experienced epidemic CA-MRSA disease, a semisynthetic or β-lactamase resistant penicillin such as oxacillin, and an extended-spectrum cephalosporin such as ceftriaxone, are often used together as initial therapy. In regions with epidemic CA-MRSA disease, empirical therapy includes clindamycin or vancomycin in combination with an extended-spectrum cephalosporin. Most antibiotics diffuse well into the pleural fluid.[644] The duration of therapy has received little critical evaluation, but a 14- to 28-day course of therapy seems appropriate.

Several options are available when it is determined that a pleural effusion constitutes an empyema that requires drainage. The choice is often dictated by local experience and beliefs as well as the early clinical response to treatment. Variation in practice reflects the paucity of randomized controlled trials comparing different treatment modalities. Children most frequently recover, irrespective of the treatment they receive, but newer treatments may be less invasive and decrease the length of hospital stay. Regimens in use include antibiotics alone or in combination with thoracentesis, chest-drain insertion, chest drain and fibrinolytics such as urokinase, open decortication, and video-assisted thoracoscopic surgery (VATS).[636]

Closed-chest drainage via a chest tube is often performed when empyema is suspected. Such drainage may not be necessary in patients with small serous effusions that remain stable. Repeated ultrasound-guided needle thoracentesis has not been shown to be more effective than chest tube placement and requires repeated trauma. The chest tube should be positioned in a dependent part of the empyema and should be of sufficient diameter to prevent clogging. The tube should be connected to a drainage system with an underwater seal. Clinical and radiologic improvement should be evident within 24 to 72 hours, and the tube may be removed when the pleural drainage is lower than 50 mL/24 hours and the fluid is clear or yellow.

Despite these measures, the condition in some patients may fail to improve or may have a protracted, acute course; there are many reasons for this. Antibiotics may have a suboptimal antibacterial effect because of previously undetected resistant bacteria, poor penetration into an abscess-like loculation, inactivation of the antibacterial compound (e.g., a β-lactam antibiotic by β-lactamase), suboptimal antibacterial activity in the presence of low pH, or a high degree of protein binding.[637] Alternatively, pleural drainage may be inadequate. The most common explanations are loculation with obstructed communication of empyema fluid or tenacity of the exudate with obstruction of the drainage tube. Ultrasonography or CT may help clarify this situation.

Management of a patient whose condition is unresponsive to standard therapy may include reformulation of the antibacterial regimen, placement of one or more additional chest tubes, or use of fibrinolytics or surgery. The use of urokinase as a thrombolytic agent instilled into the pleural space via an existing chest tube has been enthusiastically received as a strategy for dissolving fibrinous loculated walls of an empyema before fibroblast collagen production has ensued.[638] This enzyme, produced by the human kidney, is less often associated with the allergic reactions attributed to streptokinase and streptodornase. Typically, it is instilled into the chest tube and left in the pleural space for 2 to 4 hours[639] or overnight.[640] The dose instilled should be 10% of the dose used intravenously to lyse clots.[638] A prospective trial randomized patients older than 1 year to receive either 40,000 units of urokinase in 40 mL saline or 0.9% saline instilled in the pleural space twice a day over 3 days. Patients in the urokinase group were discharged from the hospital an average of 2 days sooner than those in the saline control group, a difference that was statistically significant.[641]

Surgical options are also available in the treatment of empyema complicated by fibrinous peel and loculations. Open decortication involves removal of the pleural peel and irrigation of the pleural cavity through a large incision made in the chest wall. In video-assisted thoracoscopic surgery (VATS) 2 or 3 small incisions are made in the chest wall; a camera and 1 or 2 grasping instruments are then used to disrupt adhesions in the pleural space, drain loculated effusions, and mechanically lyse intrapleural septations. Proponents of VATS have suggested that it results in less morbidity to skin,

muscles, and nerves and faster healing times than open decortication. Proponents of open decortication believe that those who undergo that procedure recover more quickly. Prospective randomized trials comparing the two surgical procedures are lacking.

A recent prospective randomized trial compared the use of percutaneous chest drain with urokinase and VATS for the treatment of empyema in children. Outcome measures studied included number of hospital days after intervention, number of chest drain days, total hospital stay, failure rate, radiologic outcome at 6 months, and total treatment costs. There was no difference in clinical outcome, hospital stays, or failure rate but the treatment cost of patients in the urokinase group was significantly lower.[642]

Some have proposed that VATS should occur early in treatment rather than reserving intervention for cases in which medical management has failed. One small trial involving 20 patients suggested that patients treated with immediate VATS had higher immediate success and shorter hospital stays than patients who received intrapleural streptokinase instilled into a chest drain.[643] Research in this area to clarify the roles of the various treatment modalities is needed.

Chronic empyema is a vaguely defined term used to refer to a situation in which the patient's condition fails to improve despite therapy and there is evidence of restrictive lung function, increasing fibrosis, and lung fixation.[638,644] Decortication and even rib resection or permanent external drainage have rarely been used to treat a patient with this diagnosis. Empyema complicating pneumonectomy may also be refractory to standard therapies and therefore "chronic." In addition to these measures, treatment for postpneumonectomy empyema has included irrigation of the thoracic cavity with antibiotic solutions, open window thoracotomy, and obliteration of the cavities with muscle flaps—although the last is a therapeutic effort of last resort.[638]

Complications

Complications associated with empyema include the creation of a bronchopleural fistula by direct extension of infected pleural fluid into the lung (empyema necessitatis) or the formation of a cutaneous fistula. Other infectious complications include bacteremia and pericarditis by direct extension or bacteremic seeding and pneumothorax.[611]

Prognosis

Morbidity and mortality rates from empyema remain high even in the modern era. Risk factors for bad outcome include inadequate antibiotic therapy (choice of medications, duration of therapy, or poor compliance with a prescribed unsupervised regimen), inadequate surgical management (when indicated), and probably certain underlying conditions that compromise the immune response. An important long-term consequence of untreated empyema relates to the formation of restrictive scar tissue or peel in the pleural space and includes decreased exercise tolerance, chest contour changes, and chronic restrictive pulmonary disease. Some have suggested that scoliosis can complicate empyema.[638]

The mortality rate among patients with empyema has been estimated at 2% to 15%.[638] Risk factors for death include duration of illness, severity of infection, and young age.[638]

CHAPTER 36 Respiratory Infections in Immunocompromised Hosts

Dennis C. Stokes and Surender Rajasekaran

TEACHING POINTS

- Pulmonary infections are common among patients with altered host immunity.
- The numbers of patients at risk have increased owing to improved overall survival and new patient risk groups.
- As therapy and preventive strategies for common bacterial and fungal infections have improved, new resistant pathogens have continued to emerge.
- Many noninfectious processes occur in these populations and complicate the diagnosis of infection.
- Outcome for many pulmonary infections in immunocompromised hosts is poor, particularly when specific diagnosis is delayed.

The use of the term *immunocompromised host* is relatively new. Utz first described the terms *opportunistic pathogens* and *immunodeficiency* in 1962, and in 1967, Ruskin and Remington used the term *compromised host*.[1,2] The numbers of individuals at risk for infection owing to altered immunity have expanded greatly since that time, primarily because of improved survival of childhood cancer patients with aggressive but effective treatment protocols, expanded use of solid organ and bone marrow transplantation, and the human immunodeficiency virus (HIV) epidemic. The list of pathogens that can cause pulmonary infections in immunocompromised hosts is extensive and continually growing. As effective therapy and preventive therapies have reduced the impact of some infections such as *Pneumocystis* and varicella, other infectious agents including rarer saprophytic fungi, multiply resistant bacterial pathogens, and common viral infections such as adenovirus and respiratory syncytial virus (RSV) continue to plague this population. Many noninfectious pulmonary complications also occur in immunocompromised pediatric patients, including those with acquired immunodeficiency syndrome (AIDS) and must thus be included in the differential diagnosis of infectious pneumonias. Newer diagnostic studies, including bronchoscopy with bronchoalveolar lavage (BAL), and computed tomography (CT)-guided needle aspiration biopsy coupled with new molecular diagnostic techniques have helped in making earlier specific diagnosis possible. Although outcome for many infections (particularly with early diagnosis) has improved significantly, care of the critically ill immunocompromised host with pulmonary involvement remains a difficult challenge and the prognosis for many patients with advanced lung disease is often poor.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Epidemiology

During the 1960s, improved therapeutic programs for childhood malignancies, principally acute lymphocytic leukemia (ALL), resulted in longer survival times and increased numbers of children at risk for opportunistic infections. Children who no longer died quickly during initial therapy were at risk for pulmonary infections over prolonged remissions while receiving maintenance chemotherapy for at least 5 years. *Pneumocystis jiroveci* (previously *carinii* and some still prefer this name), previously identified as a pathogen primarily in outbreaks in malnourished infants, emerged as a major problem for these children.[3-5] Varicella-zoster pneumonia was also a major problem because of its frequency in childhood and the lack of effective antiviral therapy.[6] During the late 1960s, the first bone marrow transplants were attempted in children with refractory malignancies. Bacterial pneumonias were generally treatable with effective antimicrobial therapy, but fungal pneumonias became a major problem in children with prolonged neutropenia, such as those with aplastic anemia or those receiving intensive chemotherapy. *Aspergillus* pneumonia was a common problem, and the association with hospital construction and other risk factors such as prolonged neutropenia was recognized.[7] In 1976 and 1977, Hughes and colleagues[8] described effective treatment and prophylaxis for *P. jiroveci* pneumonia (PCP) in oncology patients with trimethoprim/sulfamethoxazole (TMP/SMX). This replaced the more toxic medication pentamidine that was available only for biopsy-proven PCP. The use of TMP/SMX prophylaxis effectively eliminated PCP as a cause of pneumonia in this population, and the availability of a safer alternative to pentamidine provided a rationale for the empirical treatment of pneumonia in immunocompromised patients.[9] This often delayed more invasive diagnostic studies such as open-lung biopsy and generated considerable controversy on the role and timing of open-lung biopsy.[10-12] In the late 1970s, pediatric flexible bronchoscopy became increasingly available as

an alternative to surgery, providing a specific diagnosis for many opportunistic infections.[13-17] In the 1980s the epidemic of HIV infection and AIDS resulted in a major new group of immunocompromised children, first in those who received contaminated blood transfusions for cancer, hemophilia, or other indications and later in infants of HIV-infected mothers. *P. jiroveci* re-emerged as the major pulmonary pathogen in this group, both as the presenting infection and as the cause of death.[18] In addition to patients with AIDS, new high-risk groups included patients with acute nonlymphocytic leukemia, lymphoma, and solid tumors (including brain tumors) who were receiving aggressive combined therapy with chemotherapy and radiation therapy.[19] The number of bone marrow and other tissue transplants also continued to expand, and major noninfectious pulmonary complications were described in these populations, including bronchiolitis obliterans organizing pneumonitis (BOOP) in recipients of bone marrow transplants and lymphoid interstitial pneumonia in pediatric patients with AIDS.[20,21] The use of varicella-zoster immune globulin (VZIG) for prophylaxis and acyclovir for treatment significantly reduced the importance of varicella-zoster virus (VZV) as a cause of mortality.[22]

Since the late 1980s and 1990s trends in the epidemiology of infections in immunocompromised hosts include re-emergence of gram-positive organisms, including *Staphylococcus epidermidis*, methicillin-resistant *Staphylococcus aureus*, streptococci, and C*orynebacterium jeikeium*, as major causes of sepsis and bacteremia. Effective antiviral therapy with ganciclovir and immunoglobulin have provided a significant advance in preventing and treating cytomegalovirus (CMV) pneumonitis in high-risk populations.[23-26] Cytokines to accelerate marrow recovery and activate macrophages have helped reduce the risk of bacterial and fungal pathogens in many patients.[27] Fungal pathogens, particularly the rare saprophytic organisms, remain a major problem because of their resistance to antifungal therapy. Use of highly active antiretroviral therapy has reduced the prevalence of PCP in HIV.[28]

Risk Factors

Many nonimmunologic aspects of pulmonary host defense, including physical barriers, mucociliary clearance, and cough, predispose to pulmonary infections when altered. However, the primary groups of immunocompromised children are those with either congenital or acquired defects in immunologic defenses of the lung. A detailed discussion of pulmonary immunologic defenses is beyond the scope of this chapter but Table 36-1 and Box 36-1 summarize the major host defenses of the lung and associated disorders that predispose to pulmonary infections.

HUMORAL IMMUNITY

Immunoglobulin G (IgG) and IgA are major components of respiratory secretions, with IgA (and secretory IgA) most important in the upper airway. In the lower respiratory tract, IgG provides primary protection against local and systemic infections. Humoral immunity deficiencies account for 70% of all immunodeficiencies. Defects of subclasses of IgG, including both IgG2 and IgG4, have been associated with recurrent sinopulmonary infections, although the importance of minor reductions of subclasses in patients with recurrent pneumonias is debated.[29,30] Some individuals with normal levels of total antibody are unable to make IgG to certain important pathogens.[31] Although patients with complement deficiencies are more likely to have systemic infections, some with such defects have pneumonias.

CELLULAR IMMUNITY

Alveolar macrophages are the major phagocytic cells in the lung and are able to handle small numbers of pathogenic

Table 36-1
Host Defense Disorders Leading to Pneumonia

Pulmonary Host Defense	Defective in
Upper airway	
Turbinates	Intubation
Epiglottis	Tracheostomy, aspiration syndromes
Mucociliary clearance	
Cilia	Primary ciliary dyskinesia (PCD), infections
Mucous blanket	Cystic fibrosis, bronchitis
Cough	Muscle weakness, sedation
Immunoglobulin	
Secretory IgA, IgA	IgA deficiency
IgG, including subclasses	Agammaglobulinemia, hypogammaglobulinemia, IgG subclass deficiency
IgE	Elevated in hyperimmunoglobulinemia E with recurrent infections (Job syndrome)
Cells	
Alveolar macrophages	Corticosteroids, chemotherapy, chronic granulomatous disease
Polymorphonuclear leukocytes	
Numbers	Chemotherapy, congenital neutropenia
Motility	Motility disorders
Function	Chronic granulomatous disease
Lymphocytes	
Numbers	AIDS
Function	T cell disorders, including severe combined immunodeficiency disease, others
Other	
Surfactant	Adult respiratory distress syndrome (?), edema
Fibronectin, lysozyme complement	C3 or C5 deficiency

BOX 36-1 Attack Rates for *Pneumocystis jiroveci* Pneumonia (PCP) by Underlying Condition*

Underlying Disorder	Attack Rate (%)
Acute lymphoblastic leukemia	6.5-42.9
Severe combined immunodeficiency syndrome	27-42
Rhabdomyosarcoma	4-25
Wegener granulomatosis	3.5-12
Hodgkin disease	1.3
Collagen vascular disease	2
Primary or metastatic central nervous system tumor	1.3-1.7
Organ transplantation	
Heart-lung/lung	6.5-43
Heart	2-41
Renal	0.6-14
Liver	3-11
Allogeneic bone marrow	5-16

*Patients not receiving prophylaxis.

Table 36-2 Noninfectious Processes Complicating or Simulating Pneumonia

Process	Association
Chemical pneumonitis	Aspiration syndromes, smoke inhalation
Immune-mediated infection	Hypersensitivity pneumonitis, collagen vascular disease
Atelectasis	Reactive airways disease, endobronchial obstruction
Hemorrhage	Hemosiderosis, thrombocytopenia, coagulopathy, infection (*Aspergillus,* cytomegalovirus [CMV]), drug therapy (retinoic acid)
Pulmonary embolus	Condition secondary to intravascular abnormalities
Pulmonary edema	
Cardiogenic	Anthracycline cardiotoxicity, sepsis, myocarditis
Noncardiogenic	Acute respiratory distress syndrome, pancreatitis, fluid overload
Drug-induced lung injury	Chemotherapy agents, azathioprine
Radiation pneumonitis	Radiation treatment 6-8 wk previously
Leukostasis	Hyperleukocytosis, use of amphotericin B, transfusions of white blood cells
Leukemia, lymphoma	Active disease
Lymphocytic interstitial pneumonitis (LIP)	HIV infection in children
"Idiopathic pneumonitis"	Allogeneic bone marrow transplant
Other	Thymus, sequestration, tumor

organisms. Neutrophils are present in the lung in small numbers but can be rapidly recruited from the vascular compartment via a variety of chemotactic factors produced by complement activation or secreted by macrophages. A reduction in the number of circulating neutrophils is a major cause of pneumonias in immunocompromised hosts. Chronic granulomatous disease, neutrophil motility disorders, and other forms of phagocytic dysfunction also lead to pulmonary infections.

SECRETORY FACTORS

Macrophages secrete a number of important cytokines, such as tumor necrosis factor-alpha (TNF-α) and interleukin-1, which have local immunomodulating effects within the lung and systemic effects such as fever and shock. Nonspecific antibacterial defenses such as lysozyme and surfactant proteins may also be important when altered by lung injury.

Pathogenesis: Common Causes of Pneumonia in the Immunocompromised Host

NONINFECTIOUS PULMONARY DISEASE

Immunocompromised patients are at risk for a variety of noninfectious complications that simulate infection and complicate the diagnostic work-up (Table 36-2).

INFECTIOUS PNEUMONIAS

Viruses

HERPESVIRUSES

The herpesviruses that cause infectious viral pneumonia are cytomegalovirus (CMV), varicella-zoster virus (VZV), herpes simplex virus (HSV), and human herpesvirus type 6 (HHV-6).

Cytomegalovirus. CMV is a herpesvirus that commonly infects both neonates and older immunocompromised children.[23,32] Whether the virus results in disease depends on the age and the immune status of the infected individual. The organism can be transmitted through an infected birth canal and via breast milk, saliva, and blood (through infected white cells). Both humoral and cellular immune mechanisms are important in establishing protection against CMV. Individuals who are CMV negative before acquired immunosuppression resulting from organ or marrow transplantation and who acquire the virus by transfusion are particularly at risk for disease. CMV-positive individuals who are then immunosuppressed also run a significant risk for "reactivation" pneumonia.

CMV-infected cells typically contain nuclear inclusions that are deeply basophilic and surrounded by a clear halo, giving the "owl's eye" appearance (Fig. 36-1). Typically, inclusions are seen in alveolar cells. The pathologic situation varies from small hemorrhagic nodules scattered throughout the

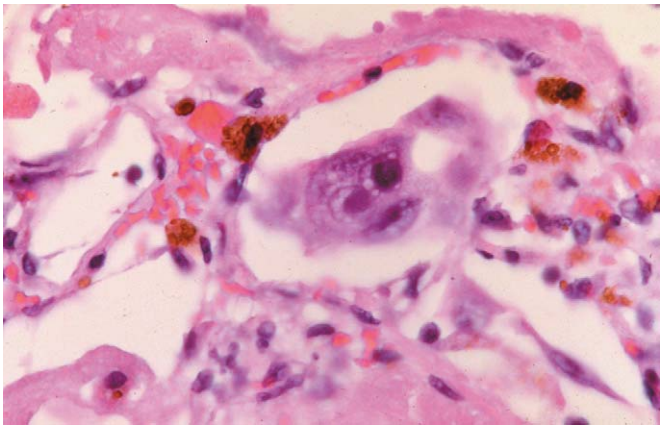

Figure 36-1 Lung biopsy from cytomegalovirus (CMV) pneumonia showing typical "owl's eye" inclusion.

lung and surrounded by relatively normal lung to diffuse alveolar damage or chronic interstitial pneumonitis.

Unless they acquire the virus before birth, most infants infected with CMV are asymptomatic, although occasional cases of protracted pneumonia have been reported. The major risk factors for CMV pneumonia include AIDS, congenital immunodeficiencies, and organ transplants, particularly kidney, bone marrow, and heart-lung. The radiographic pattern of the pneumonia is usually a diffuse reticulonodular pattern that is less alveolar in pattern than PCP. Approximately 50% of patients with aplastic anemia or hematologic malignancy treated by allogeneic marrow transplantation develop CMV infection, and CMV pneumonia had a 90% mortality rate in this population before the availability of antiviral therapy. CMV frequently is found as a co-pathogen with other opportunistic organisms, including *P. jiroveci* and *Aspergillus* species, particularly in patients with AIDS.

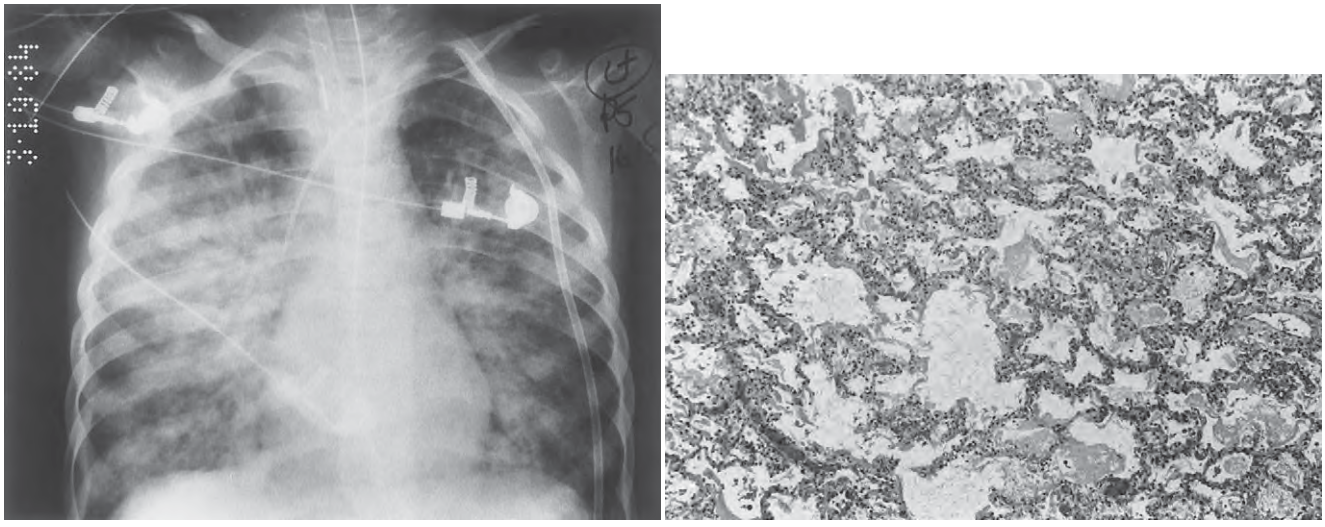
The diagnosis of CMV pneumonia is usually made by demonstrating typical inclusions in lung tissue. The isolation from the urine is not sufficient evidence that CMV is the cause of the pneumonia. Recently, immunofluorescence, deoxyribonucleic acid (DNA) hybridization, and shell-vial culture have been combined to provide rapid diagnosis of CMV infection from bronchoalveolar lavage fluid.[33-35] Although highly sensitive, the results from such techniques must be interpreted cautiously because CMV can be detected in asymptomatic individuals.

The use of CMV-negative blood products reduces the incidence of CMV pneumonia in seronegative but not seropositive recipients of transplants. Polymerase chain reaction (PCR) for CMV has been used in recipients of bone marrow transplants in an attempt to predict the development of CMV disease. PCR had excellent negative predictive value but a positive predictive value of only 61%. Acute graft-versus-host disease (GVHD) is associated with CMV disease, as is the development of lymphopenia (predominantly CD4+ T cells) starting 49 days after transplant. PCR evidence of viremia and lymphopenia predicted CMV disease 100% of the time.[35] PCR detection precedes culture isolation of CMV by 1 week, and the organism can be detected longer with PCR than with culture. Lack of PCR resolution or a positive culture has a positive predictive value of 60% for the development of CMV disease in recipients of bone marrow transplants.

Varicella-Zoster Virus and Herpes Simplex Virus. VZV and HSV are DNA viruses that typically cause benign infections of the skin and mucous membranes.[6,22] However, in certain groups (including neonates; patients with cancer, AIDS, and congenital defects of cell-mediated immunity; and recipients of bone marrow transplants), VZV and HSV can lead to visceral dissemination and pneumonia. In patients with cancer, pneumonitis occurs in 85% of cases of visceral dissemination and is the principal cause of death. Before the availability of specific antiviral therapy, the VZV pneumonitis mortality rate was 85%. Pneumonitis is much less common with reactivation of herpes zoster, but it is a potentially serious infection in recipients of bone marrow transplant. HSV is a less common cause of dissemination in oncology patients but is a significant infection in neonates.

The clinical presentation is nonspecific and includes fever, cough, dyspnea, and chest pain. Patients with VZV who have an increasing number of skin lesions, abdominal or back pain, or persistent fevers are at high risk for dissemination and pneumonia. HSV pneumonitis may be more subtle in its presentation, and pneumonitis can occur in the absence of mucocutaneous lesions in newborns and recipients of bone marrow transplants. Chest radiographs of herpesvirus pneumonias typically show ill-defined nodular densities scattered through both lung fields, often beginning at the periphery (Fig. 36-2A). These nodules progress and coalesce into extensive infiltrates. Secondary infections such as staphylococcal pneumonia were more commonly seen in the era before antibiotics. Microscopically the infection involves the alveolar walls, blood vessels, and small bronchioles (see Fig. 36-2B). Electron microscopy shows intranuclear inclusions of herpesvirus. Hemorrhage, necrosis, and extensive alveolar edema are seen in severe areas of involvement. The trachea and large bronchi are often involved.

Human Herpesvirus-6. HHV-6 is a DNA virus that is the etiologic agent for roseola. It persists in normal hosts and can



A B

Figure 36-2 Varicella-zoster virus (VZV) pneumonia. **A,** Chest radiograph. **B,** Histologic section.

be isolated from lymphocytes and other sites. In the abnormal host, reactivation can lead to fever, hepatitis, bone marrow suppression, and pneumonia.[36-38]

Cone and associates[37] described identification of HHV-6 by PCR in all of 15 lung biopsy specimens from patients with idiopathic pneumonitis after bone marrow transplant; serologic studies also supported its role in pneumonitis after transplant. Further studies are documenting other clinical situations in which HHV-6 causes disease in immunocompromised populations, including renal transplant and AIDS.[38,39]

Adenovirus

Adenovirus is a DNA virus that commonly causes community-acquired lower respiratory disease. Serotypes 1, 2, and 5 are common causes of sporadic respiratory disease, and types 3 and 7 are associated with epidemics of bronchiolitis and pneumonia in the general population. In immunocompromised patients, adenovirus is one of the most important viral causes of serious morbidity and mortality.[40-43] Adenoviral pneumonia acquired by immunocompromised patients often originates as a nosocomial infection from infected members of the hospital staff.

Adenovirus typically causes fever, pharyngitis, cough, and conjunctivitis. Pneumonia is usually mild in normal hosts, but rapid progression can occur in immunocompromised patients with necrotizing bronchitis and bronchiolitis (Fig. 36-3). The radiographic picture is nonspecific and resembles that of other causes of diffuse pneumonia. The diagnosis is usually made by lung biopsy or brushings demonstrating typical adenoviral inclusions or by culture, but the diagnosis may be delayed by the institution of empirical antibiotic and antifungal therapy and a delay in open biopsy. Viral titers may provide a delayed diagnosis. Failure of diffuse pneumonia to respond despite therapy, particularly when there have been epidemics of typical acute respiratory disease in the community or when there is associated renal or liver involvement, should raise the strong possibility of adenovirus.

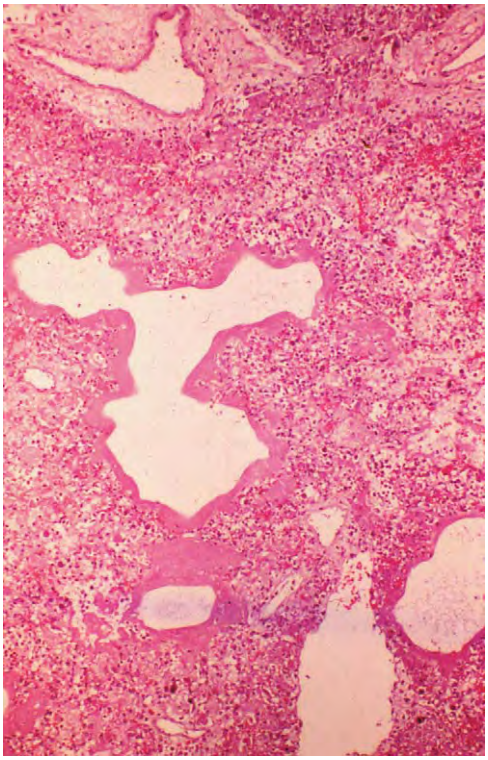


Figure 36-3 Adenovirus pneumonia: histologic section showing severe interstitial pneumonia in a recipient of a bone marrow transplant.

Fungi

Aspergillus *Species*

Aspergillus is a group of ubiquitous fungal organisms found in soil and other settings, including the hospital. *Aspergillus fumigatus* is the most common cause of pneumonia in immunocompromised hosts, but other pathogenic species include *Aspergillus niger* and *Aspergillus flavus*. In tissue, the organisms form septate hyphae with regular 45-degree dichotomous branching that is best seen with methenamine-silver staining (Fig. 36-4).

Aspergillus species causes both acute invasive pulmonary aspergillosis and a more chronic necrotizing form. The former occurs most commonly in patients undergoing cancer therapy as well as other immunocompromised patients such as those with aplastic anemia. *Aspergillus* infection of the lung is often preceded or accompanied by invasion of the nose and paranasal sinuses in susceptible hosts. In a series on invasive *Aspergillus* infection in children (24 definite cases, 15 probable), Walmsley and colleagues[44] confirmed observations in other populations, including those with the major risk factors of prolonged neutropenia, concurrent chemotherapy, and steroid therapy—as well as therapy with broad-spectrum antibiotics. The common occurrence of cutaneous aspergillosis in this pediatric series was also noteworthy. A total of 15 of the 16 patients with pulmonary disease in this series died, and premorbid diagnosis was often difficult. In the lungs, *Aspergillus* species can cause tracheobronchitis, pneumonia, abscesses and cavity formation, and diffuse interstitial pneumonia. The organisms often extend along blood vessels, and nodular lesions of necrosis surrounded by air often develop within an area of pneumonia, leading to the typical air crescent sign.

Computed tomography of the chest is often very helpful in patients with disseminated fungal disease caused by *Aspergillus* species and other fungal pathogens. In a review of computed tomography findings from the chests of 14 pedi-

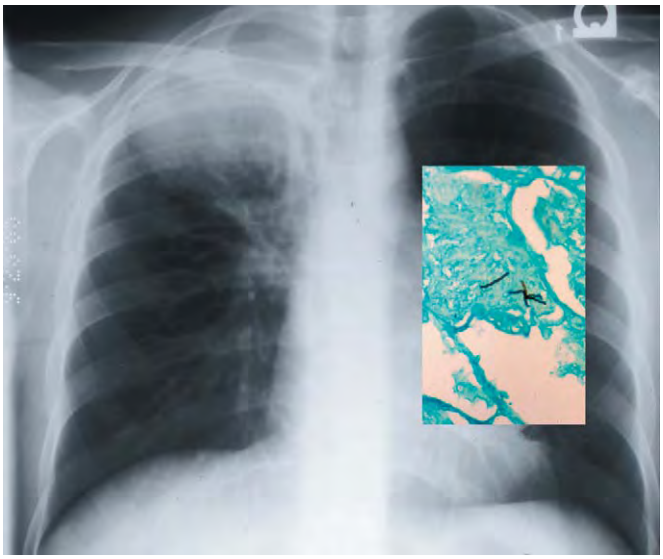

Figure 36-4 *Aspergillus* species: chest radiograph and histologic section (inset). (Grocott-Gomori methenamine-silver nitrate stain.)

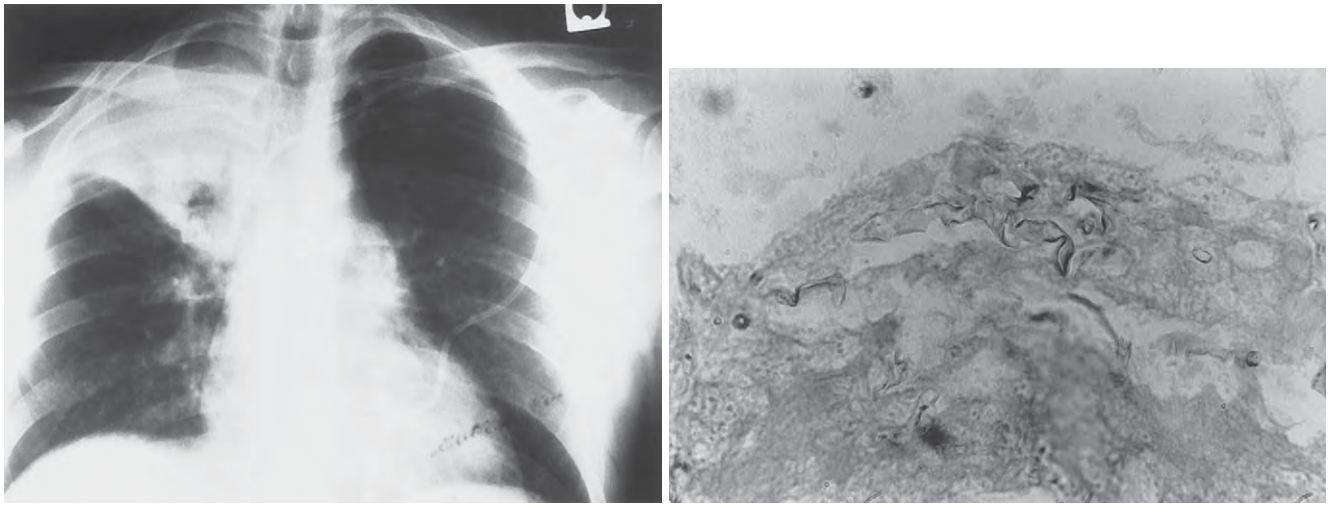

A B

Figure 36-5 *Mucor* species: Chest radiograph showing a cavitary lesion in the right upper lobe **(A)** with histologic section **(B)**.

atric patients with malignancy and pulmonary fungal disease caused by *Aspergillus* species, two basic types of involvement were seen: multiple nodules and fluffy masses. Cavitation occurred in 6 of 14 patients.[45] Computed tomography is more sensitive than plain radiographs and can reveal early evidence of cavitation.

Diagnosis of *Aspergillus* pneumonia is generally made by tissue examination. *Aspergillus* organisms can be isolated from bronchoalveolar lavage fluid in approximately 50% of cases, and needle aspiration biopsy of suspected lesions can also demonstrate typical fungal lesions. Isolation of the organism from a nasal culture in a patient with typical clinical risk features (e.g., prolonged neutropenia, progressive nodular infiltrates, cavitary lesion) may be helpful, but negative cultures do not exclude *Aspergillus* infection.

Mucor, Rhizopus, *and* Cunninghamella *Species*. Mucormycosis includes fungal disease caused by a variety of species in the genera *Mucor, Rhizopus,* and *Cunninghamella*. In tissues, these organisms are differentiated from *Aspergillus* organisms by their broad, nonseptate hyphae that branch at angles up to 90 degrees and that have an appearance of twisted ribbons (Fig. 36-5B). *Rhizopus* organisms cause disease only in patients with underlying disease. In adults, it is associated with chronic acidosis states, such as diabetes mellitus with ketoacidosis. Most pediatric cases of pneumonia occur in the oncology population, in whom the organism is found in the same risk groups as *Aspergillus* species.

Pneumonia caused by *Rhizopus* organisms is usually an insidious segmental pneumonia that is slowly progressive despite antifungal therapy. Persistent fever, chest pain, hemoptysis, and weight loss are typical. Cavitation may occur, and dissemination to the brain and other sites occurs because of the propensity of the organism to invade the blood vessels (see Fig. 36-5). Death may occur suddenly and is caused by massive pulmonary hemorrhage, mediastinitis, or airway obstruction (Fig. 36-6). The specific diagnosis usually depends on demonstration of the organism in open, transbronchial, or needle aspiration lung biopsy specimens.

Figure 36-6 Fatal mucormycosis due to invasion of mediastinal vessels from primary pulmonary lesion.

Candida *Species*. Although important as a cause of fungal sepsis and secondary hematogenous pulmonary involvement, primary *Candida* pneumonia is unusual.[46] *Candida albicans* and *Candida tropicalis* are the most important causes of fungal sepsis and secondary pulmonary involvement.[47] Patients with HIV infection, primary immunodeficiencies, and prolonged neutropenia are at greatest risk, but other predisposing conditions include diabetes, corticosteroid administration, treatment with broad-spectrum antibiotics, intravenous hyperalimentation, and venous access devices. In tissue, silver stains show oval budding yeasts 2 to 6 μ in diameter with pseudohyphae. In primary *Candida* pneumonia, the prominent histologic features include bronchopneumonia, intra-alveolar exudates, and hemorrhage.

Histoplasma *and* Blastomyces *Species*. *Histoplasma capsulatum* and *Blastomyces dermatitidis* are ubiquitous soil fungi endemic to the eastern and southwestern United States. Histoplasmosis, a common infection, may be asymptomatic or lead to an acute pneumonia with fever, hilar adenopathy, and pulmonary infiltrates. Blastomycosis is a less common, more serious infection. Both can cause chronic granulomatous

pulmonary disease as well as disseminated disease. In the immunocompromised patient, including those with AIDS, the major risk factor is dissemination with pulmonary infiltrates, hepatosplenomegaly, fever, and adenopathy. Histoplasmosis is more common in the immunocompromised host than is blastomycosis.

Cryptococcus neoformans. *Cryptococcus neoformans* is a yeast that causes protean clinical manifestations in immunocompromised patients, particularly those with AIDS. The meninges, endocardium, skin, and lymph nodes are often involved. The lungs are the portal of entry for *C. neoformans*, and pulmonary involvement may be minimal if dissemination occurs quickly. Pneumonia is typically accompanied by chest pain, fever, and cough. Pulmonary disease with *Cryptococcus* organisms is rarer in pediatric patients with AIDS than in adults.

Rare Fungi. Non-*Candida* fungal infections are commonly seen after bone marrow transplantation with the respiratory tract being involved in 95% of single-organ infections and 84% of disseminated infections.[48] Several recent trends have been noted in fungal infections caused by rarer fungal pathogens, including saprophytic fungi[49] (Box 36-2). These fungi cause skin and soft tissue infections and occasionally invade the lungs and sinuses. They are often difficult to diagnose, and their response to therapy with amphotericin B may be very poor. Fungal infections that are associated with a high mortality rate include those caused by *Chrysosporium*, *Fusarium*, *Mucor*, and *Scopulariopsis*.

Pneumocystis jiroveci. *P. jiroveci* (formally *carinii;* some reserve *P. carinii* for the similar organism occurring in the immunosuppressed rat) has been an organism of uncertain taxonomy and was regarded as a parasite because of its resemblance to cystic spore-forming protozoa.[50-52] More recent studies using DNA hybridization methods place *P. jiroveci* as a fungus.[53,54] The organism exists in three forms in tissues: the trophozoite, the sporozoite, and the cyst (Fig. 36-7A). The trophozoites are 2 to 5 μ in diameter and stain best with Giemsa stains but are not visible with Grocott-Gomori methenamine-silver nitrate or toluidine blue O stains, which stain the 5- to 8-μ cyst forms. The cysts are spherical or cup shaped and often appear to contain up to eight 1- to 2-μ sporozoites within the cyst wall (see Fig. 36-7B). The organism cannot be cultured from routine clinical specimens and must be identified in tissue, sputum, or alveolar lavage fluid.

The organism is found primarily within the alveoli, although the extrapulmonary occurrence of organisms has been commonly reported in patients with AIDS. The trophozoites appear to attach to type I cells through surface glycoproteins related to lectins and there undergo encystation[55,56] (Fig. 36-8). This interaction directly or through soluble factors leads to cell injury. The alveoli of lungs infected with *P. jiroveci* are filled with trophozoites and protein-rich debris, and the altered permeability produced by the organism contributes to the development of pulmonary edema and surfactant abnormalities, which lead to stiff lungs.[57,58]

BOX 36-2 Unusual Fungal Infections with Pulmonary Involvement

Aspergillus, Candida, and *Mucor* are the primary pathogens.
Primary *Candida* pneumonia (as opposed to secondary pneumonia after septicemia) is rare.
Infection by *Candida* organisms other than *C. albicans* has become increasingly important (primarily fungemia with secondary pulmonary involvement); species include *C. tropicalis*, *C. parapsilosis, C. krusei,* and *C. glabrata* (formerly *Torulopsis glabrata*).
Emerging infections and their pathogens follow:
Phaeohyphomycoses
—*Curvularia* species: sinusitis
—*Bipolaris, Exserohilum, Alternaria* species: clinical presentation similar to that of *Aspergillus* species
Hyalohyphomycoses
—*Fusarium* species: sinusitis or rhinocerebral disease
—*Scopulariopsis* species
—*Pseudallescheria boydii*: sinusitis, pneumonia
—*Trichosporon* infection: risk factors similar to those of *Candida* species (primarily hematogenous)
—*Malassezia furfur:* hematogenous infection

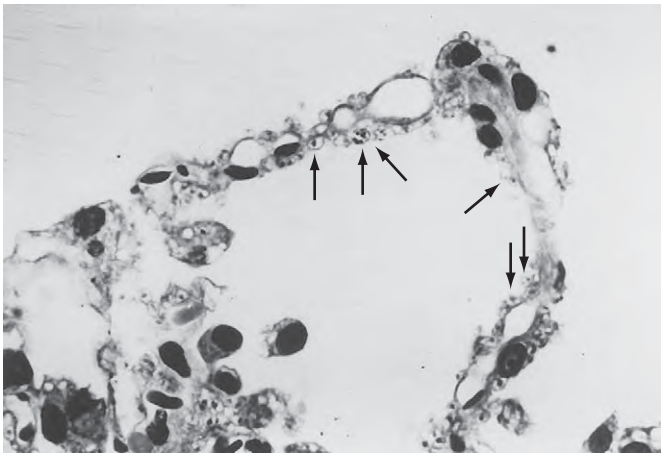

Figure 36-8 ***Pneumocystis jiroveci.*** Alveolar thin section showing cysts (*arrows*) lining the alveolar wall.

The earliest reports of PCP were in epidemics occurring in severely malnourished infants, a type rarely seen in developed countries. The majority of PCP cases occurs in infants and children with congenital or acquired immunodeficiencies. Latent infection with *P. jiroveci* was thought to be common because serologic studies indicated that 40% of children have antibodies to the organism. Based on this finding, disease was thought to be caused primarily by reactivation of a primary infection, but more recent studies using sensitive PCR and fluorescent antibody tests have failed to demonstrate *P. jiroveci* in autopsy or BAL fluid specimens from normal lungs. More likely, disease in immunocompromised patients originates from an environmental source, including other infected patients.[59]

In patients with congenital immunodeficiency or malignancy, the clinical features of PCP are nonspecific and include dyspnea, tachypnea, fever, and mild cough. Hypoxemia with a mild respiratory alkalosis is common, but cyanosis occurs later. The most common chest radiographic findings are diffuse bilateral infiltrates commencing in the perihilar regions.

Since 1980, the most common underlying host defect in patients with *P. jiroveci* is AIDS. The clinical features of PCP in the pediatric AIDS population differ from the pneumonias seen in other populations. In patients with AIDS, the duration of symptoms is typically longer, and the presentation is more insidious. Hypoxemia is less intense. Organisms appear to be abundant in patients with AIDS and can usually be identified in sputum, bronchoalveolar lavage fluid, or even gastric lavage samples. Other superinfections (such as CMV) and pulmonary complications are often present in patients with AIDS, however, and it may be difficult to know what role these infections play in the symptoms. In patients with AIDS, *P. jiroveci* is more likely to spread to the nodes, spleen, bone marrow, and other sites. These patients are more likely to have atypical radiographic images, including lobar pneumonias, unilateral disease, and solitary nodules, although atypical radiographic presentations can also occur in other host disorders.

Bacteria

The bacterial pathogens associated with pneumonia in immunocompromised hosts include those typically associated with pneumonia in children, including *Staphylococcus aureus*, *Haemophilus influenzae* type b, and *Streptococcus pneumoniae*. They may cause chronic suppurative lung disease and are discussed further in Chapter 35.

Gram-Positive Organisms. *Listeria monocytogenes* is a gram-positive rod that causes primarily septicemia with subsequent pulmonary involvement in immunocompromised patients. Corynebacteria (commonly called *diphtheroids*) are gram-positive bacilli or coccobacilli that exist as saprophytes on the mucous membranes and skin. C. *jeikeium*, a strain from this group, causes sepsis and pneumonia in oncology patients and recipients of bone marrow transplants.[60]

Gram-Negative Organisms. *Pseudomonas aeruginosa* is an important cause of pneumonia in immunocompromised children, particularly hospitalized patients. In a large series of 98 children with bacteremia caused by *P. aeruginosa*, 21% had evidence of pneumonia, and the overall mortality rate from *P. aeruginosa* infection was 27%. Significant risk factors included neutropenia and perineal skin lesions.[61] Other gram-negative organisms that cause pneumonia include *Legionella pneumophila* and *Capnocytophaga* species.

Mycobacteria

Until recent years, the incidence of pulmonary disease caused by *Mycobacterium tuberculosis* had been declining. With the onset of the AIDS epidemic, however, disease caused by *M. tuberculosis* and atypical strains such as *Mycobacterium avium-intracellulare* has increased.[62] A detailed discussion of mycobacterial infections in patients with AIDS is beyond the scope of this chapter but is covered in Chapters 37 and 39.

Parasites and Other Organisms

Toxoplasma gondii *and* Cryptosporidium parvum. *Toxoplasma gondii* and *Cryptosporidium parvum* are both parasites. *T. gondii* infects cats and other animals and secondarily infects man, causing congenital toxoplasmosis during intrauterine infection; primary infection later in life usually causes only lymphadenopathy and mild systemic symptoms. C. *parvum* infects a variety of hosts and often occurs with waterborne outbreaks.[63]

In patients with AIDS, *Toxoplasma* primarily causes central nervous system disease but can cause disseminated disease with secondary pulmonary involvement. C. *parvum* causes severe diarrhea, but disseminated disease with pulmonary involvement can occur.

CLINICAL FEATURES

Patterns of Pneumonia

Recurrent or Persistent Pneumonia. Often the first clue to an abnormal host disorder is the development of recurrent or persistent pneumonia. Patients usually have persistent or recurrent radiologic evidence of pneumonia that is associated with the typical signs of infection such as fever and tachypnea. It is important to note whether these infiltrates clear completely after therapy, whether they involve one lobe or more than one lobe, and whether they are associated with other radiologic findings such as hyperinflation or situs inversus. The differential diagnosis of recurrent or persistent pneumonia is extensive and includes many underlying causes other than immunodeficiency.[64]

Severe Pneumonia with Usual Infections. The patient with an abnormal ability to deal with infection often has an atypical course when that patient is infected with a "usual" childhood respiratory pathogen. Varicella, influenza, parainfluenza, measles, and respiratory syncytial virus (RSV) are all potentially devastating pulmonary infections in immunocompromised hosts.[65-67] Although adenovirus is capable of causing severe pneumonia in any child, it is particularly devastating in immunocompromised hosts and possibly exceeds VZV and *P. jiroveci* as a cause of fatal pneumonias in high-risk populations such as recipients of bone marrow transplants.[68] Suppurative bronchitis related to common bacterial pathogens *H. influenzae* and *S. pneumoniae* infection is common in immunoglobulin deficiency.

Opportunistic Pneumonias. The "opportunistic" pathogens are those typically not seen except in the patient with altered host defense. PCP is probably the best example of pulmonary infection caused by an opportunistic pathogen and occurs in a variety of immunocompromised patients, including those with AIDS, T cell disorders, and agammaglobulinemia, pediatric oncology patients; and patients receiving high doses of corticosteroids.

Pathogens and Underlying Host Disorder

Another useful way to consider the types of pulmonary infections that occur in immunocompromised hosts is by considering the underlying host disorder. Childhood cancer therapy, bone marrow transplant and organ transplants, primary immunodeficiencies, and AIDS are each associated with specific pathogen groups (Table 36-3).

CHILDHOOD CANCER

Patients with childhood cancer are at high risk for respiratory infections for a variety of reasons in addition to the immunosuppressive effects of chemotherapy and radiation (Box 36-3). Among childhood cancer groups, there are differing risks for various pathogens.

The major risk factor for pneumonia in patients with leukemia is chemotherapy-induced neutropenia. Because patients with nonlymphocytic leukemia undergo the most intensive chemotherapy, they are at greatest risk for developing pneumonia. Bacterial pneumonias are most common, but RSV, adenovirus, and enteroviruses are also significant causes of pneumonia in patients with leukemia. Fungal pneumonias occur in patients with prolonged neutropenia, hospitalization, and broad-spectrum antibiotic therapy. *Aspergillus* species and Zygomycetes (*Mucor*, *Rhizopus*, and *Cunninghamella* species) are the two most common fungal pulmonary patho-

Typical Pulmonary Pathogens Associated with Immune Disorders

	Pathogens		
	Bacterial	**Fungal**	**Viral, Protozoal, or Other**
Neutropenia			
Chronic	*Haemophilus influenzae, Streptococcus pneumoniae, Staphylococcus aureus, Klebsiella* spp	—	—
Acute	*S. aureus*	—	—
Prolonged hospitalization	Gram-negative organisms, including *Pseudomonas* spp	*Candida* spp, *Aspergillus* spp, *Mucor* spp	—
Agammaglobulinemia, hypogammaglobulinemia	*S. pneumoniae, H. influenzae, Pseudomonas* spp	*Aspergillus* spp	*Pneumocystis jiroveci*
Congenital T cell disorders	*Legionella* spp, *Nocardia* spp, *Listeria* spp, Mycobacteria infections (including atypical strains), *Salmonella* spp	*Candida* spp, *Cryptococcus* spp	Cytomegalovirus (CMV), *P. jiroveci,* Varicella-zoster virus (VZV), herpes simplex virus (HSV)
AIDS	*Mycobacterium tuberculosis, Mycobacterium avium-intracellulare*	*Cryptococcus* spp	CMV, *P. jiroveci, Toxoplasma* spp
Complement deficiencies	Virulent encapsulated spp (e.g., *S. pneumoniae, H. influenzae*)	—	—
Immunosuppressive therapy (e.g., renal, liver, lung transplant)	*S. aureus, Listeria* spp, *Mycobacterium tuberculosis*	*Aspergillus* spp, *Mucor* spp, *Histoplasma* spp	CMV, *P. jiroveci,* VZV, *Toxoplasma* spp, HSV, *Cryptococcus* spp
Bone marrow transplant			
Early (<30 days)	*Pseudomonas* spp, other gram-negative and gram-positive spp	*Candida* spp	—
Late (>30 days)	*S. aureus*	*Aspergillus* spp	CMV, *Toxoplasma* spp, VZV, *P. jiroveci,* Epstein-Barr virus, adenovirus
Late (>100 days)	Encapsulated gram-positive (*H. influenzae, S. pneumoniae*)	—	VZV

Table 36-4
Pulmonary Complications after Bone Marrow Transplant

Pulmonary Host Defense	Association	Organisms	Other Pulmonary Disorders
Pretransplant	Neutropenia, chemotherapy, prolonged use of antibiotics, iatrogenic procedures	Bacteria, fungi	—
Early post-transplant (<1 mo)	Neutropenia, mucositis, use of antibiotics, radiation	Bacteria (particularly gram-negative), HSV, RSV, *Candida* spp, *Aspergillus* spp,	Pulmonary edema, ARDS
Later post-transplant (1-4 mo)	Acute GVHD, failed engraftment	CMV, adenovirus, PC, *Aspergillus* spp, *Mucor* spp, HHV-6, EBV	Interstitial pneumonia, lymphoproliferative syndromes
Late post-transplant (>4 mo)	Chronic GVHD, poor antibody response	VZV, encapsulated gram-positive bacteria, PC	Bronchiolitis obliterans, BOOP

ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans–organizing pneumonia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; GVHD, graft-versus-host-disease; HHV-6, human herpesvirus type 6; HSV, herpes simplex virus; PC, *Pneumocystis jiroveci;* RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

gens Patients with lymphoma are at risk for pneumonia because of neutropenia during therapy and because of a variety of nonspecific immunologic defects, including anergy.[69,70] Patients with Hodgkin disease are often infected with *Toxoplasma gondii* and fungi such as C*ryptococcus neoformans*. The mediastinal adenopathy and lung nodules commonly seen in these children at diagnosis often require extensive evaluation to differentiate lymphoma from granulomatous pulmonary infections such as tuberculosis and histoplasmosis.

TISSUE TRANSPLANTATION: BONE MARROW AND SOLID ORGAN

The types of pulmonary complications in allogeneic bone marrow transplant vary with the period after transplantation (Table 36-4). Immediately after transplantation, patients are neutropenic and at risk for bacterial pneumonias caused by *P. aeruginosa* and *S. aureus*. As the transplant becomes established and the neutrophil count rises, acute GVHD becomes a serious concern. Immunosuppressive therapy for GVHD with corticosteroids or cyclosporine A adds to the risk of pneumonia caused by viral pathogens (CMV, herpes simplex virus [HSV], adenovirus) as well as *P. jiroveci* and other fungi.

If engraftment fails and prolonged neutropenia occurs, the risk of fungal pneumonia rises significantly. Idiopathic interstitial pneumonias also occur during this later time, possibly because of radiation or chemotherapy.[71] Late (more than 4 to 6 months after the transplantation) causes of pneumonia include *H. influenzae* and *S. pneumoniae* and are associated with persistent humoral immune deficits to these encapsulated organisms. A frequent cause of morbidity in the late transplant period is BOOP, which is thought to be an immunologic disorder related to chronic GVHD.[72-76] The frequency of this complication in pediatric recipients of bone marrow transplants is not clear, and it may be less common than in adult recipients.[74] Infection may play a role in provoking or exacerbating chronic lung damage caused by BOOP.[75,76]

CMV infection remains a major cause of morbidity and mortality in pediatric recipients of bone marrow transplants. CMV occurs more frequently in recipients of allogeneic bone marrow transplants than in those receiving antologous transplants (12.4% versus 3.3%) and in patients who are seropositive before transplant or who receive marrow from seropositive donors.[77] The incidence increases with age and is 1.3% from birth to 9 years of age and 2.1% from 10 to 19 years of age. The mortality rate of CMV pneumonitis was greater than 90% before the use of ganciclovir and immunoglobulin therapy, which must be started early to be effective. In one series, only 10 of 75 recipients of bone marrow transplants with CMV pneumonitis survived for a long time, and of these, 9 were ventilator independent at the initiation of therapy with ganciclovir and immunoglobulin.[78] Studies of risk groups for CMV pneumonitis in a group of 62 allogeneic pediatric and adult recipients of transplants confirmed a low incidence in seronegative recipients who received grafts from seronegative donors and screened blood products. T cell depletion to prevent GVHD in a CMV-seropositive recipient whose tissue was grafted from a nonimmune donor is associated with a high risk of CMV interstitial pneumonia.[79] Fungal infections, including invasive pulmonary disease, are another major cause of morbidity and mortality in the bone marrow transplant population. Prolonged neutropenia is a major risk factor for the development of fungal infections.

The development of pulmonary infections after renal and other solid organ transplants is attributable to chronic immunosuppression with cyclosporine A and corticosteroid therapy.[80] CMV is the most significant pulmonary infection in recipients of all transplants, and in recipients of heart-lung transplants, *P. jiroveci* and *Toxoplasma* infections are also quite common.[81,82] In pediatric recipients of 58 consecutive renal transplants who were followed for up to 72 months, CMV infection occurred in 40% and CMV disease in 15% (1 death).[83] The highest risk for CMV infection occurs in the first 12 weeks after the transplantation, and donor CMV seropositivity, regardless of recipient CMV serostatus, is significantly associated with CMV infection.

Gram-negative and fungal infections are the most common pulmonary complications in recipients of liver transplants. They occur primarily in the first month after transplantation.[84]

PRIMARY IMMUNODEFICIENCY

In patients with common variable immunodeficiency and X-linked agammaglobulinemia, repeated bacterial pneumonias are most common, and *P. jiroveci* is occasionally seen in patients with hypogammaglobulinemia.[85-88] Patients with

congenital T cell disorders, including severe combined immunodeficiency, are at risk for most of the same opportunistic pathogens as patients with AIDS, including PCP.

Fungi, primarily *Aspergillus* species, and *S. aureus* are the most common lung infections in children with chronic granulomatous disease. Extensive lung destruction and hilar adenopathy are common in these patients.[89-91] Patients with chronic mucocutaneous candidiasis, a T cell disorder, have persistent and recurrent *Candida albicans* infection of the mucous membranes and skin but 50% have recurrent bacterial pneumonias, and they are at risk for infections caused by other opportunistic pathogens, including *P. jiroveci*, *Nocardia*, and varicella-zoster virus pneumonias. Pulmonary complications, including bronchiectasis, empyema, and lung abscess, frequently occur.[91]

AIDS

The extensive list of pulmonary infections associated with AIDS includes *P. jiroveci*, CMV, bacteria, and atypical mycobacteria as major causes of pneumonia in this group[92] (Fig. 36-9).

Radiographic Presentation

Pneumonias in this population can be classified by the general appearance of the radiograph. Findings include diffuse alveolar and interstitial pneumonias, localized alveolar lobar or lobular pneumonias (which may involve more than one lobe), and nodular infiltrates (which may be cavitary or progress to frank lung abscess). The common causes of these general radiographic patterns are listed in Box 36-4, but it must be emphasized that radiographic appearances are often deceptive in immunocompromised hosts and are usually not helpful in making a specific etiologic diagnosis. The value of CT over plain radiography in this population is also clear. In neutropenic patients with unexplained fever and normal chest radiography, CT scans of the chest are frequently abnormal before plain radiographs and CT scans also can show early changes such as peripheral halo effects that can suggest a specific diagnosis (*Aspergillus* or similar fungi).

P. jiroveci is the prototypical organism associated with the radiographic pattern of diffuse interstitial and alveolar pneumonias (Fig. 36-10). Although the incidence of *P. jiroveci*

Figure 36-10 Chest radiograph of *Pneumocystis jiroveci* pneumonia.

infection has declined significantly in patient populations receiving prophylaxis, PCP remains the major pathogen associated with AIDS, and atypical radiographic appearances of *P. jiroveci* are common and include normal radiographs; radiographs showing cystic, unilateral, and granulomatous changes; and radiographs showing associated pleural disease.[92-95] The use of aerosolized pentamidine for PCP prophylaxis in AIDS may alter the radiographic presentation more toward upper lobe disease. This was thought to occur because of the preferential distribution of the medication to the lower lobes, but studies of drug levels suggest that other factors may be involved because medication levels are similar in both upper and lower lung zones despite larger numbers of organisms in the upper lung zones.[96] CMV is also associated with diffuse pneumonia in immunocompromised patients and is frequently seen in association with other infectious agents. Viral infections, including adenovirus and influenza, are also important causes of diffuse pneumonia.

Bronchopneumonias and lobar consolidation can occur in immunocompromised patients and are caused by the usual pathogens, such as *S. pneumoniae*, *H. influenzae*, and *S. aureus*. However, because the radiographic pathology is a product of the host's response to the organism, patients with abnormal host defenses often have an altered initial radiographic pattern.

Solitary pulmonary nodules, either unilateral or bilateral, are less common presentations of infection in most immunocompromised patients but do occur frequently in pediatric oncology patients. Although these most often represent fungal pneumonias, infections of other organisms, including *Nocardia* species, can also manifest as pulmonary nodules. The development of a lung abscess generally indicates a degree of host immunity sufficient to localize an infection. The most common cause of cavitary lesions in pediatric patients with cancer is fungal infection, especially with *Aspergillus* species. Both PCP and mycobacterial infections can be associated with cavitary disease in patients with AIDS.[94,95]

DIAGNOSIS

General Approach to Immunocompromised Children with Pneumonia

Although clinical information such as the general association of certain types of pulmonary pathogens with certain at-risk groups and general radiographic patterns may be useful, both approaches have limitations in the immunocompromised patient with pneumonia. Many noninfectious pulmonary processes also occur in this group, and the list of organisms causing pneumonia is extensive. Generally, empirical broad-spectrum antibiotic therapy must be started in patients with known immunodeficiency at the first sign of fever and often before the development of overt pneumonia. This often complicates subsequent diagnostic studies. The laboratory diagnosis of opportunistic pulmonary infections is a complicated and evolving field and the choice of diagnostic tests depends on the experience and skill of the clinical laboratory.[97]

Indirect Diagnostic Tests

The utility of various respiratory specimens for direct detection or culture of opportunistic infections is shown in Tables 36-5 through 36-8 and Box 36-5.

SPUTUM EXAMINATION AND CULTURE

Sputum samples are difficult to obtain in children younger than 10 years of age and when obtained, must be interpreted cautiously. Analysis of sputum produced by cough induced with the inhalation of hypertonic saline aerosols has been useful in diagnosing infection in older children with AIDS and PCP.[98] Gastric aspirates can be used in the younger child and are particularly helpful when the pathogen being consid-

Legionella species	Direct fluorescent antibody	PCR,† urine antigen (RIA)	Special *Legionella* media (BCYE)	2-7 d
Fungi	Wet mount or calcofluor white	Serum cryptococcal antigen Serum histoplasma antigen	Mycologic media (e.g., Sabouraud, BHI agar)	6-8 wk
Mycobacterium species	Acid-fast stain	PCR‡	Mycobacterial media (Middlebrook 7H 10/11)	≥8 wk
Nocardia species	Modified acid-fast stain	Not available	Blood agar, Sabouraud	4-6 wk
Pneumocystis species	Fluorescent antibody, Giemsa, toluidine blue O	PCR‡	Noncultivable organism	
Viruses	Fluorescent antibody for specific viruses§	EIA‡ for RSV, influenza A FAB for CMV, VZV, HSV	Traditional tissue culture Shell vial culture‖	≥2 wk 2-5 d
Chlamydia species	None¶	PCR‡	HL or HEp-2 cells	3-5 d
Mycoplasma species	None	PCR‡	Selective media	7-10 d

*These stains usually done by microbiology laboratories on sputum, bronchoscopic, or biopsy specimens.
†The PCR assay is available in a few diagnostic laboratories but is not generally available.
‡Research technique.
§Direct fluorescent antibody and EIA are available only for some viruses (see text).
‖Influenza A and B; parainfluenza 1, 2, and 3; RSV, CMV, HSV, and VZV are commonly available.
¶None for *Chlamydia pneumoniae*.
BCYE, buffered charcoal yeast extract; BHI, brain-heart infusion; CMV, cytomegalovirus; EIA, enzyme immunoassay; FAB, fluorescent antibody; HSV, herpes simplex virus; PCR, polymerase chain reaction; RIA, radioimmunoassay; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

ered is not a usual colonizing organism of the upper airway (e.g., pathogen causing tuberculosis).

ENDOTRACHEAL TUBE ASPIRATES

If the child requires endotracheal intubation for respiratory distress, endotracheal aspirates are easy to obtain. The diagnostic yield in complex immunocompromised patients is improved by using wax-protected microbiological brushes or nonbronchoscopic bronchoalveolar lavage.[99,100]

BLOOD CULTURES

Although blood culture should be obtained in all immunocompromised children suspected of having bacterial or fungal pneumonia, positive cultures are unusual, although generally highly specific.

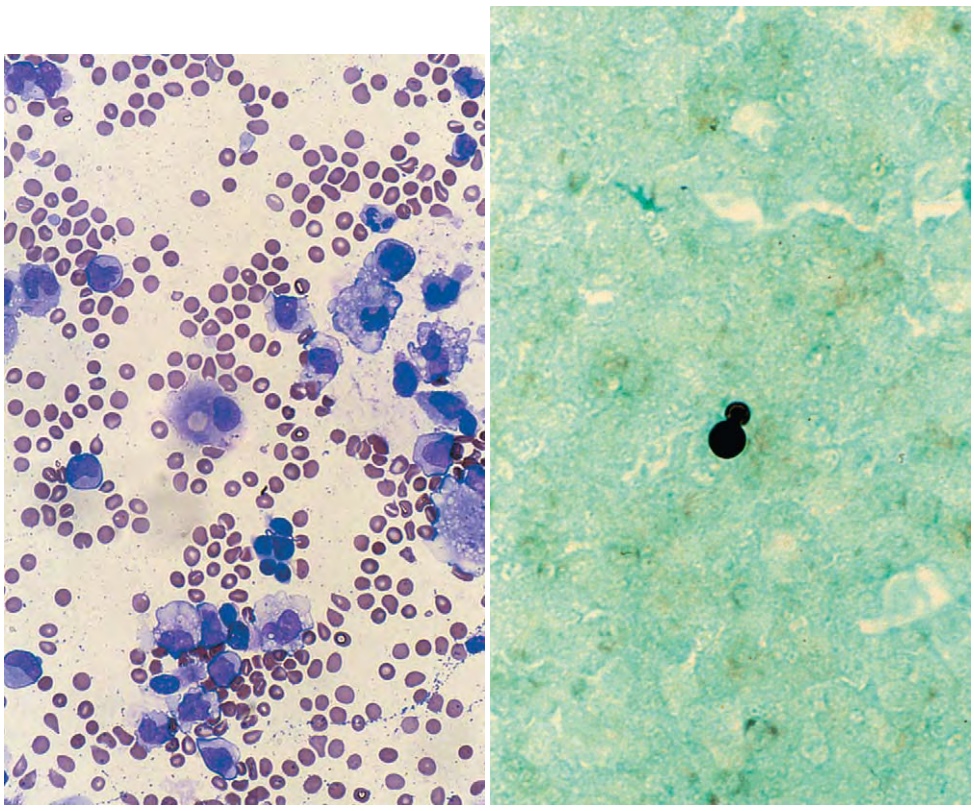
ANTIGEN AND ANTIBODY DETECTION METHODS

The rapid diagnosis of RSV, influenza A virus, parainfluenza virus, and *Chlamydia* infections by enzyme-linked immunosorbent assay and direct immunofluorescence is now available routinely. The sensitivities of these tests depend partly on the adequacy of the sample provided to the laboratory. Viral cultures are generally available, and the shell vial technique for the rapid identification of CMV and other viral pathogens has proved very useful, although the significance of viral isolates depends on the virus and the site from which it is isolated (see Table 36-6). Although *Mycoplasma pneumoniae* can be cultured on enriched media, this usually takes several weeks, and the diagnosis is usually based on serologic conversion. Genetic probes for detecting *Legionella* species, *Mycobacterium* species, and *M. pneumoniae* are now commercially available. Fungal infections can also be identified from a variety of specimens. A number of tests for the direct detection of fungal antigens have been described, but none is in widespread clinical use with the exception of *Cryptococcus* antigen.

Flexible Bronchoscopy

Flexible bronchoscopy is safe in experienced hands and provides excellent culture material in the immunocompromised child with pneumonia.[101-108] Indications in children with pneumonia include (1) failure of the pneumonia or fever to clear with appropriate antibiotic therapy; (2) suspicion of endobronchial obstruction by an infection or a tumor; (3) recurrent pneumonia in a lobe or segment; and (4) suspicion of unusual organisms such as *P. jiroveci*, fungi, and the pathogen that causes tuberculosis. Although the yield of gastric aspiration is probably superior to that of bronchoscopy for tuberculosis, bronchoscopy can also be useful to evaluate for endobronchial disease or bronchial compression.

The bronchoscope suction channel is contaminated by organisms of the upper airway, and simple washings obtained through the bronchoscope channel are generally useless for culture. Several techniques, including the use of a double-sheath, wax-protected sterile brush and quantitative cultures of bronchoalveolar lavage fluid, have been developed to avoid this problem. Bronchoalveolar lavage is the most useful technique for diagnosing infection in the immunocompromised host, and a variety of infectious and noninfectious diagnoses, including hemorrhage and pulmonary involvement with leukemia (Fig. 36-11), can be made using it. Bronchoalveolar lavage is generally safe even in patients with reduced numbers of platelets. Brushings obtained through the bronchoscope can be used for cytologic examination and viral cultures, but the yield is usually low.



A B

Figure 36-11 Diagnosis of conditions from specimens obtained from bronchoalveolar lavage. **A,** Monocytic leukemia. **B,** Blastomycosis.

Although the safety and usefulness of bronchoscopy are well documented in this population, it is important for the clinician to recognize the limitations of bronchoscopy. In patients on empirical broad-spectrum antibiotic therapy, the yield of bacterial pathogens is likely to be low. In oncology patients and other non-AIDS immunocompromised patients, the number of *P. jiroveci* organisms is usually low compared to the number obtained from patients with AIDS, so the results may be falsely negative. In populations receiving prophylaxis for this infection, the yield for PCP is likely to be low, reducing the overall yield of bronchoscopy for treatable infections. CMV can also be diagnosed rapidly by bronchoscopy, but patients may have other complicating infections, such as those caused by fungi and CMV, that are more easily missed by bronchoscopy. Infections caused by *Aspergillus* and other fungi are often difficult to diagnose by bronchoscopy, particularly early in the infection when therapy is most likely to be effective.

Transbronchial biopsies (TBB) can also be taken through the bronchoscope. Although safe in older patients, transbronchial lung biopsies yield an unacceptable number of false-negative results in immunosuppressed patients and are most useful when organisms such as *P. jiroveci* or granulomatous lesions are likely. Reported experience in pediatric patients is limited, but transbronchial biopsy has a significant role in monitoring rejection and infections in the pediatric patient after lung transplantation.[109]

Transthoracic Needle Aspiration Biopsy

Needle aspiration of the lung is useful for the diagnosis of PCP in pediatric patients with cancer and for the diagnosis of localized infections in other immunosuppressed patients.[110,111] Pneumothorax was a complication in 37% of the needle aspirates done for PCP, and this risk must be considered. Hemorrhage is more serious but less common. The use of computed tomography or fluoroscopic guidance greatly improves the yield and safety of this procedure, and it is the procedure of choice for many children with suspected peripheral fungal lesions that can safely be aspirated.

Open Lung Biopsy

Open lung biopsy is the standard by which other diagnostic modalities are judged. Because it uses current surgical techniques, open lung biopsy is generally a procedure with a low morbidity that can be done rapidly and allows the surgeon to obtain the optimal tissue for culture and microscopic examination. "Minithoracotomy" and lingular biopsy may be all that are necessary in patients with diffuse pulmonary processes. Biopsy using fiberoptic pleuroscopy may be adequate for pleural-based lesions and reduces the morbidity associated with open biopsy.

TREATMENT

Early treatment is necessary for the immunocompromised patient with pneumonia, and empirical antibiotic therapy is generally started at the first sign of clinical pneumonia. In many patients (e.g., the febrile, neutropenic patient), empirical antibiotic therapy may already have started before the pneumonia becomes clinically or radiographically apparent. Antibiotic therapy is typically broad spectrum, aimed at both gram-positive and gram-negative bacterial infections (e.g., vancomycin-aminoglycoside or semisynthetic penicillin, third-generation cephalosporin). If a patient has new diffuse, bilateral pneumonia with respiratory distress and hypoxemia, the clinician must make a rapid decision about whether to proceed to bronchoscopy or open lung biopsy before the patient's condition progresses to respiratory failure and any procedure becomes more hazardous. Empirical therapy is usually guided by the underlying disorder and the radiographic and clinical features of the pneumonia and would usually include TMP/SMX for PCP as well as erythromycin for *Mycoplasma* and *Legionella* infection. Amphotericin B is often started in the febrile neutropenic patient who develops a new pulmonary infiltrate while on antibiotics. Because of its low morbidity, flexible bronchoscopy should be considered early in the course of the pneumonia. If bronchoscopy is negative, the risks and benefits of open lung biopsy must be weighed in each patient, particularly if the pneumonia progresses despite appropriate antimicrobial therapy. A good response to empirical antibiotic therapy indicates that it should be continued for a minimum of 2 weeks, but in the case of antifungal therapy, treatment may be required for much longer periods.

Viral Infections

CYTOMEGALOVIRUS

Immunoglobulin enriched for anti-CMV activity has been used intravenously for prophylaxis in high-risk populations without clear benefit. However, when CMV-IVIG (intravenous immunoglobulin) is combined with the antiviral medication ganciclovir, the mortality rate in CMV pneumonitis in recipients of bone marrow transplants is reduced. At present, ganciclovir and CMV-IVIG are the primary therapies for CMV pneumonitis in immunocompromised patients.

HERPES SIMPLEX VIRUS/VARICELLA

VZIG can modify or prevent varicella in high-risk hosts exposed to the infection if administered within 48 to 72 hours of exposure. Acyclovir and VZIG have been the major factors accounting for the reduced incidence of serious VZV pneumonias in immunocompromised hosts.

HHV-6

No specific treatment is available.

ADENOVIRUS

Supportive therapy includes the administration of oxygen, treatment of bacterial superinfections, IVIG, and assisted ventilation. Cidofovir, a nucleotide analog with broad antiviral activity against DNA viruses, including adenovirus, was safe and effective in treatment of adenoviral infection in pediatric stem cell transplant patients.[112]

Fungal Infections

ASPERGILLUS *AND* CANDIDA *SPECIES*

The treatment of *Aspergillus* pneumonia includes amphotericin B, given at a dose of 1 to 1.5 mg/kg. Sometimes, flucy-

tosine or rifampin is also administered. The surgical excision of *Aspergillus* lesions is somewhat controversial.[113-116] Invasive pulmonary aspergillosis during treatment of hematologic malignancy is generally considered a contraindication to subsequent bone marrow transplantation, but adults treated with amphotericin B and surgery have survived without disease and without reactivation of *Aspergillus* infection after bone marrow transplantation.[117] The outcome of *Aspergillus* pneumonia depends primarily on host factors, the degree of immunosuppression, and the return of neutrophil counts to normal levels. Amphotericin B has been the treatment of choice for invasive candidal infections; flucytosine is used if synergism is desired. The imidazole antifungal agents, including ketoconazole, fluconazole, and itraconazole, have activity against *Candida* species and have been used successfully. Use of the imidazole antifungal agents for prophylaxis has helped kill more resistant fungal organisms in high-risk populations. These newer antifungal therapies have replaced conventional amphotericin B in the treatment of aspergillosis and candidiasis, including voriconazole for invasive aspergillosis and caspofungin for invasive candidiasis.[118,119]

MUCOR

As with *Aspergillus* organisms, treatment with amphotericin B and possibly surgical resection as early as possible is critical to achieving a cure. Correction of chronic acidosis if present also appears to be important in some forms of this infection.

HISTOPLASMOSIS AND BLASTOMYCOSIS

Amphotericin B is indicated for both histoplasmosis and blastomycosis in immunocompromised hosts. Itraconazole is also effective for histoplasmosis and moderate blastomycosis without central nervous system involvement.

CRYPTOCOCCUS NEOFORMANS

Treatment includes intravenous amphotericin B and oral fluconazole.

PNEUMOCYSTIS

All patients at known risk for *P. jiroveci* infection should receive prophylaxis (Box 36-6). For pediatric oncology and immunocompromised patients, oral TMP/SMX given 3 days a week is effective. However, if patients or parents are noncompliant, there is a risk of breakthrough pneumonias. For most patients, TMP/SMX remains the drug of choice, but other prophylactic regimens have been used, particularly in patients with AIDS; these include aerosolized and intravenous pentamidine and dapsone. Intravenous pentamidine may be associated with a higher risk of failure. Although there is extensive experience with aerosolized pentamidine in adults, there is less information on its use in infants and children.

PCP can be treated using several medications. The earliest medication available for PCP was pentamidine, which appears to work by inhibiting dihydrofolate reductase. Pentamidine was initially given by the intramuscular route, but subsequent studies showed that dosages of 4.0 mg/kg/day by the intravenous route are as safe as those given via the intramuscular route, although both are associated with high rates of immediate reaction, such as hypotension, tachycardia, and nausea. Hypoglycemia and nephrotoxicity are the most serious side effects of parenteral pentamidine. Pentamidine is also given by the aerosol route for the treatment of mild to moderate pulmonary disease in patients with AIDS, but its effectiveness is highly dependent on the delivery system used, and the aerosol route may predispose patients to extrapulmonary disease with *P. jiroveci*. TMP/SMX is as effective as pentamidine (approximately 70%) with fewer side effects. Some 60% of patients who do not have AIDS and in whom TMP/SMX therapy fails respond to treatment with pentamidine. In addition to pentamidine and TMP/SMX, a number of other medications are effective for the treatment of PCP; these include dapsone and trimetrexate. Patients with AIDS have a high incidence of reactions to many types of medications, including TMP/SMX.

Supportive therapy is a major part of the treatment for PCP. Oxygen, continuous positive airway pressure, continuous negative pressure, and assisted ventilation have all been used effectively in PCP. Trials in patients with AIDS indicate that corticosteroid administration during therapy improves outcome.[120-123] Typically, 4 to 6 days pass before improvement occurs with either pentamidine or TMP/SMX, and failure to improve warrants consideration of other infections and a change to another anti-*Pneumocystis* drug.

BOX 36-6 Indications for the Use of Anti-*Pneumocystis* Prophylaxis

- Solid-organ transplant recipients and allogeneic hematopoietic stem cell transplant or bone marrow transplant recipients with institutional incidence of 5% or in high-risk patients:
  - —History of PCP or frequent opportunistic infections
  - —With invasive cytomegalovirus (CMV) infection or at high risk for CMV disease
  - —During intensified immune suppression for acute allograft rejection or graft-versus-host disease (GVHD)
- Individuals receiving anti–T cell therapies
- Autologous bone marrow transplant recipients with leukemia or lymphoma, undergoing intensive conditioning or graft manipulation, or after fludarabine or 2-CDA administration
- Individuals with prolonged neutropenia (if marrow suppression is tolerable)
- Individuals with corticosteroid doses of >20 mg of prednisone per day for >2-3 wk

Bacterial Infections

Listeria infection is treated using ampicillin plus an aminoglycoside. Significantly, newer cephalosporins are not active against this species. C. *jeikeium* is resistant to most antibiotics except vancomycin. In most immunocompromised patients with pneumonia, vancomycin should be included in the treatment regimen to cover methicillin-resistant S. *aureus* and C. *jeikeium* when suspected.

TOXOPLASMA GONDII *AND* CRYPTOSPORIDIUM PARVUM

Treatment of *T. gondii* includes pyrimethamine-sulfadiazine. Treatment of C. *parvum* is with azithromycin.

CLINICAL COURSE AND PROGNOSIS

The clinical course and prognosis for immunocompromised patients with pulmonary infections are highly variable and depends on a number of factors including the underlying host disorder, the infectious agent, and how early effective treatment is started (Box 36-7). The clinical course may also be altered by the degree of residual host immunity. For example, corticosteroid therapy accelerates the resolution of *P. jiroveci* infection in patients with AIDS, suggesting that the residual host inflammatory response to this organism is important in the pathogenesis of respiratory dysfunction with PCP, even in profoundly immunosuppressed patients—a finding supported by reports of development of respiratory failure during reversal of immunosuppression in non-HIV patients.[124]

Fungal pulmonary infections in patients with chemotherapy-induced neutropenia often result in mild clinical symptoms and radiographic findings until a rise in the neutrophil counts results in significant inflammation, lung destruction and cavitation, and clinical deterioration. Because it is a relatively common opportunistic infection, the prognosis for invasive aspergillosis is well characterized. In solid organ transplants the incidence of infection ranges from 1% in renal transplant recipients to 7% to 9% in lung and bone marrow transplantation. Mortality rate for these populations ranges from 55% to 92% and depends significantly on early diagnosis.[125]

Adult and pediatric recipients of bone marrow transplants who were treated with recombinant human macrophage colony-stimulating factor had greater overall survival rate (27% versus 5% because of a 50% survival rate in patients with *Candida* infections)—although the survival rate in patients who developed *Aspergillus* infection remained poor.[126]

BOX 36-7 Common Clinical Scenarios in Immunocompromised Patients

Slow Progression, Absent (or Mild) Fever, Diffuse Pulmonary Opacity

Likely causes: pulmonary edema, pulmonary involvement with primary disease, drug or radiation injury
Evaluations: CT, bronchoscopy with bronchoalveolar lavage (BAL), cardiac ECHO

Rapidly Progressive, Fever, Diffuse Opacity

Likely causes: opportunistic infection, drug-induced
Evaluation: early bronchoscopy with BAL

Pneumonia and Sepsis/ARDS

Likely causes: bacterial
Evaluation: blood cultures, BAL, early empirical antibiotic therapy

Moderate Progression, Fever, Nodular/Round Density Progressing toward Cavitation

Likely causes: fungal, *Legionella, Nocardia*
Evaluation: CT, bronchoscopy, CT-guided aspiration biopsy

PITFALLS AND CONTROVERSIES

The major difficulty with immunocompromised patients is balancing institution of early empirical therapy (based on expected pathogens) with invasive diagnostic studies such as bronchoscopy (with or without transbronchial biopsy), CT-guided needle aspiration biopsy, and open lung biopsy (see Box 36-5).

Although bronchoscopy is generally the initial procedure of choice for pneumonia that has not responded to empirical therapy, there are several limitations to bronchoscopy for some types of infection (Box 36-8).

In immunocompromised patients, it is difficult to make generalizations about open lung biopsy, and much depends on local factors such as the availability of flexible bronchoscopy, the age of the child, the underlying conditions, complications such as thrombocytopenia and coagulopathies, and prior antibiotic or antifungal therapy. Some studies have questioned how often the results of open lung biopsy have led to a change in therapy if patients with nonspecific histologic findings and organisms treated by empirical therapy (e.g., *P. jiroveci*) are excluded. Published results in immunocompromised pediatric patients have indicated yields that range from 36% to 94% for a specific diagnosis.

Although open lung biopsy is the procedure of choice for obtaining definitive diagnostic information in immunosuppressed patients with pulmonary infiltrates, the timing of the biopsy is difficult. The clinician does not want to perform the procedure too early, especially if empirical therapy appears to be working and the patient is in good condition. On the other hand, when therapy is marginally successful, the surgeon does not want to wait so long that the patient's condition deteriorates and the risk of biopsy significantly increases. The authors generally suggest relatively early biopsy in immunosuppressed patients with pneumonia (see Fig. 36-10). Any patient with a condition not clearly responding to therapy chosen on the basis of other diagnostic techniques (including bronchoscopy) or therapy chosen empirically would usually benefit from a specific diagnosis by biopsy. In most medical centers, this is a relatively safe procedure, especially when performed before the patient has the need for respiratory support. The risks increase only when the biopsy is delayed until the patient has become critically ill. When the technique is used for the diagnosis of diffuse disease, only a limited thoracotomy with a superficial subsegmental resection is necessary. In localized disease typical of fungal infections, a more extensive procedure may be required to obtain an adequate specimen.

In specific patient groups such as recipients of bone marrow transplants and patients with AIDS, the use and timing of open biopsy may be different. In patients with AIDS, open lung biopsy is rarely necessary because a specific diagnosis can usually be made by using the results of bronchoalveolar lavage or transbronchial lung biopsy (see Fig. 36-11). If the disease progresses despite apparently adequate therapy or bronchoscopy is not diagnostic, open lung biopsy

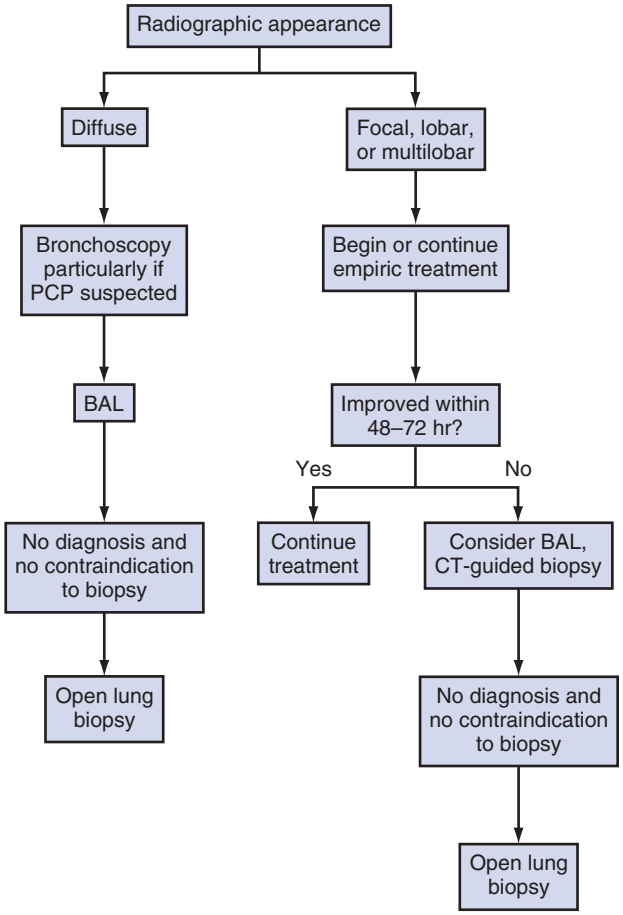


Figure 36-12 Flow diagram for the diagnosis of pneumonia in immunocompromised hosts. BAL, bronchoalveolar lavage; CT, computed tomography.

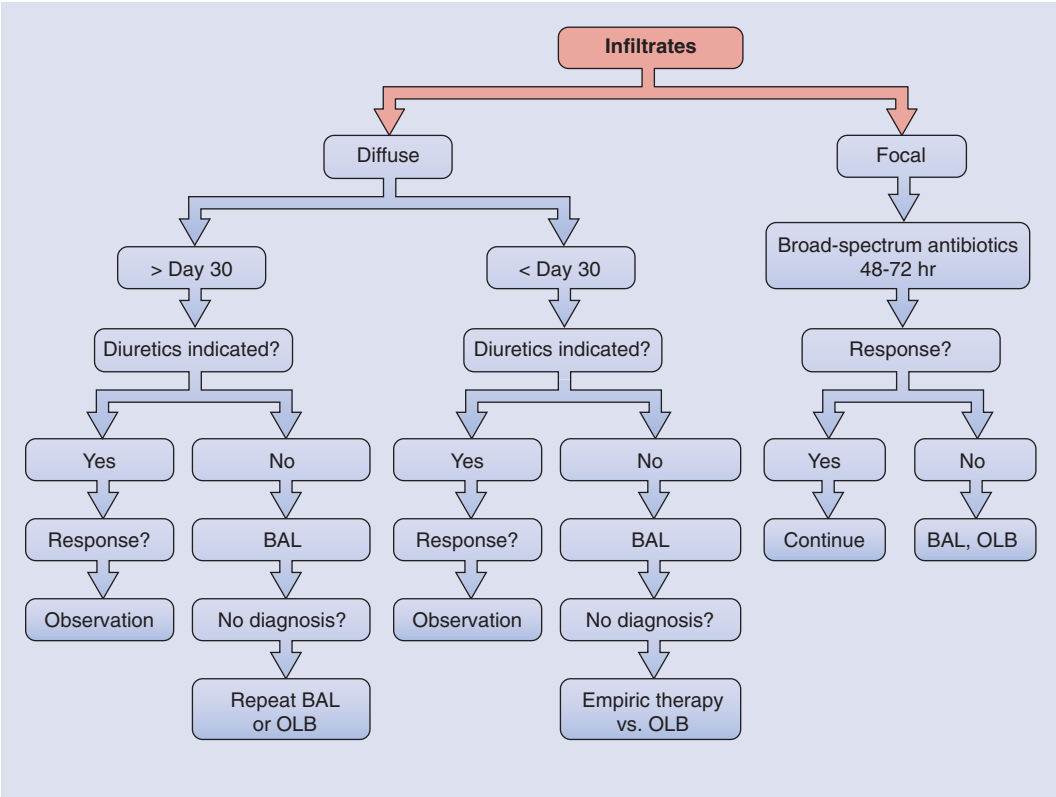

Figure 36-14 Flow diagram for the diagnosis of pulmonary disease in recipients of bone marrow transplants. BAL, bronchoalveolar lavage; OLB, open-liver biopsy. (From Dichter J, Levine SJ, Shelhamer JH: Hematol Oncol Clin North Am 7:887-912, 1993.)

BOX 36-8 Limitations of Bronchoscopy in Immunocompromised Patients

FALSE POSITIVES: *Candida* spp., cytomegalovirus (CMV) (particularly in bone marrow transplant patients)
FALSE NEGATIVES: aspergillosis and other fungal pathogens (particularly early), tuberculosis, *Nocardia,* tumor or involvement with hematologic malignancy

should be considered to rule out other co-pathogens (Figs. 36-12 and 36-13). In recipients of bone marrow transplants the approach may be modified to allow therapy of common noninfectious complications such as pulmonary edema before embarking on invasive diagnostic studies (Fig. 36-14).

Another area of relative controversy is the role of aggressive lung resection for fungal pneumonias. Patients with invasive aspergillosis and *Mucor* have a significant risk of death from pulmonary hemorrhage, and organisms may persist even after neutropenia has resolved, predisposing to recurrent infection with additional chemotherapy. It has been suggested that wedge resection or lobectomy may reduce the risk in these clinical situations.

For the immunocompromised patient who develops respiratory failure secondary to pulmonary complications, the outcome in the past has been poor, with very high mortality rates. Advances in treatments and supportive care have improved the outcome considerably for many patient groups, but these patients continue to present very challenging management and ethical dilemmas.[127-129]

CHAPTER 37 Human Immunodeficiency Virus Infection

Heather J. Zar and Michael R. Bye

TEACHING POINTS

- Respiratory illness is the predominant cause of mortality and morbidity in HIV-infected children.
- Severe pneumonia is often caused by co-infection with more than one pathogen.
- *Streptococcus pneumoniae* is the major bacterial pathogen causing pneumonia.
- Viral respiratory infections account for a lower incidence of pneumonia in HIV-infected compared with HIV-negative children, but are associated with more severe disease and a higher case fatality rate.
- *Pneumocystis jiroveci* (formerly *Pneumocystis carinii* pneumonia, hence [PCP]) is frequently the manifesting illness in infants undiagnosed with HIV; HIV-exposed infants are also at risk of PCP.
- With use of highly active antiretroviral therapy (HAART), the rate of opportunistic and respiratory infections has declined substantially.
- Cotrimoxazole prophylaxis may reduce mortality and morbidity in HIV-infected children of all ages, who are not taking HAART.
- The incidence of chronic lung disease increases with longer survival of HIV-infected children.

A changing pattern in the epidemiology of pediatric HIV and HIV-associated lung disease has emerged in developed countries over the last decade. In these countries, programs to prevent mother-to-child HIV transmission (MTCT), early diagnosis of HIV infection in infants, and use of *Pneumocystis* prophylaxis and highly active antiretroviral therapy (HAART) have led to a substantial decline in the incidence of pediatric HIV and HIV-associated respiratory infections. Concomitantly, with improved survival of HIV-infected children on HAART, the incidence of HIV-associated chronic lung disease has increased. In contrast, in developing countries, particularly those in sub-Saharan Africa, the HIV epidemic has escalated with a rise in acute and chronic HIV-associated pulmonary diseases. This has been compounded by poor access and unavailability of preventive strategies and of HAART for HIV-infected children. As a result, HIV-associated lung disease is a major cause of childhood morbidity and mortality in developing countries.

EPIDEMIOLOGY

The total number of pediatric AIDS cases has declined substantially in developed countries in the last decade owing to a dramatic reduction in perinatal HIV transmission. New cases of HIV infection in children in developed countries occur predominantly in adolescents owing to sexual transmission, but most adolescents will remain asymptomatic until adulthood.[1] However, globally there are approximately 2.3 million HIV-infected children, most of whom live in sub-Saharan Africa.[2] Approximately 540,000 children are infected with HIV annually; approximately 470,000 of these cases occur in developing countries.[2]

In the absence of HAART, up to 90% of HIV-infected children will develop a serious respiratory illness sometime in the course of their HIV disease, resulting in a large increase in the incidence and severity of childhood respiratory illness in developing countries and an exponential increase in infant and under-5 mortality rates.[3] Mortality rates among HIV-infected African children are much higher than those for developed countries; 26% to 59% of HIV-infected African children die within the first year of life and under-5 mortality rates exceed 60% in some countries.[4,5] Respiratory disease, principally pneumonia, is the predominant cause of childhood mortality in children in developing countries—accounting for approximately 2 million deaths annually in children younger than 5 years.[6] Pneumonia is also the most common cause of hospitalization in African HIV-infected children. Pneumonia-specific mortality rates are higher in HIV-infected children with case fatality rates consistently reported as three to six times those of HIV-negative patients.[7] In a U.S. cohort of HIV-infected children in the pre-HAART era followed longitudinally, respiratory infection was the most common cause of death in children under 6 years of age, with 32% caused by pulmonary infection.[8] The frequency of pulmonary disease as the underlying cause of death decreased significantly with increasing age, with 56% of respiratory-related deaths occurring within the first year of life.[8]

Clinical Features

HIV-associated respiratory involvement may manifest as acute or chronic disease, involving the upper and/or lower respiratory tract. Infections, especially pneumonia, are the major cause of acute lung disease whereas chronic disease

may manifest as chronic infection, bronchiectasis, or lymphocytic interstitial pneumonia (LIP).

INFECTIOUS DISEASES

The rate of acute respiratory infections has decreased dramatically with the use of HAART.[9] In the pre-HAART era, the most common opportunistic infection in children in the United States was serious bacterial infection, principally pneumonia.[10] Other common opportunistic infections (event rates >1 per 100 child-years) involving the respiratory tract were PCP, disseminated *Mycobacterium avium* complex (MAC) and tracheobronchial candidiasis.[10] Less commonly (event rates <1 per 100 child-years) tuberculosis (TB), cytomegalovirus (CMV) disease, and systemic fungal infections occurred.[10]

In the HAART era, the number of opportunistic infections has declined substantially, although the relative prevalence of AIDS-defining infections has remained constant.[11] In children not taking HAART or those resistant to antiretroviral therapy, acute respiratory infections are common and may be severe. Infection of the upper airways may produce sinusitis, ear disease, supraglottitis, epiglottitis, or laryngotracheobronchitis. More severe acute infection may involve the lower airways and manifest as pneumonia, pleural effusion, bronchiolitis, a lung abscess or localized parenchymal disease. A number of bacteria, viruses, or fungi may cause respiratory infections in HIV-infected children (Box 37-1); mixed infections also occur commonly.

Bacterial Infections

Pre-HAART, bacterial pneumonia was the most common serious bacterial infection, with an event rate of 11 per 100 child-years[12]; this has declined to a rate of 2.2 in the HAART era.[9] Bacterial pneumonia is still a major cause of hospitalization and mortality in HIV-infected children who are unable to access HAART, particularly in developing countries.[3,13] The clinical signs of pneumonia are similar in HIV-infected and uninfected children but bacteremic illness is more common in HIV-infected children, occurring in approximately 15% to 20%, and the case fatality rate is higher.[14,15]

The etiology of bacterial pneumonia is similar to that in HIV-uninfected children (see Chapter 35), with *S. pneumoniae* the most common cause and accounting for more than 50% of associated bacteremic illness.[14-19] The risk of pneumococcal infection or invasive disease is significantly higher in HIV-infected than uninfected children.[14,19] The incidence of *Staphylococcus aureus* respiratory infection is increasing in HIV-infected children and may manifest as an empyema, pneumatocele, or lung abscess.[20] *S. aureus* is the most common pathogen occurring in catheter-associated bacteremia.[21] In addition, gram-negative pathogens such as *Klebsiella pneumoniae, Pseudomonas aeruginosa, Haemophilus influenzae,* non-typhoid *Salmonella* and *Escherichia coli* may cause pneumonia with or without bacteremia in HIV-infected children.[14,15,22,23]

HIV infection has been associated with an increase in the antimicrobial resistance patterns of bacterial pathogens causing pneumonia, with implications for empirical antibiotic therapy.[14] Methicillin-resistant *S. aureus* has increasingly emerged as a pathogen in HIV-infected children. There are variable data on the prevalence of penicillin-resistant pneumococcal infection in HIV-infected children but no clear differences in clinical outcome for susceptible and resistant strains have been shown, except for isolates with high level resistance.[24]

Immunization with the pneumococcal conjugate vaccine reduces the incidence of pneumonia and invasive disease.[25-27] In HIV-infected children, immunization reduces the incidence of invasive disease due to vaccine strains by 65% and also prevents 13% of radiologically confirmed pneumonia.[25] Although the efficacy is lower than that in HIV-uninfected children, vaccination still offers protection to a substantial proportion of HIV-infected children. Moreover, immunization reduced the incidence of infection with drug-resistant pneumococcal strains.[25] Immunization also reduces the incidence of hospitalization for viral-associated pneumonia, suggesting that more severe pneumonia requiring hospitalization may occur due to viral and *S. pneumoniae* coinfection.[28]

BOX 37-1 Etiology of Pneumonia in HIV-Infected Children

Bacteria

Streptococcus pneumoniae
Haemophilus influenzae
Staphylococcus aureus
Mycobacterium tuberculosis
Non-tuberculous *Mycobacteria*
Non-typhoid *Salmonella*
Klebsiella pneumoniae
Streptococcus milleri
Escherichia coli
Moraxella catarrhalis

Atypical Bacteria

Mycoplasma pneumoniae
Chlamydia trachomatis
Chlamydia pneumoniae

Viruses

Respiratory syncytial virus
Cytomegalovirus
Human meta-pneumovirus
Parainfluenza virus types 1 and 3
Adenovirus
Influenza virus A or B
Measles virus
Varicella-zoster virus
Human papillomavirus type 6 or 11

***Pneumocystis* and Fungi**

Pneumocystis jiroveci (previously *Pneumocystis carinii*)
Candida species
Aspergillus species
Histoplasma capsulatum
Cryptococcus neoformans
Coccidioides immitis

Mycobacterial Infections

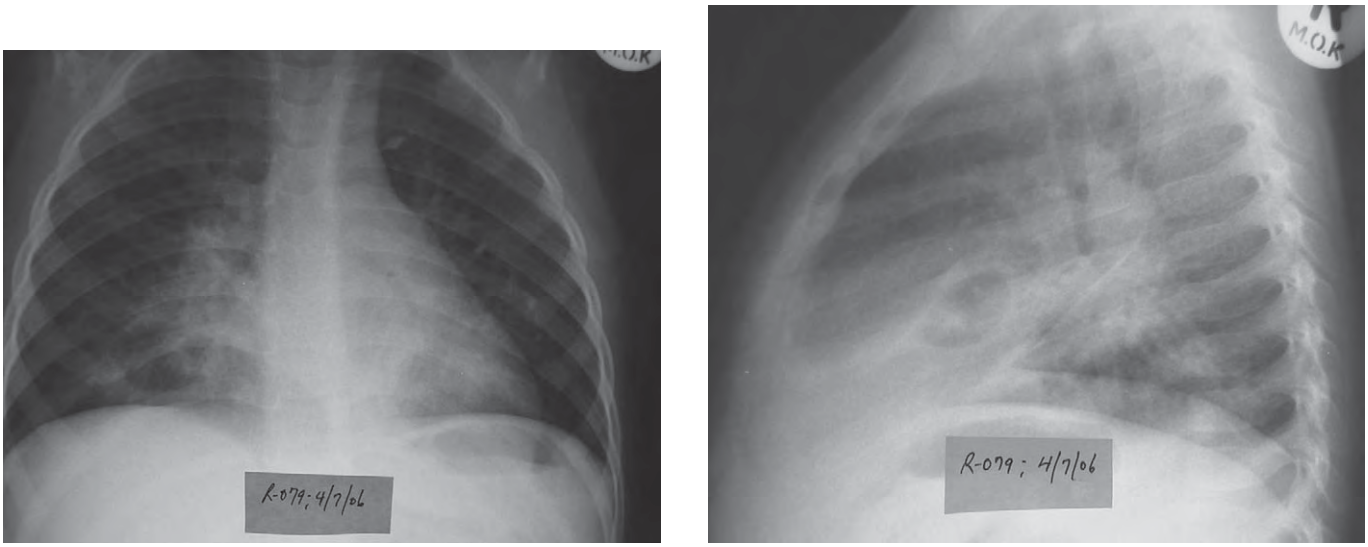
Mycobacterium tuberculosis is an important cause of acute pneumonia in HIV-infected children living in high TB prevalence areas, with culture-confirmed pulmonary tuberculosis occurring in approximately 8% of children hospitalized with pneumonia.[14,15,29] Pediatric TB infection is usually acquired from an infectious adult contact (see Chapter 39). The incidence of TB and risk of disease are higher in HIV-infected compared to immunocompetent children.[29-31] Primary infection rather than reactivation disease is usual in children.[32] Co-infection with *M. tuberculosis* and HIV results in more rapid deterioration of immune dysfunction, viral replication, and HIV progression and more frequent and severe other infections.[33-36]

HIV-infected children with TB may present with nonspecific signs including weight loss, failure to thrive, and fever or with signs and symptoms of acute pneumonia or airway obstruction.[29,33-36] Pulmonary TB may also manifest as chronic, persistent respiratory symptoms and failure to thrive (see Chapter 39). The clinical presentation is similar in HIV-infected and uninfected children, although more severe disease, cavitary disease, and more rapid progression may occur in HIV-positive children (Fig. 37-1).[29,33-36] Extrapulmonary and miliary disease (Fig. 37-2) occur more commonly and progression to death is more rapid than in HIV-negative children.[29,33-36] Multidrug resistant (MDR) TB is increasingly prevalent in TB-endemic areas; the clinical features are similar to drug susceptible TB, although the prognosis is poorer.[37] In the United States, MDR TB, reported in 2.8% of foreign-born and 1.4% of U.S.-born children with TB, is uncommon.[32]

Localized or disseminated *Mycobacterium bovis* infection including pneumonia has been reported in HIV-infected children who received bacille Calmette-Guérin (BCG) immunization; this may occur weeks to years after vaccination.[38-40] Ulceration at the site of vaccination and localized lymphadenopathy are not uncommon in HIV-infected children; systemic dissemination occurs more rarely.[38-40] The risk of disseminated BCG disease is increased several hundred-fold in HIV-infected infants compared to HIV-uninfected infants.[38] The clinical presentation of disseminated *M. bovis* may be indistinguishable from *M. tuberculosis* infection.[40] Disseminated *M. bovis* infection has a poor prognosis with a case fatality rate of approximately 50%.[40]

Non-tuberculous mycobacteria (NTM), particularly MAC, may cause disseminated disease including pulmonary infection in severely immunosuppressed HIV-infected children; isolated pulmonary disease is rare.[10,41] Children with pulmonary disease are at high risk for developing dissemination; up to 72% develop systemic disease within 8 months.[10] Disseminated MAC appears to be more common in children who have transfusion-acquired HIV than perinatal acquisition.[42] Epidemiologically, disease occurs in adults with CD4 counts less than 50 cells/μL but the threshold has been less well established in young children.[43] Primary and secondary prophylaxis is, therefore, recommended for severely immunosuppressed children based on CD4 counts.[43,44] The incidence of NTM disease has declined significantly with successful use of HAART from a rate of 1.8 per 100 child-years pre-HAART to 0.1 post-HAART.[9,12]

With increasing use of HAART, an immune reconstitution syndrome (IRIS) associated with mycobacterial infection has been reported.[45] Immune reconstitution syndrome may occur weeks to months after initiation of HAART therapy and may result either from unrecognized mycobacterial infection or from a florid immune response directed against a mycobacterial antigen in those already on therapy for mycobacterial infection.[45] IRIS has been described with different mycobacterial species including *M. tuberculosis*, *M. bovis*, or MAC infection.[46-48] Most cases of IRIS with *M. tuberculosis* have been described in HIV-infected adults,[49-50] but this is increasingly being recognized in HIV-infected children from high TB-prevalent areas.[51] Clinically, IRIS is characterized by a seemingly paradoxical worsening in signs with increasing lymphadenopathy, new clinical and radiological respiratory signs, and fever (Fig. 37-3).[47,48,50,51] The tuberculin skin test may become positive and chest radiographs may show devel-



A B

opment of lymphadenopathy or new infiltrates.[50,51] IRIS must be distinguished from other infections, multidrug resistant TB, or non-response to TB therapy because of noncompliance.[50] To minimize the risk of IRIS, HIV-infected children with confirmed or probable TB should be treated with antituberculous drugs for 1 to 2 months before commencing HAART.[50] When IRIS develops in a child who was not known to have TB, therapy for TB should be initiated. If lymphadenopathy or respiratory signs are particularly severe, oral corticosteroids may be beneficial, although there are no controlled trials in children.[50]

Viral Infection

Viral respiratory infection, although accounting for less pneumonia in HIV-infected compared with HIV-negative children, is associated with more severe disease and a higher case fatality rate.[52] The presence of wheezing suggests a viral etiology; however, HIV-infected children with viral lower respiratory infection are more likely to develop pneumonia rather than wheezing.[52] Respiratory syncytial virus (RSV) is the most common cause of viral pneumonia, especially in the first 3 years of life (see Chapter 33). Concurrent bacterial infection has been reported in 30% to 50% of children hospitalized with viral pneumonia. Human meta-pneumovirus (hMPV),

C

Figure 37-3 Immune reconstitution in a child with undiagnosed tuberculosis (TB) started on HAART. **A,** Chest radiograph prior to HAART initiation when a TB work-up was negative. **B,** Chest radiograph 1 month into HAART therapy showing development of right-sided disease. **C,** Chest radiograph 2 months into HAART therapy showing extensive right-sided disease and compression of the right bronchus. A gastric lavage culture obtained prior to initiating HAART then grew *Mycobacterium tuberculosis* and the tuberculin skin test became positive.

is emerging as an important respiratory pathogen in HIV-infected children and produces a similar spectrum of disease to RSV.[53] Other respiratory viruses that may produce lower respiratory tract infection include parainfluenza virus types 1 and 3, adenovirus and influenza A or B virus (see Box 37-1).[52]

Cytomegalovirus (CMV) may produce severe, disseminated disease including pneumonia in HIV-infected children.[10] CMV can cause primary pneumonitis or may be found in association with other pathogens, especially *Pneumocystis*. Co-infection with CMV and HIV results in more rapid progression of HIV disease.[54] Therefore, CMV prophylaxis should be provided for severely immunosuppressed children or those with a history of CMV disease. The incidence of CMV infection has decreased with the use of HAART.[9]

Herpesvirus infections may involve the respiratory tract in HIV-infected children. Oral herpes-simplex virus lesions may spread to involve the larynx and upper airways resulting in croup[55]; disseminated disease including pneumonia may also occur. Pneumonia may occur as a complication of varicella-zoster virus infection.[56] Measles virus infection may result in severe pneumonia; in HIV-infected children infection may occur without a typical skin rash, making diagnosis particularly difficult.[57]

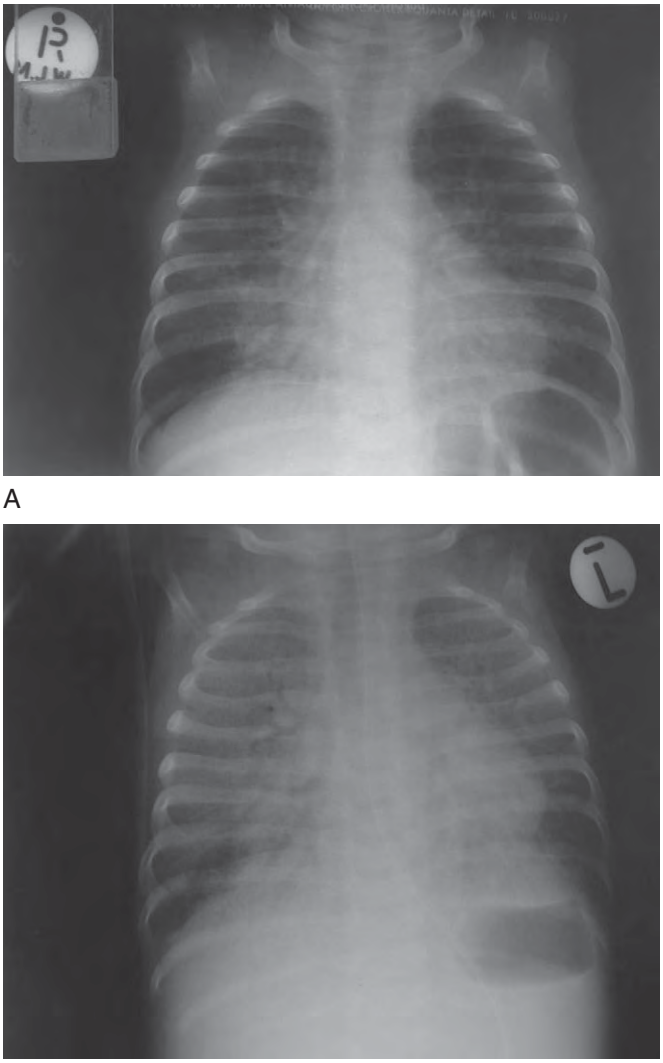
Human papillomavirus (HPV) type 6 or type 11 may produce lesions in the oral cavity, pharynx, larynx, and rarely in the lower airways or lungs; the disease has a tendency to recur.[58] Clinically, disease may manifest as progressive hoarseness, stridor, airway obstruction, and respiratory distress.[59] Rarely lung nodules, cysts, recurrent pneumonia, emphysema, or atelectasis have been described in immunocompetent children.[58,59] Little is known about the epidemiologic risk of disease in HIV-infected children. An increased prevalence of HPV in HIV-infected compared with HIV-uninfected women has been reported; however, the rate of HPV transmission to children has not been associated with the HIV status of the mother or child.[60,61]

PNEUMOCYSTIS *INFECTION*

Pneumocystis jiroveci pneumonia (PCP) was the most common opportunistic infection in HIV-infected infants prior to widespread prenatal HIV screening, trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis, and HAART.[12] The incidence of PCP has declined significantly in developed countries following these advances; the rate of PCP was 1.3 per 100 child years pre-HAART, declining to 0.1 with HAART.[9,12] PCP remains the most common AIDS indicator of disease among HIV-infected children, accounting for 57% of AIDS-defining conditions among those younger than 1 year of age.[10] PCP may frequently be the initial clinical presentation of HIV infection in infants; in developed countries, PCP occurs most commonly in infants born to women with unrecognized HIV infection.[62] In developing countries, PCP is a major cause of severe pneumonia and death in HIV-infected children, with the peak incidence at 3 to 6 months of age.[63-65] In these countries, the incidence of PCP varies from 8% to 49% among HIV-infected children hospitalized for pneumonia—depending on the patient population and the methods used for diagnosis.[63-65] PCP is the most common cause of death in African HIV-infected infants younger than 6 months, accounting for approximately 50% of respiratory related deaths.[13] Increasingly PCP has also been reported in older HIV-infected children; 25% of cases in a Zambian postmortem study occurred in those older than 6 months.[13]

Symptoms of PCP include tachypnea, fever, dyspnea, and cough.[66] HIV-infected infants under 6 months of age are especially at risk for PCP and have an acute, severe illness characterized by prominent and progressive hypoxia and increasing respiratory difficulty.[67] Auscultation of the lungs is usually normal, although crepitations or wheezing may occur. No specific clinical features can reliably distinguish children with PCP from those with other lower respiratory tract infections; however, disease is characterized by severe, progressive, clinical and radiologic signs and hypoxia (Fig. 37-4). Clinical signs may be compounded by co-infection with bacterial or viral co-pathogens.[68,69] Less commonly, PCP has also been reported to manifest with a pneumothorax, cyst, pneumatocele, or a bronchiolitis-like picture.[70,71]

PCP is associated with mortality rates ranging from 35% to 87% with higher rates in children with acute respiratory failure.[63-65,72,73] Timely anti-*Pneumocystis* therapy may



A

B

Figure 37-4 Radiologic progression of *Pneumocystis jiroveci* pneumonia (PCP) in an HIV-infected infant. **A,** initial radiograph and **B,** rapid progression of opacification within 24 hours.

improve outcome as suggested by historical comparisons and adult studies in which early use of corticosteroids for PCP has been associated with better survival.[74-76] Mutations in *P. jiroveci* dihydropteroate synthase genes (a key enzyme target of TMP-SMX) have been described in HIV-infected patients with PCP—especially with widespread use of TMP-SMX as prophylaxis.[74] However, the clinical importance of mutant strains is unclear and the response to TMP-SMX treatment is variable.[74]

HIV-exposed but uninfected children may also be at increased risk of PCP compared to HIV unexposed children. Probable transmission of *P. jiroveci* from an HIV-infected mother to her HIV-uninfected infant has been reported in a few cases.[77-79] HIV-exposed children may be at risk for PCP owing to close and early exposure to the organism from the mother, reduced passage of functional maternal antibody, impaired cell-mediated immunity, or concomitant malnutrition.

Fungal Infections

Chronic *Candida* infection is common in HIV-infected children and may produce oropharyngeal, laryngeal, or esophageal candidiasis and promote the development of gastroesophageal reflux disease.[10,80] Infection of the upper airways may result in *Candida* supraglottitis, epiglottitis, and a croup-like picture.[81,82] Laryngeal candidiasis may manifest as severe acute airways obstruction.[82] Pulmonary disease may also occur in the context of severe disseminated disease. Other fungal infections including aspergillosis, histoplasmosis, cryptococcosis, and coccidioidomycosis may produce respiratory illness usually in the context of severe immunosuppression and disseminated disease.[10] Pulmonary cryptococcosis without dissemination may manifest with fever, intrathoracic adenopathy, and pulmonary infiltrates.[10] Occasionally, pulmonary cryptococcosis may be asymptomatic and manifest on routine chest radiographs as pulmonary nodules.[10] Pulmonary coccidioidomycosis may produce diffuse reticulonodular infiltrates associated with fungemia and systemic disease.[10] Other pulmonary manifestations include nodules or cavities.

DIAGNOSIS

Diagnosis of the etiology of respiratory infection is difficult because signs are nonspecific and co-infection with more than one organism occurs frequently. For bacterial pneumonia, blood culture may be useful because HIV-infected children have higher rates of bacteremic pneumonia than do HIV-uninfected children; approximately 15% of HIV-infected children hospitalized for pneumonia have a positive blood culture.[14] Current evidence suggests that no radiologic or laboratory findings can distinguish the etiology of pneumonia with sufficient sensitivity or specificity.

Diagnosis of pulmonary tuberculosis is particularly difficult in HIV-infected children for whom clinical scoring systems have not been developed and in whom anergy may reduce the reliability of the tuberculin skin test (see Chapter 39). Diagnosis is frequently based on a combination of epidemiologic history of a TB contact and suggestive clinical and radiologic findings. A tuberculin skin test of 5 mm or more of induration is regarded as positive.[10] Tests of T lymphocyte γ-interferon production are promising. A study of African children with suspected TB reported that the T cell–based enzyme-linked immunospot assay (ELISPOT) had a higher sensitivity than the tuberculin skin test, particularly in HIV-infected children in whom the ELISPOT sensitivity was 73% compared with 36% for the skin test.[83] Definitive diagnosis requires culture confirmation of *M. tuberculosis* from sputum, bronchoalveolar lavage (BAL), gastric lavage, or lung or lymph node biopsy. A concerted effort should be made to obtain diagnostic specimens in children in whom TB is suspected because this may provide diagnostic confirmation and drug susceptibility.[84] Recently, induced sputum examination has been reported to be effective and safe for culture confirmation in infants and children; approximately 25% of HIV-infected children hospitalized with suspected pulmonary TB were culture-positive from sputum.[85] The yield from a single induced sputum sample was equivalent to that obtained from three gastric lavages.[85] Therefore, a single induced sputum sample should be the primary diagnostic procedure in a child with suspected pulmonary TB. In contrast, the culture yield from a single BAL is lower than that from three properly performed consecutive gastric lavages.[86] The efficacy of polymerase chain reaction (PCR) has been disappointing with sensitivity on gastric aspirates varying from 45% to 83% in HIV uninfected children.[84]

Definitive diagnosis of *Mycobacterium bovis* or MAC relies on isolation of the organism from the blood or from biopsy specimens from normally sterile sites.[10] If lymphadenopathy is present, an aspirate and culture can be diagnostic. Multiple mycobacterial blood cultures may be necessary to improve the yield.[10] Culture is essential to differentiate nontuberculous mycobacteria from *M. tuberculosis* and to determine the drug susceptibilities.

Diagnosis of PCP should be based on the clinical presentation and empirical treatment initiated.[67] PCP should be suspected in any infant presenting with acute, severe pneumonia who has signs of HIV infection or who comes from an area of high HIV prevalence, particularly if *Pneumocystis* prophylaxis is not being given. In such infants, a presumptive diagnosis of PCP should be based on a history of acute respiratory decompensation, lack of auscultatory signs, and hypoxemia. In HIV-infected children not taking HAART, four clinical variables have been reported to be associated with PCP—age less than 6 months, a respiratory rate >59 breaths per minute, arterial hemoglobin saturation less than 92%, and absence of a history of vomiting.[67] Most children have significant hypoxemia with an alveolar-arterial oxygen gradient >30 mm Hg. Serum lactate dehydrogenase (LDH) may be markedly elevated (>1000 IU/L) but this is nonspecific and may reflect the extent of lung involvement.[87,88] The chest radiograph usually shows a diffuse interstitial pattern which progresses to alveolar opacification; however, hyperinflation, focal infiltrates, cavities, a miliary pattern, pneumothoraces, pleural effusion, or a normal appearance may also occur.[70,71,89]

Definitive diagnosis requires identification of *P. jiroveci* from lower respiratory tract secretions including BAL, lung biopsy, or induced sputum tests.[74] Bronchoscopy with BAL is the diagnostic procedure of choice in young children, with reported sensitivity ranging from 55% to 97%.[10] Transbronchial biopsy is not recommended unless BAL is nondiagnos-

tic.[10] Transbronchial biopsy may be positive up to 10 days after starting therapy; the sensitivity of biopsy is 87% to 95%.[10] Induced sputum analysis using hypertonic nebulized saline may be useful; a positive yield has been described in infants as young as 1 month of age.[64] Nasopharyngeal secretions may also yield *P. jiroveci* in cases of severe infection.[63,65] Induced sputum in combination with nasopharyngeal aspiration (NPA) may provide a higher yield than either specimen alone; the sensitivity and specificity for induced sputum and NPA for diagnosis of PCP compared to the yield on autopsy have been reported to be 75% and 80%, respectively.[65]

As *P. jiroveci* cannot be cultured, identification of the organism requires special stains.[66] Silver methenamine, toluidine-blue or calcofluor white are useful for staining cyst forms, whereas Giemsa, modified Wright-Giemsa, or modified Papanicolaou stains identify trophozoites.[66,74] Fluorescein-conjugated monoclonal antibodies provide greater sensitivity, detecting both the cyst and trophozoite forms.[74] Polymerase chain reaction techniques, with a high sensitivity and specificity and potential to improve diagnostic accuracy, are not widely available and are currently mainly a research tool.[74] Nasopharyngeal secretions may be useful for detection of respiratory viruses or atypical organisms such as *Chlamydia trachomatis*.

TREATMENT (Table 37-1)

Bacterial Infections

Empirical antibiotic therapy for pneumonia should be broad spectrum and consider the local prevalence of antimicrobial resistance and recent use of prophylactic or therapeutic antibiotics.[10] A combination of a β-lactam with an aminoglycoside antibiotic or a second or third generation cephalosporin alone is appropriate empirical therapy. The choice of antimicrobial agent should be modified according to culture results and susceptibility testing.

Table 37-1
Recommended Therapy of Lower Respiratory Infections in HIV-Infected Children by Etiology

Infection	First Line Therapy
Bacterial pneumonia	Broad-spectrum antibiotic—β-lactam with an aminoglycoside *or* a second or third generation cephalosporin Add methicillin or vancomycin if *Staphylococcus aureus* is suspected
PCP	Trimethoprim-sulfamethoxazole Corticosteroids if hypoxic
Mycobacterial infections	
Mycobacterium tuberculosis	INH, rifampicin, pyrazinamide as induction for 2 months (add 4th drug if suspected drug resistance or severe disease); then maintenance with INH, rifampicin for at least 7 months for pulmonary TB Corticosteroids if endobronchial disease or airway compression
Mycobacterium bovis	Surgical excision of localized disease; four-drug therapy for disseminated disease (INH, rifampicin, ethambutol, ofloxacin, or ciprofloxacin) Clarithromycin plus ethambutol
Cytomegalovirus	Ganciclovir

INH, isoniazid; PCP, *Pneumocystis jiroveci* pneumonia (formerly *Pneumocystis carinii* pneumonia); TB, tuberculosis.

MYCOBACTERIAL INFECTIONS

Treatment of pulmonary TB is similar to that in HIV uninfected children although the response to standard therapy in HIV-positive children is poorer than in HIV-negative children with lower cure rates and higher mortality.[36,37] Mortality is particularly high within the first 2 months of treatment. Optimal therapy for HIV-infected children with TB has not been tested in well-designed studies. Empirical therapy for pulmonary TB in HIV-infected children should include three drugs (isoniazid [INH], rifampicin, and pyrazinamide) daily for a 2-month induction period; a fourth drug (either ethambutol, ethionamide, or streptomycin) should be added if drug resistance is suspected or for severe disease.[10,35,90] Following a 2-month induction phase, therapy with two drugs (INH, rifampicin) should be continued either daily or three times a week in drug susceptible isolates. Directly observed therapy (DOT) is advised to promote adherence and reduce the rate of treatment relapse or failure; for the induction phase DOT should be administered daily, whereas for the continuation phase, two to three times weekly is sufficient.[91] However, children with severe immunosuppression should receive therapy daily or three times weekly during the continuation phase because less intense regimens have been associated with the acquisition of resistance in adults with CD4 counts <100 cells/μL.[92] High rates of treatment failure have occurred in children treated for 6 months; therefore, a minimum of 9 months of therapy is advised.[10,93,94] For extrapulmonary TB, the duration of therapy should be at least 12 months.[10] Therapy for drug resistant TB should be individualized, using a minimum of three drugs, at least two of which are bactericidal (see Chapter 39).[10] Adjunctive corticosteroids may be beneficial for children with an endobronchial lesion and airway compression; a suggested regimen is 1 to 2 mg/kg/day prednisone tapered over 6 to 8 weeks.[10]

For children on HAART, the antiretroviral regimen should be reviewed to ensure optimal TB and HIV therapy and minimize potential toxicity and drug interactions.[35] Rifampicin induces hepatic cytochrome P450 enzymes and may, therefore, reduce levels of antiretroviral agents, particularly the protease inhibitors (PIs) and non-nucleoside reverse transcriptase inhibitors (NNRTI). Therefore, rifampicin should not be used in conjunction with single protease inhibitors except for ritonavir.[10] Alternatively rifampicin may be used in conjunction with ritonavir-boosted saquinavir, provided that high-dose ritonavir boosting is used.[10] Concurrent rifampicin with the NNRTI delavirdine is not recommended; however, use with efavirenz is possible. Use with nevirapine is recommended only when there are no other options because of the potential decrease in nevirapine levels.[10] Rifabutin is a less potent inducer of the P450 enzymes and is, therefore, a suitable alternative to rifampicin, but there is limited experience of its use in children.[10] Adjustments in dosage of rifabutin and co-administered antiretroviral drugs may be necessary because some drugs (e.g., efavirenz) lower rifabutin levels, whereas others (e.g., the PIs, ritonavir, indinavir, nelfinavir, ritonavir-boosted saquinavir) increase levels.[10] For antiretroviral-naïve children, TB therapy should be given for 4 to 8 weeks before

starting HAART to minimize the risk of immune reconstitution syndrome, optimize adherence, and differentiate potential side effects due to TB or antiretroviral drugs.[48-51]

Monitoring of HIV-infected children on TB treatment should include regular evaluation of clinical response, monitoring for drug adverse effects and liver enzyme measurements (at baseline and monthly for the first few months), particularly in the initial months of therapy owing to the potential for hepatotoxicity.[10,91] Elevations of transaminase levels of two to three times normal do not require discontinuation of drugs. A chest radiograph should be done at baseline and repeated 2 to 3 months into therapy to evaluate response; however, the chest radiograph may remain abnormal for months to years and a normal chest radiograph is not a criterion for discontinuing therapy.

Management of BCG disease is difficult. Treatment is complicated by the inherent resistance of *M. bovis* to pyrazinamide, inherent intermediate resistance of some BCG strains to isoniazid, and the emergence of resistance during inappropriate therapy.[95] In immunocompetent children, localized BCG disease is usually self-limiting. However, in HIV-infected children, treatment is warranted because of the risk of dissemination and poor outcome.[40] Surgical excision of localized lymphadenopathy is one strategy. Alternatively, medical therapy with four drugs (INH, rifampicin, ethambutol, ofloxacin or ciprofloxacin) in high doses is recommended.[40] The optimal duration of therapy is not known but at least 9 months of treatment is recommended, based on adult experience.[96]

Treatment of MAC should comprise combination therapy with a minimum of two drugs because monotherapy with a macrolide leads to rapid evolution of resistance.[10] Initial recommended therapy is clarithromycin or azithromycin plus ethambutol.[10] Rifabutin may be added as a third drug in patients with severe disseminated infection; addition of ciprofloxacin, amikacin, or streptomycin may be considered depending on the severity of illness.[10]

Viral Infections

Treatment of CMV disease focuses on preventing disease progression and not on cure. Ganciclovir is most widely used, with drug dosing separated into induction and maintenance dosage (see Chapter 33). Other possible agents include valganciclovir, foscarnet, or cidofovir.[10] These drugs may produce significant side effects including bone marrow depression and renal toxicity. For children with CMV disease who have sustained immune reconstitution on HAART, there are no data on when maintenance therapy may be safely discontinued; this should be considered on an individual basis.

Laryngeal HPV lesions are difficult to treat. Therapy is directed at maintaining airway patency, so obstructing papillomas should be removed. Adjuvant therapy using intralesional cidofovir has been reported to result in regression and reduced need for surgery in HIV-uninfected children.[97]

Pneumocystis and Fungal Infections

Empirical therapy for *Pneumocystis* should be given to any child with suspected PCP because untreated infection is usually fatal.[66] The most effective therapy is TMP-SMX (15 mg/kg/day TMP) intravenously three to four times a day for 21 days (Table 37-2).[10,66,74] Oral treatment can be used if intravenous therapy is not feasible, if disease is mild or when clinical improvement occurs. The response to therapy may be slow with clinical improvement occurring only after 3 to 5 days.[66] Adverse reactions to TMP-SMX occur in approximately 15% of cases, but treatment should be discontinued only if reactions are severe—such as neutropenia or a

Table 37-2
Treatment of PCP in Children

Drug	Dose	Route	Comments
Trimethoprim-sulfamethoxazole (TMP-SMX)	15-20 mg/kg TMP with 75-100 mg/kg SMX per day given q6h	Intravenous *or* oral	First choice Oral therapy only if mild disease or when clinical improvement occurs
Pentamidine	4 mg/kg daily	Intravenous	In those who cannot tolerate TMP-SMX or where no response after 5 to 7 days High incidence of side effects. Should not be administered with didanosine due to risk of pancreatitis
Atovaquone	30 to 45 mg/kg/day	Oral	Limited experience in children
Trimetrexate glucuronate with leucovorin	No studies of established doses in children Adult dose 45 mg/m^2/day trimetrexate glucuronate with leucovorin 20 mg/m^2 q6h	Intravenous	Limited experience in children
Dapsone and trimethoprim (TMP)	No studies of established doses in children Adult dose is 100 mg dapsone daily (pediatric equivalent 2 mg/kg) and 15 mg/kg TMP	Oral	Limited experience in children
Primaquine and clindamycin	No studies of established doses in children Primaquine adult dose is 30 mg daily orally Pediatric equivalent is 0.3 mg/kg daily orally Clindamycin adult dose is 600 mg intravenously q6h for 10 days; then 300-450 mg orally q6h for 11 days. Pediatric equivalent is 10 mg/kg q6h orally or intravenously	Oral/intravenous	Limited experience in children Most effective alternate therapy for adults with PCP unresponsive to primary therapy

Corticosteroids should be added in moderate or severe *Pneumocystis jiroveci* pneumonia. PCP, *Pneumocystis jirovecii.*

severe dermatologic reaction.[66,98] Intravenous pentamidine (4 mg/kg) may be an alternative drug for children who cannot tolerate TMP-SMX or who have not responded after 5 to 7 days of TMP-SMX (see Table 37-2).[10] Pentamidine is associated with a high incidence of adverse reactions including pancreatitis, alterations in blood glucose, renal dysfunction, cardiac dysrhythmias, fever, neutropenia, and hypotension.[99] Patients who show clinical improvement after 7 to 10 days of intravenous pentamidine may be switched to an oral drug to complete 21 days of therapy. Other alternative anti-*Pneumocystis* agents include atovaquone, dapsone with trimethoprim, trimetrexate glucuronate with leucovorin and clindamycin with primaquine, but there is little information on the efficacy or tolerability of these regimens in children (see Table 37-2).[10,91]

Corticosteroids are recommended in hypoxic children with moderate to severe PCP. Although no controlled trials on the use of corticosteroids in children have been performed, use has been reported to reduce the need for mechanical ventilation and to improve survival compared with historical controls.[75,76,100] Data from adult studies has found that corticosteroids are beneficial, improving oxygenation and reducing the incidence of respiratory failure when used within 72 hours of commencing anti-*Pneumocystis* therapy in hypoxic HIV-infected adults.[74] Corticosteroids are, therefore, recommended for a PaO_2 < 70 mm Hg or an alveolar-arterial oxygen gradient of >35 mm Hg.[10] The optimal dose and duration have not been determined, but a recommended regimen is prednisone 2 mg/kg for 5 to 7 days with tapering doses over the next 10 to 14 days.[75]

A few case reports have described use of surfactant to improve pulmonary function in children with severe PCP.[101,102] Children with PCP may be co-infected with bacterial or viral pathogens[68,69]; additional antimicrobial therapy for these should be used when appropriate. Specifically, CMV co-infection has been associated with more severe disease requiring mechanical ventilation and a poor outcome. The effect of corticosteroid therapy for PCP on CMV pneumonitis is unclear.

Uncomplicated oropharyngeal candidiasis can be treated with topical therapy.[103] Oral fluconazole, itraconazole, or ketoconazole are effective alternative agents.[10,104] For esophageal disease fluconazole or itraconazole is recommended.[10] Children with severe pulmonary cryptococcosis should be treated with amphotericin B; maintenance therapy with fluconazole or itraconazole can be substituted when improvement has occurred.[10] Mild or moderate pulmonary cryptococcosis can be treated with oral fluconazole or itraconazole.[10] Life-long suppressive therapy with fluconazole or itraconazole is necessary to prevent relapse.[10] There are little data on treatment of pulmonary coccidioidomycosis in children and recommendations are based on adult data with amphotericin B recommended for the acute illness followed by chronic suppressive therapy with fluconazole or itraconazole.[105] Alternatively, in mild disease, therapy may be initiated with fluconazole or itraconazole.[10]

PREVENTION

Prevention of HIV-associated lung disease is an important goal. Although the efficacy of preventive measures such as immunization is reduced in HIV-infected children, efficacy may depend on the degree of immunosuppression and use of antiretroviral therapy. General and specific preventive measures (Table 37-3) are discussed subsequently.

General Measures

General preventive strategies such as avoidance of passive smoke exposure, preventing exposure to indoor biomass fuels, and improved nutrition and growth may reduce the incidence and severity of respiratory infections.[106] Micronutrient supplementation, particularly the use of vitamin A to prevent measles-associated pneumonia and daily prophylactic elemental zinc (10 mg to infants, 20 mg to older children) may substantially reduce the incidence of pneumonia, particularly in malnourished children.[106,107]

CHEMOPROPHYLAXIS

Prevention of Pneumocystis jirovecii *Pneumonia*

Prophylaxis against *Pneumocystis* infection is very effective if initiated in HIV-exposed infants within the first few months of life. The most effective prophylactic agent is oral TMP-SMX, a widely available, well tolerated, and inexpensive drug. A randomized controlled study of TMP-SMX prophylaxis in HIV-infected Zambian children reported that this treatment reduced mortality by 43% and morbidity, including hospitalization, by 23%.[108] The impact on mortality occurred in children of all ages.[108] Although most children were not investigated for *P. jiroveci* or other pathogens, the authors hypothesize that the effect of TMP-SMX prophylaxis may also provide protection against bacterial infection.

Current recommendations for PCP prophylaxis include (Table 37-4):[91,109]

1. All infants born to HIV-infected mothers from 6 weeks of age until HIV infection has been excluded in the child and the mother is no longer breastfeeding
2. All HIV-infected children from 6 weeks until 1 year of age. HIV-infected children older than 1 year should receive prophylaxis if their CD4 counts are less than 15% of lymphocytes or if they have symptomatic HIV disease. However, a higher CD4 threshold for providing prophylaxis may be applicable in developing countries, as evidenced by a trial in Zambia where prophylaxis reduced mortality in children even in those with higher CD4 counts.[108,109] Prophylaxis should be continued indefinitely irrespective of age or CD4 counts when HAART is unavailable.[109]
3. Prophylaxis should be continued in children taking HAART for at least 6 months. There is little information on the safety of discontinuing prophylaxis once immune reconstitution has occurred. Discontinuation of prophylaxis may be considered in those with confirmed immune restoration for 6 months or more as indicated by two measurements of CD4 > 25% at least 3 to 6 months apart in children 2 to 6 years of age.[110]
4. Lifelong prophylaxis should be given to all children who have had an episode of PCP; the safety of discontinuing secondary prophylaxis in the context of immune reconstitution has not been established.

Table 37-3
Preventive Measures and Indications

Intervention	Indications
General	
Vitamin A	Malnourished children
	Measles-associated pneumonia
Zinc	Malnourished children
Avoidance of passive smoke exposure	All
Adequate nutrition	All
Immunization	
Routine EPI immunizations (DPT, inactivated poliovirus, measles, HiB)	All
Pneumococcal conjugate	All
Influenza vaccine	All
Measles, mumps, rubella vaccine (MMR)	Mild or moderately immunocompromised children (CDC immune category 1 or 2)
Varicella vaccine	Asymptomatic or mildly symptomatic children without immunosuppression (CDC category N1 or A1)
Chemoprophylaxis	
TMP-SMX	PCP prophylaxis in all infants and in children >1 year with moderate or severe immunosuppression or if clinically symptomatic
	Secondary prophylaxis in children with prior PCP
INH prophylaxis	Children exposed to a close contact with TB once TB disease has been excluded in the child
	Tuberculin skin test–positive children
Azithromycin/clarithromycin	Prophylaxis for nontuberculous mycobacteria in severely immunosuppressed children
	Lifelong secondary prophylaxis in children with prior infection
Ganciclovir	Prophylaxis for CMV in severely immunosuppressed children
	Lifelong secondary prophylaxis in children with prior CMV disease
Immune Prophylaxis	
Intravenous immunoglobulin (IVIG)	Consider to prevent bacterial infections in children with hypogammaglobulinemia *or* recurrent, severe infections *or* inability to form antibodies to common antigens
Varicella-zoster globulin	Children exposed to varicella or zoster without a prior history of varicella infection or immunization within 2 weeks of exposure
Measles immunoglobulin	Children exposed to measles
RSV immunoglobulin	Children at risk for severe RSV (premature infants, those <2 years with chronic lung disease, or severely immunosuppressed children) monthly for the duration of the RSV season
HAART	At appropriate stage of immune suppression

CDC, Centers for Disease Control and Prevention; CMV, cytomegalovirus; DPT, diphtheria pertussis tetanus; HAART, highly active antiretroviral therapy; INH, isoniazid; RSV, respiratory syncytial virus; TMP/SMX, trimethoprim sulfamethoxazole.

Table 37-4
Indications for PCP Prophylaxis in HIV-Infected Children

Age	*CD4 T-Lymphocyte Count
†4-6 weeks to 12 months	All patients irrespective of CD4 count
1-5 years	<500/mm^3 *or* if percentage is less than 15%
>5 years	<200/mm^3 *or* if percentage is less than 15%

*If CD4 measurements are unavailable, then prophylaxis should be given to all symptomatic children indefinitely.[109]
†HIV-exposed children should receive prophylaxis from 4-6 weeks to 4 months; thereafter prophylaxis may be discontinued if HIV infection has been excluded and the mother is not breastfeeding.
PCP, *Pneumocystis jiroveci* pneumonia.

TMP-SMX prophylaxis (150 mg/m^2/day of TMP) may be given three times a week (single dose on 3 consecutive days, or two divided doses on consecutive or alternate days or 7 divided doses each dag for a week).[91] If TMP/SMX is not tolerated or cannot be used, alternatives include dapsone (2 mg/kg once daily), atovaquone (30-45 mg/kg once daily) or aerosolized pentamidine (300 mg via Respigard II inhaler every 4 weeks) if the child is older than 5 years of age.[91,111-114] Safety and efficacy concerns regarding aerosolized pentamidine preclude its use in young children. A study of the safety of inhaled pentamidine in young children reported cough, wheeze, or oxygen desaturation in five of seven infants.[114]

Prevention of Mycobacterial Disease

INH prophylaxis is currently not routinely recommended for HIV-infected children, except if a child has been exposed to a household contact with TB (see Chapter 39), when INH prophylaxis (5-10 mg/kg) should be given daily for 6 to 9 months once active tuberculosis disease has been excluded (see Table 37-3). Prophylaxis should also be given to HIV-infected children with TB infection (tuberculin skin test >5 mm induration) but not disease. A recent study in a high TB prevalence area reported that INH prophylaxis given to HIV-infected children, irrespective of tuberculin skin reactivity or a household TB contact, substantially reduced mortality and TB incidence; however, further studies are needed before this can be widely recommended.[115]

Primary prophylaxis for NTM with azithromycin or clarithromycin should be considered for severely immunosuppressed children (see Table 37-3) as follows: for children younger than 1 year, CD4 < 750/uL; children 1 to 2 years CD4 < 500/uL; children 2 to 6 years, CD4 < 75/uL; children 6 years or older CD4 < 50/uL.[91] Rifabutin may be an alternative agent in children older than 6 years.[91] Secondary prophylaxis should be given to children with a history of dis-

seminated MAC to prevent recurrence.[91] Lifelong prophylaxis is indicated; the safety of discontinuing secondary prophylaxis in the context of sustained immune restoration following HAART has not been well studied in children.

Prevention of Cytomegalovirus Infection

Oral ganciclovir or valganciclovir may be used for primary prophylaxis in severely immunosuppressed HIV-infected children as reflected by a CD4 count less than 50 cells/μL (see Table 37-3).[116] Secondary lifelong prophylaxis should be given to children with a history of disseminated CMV disease to prevent recurrence; there are little data on the safety of discontinuing prophylaxis once sustained immune reconstitution on HAART has occurred.

Immunization

The nature and degree of immunosuppression determine the safety and efficacy of vaccination in HIV-infected children. The efficacy of immunization may be substantially reduced in symptomatic HIV-infected subjects who are not on HAART. Immunization with inactivated vaccines (diphtheria, pertussis, tetanus toxoids; inactivated poliovirus, *H. influenzae b*, hepatitis B, and pneumococcal conjugate vaccine) should be given to HIV-infected children at the usual recommended age as for uninfected children (see Table 37-3).[91] Although the pneumococcal conjugate vaccine has lower efficacy in HIV-infected children who are not on HAART compared with HIV-uninfected children, it reduces the incidence of invasive disease and pneumonia in a substantial proportion of HIV-infected children. In a large South African study, the nine valent vaccine prevented 13% of radiologically diagnosed pneumonia and 65% of invasive pneumococcal disease in HIV-infected children.[25] A booster dose of the vaccine may be required during the second year in HIV-infected children.

Measles, mumps, rubella vaccine (MMR), a live attenuated vaccine, should be given to HIV-infected children at 12 months of age, unless they are severely immunocompromised.[91] Varicella vaccine should be considered at 12 to 15 months for asymptomatic or mildly symptomatic HIV-infected children without immunosuppression (CDC categories N1 and A1); vaccine should not be administered to symptomatic immunosuppressed children due to the potential for disseminated disease.[91] Influenza vaccine should be given annually to all HIV-infected children at the start of the influenza season.[91] BCG vaccine is not recommended in HIV infected infants due to the risk of disseminated disease.

Immune Prophylaxis

PREVENTION OF BACTERIAL INFECTIONS

Intravenous immunoglobulin (IVIG) for prevention of bacterial infections including pneumonia may be indicated for HIV-infected children who have hypogammaglobulinemia (IgG < 4 g/L) *or* recurrent, severe infections (two or more bacterial infections including pneumonia in 1 year) *or* inability to form antibodies to common antigens.[16,17,91,117] However, IVIG may not offer additional protection if children are taking TMP-SMX prophylaxis.[17] Moreover, there is no evidence to suggest that immunoglobulin offers additional protection in children taking HAART. Children with bronchiectasis may benefit from monthly immunoglobulin.[91] Immunoglobulin is usually given as a monthly injection.

PREVENTION OF VARICELLA

Administration of varicella-zoster globulin should be considered for HIV-infected children exposed to varicella or zoster who have no history of varicella infection or immunization and who have not received immunoglobulin within 2 weeks of exposure.[91]

PREVENTION OF MEASLES

HIV-infected children exposed to measles should receive a dose of intramuscular immunoglobulin irrespective of immunization status.[91]

PREVENTION OF RESPIRATORY SYNCYTIAL VIRUS

The efficacy of the humanized monoclonal specific antibody against RSV (palivizumab) or RSV immune globulin (RSV-IVIG) has not been well studied in HIV-infected children. Nevertheless, those at risk for severe RSV infection such as premature HIV-infected infants, those under 2 years of age with chronic lung disease, or severely immunosuppressed children may benefit from prophylaxis.[91] A dose should be given monthly for the duration of the RSV season.[91]

CHRONIC LUNG DISEASE

Chronic lung radiologic changes are common among HIV-infected children with increasing age[118,119]; a longitudinal birth cohort study reported that the cumulative incidence of chronic radiographic lung changes in HIV-infected children was 33% by 4 years old.[118] The most common chronic radiologic changes are increased bronchovascular markings, reticular densities, or bronchiectasis.[118,119] Chronic changes are associated with lower CD4 cell counts and higher viral loads; radiologic resolution of these may reflect declining immunity.[118] The spectrum of chronic HIV-associated lung disease includes lymphocytic interstitial pneumonia (LIP), chronic infections, bronchiectasis, malignancies, bronchiolitis obliterans, and interstitial pneumonitis.

Lymphocytic Interstitial Pneumonia and Pulmonary Lymphoid Hyperplasia

Lymphocytic interstitial pneumonia (LIP) and pulmonary lymphoid hyperplasia (PLH) represent a spectrum of chronic lymphocytic infiltrative diseases of the lungs, occurring commonly in HIV-infected children. The etiology is unknown; evidence suggests that infection with Epstein-Barr virus may initiate a lymphoproliferative response in the presence of HIV infection.[120] Clinically children develop insidious, chronic respiratory symptoms—principally cough and mild tachypnea.[121] Lymphoproliferation, occurring in other organs, may produce associated generalized lymphadenopathy, digital clubbing, bilateral nontender parotid enlargement and hepatosplenomegaly.[121-123] Hypoxemia, if present, is usually mild. Children may survive for years with a course characterized by recurrent episodes of acute lower respiratory tract infections.[124] Long-term cor pulmonale or bronchiectasis may develop.[125]

Children with LIP have moderately elevated serum IgG and LDH levels and titers to viral capsid antigen of Epstein-Barr virus.[120] Chest radiographs often show a diffuse reticulonodular pattern, more pronounced centrally (Fig. 37-5A) and bilateral hilar adenopathy which may be difficult to distinguish from pulmonary or miliary TB.[123] Clinically, relatively mild respiratory illness, the presence of parotid enlargement, and a reticulonodular pattern on chest radiograph or CT scan may help to distinguish children with LIP from those with miliary TB.[123] Peribronchiolar thickening alone or normal chest radiographs may also occur.[122,123] Radiographic lesions may resolve in association with worsening immune status.[126,127] Respiratory status may improve with the use of HAART[127]; among HIV-infected adults with LIP, HAART has been reported to result in resolution of radiographic abnormalities.[128]

High-resolution CT may improve diagnostic certainty; typical features include micronodules of 1 to 3 mm in diameter, with a perilymphatic distribution and subpleural nodules (see Fig. 37-5B).[129] The role of nuclear scanning in confirming the diagnosis has not been well studied, but diffuse pulmonary gallium uptake has been reported in an HIV-infected child with LIP.[130]

Children with LIP have marked BAL lymphocytosis, but this is nonspecific. Definitive diagnosis requires open lung biopsy.[122] Lung biopsies revealed collections of lymphoid aggregates, often with germinal centers, surrounding the airways and a significant interstitial infiltrate composed primarily of lymphocytes (Fig. 37-6).

Treatment is symptomatic, including antibiotics for acute infections and inhaled bronchodilators. Although there are no trials of efficacy, case reports indicate a response to systemic corticosteroids.[131-133] Oral corticosteroids are, therefore, recommended for children with hypoxemia.[133] A suggested regimen is prednisone, 2 mg/kg/day for 2 to 4 weeks, until the partial pressure of oxygen increases. Corticosteroids are then tapered to 0.5 to 0.75 mg/kg alternate days provided that the partial pressure remains adequate.[133] Further tapering may be possible as long as adequate oxygenation is maintained. No data exist on the use of inhaled corticosteroids.

LIP is categorized as a World Health Organization (WHO) stage 3 AIDS-defining illness and is thus an indication for initiating HAART in children who are not yet taking antiretroviral therapy.[134]

The nodules are larger centrally than peripherally. Also noted are hilar adenopathy and widening of the mediastinum. **B,** High resolution chest CT scan of a child with LIP showing a diffuse micronodular pattern. (**A,** Courtesy Henry Pritzker, Bronx, NY.)

Chronic Pulmonary Infections

Chronic infection resulting from recurrent or persistent pneumonia may produce chronic lung disease. Infectious causes of chronic lung disease include many of the bacterial, viral, or fungal pathogens in Box 37-1. Infection with *M. tuberculosis* is a particularly important and prevalent cause of chronic lung disease in developing countries.[29,30,33-36,123] Distinguishing pulmonary or miliary *M. tuberculosis* from LIP may be difficult; in general, children with LIP are older and less severely ill, enlarged parotid glands may occur, and chest radiology demonstrates a reticulonodular pattern.[123] A few case reports have described chronic *Pneumocystis jiroveci* infection occurring in HIV-infected children, usually manifesting with cystic disease or with pneumatocele formation.[71,135]

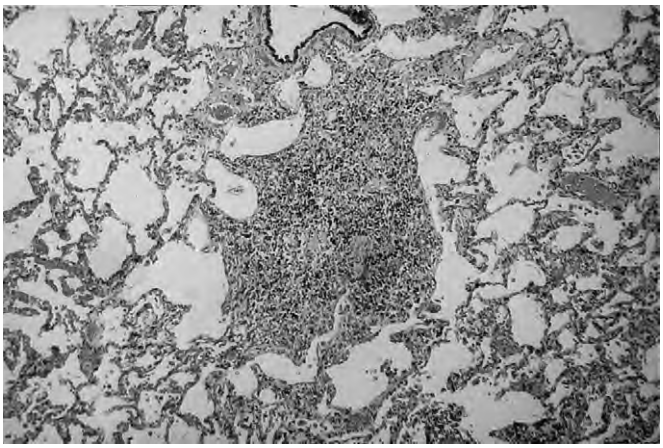

Figure 37-6 Lung biopsy specimen of a patient with lymphocytic interstitial pneumonia. There is a diffuse lymphocytic infiltrate present throughout. An aggregate of cells into a germinal center is also seen in the center of the field. (Courtesy Sumi Mitsudo, Bronx, NY.)

BRONCHIECTASIS

Bronchiectasis may occur following recurrent bacterial infection, secondary to chronic infection including *M. tuberculosis* and as a consequence of LIP.[125,136] The clinical presentation is similar in HIV-infected and uninfected children (see Chapter 69). Clinical features include sputum production, halitosis, digital clubbing, and abnormalities on chest auscultation. Development of bronchiectasis may be associated with the degree of immunosuppression; among 23 HIV-infected children (median age of 7.5 years) with bronchiectasis, all had CD4 T cell counts less than 100 cells/mm^3.[136] Therapy includes physiotherapy and aggressive treatment of intercurrent infections.

MALIGNANCY

Children with HIV have an increased risk of malignancy, which is reported in 2.5% of children with AIDS in the United States.[137] The most common malignancy is non-Hodgkin lymphoma (NHL) followed by Kaposi sarcoma (KS), leiomyosarcoma, and Hodgkin lymphoma.[137,138] Infection with EBV virus has been associated with the development of NHL in HIV-infected children—including those with mild immunosuppression.[138] Primary NHL may arise in a lymph node or be extranodal.[137,138] AIDS-related NHL may occur in almost any extranodal site including the lungs; in addition, pulmonary disease may result from dissemination from a primary focus.

In African HIV-infected children, KS is the most common AIDS-defining malignancy.[139] The epidemiology of childhood HIV-associated KS is probably related to the prevalence of human herpes virus-8 infection, which may be transmitted from an infected mother.[139-141] The most common clinical presentation is that of violaceous plaques on the skin.[142] Pulmonary dissemination may produce chronic progressive dyspnea, cough, and fever. Kaposi sarcoma may also produce upper airway obstruction. Hemoptysis may occur with endobronchial lesions.[140,142] Chest radiograph abnormalities include bilateral adenopathy, perihilar infiltrates, pleural effusion, or combinations of interstitial, alveolar, or nodular patterns. The finding of poorly marginated discrete lesions on CT scan may be specific for KS.[143] Thoracentesis may reveal serosanguineous or hemorrhagic exudates, but is nonspecific for KS. The diagnosis is best made by open lung biopsy. The outcome is generally poor.

MISCELLANEOUS

Desquamative interstitial pneumonitis, bronchiolitis obliterans, and nonspecific interstitial pneumonitis occur in children with AIDS. The manifestations are progressive dyspnea, hypoxemia, cough, and sometimes fever; radiographs reveal interstitial pneumonitis. These conditions may be difficult to distinguish from LIP or miliary TB without open lung biopsy,[123] which is required for definitive diagnosis.

PITFALLS AND CONTROVERSIES

- HIV-infected children are at higher risk for pneumococcal pneumonia or bacteremia than HIV-uninfected children; but the efficacy of the pneumococcal conjugate vaccine is lower in HIV-infected children.
- Diagnosis of TB in HIV-infected children is difficult owing to anergy, nonspecific signs and radiologic changes, and difficulty in obtaining microbiologic confirmation.
- An immune reconstitution inflammatory syndrome (IRIS) characterized by a paradoxical worsening in clinical signs occurs with mycobacterial infections and is difficult to distinguish from other infections, multidrug resistant mycobacterial infections, or nonresponse to mycobacterial therapy.
- The use of corticosteroids in PCP has not been tested in any randomized trials in children but historical comparisons and adult studies report efficacy. However, the impact of corticosteroids on CMV pneumonitis, which may coexist with PCP, is unclear.
- Chronic pulmonary TB or miliary TB may be difficult to distinguish clinically or radiologically from LIP.

CHAPTER 38 Pertussis

Ziad M. Shehab

TEACHING POINTS

- The most severe morbidity and essentially all the mortality from pertussis occur in infants under 6 months of age, who cannot be protected by immunization.
- Reports of pertussis continue to increase sharply, especially among adolescents and adults as immunity to pertussis wanes with time. Natural disease results in protection for about 15 years, while vaccination is protective for about 6 years.
- Pertussis in older children and adults may be manifested by chronic cough. Up to 25% of adults with coughing illnesses of more than 1 week's duration have serologic evidence of pertussis.
- Older children, adolescents, and adults are a major source of exposure of young infants. Routine immunization of children 11 to 12 years of age is now recommended with a vaccine with reduced dose diphtheria and tetanus toxoids and acellular pertussis vaccine (Tdap). These vaccines were licensed in the United States in 2005. Appropriate immunization of all household members of infants under 1 year of age is critical in their protection from exposure to pertussis.
- Treatment and prophylaxis of pertussis are best achieved with a 5-day course of azithromycin.

Pertussis is a serious respiratory illness caused by the bacterium *Bordetella pertussis*. The disease was described as early as the fifteenth century, and the first report of an epidemic is credited to Guillaume de Baillou for his description of the 1578 epidemic in Paris.[1] The organism was first identified and cultured by Jules Bordet and Octave Gengou at the Pasteur Institute in 1906.[2] The name *pertussis*, meaning "violent cough," was coined by Sydenham in 1679.[3] This prolonged tussive illness is fittingly described by the Chinese as the "100-day cough."

The illness is characterized by paroxysmal bouts of coughing followed by the classic whoop in an afebrile or a mildly febrile person. Not all infected individuals with the infection develop these symptoms; neonates sometimes present with apnea without coughing spells.[2-6] Pertussis is the cause of significant morbidity and mortality in infants under 1 year of age, especially in preterm infants and those born to young mothers.[7,8] About one fourth of children and adults with a coughing illness lasting longer than 7 days have serological evidence of pertussis. Prevention of pertussis disease has been largely accomplished by immunization, first with the whole cell vaccine and, more recently, with the acellular pertussis vaccines. The infection that remains endemic in adolescents and adults, where it is underrecognized, is responsible for the persistence of the epidemics that are seen in young infants approximately every 3 years.[9] Over the past 25 years, a better understanding of the epidemiology and biology of pertussis is leading to efforts toward the control and perhaps eradication of pertussis.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Pertussis is highly contagious and is distributed worldwide, resulting in an estimated burden of 42.7 million cases in 2002 and leading to the death of about 293,699 people, essentially all infants under 4 years of age,[10] with 90% of cases occurring in developing countries.[11] In the United States, pertussis was responsible for 270,000 cases of severe tussive illness and 10,000 deaths each year in the prevaccine era.[12] After the introduction of the whole cell vaccines in the 1940s, there was a sharp decline in the number of cases, with a nadir of 1010 cases reported in 1976, followed by a steady rise to record levels of 25,827 in 2004[13] (Fig. 38-1). Most of this increase comes from reports in adolescents and adults, with a significant component coming from improved recognition of the disease such as was seen in Massachusetts in 1989 through 1998[14] and Wisconsin in 2000 through 2004.[13] Even though the rate of pertussis has decreased by 150-fold with the introduction of pertussis immunization, epidemics of disease continue to occur in 2- to 5-year cycles, and the infection remains endemic in adolescents and adults. Pertussis remains largely underreported in the United States and worldwide, with only 5% to 25% of cases being reported in developing countries.[9,11]

Patients are most infectious during the first week of illness. Infectivity decreases during the 2 weeks that follow. Transmission occurs by droplet nuclei, especially from individuals with cough. Although no long-term carrier state has been identified, asymptomatic "transient carriers" have been described but their role in transmission of the organism is thought to be minimal.[15] Silent carriage is infrequent, is transient, and is most likely unimportant in the epidemiology of the disease.[16]

Fomites are not a factor in transmission, and there is no known animal reservoir for pertussis. Attack rates among susceptibles are very high, ranging from 50% to 100% depending on the nature of the exposure.[17] The risk of transmission

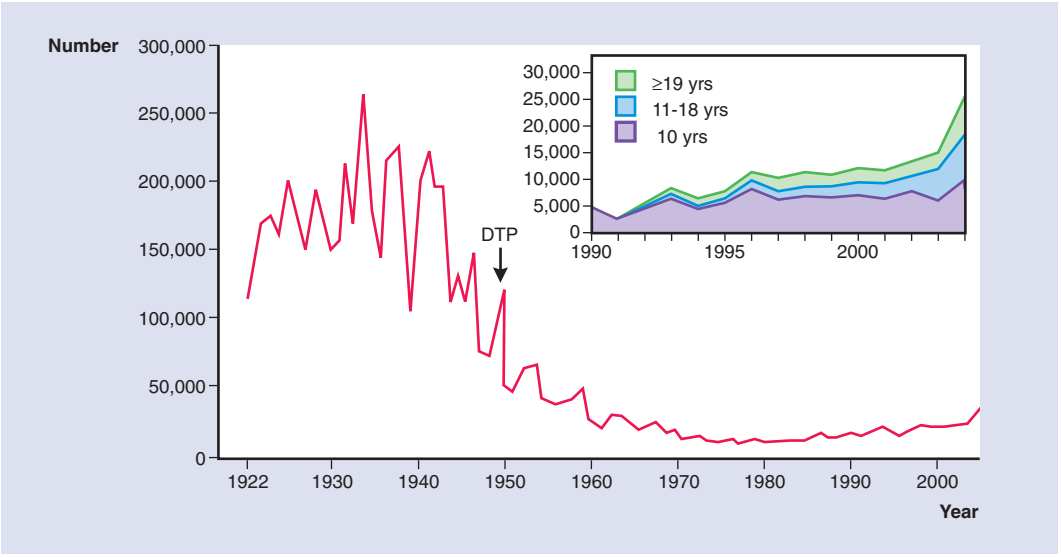

Figure 38-1 Number of pertussis cases per year: 1922-2004, United States. (Reprinted from Centers for Disease Control and Prevention: Preventing tetanus, diphtheria, and pertussis among adolescents: Use of tetanus toxoid, reduced diphtheria toxoid and acellular pertussis vaccines. Recommendations of the Advisory Committee on Immunization Practices. MMWR 55(RR-3):1-43, 2006.)

is related to the closeness of contact to the index case. Attack rates have ranged from 25% to 50% among unimmunized school contacts and 70% to 100% in households. Natural disease provides almost complete protection during childhood, whereas vaccine-induced immunity is less complete, with an incidence rate of 10% to 20% in fully immunized children and up to 50% in household settings.[18] Natural disease confers protection for about 15 years, whereas vaccine-induced immunity lasts up to 6 years.[19]

Immunity secondary to natural disease is not complete. In such adults and children, reinfection may result in a typical pertussis syndrome; a short, atypical illness; or it may be asymptomatic. The rate of infection in adolescents and adults with a history of pertussis or serologic evidence of prior immunity ranges from 5% to 20%.[13,20] These infections may be important in boosting immunity.

Vaccine-related immunity also wanes with time. During an epidemic, Lambert[17] demonstrated a household attack rate of 20% for recipients of whole cell vaccine in those immunized within 3 years, whereas the attack rate was 95% for those immunized 12 or more years earlier. Jenkinson[21] showed a decline in protective efficacy in young infants from 100% in the first year after immunization to 52% four years later, highlighting the need for a preschool booster immunization. Asymptomatic infection is now more common in preschoolers than in school-aged children, and the attack rate of laboratory-confirmed pertussis increases with the age of the child. The protection provided by the vaccine is therefore short lived, and immunization of school children, adolescents, and adults is necessary.[9,13,22] Pertussis has a moderate seasonality with a higher incidence in the summer and autumn.

The epidemiology of pertussis is changing since the introduction of pertussis vaccines. In areas of low vaccine penetration pertussis affects mostly children in the 2- to 6-year-old age group; approximately half of unimmunized children develop pertussis by age 5, and essentially all were infected by age 15, with about three fourths experiencing symptomatic infection. It is mostly a disease of young children and less so of young infants who were partially protected by transplacental maternal antibody. Repeated exposures during epidemics resulted in high levels of protection by the time these children reached adulthood. Whole cell pertussis vaccine is responsible for a major reduction in the number of cases of pertussis and has caused a significant shift in the peak age of disease. Thus, children are protected well during childhood, but because of the limited duration of vaccine-induced protection and the decrease in opportunities for reexposure, adults become susceptible again, and newborns and young infants are no longer protected by maternally derived antibody.[23] As a result, the disease becomes most prevalent among young infants who are at highest risk for high morbidity and mortality from this disease.[24] Although the size of the epidemics has been reduced, the interval between epidemics has not significantly changed since the introduction of the vaccine.[9] In Canada, a change of the epidemiology was observed in the outbreak of 2000; namely, a decrease in pertussis in children less than 5 years of age and a significant rise in infections in preteens and teens. The drop in pertussis among infants and preschoolers may be the result of the introduction and widespread use of five-component acellular pertussis vaccine since 1996 or may be the result of the use of a relatively ineffective whole cell vaccine in Canada in the 1980s and early 1990s.[25]

After a nadir in 1976, the reported incidence of pertussis has been increasing in all age groups, with a disproportionate increase in preadolescents, adolescents, and adults. Over the past 15 years, there was an 18.8-fold increase in reported cases in 10- to 19-year-olds and a 15.5-fold increase in adults, compared to a 1- to 5-fold increase in younger age groups. Thus, in 2004, adults accounted for 29% of reported cases, 11- to 18-year-olds for 34%, those younger than 12 months for 13%, and 1- to 10-year-olds for 21%. The incidence outside of the first year of life is highest for those 10 to 19 years old.[7,26]

Adults and adolescents have been recognized as a source of exposure of infants for over 25 years. Nelson[27] and other investigators have demonstrated that pertussis in adults is often atypical and asymptomatic and occurs in individuals with a history of prior immunization and even prior disease.[28-32] Endemic infection in adults may act as a reservoir from which infection is spread.[33] A recent study involving surveillance in four states shows that in 75% of the cases, the source of exposure is in the household and is typically an adolescent or adult.[34,35]

Indeed, antibody levels to pertussis antigens are often undetectable in the serum of adolescents and adults.[36] *B. pertussis* is a gram-negative, faintly staining, pleomorphic, nonmotile coccobacillus whose only reservoir is human. It is transmitted by the inhalation of aerosols of *B. pertussis* produced by a patient in the catarrhal or paroxysmal phase of the illness. Patients who have had symptoms for 4 weeks or longer are generally noninfectious.

The genus *Bordetella* includes nine species, of which four are closely related and cause disease in humans. *B. pertussis* is the major cause of the pertussis syndrome, while pertussis associated with *B. parapertussis* is less severe and lacks the typical lymphocytosis. *B. bronchiseptica,* the cause of canine distemper, can result in coughing illnesses in humans. *B. holmesii* has been associated with septicemia and some respiratory infections.[37] Infections with members of the genus *Bordetella* other than *B. pertussis* are not preventable by pertussis vaccines.

Pertussis is not an invasive infection of the respiratory tract. The illness is mediated by the effect of the toxins of *B. pertussis* on respiratory epithelial cells. Attachment to these cells is the first step in the pathogenesis of this infection and is mediated by a number of adhesins such as filamentous hemagglutinin (FHA), fimbriae (FIM), pertussis toxin (PT, also known as lymphocytosis promoting factor), lipopolysaccharide (LPS), and pertactin (PRN), resulting in redundancy in the adhesion function. In vitro, FHA is the major adhesin; however, its role in attachment does not seem to be critical in the presence of other adhesins. Vaccine studies point to pertactin as the most important vaccine antigen with regards to protection. The second step in pathogenesis, cell evasion from the immune system, is facilitated by PT, which inhibits migration of lymphocytes and macrophages to areas of infection, and adenyl cyclase, which impairs phagocytosis by excessive production of cAMP by the cell. Local tissue damage to ciliated epithelial cells is mediated by tracheal cytotoxin, dermonecrotic toxin, and perhaps adenyl cyclase, and may be responsible for the paroxysmal cough. The nature of the toxin and the identity of the cell that triggers the cough are not known.[37,38] The systemic manifestations of the toxins that are most easily recognized are leukocytosis and lymphocytosis seen in young infants and is the result of PT. It is also responsible for the hyperinsulinemia that may manifest as hypoglycemia in some young infants. Encephalopathy is likely related to anoxia associated with paroxysms of cough.[39]

CLINICAL FEATURES, COURSE, AND PROGNOSIS

> It comes only by degrees, and is at first dry, but when it has continued ten or twelve days, it turns humid, and the matter which is then coughed up looks ripe; nevertheless it increases more and more, leaving long intervals; the fits return at certain hours, but continue at each time with such violence and for so long a time, that the child grows blue in the face, its eyes look as if they were forced out, and they run besides, and a bleeding of the nose is sometimes brought on; it coughs till it is quite out of breath, that one is in apprehension of its being choaked [sic]; for if the patient now and then is capable of drawing some breath, it is with a sounding which very much indicates with what difficulty the lungs can admit air. The coughing continues, and does not leave off for that time, till the child vomits up a quantity of slime.
>
> ROSEN VON ROSENSTEIN (1776)[40]

The incubation period of pertussis is usually 7 to 10 days with a range of 4 to 21 days. However, in household settings, one fifth of the cases occur more than 4 weeks after onset of symptoms in the primary case.[41] *B. pertussis* attaches to the mucosa of the nasopharynx, trachea, bronchi, and bronchioles, increasing the secretion of mucus, which is initially thin and later viscid and tenacious. The classic disease, most often seen in unimmunized children, lasts 6 to 12 weeks and is divided clinically into three stages: catarrhal, paroxysmal, and convalescent.[42,43] The catarrhal phase, which lasts for 1 to 2 weeks, starts with symptoms that are indistinguishable from those of an upper respiratory tract infection and include rhinorrhea, conjunctival injection, sneezing, anorexia, listlessness, and a hacking nocturnal cough that gradually becomes diurnal. The cough is usually not associated with fever and gradually increases in severity and intensity to become explosive and paroxysmal in the second week after the onset of symptoms (Fig. 38-2). The patient is most infectious during the catarrhal phase, and infectivity decreases during the paroxysmal phase.

Figure 38-2 Child with cough due to pertussis. (Image at http://phil.cdc.gov/phil/quicksearch.asp ID# 6378; courtesy of Centers for Disease Control and Prevention.)

The paroxysmal phase persists for 1 to 4 weeks and is dominated by severe coughing that can occur in paroxysms characterized by five or more short coughs *without an inspiration* followed by a deep inspiratory effort, which may result in the characteristic whoop. During these episodes, large amounts of mucus are expelled, often causing vomiting and, in young infants, choking spells and cyanosis. The child may be exhausted after a paroxysm. The paroxysmal episodes can occur in rapid succession and may be triggered by stimuli such as feeding, sucking, or crying. Weight loss can be seen as a result of frequent vomiting or the refusal of the child to eat. Apneic spells may occur in infants under 6 months of age, in whom paroxysmal spells are sometimes not seen. Infants with pertussis have a higher frequency of apneic pauses and hypoxemia along with ventilation-perfusion mismatch, resulting in the rapid onset of hypoxia.[44] Whoops may not be present in atypical cases, in young infants, in immunized individuals, and in children with pneumonia. Immunized children can develop subclinical infections.[45] Unfortunately, even in the presence of classic symptoms, the diagnosis is often missed.[46]

The convalescent phase usually starts 4 to 6 weeks after the onset of disease and is characterized by a gradual decrease in the frequency and severity of the episodes. A nonparoxysmal cough may persist for many months. The duration of the illness in uncomplicated cases is 6 to 20 weeks.[43]

In the neonate, initial symptoms consist of poor feeding, tachypnea, and cough. The catarrhal phase may be short or absent, and many neonates do not develop a paroxysmal cough. Apnea, gagging, cyanosis, and bradycardia may be the first manifestations and are sometimes not initially associated with cough. Their symptoms often start at about 1 week of age and these young infants often require hospitalization, typically at 2 to 3 weeks of age, and sometimes require endotracheal intubation and mechanical ventilation.[4-6]

Pertussis in adults may be similar to that in young infants. Severe disease is unusual in this age group; however, the illness is often long lasting[47] and is unrecognized.[48] In their study of 664 adolescents and adults with pertussis, De Serres and colleagues found that 97% of patients had coughing illness lasting longer than 3 weeks, and 52%, longer than 9 weeks. The paroxysmal episodes lasted 3 weeks or longer in 73%, and 69% had a whoop. Complications were more frequent in adults (28%) than in adolescents (16%), as was cyanosis (9% and 6%, respectively) and hospitalization (3.5% and 1.4%, respectively). Pneumonia occurred in 2% of individuals under 30 years of age and 5% to 9% of those over 30.[49] Milder disease may present as an illness with a nonspecific cough; indeed, prolonged coughing may be the only manifestation of pertussis among immunized individuals. Household contacts of individuals with primary pertussis experience a high rate of infection, many of which are subclinical; in this setting, the infection rates were 46% in those contacts who remained well, 43% of those with mild disease, and 80% in those with pertussis.[50] During outbreaks, a coughing illness of 7 or more days is associated with serologic evidence of pertussis in 17% to 52% of adolescents and adults.[51-56] Post-tussive vomiting occurs in 17% to 50%. Thirty-eight percent of adolescents with pertussis reported in Massachusetts in 1989 through 2004 had already been coughing for more than one month at the time of diagnosis.[13] Other manifestations include pharyngeal symptoms in one third of adults, and sweating in 40% to 50% of persons over 30 years of age. Recurrences of a pertussis-like illness can occur after upper or lower respiratory tract infections.

Major complications are most commonly respiratory in nature, such as pneumonia (which may be primary or the result of secondary infection), apnea, asphyxia, bronchopneumonia, atelectasis, bronchiectasis, interstitial and subcutaneous emphysema, and pneumothorax.[32,43] Central nervous system complications have been reported in up to 14% of cases.[17] Acute encephalitis can progress to coma, stupor, or convulsions. Cerebral edema and hemorrhage can be seen. Long-term sequelae include spastic paralysis, mental retardation, and other permanent neurologic sequelae. In the recent U.S. experience, isolated seizures occurred in 2.2% of cases and encephalopathy in 0.7%.[39] Patients may also develop ulceration or laceration of the frenulum of the tongue, epistaxis, melena, subconjunctival hemorrhage, diaphragmatic rupture, hernias, rectal prolapse, apnea, or rib fractures.[37]

Severe complications of pertussis occur primarily in infants younger than 6 months.[57,58] They have the highest rates of hospitalization (63%), pneumonia (12%), seizures (1.4%), and encephalopathy (0.2%). These rates are even higher in infants under 2 months of age. Most deaths secondary to pertussis occur in young infants, especially those under 2 months of age.[59,60]

Nutritional deficiencies are the direct result of the infant's inability to eat because of the paroxysms associated with feeding. The malnutrition that follows, combined with the disease, can lead to death.

The case-fatality rate is 1.3% in children younger than 1 month and 0.3% in those aged 2 to 11 months old.[43,61] The mortality rate among infants in the United States is 2.4 per million, and 90% of all pertussis fatalities occur in infants under 6 months of age. Marked leukocytosis and the presence of pneumonia tend to predict poor outcomes.[24,62]

After pertussis, there is a decrease in forced expiratory flow at low lung volumes, reflecting obstruction of the more peripheral airways, and a lower mixing index, indicating a maldistribution of ventilation, findings consistent with the diffuse pulmonary inflammation and inspissated mucus seen in this disease. These decreases in pulmonary function persist into later childhood.[41] Other studies fail to show differences in respiratory symptoms or asthma in adolescents with a history of a pertussis-like illness in childhood.[63] There is no effect on lung function or bronchial reactivity in adults who had pertussis in childhood. The only observed association is with a reduction of forced vital capacity (FVC) in men, a finding that is difficult to interpret.[64]

DIAGNOSIS

Successful detection of *B. pertussis* depends largely on the quality of specimen collection and transport to the laboratory, stage of the disease, prior antimicrobial therapy, and immunization status. The preferred specimens are posterior nasopharyngeal (NP) swabs or aspirates. Throat swabs are not appropriate. The nature of the swab material for culture isolation should consist of Dacron or calcium alginate. Dacron swabs are recommended for PCR testing; calcium alginate swabs should not be used for PCR detection because of

inhibitory factors in the fiber. Transport systems include the Regan-Lowe (RL) transport medium, 1% acid-hydrolyzed casein, and Amies medium with charcoal. The latter two have a stability of less than 24 hours. Direct plating of NP specimens onto agar plates provides optimal sensitivity. The medium of choice for culture of the organism is charcoal agar (RL agar) supplemented with 10% horse serum. Bordet-Gengou agar is also used but the medium must be freshly made, making it less practical than charcoal agar, which has a shelf-life of 8 weeks.[37]

Detection of the organism is accomplished by direct fluorescent antibody (DFA) testing, nucleic acid detection, or culture methods. The DFA sensitivity ranges from 30% to 71% compared to culture, and the specificity is highly variable. PCR has been shown to be more sensitive than DFA or culture and remains positive longer in the course of the disease or following antibiotic exposure, presumably because of its ability to detect dead organisms. PCR also demonstrates higher sensitivity in people with mild or atypical symptoms and in older persons.[65-67]

The culture has a specificity of 100%. While the sensitivity of cultures could be as high as 80% to 90%, it typically ranges from 30% to 60% in the field. The yield drops rapidly after 2 weeks of coughing illness, after antimicrobial therapy, or prior vaccination. Culture has a sensitivity of only 1% to 3% after 3 weeks of cough.[13,68] Serologic assays, typically enzyme immunoassays, have been used to measure IgG, IgM, and IgA antibodies to PT, FHA, pertactin, and fimbriae. In general, a 2-fold increase in IgG and IgA to PT or FHA is considered a reliable indicator of infection with 90% of infected persons developing an IgG response to PT and FHA. An IgG response to PT is specific for *B. pertussis*, because no other member of the genus *Bordetella* expresses PT.[41]

The white blood cell count is usually moderately elevated to between 15,000 and 20,000/mm^3 but may be normal or may be as high as 60,000/mm^3, usually with 60% to 80% lymphocytes. Marked leukocytosis, with white blood cell counts of more than 25,000/mm^3, is seen in approximately 40% of children. Young infants under 6 months of age are less likely to have marked leukocytosis.[43] The disease caused by *B. parapertussis* resembles that caused by *B. pertussis* except for its milder nature and the absence of lymphocytosis.[69]

The differential diagnosis of atypical pertussis includes bronchitis and upper respiratory infections secondary to adenoviruses, parainfluenza and respiratory syncytial viruses, *Mycoplasma pneumoniae*, and *Chlamydophila pneumoniae*.[70,71] These agents may represent coinfections with *B. pertussis*.[72,73] Other causes of chronic cough, such as asthma, gastroesophageal reflux, postviral cough, chronic sinusitis with postnasal drip, tuberculosis, other chronic lung diseases, and malignancies, should also be considered in the differential diagnosis.[24] *Bordetella parapertussis* accounts for about 5% of pertussis illnesses and occurs in small local epidemics.

TREATMENT

Oral erythromycin, in a dosage of 40 to 50 mg/kg/day in 4 divided doses for 14 days, has been the mainstay of antimicrobial therapy. Given during the catarrhal stage, it may shorten the clinical illness and results in eradication of the organism within 5 days. It is generally thought that therapy after onset of symptoms has no effect on the clinical course. However, recent studies suggest that treatment early in the paroxysmal stage results in a decrease in the number of whoops.[74,75] Erythromycin is not indicated for neonates under 1 month of age because of the complication of hypertrophic pyloric stenosis. The erythromycin dose for adults is 1 to 2 g/day and is associated with a high rate of gastrointestinal side effects. *B. pertussis* is nearly always susceptible to the macrolides, with only three erythromycin-resistant isolates described to date. A 7-day regimen has been shown to be equivalent to the 14-day regimen[76] (Table 38-1).

The newer macrolides, azithromycin and clarithromycin, are also effective in eradicating *B. pertussis* and are better tolerated than erythromycin.[77-80] The dose of azithromycin is 10 mg/kg on days 1 to 5 for infants under 6 months of age and 10 mg/kg as a single dose on day 1 followed by 5 mg/kg on days 2 to 5 for children 6 months old and older, with a maximum dose of 500 mg on day 1 followed by 250 mg on days 2 to 5 for adults. The clarithromycin dose is 15 mg/kg/day in two divided doses for 7 days for children over 1 month of age; the dose for adults is 1 g/day in two divided doses for 7 days. Roxithromycin has similar pharmacokinetics and mechanism of action as azithromycin and clarithromycin and could be used for treatment or prophylaxis; however, no studies have been conducted with this agent.[81]

Trimethoprim-sulfamethoxazole (TMP-SMZ) can be used for those who cannot tolerate a macrolide or in the rare instances of macrolide resistance. The dose of TMP-SMZ is 8 mg/kg/day of trimethoprim and 40 mg/kg/day of sulfamethoxazole divided into two doses for 14 days. The dose for adults is 320 mg of trimethoprim and 1600 mg of sulfamethoxazole a day divided into two doses for 14 days. Ampicillin, amoxicillin, and cephalosporins have no activity and should not be used for prophylaxis or treatment.[82]

The same agents and administration regimens are used for prophylaxis of persons with direct exposure to patients with active pertussis. Prophylaxis is initiated only if the contact with the index case occurred 3 or fewer weeks from the onset of the cough in the index case except in high-risk patients (e.g., neonates), where it should be considered for the first 6 weeks from onset of symptoms.

Salbutamol is ineffective in ameliorating the symptoms of pertussis.[83-85] The benefits of the use of steroids have not been established.[86-88] Cough suppressants are not useful in the symptomatic management of pertussis, nor is diphenhydramine. Supportive therapy is a critical component of the care of infants with pertussis, including a quiet environment and gentle suctioning of respiratory secretions, which are important in preventing attacks or paroxysmal coughing. Administration of oxygen may be needed during paroxysms of cough to prevent hypoxia. Rarely, infants need to be intubated, paralyzed, and ventilated to allow for proper oxygenation. High-frequency jet ventilation is sometimes necessary. Maintenance of nutrition is essential during the acute phase of the illness. Small frequent feeds or nutrition via a nasogastric tube may be needed. Rarely, careful attention to hydration and nutrition has to be maintained with intravenous fluids. Intensive care measures may be needed in severe cases. Infants younger than 6 months or those with cyanosis or excessive vomiting during paroxysms may initially be admitted to the hospital.

Table 38-1
Recommended Antimicrobial Treatment and Postexposure Prophylaxis for Pertussis, by Age Group

Age Group	Primary Agents			Alternate agent
	Azithromycin	Erythromycin	Clarithromycin	TMP-SMZ
<1 month	Recommended 10 mg/kg/day as a single dose for 5 days	Associated with pyloric stenosis Use if azithromycin unavailable 40-50 mg/kg/day in 4 divided doses for 14 days	Not recommended	Contraindicated in <2 months (risk of kernicterus)
1-5 months	10 mg/kg/day as a single dose for 5 days	40-50 mg/kg/day in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses for 7 days	Contraindicated in <2 months TMP 8 mg/kg/day, SMZ 40 mg/kg/day in 2 divided doses for 14 days
Infants (≥6 months) and children	10 mg/kg/day in a single dose on day 1 then 5 mg/kg/day (max 250 mg) on days 2-5	40-50 mg/kg/day (max 2 g/day) in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses (max 1 g/day) for 7 days	TMP 8 mg/kg/day, SMZ 40 mg/kg/day in 2 divided doses for 14 days
Adults	500 mg in a single dose on day 1 then 250 mg/day on days 2-5	2 g/day in 4 divided doses for 14 days	1 g/day in 2 divided doses for 7 days	TMP 320 mg/day, SMZ 1600 mg/day in 2 divided doses for 14 days

From Aoyama T, Sunakawa K, Iwata S, et al: Efficacy of short-term treatment of pertussis with clarithromycin and azithromycin. J Pediatr 129:761-764, 1996; and Centers for Disease Control and Prevention: Recommended antimicrobial agents for treatment and postexposure prophylaxis of pertussis—2005 CDC guidelines. MMWR Morb Mortal Wkly Rep 54(RR-14):1-17, 2005.

Respiratory isolation should be instituted and continued until the patient has received macrolide therapy for 5 days or, in the absence of macrolide therapy, is at least 3 weeks from the onset of paroxysms.[89] Children with suspected pertussis who attend child care facilities should not be admitted to the facility until their disease is evaluated. They can return after the administration of a macrolide for 5 days. Contacts who have immunization delays should be immunized, as should infants under 4 years of age whose last vaccination was given 6 months or longer before the exposure. A macrolide may be given to household contacts irrespective of immunization status.

PREVENTION

Universal immunization of infants and children at 2, 4, 6, and 12 to 18 months and 4 to 6 years of age has been the mainstay of prevention of pertussis. Vaccines consisting of a combination of diphtheria and tetanus toxoids with whole cell pertussis vaccines consisting of killed organisms (DTP) are used worldwide in children under 7 years of age and are highly effective. They are associated, however, with frequent local and systemic reactions. Multiple uncontrolled series have implicated DTP in neurological events following vaccination. Data from the National Childhood Encephalopathy Study, a prospective case-control study in England and Wales, and subsequent studies in the United States, Denmark, and Canada show no evidence for a causal relationship between DTP and encephalopathy, epilepsy, or sudden infant death syndrome.[37]

DTP vaccines were used in the United States from the 1940s to the late 1990s, when they were replaced by acellular pertussis vaccines (DTaP) containing one or more pertussis antigens along with diphtheria and tetanus toxoids. These vaccines are immunogenic and are associated with fewer side effects than whole cell vaccines. The immunization program has been effective in reducing the incidence of pertussis from a rate of 157 per 100,000 population in the prevaccine era to less than 1 per 100,000 in the 1970s.[23] In the setting of household exposure of children 1 to 4 years of age, the efficacy is 59% to 97% depending on the case definition. The efficacy was 64% for any cough illness.[90] Vaccine efficacy depends on the number of vaccine doses and is 18%, 48%, 58%, and 68%, respectively, after one, two, three, or four DTP doses. Whole cell pertussis vaccines demonstrated excellent efficacy (89% to 96% for typical pertussis and 81% to 83% for mild or atypical pertussis), with the exception of the Connaught vaccine, which was poorly immunogenic, whereas the three- and five-component acellular vaccines now used in the United States had an efficacy of 84% and 85% against classic pertussis.[41,91,92] After a 150-fold drop in the incidence of pertussis, there has been a gradual increase in the number of reported pertussis cases in the United States, which may be explained partly by better recognition of the disease and by the use of a less effective DTP vaccine in the period from 1985 to 1992.

Acellular pertussis (DTaP) vaccines lack LPS and are less reactogenic.[93] They result in significantly fewer episodes of persistent crying, fevers of higher than 40.5° C, hypotonic-hyporesponsive episodes, and febrile seizures than do DTP vaccines. Seven trials in the 1990s have evaluated the efficacy of eight acellular vaccines. In general, vaccines that contain one, two, or three antigens (PRN, FIM) in addition to FHA and PT have better efficacy against both mild and typical pertussis than vaccines that contain only PT or PT and FHA.[41]

However, despite routine pertussis immunization in childhood, the infection remains endemic in the adolescent and adult populations and results in epidemics in young children every 2 to 5 years.[9] In order to control the circulation of *B. pertussis*, immunization programs that target adolescents and adults of all age groups are necessary.[94] To date, only Australia, Austria, Canada, France, and Germany have incorporated adolescent immunization in their program. In the United States, two vaccines for adolescents and adults (Tdap) were licensed in 2005 and are now recommended for children and adolescents 10 to 18 years of age. They consist of reduced-dose diphtheria toxoid, tetanus toxoid, and three (PT, FHA, PRN) or five (PT, FHA, PRN and FIM 1 and 2) pertussis antigens. The vaccine containing five components is licensed for use for ages 11 to 64 years, while the three-component vaccine is licensed for use in 10- to 18-year-olds. Their reactogenicity is similar to that of dT vaccines, and their immunogenicity against diphtheria and tetanus is equivalent to that of dT.[95] They generate a robust immune response against their component pertussis antigens that lasts for at least 5 years.[96] The preferred age for Tdap immunization is 11 to 12 years, replacing the usual dose of dT. The routine use of Tdap in adolescents is expected to result in net health benefits and will likely be cost effective.[97] Tdap is the preferred vaccine for adolescents aged 11 to 18 years as part of routine wound management if they have not had a dose of tetanus toxoid within the previous 5 years. It is also recommended as a single booster dose of Tdap for adults aged 19 to 64 years who never received a dose of Tdap. The interval between the last dose of dT-containing vaccine and Tdap can be as short as 2 years without dose modification or increase in its side effects. People anticipating having close contact with an infant under 12 months of age should receive Tdap, preferably at least 2 weeks before beginning such contact. The recommended interval from the last tetanus toxoid–containing vaccine is 2 years, but shorter intervals are acceptable. Pregnant women should receive a dose of Tdap in the immediate postpartum period. Women contemplating pregnancy should be encouraged to receive a dose of Tdap. Health care workers should receive a single dose of Tdap as early as 2 years after their last tetanus toxoid–containing immunization. Priority should be given to those in contact with children under 12 months of age.[98]

PITFALLS AND CONTROVERSIES

The duration of immunity afforded by Tdap is not defined at this time. Antibody levels after a booster dose are maintained for at least 5 years. It is anticipated that booster doses of vaccine would not need to be given any more often than once every 10 years based on projected kinetics of antibody decay for antibodies to pertactin.

Immunization of susceptible pregnant women will need to be considered in order to provide the newborn with a good level of antibody through placental transfer. Immunization of close contacts of infants under 6 months of age would be a major step in controlling household exposure. Universal immunization of adults remains an elusive goal especially considering the large number of nonimmunized or underimmunized high-risk adults against such known pathogens as influenza and pneumococcus.[99]

CHAPTER 39 Mycobacterial Infections

Delane Shingadia and David Burgner

TEACHING POINTS

- *Mycobacterium tuberculosis* (MTB) is the most prevalent chronic infection in the world, with two thirds of the global population infected.
- Most infection is asymptomatic (latent tuberculosis [TB] infection [LTBI]). In adults and older children, reactivation of LTBI causes active pulmonary TB disease in about 10% of individuals (so called postprimary disease).
- Children with TB are generally less infectious than adults and are almost always infected by an infectious adult.
- Children are at greatly increased risk of progression of LTBI to TB disease and of uncontrolled progressive primary infection. Identification and treatment of children with LTBI, particularly following household exposure, are therefore essential.
- There is increasing global resistance to anti-TB drugs; recent reports suggest that highly resistant TB may essentially be untreatable.

Mycobacterium Tuberculosis

EPIDEMIOLOGY

Mycobacterium tuberculosis (MTB) is the most prevalent chronic infection in the world. It has been estimated that there were 8.8 million new cases of tuberculosis (TB) globally in 2003 (140 per 100,000 population), of which 3.9 million (62 per 100,000) were smear-positive and 674,000 (11 per 100,000) were coinfected with human immunodeficiency virus (HIV). An estimated 1.7 million people (28 of 100,000) died from TB in 2003, including those coinfected with HIV (229,000).[1] Approximately one third of deaths occurred in children. Figure 39-1 shows the global TB notification rates in 2003 (rates of all TB cases per 100,000 population).[1]

The TB incidence rate has been falling or stable in five of six World Health Organization (WHO) regions but growing at 1.0% per year globally (Table 39-1). The Southeast Asian region is one of those with the largest total number of people with TB cases, with three countries—India, Indonesia, and Bangladesh—accounting for the majority of cases. However, the incidence has been rising more quickly in sub-Saharan African countries with higher HIV prevalence rates. While incidence rates in Western Europe have fallen since 1980, many Eastern European countries showed increasing rates during the 1990s, which peaked around 2001, and have since fallen.[1]

In 1989, the WHO estimated that there were 1.3 million annual cases of TB in children younger than 15 years.[2] However, there are many difficulties in estimating the burden of TB in children, and this is probably a gross underestimate. Issues include the difficulty in establishing a definitive diagnosis, the increased presence of extrapulmonary disease in young children, the lack of standard case definition, and the lower public health priority given to childhood TB compared with that of adult TB. In many resource-limited countries, surveillance data are often unreliable due to poor diagnostic facilities and reporting systems.[3] For purposes of WHO reporting, TB cases are defined as those that are sputum-smear positive for acid-fast bacilli. This means that more than 80% of children with TB will not be represented, as they will not be sputum-smear positive. The proportion of TB cases in individual countries that occur in children is highly variable. In low-prevalence countries this may be less than 5%, whereas in some high-prevalence countries it is estimated to be four times this figure.

Most of the accurate pediatric data come from low prevalence countries such as the United States and those in Western Europe. In the United States, the Centers for Disease Control and Prevention (CDC) case definition of TB includes a positive tuberculin skin test (TST), diagnostic investigations, signs and symptoms compatible with TB, and treatment with two or more antituberculous drugs. National rates in children aged 0 to 14 years have been falling from 3.1 per 100,000 in 1992 to 1.5 per 100,000 in 2001, with a constant 6% of total cases occurring in children. Case rates are the highest for ethnic minority groups. White children younger than 5 years have a rate of 0.5 per 100,000, compared with Hispanic, black non-Hispanic, and Asian/Pacific Island children, whose rates are 7.0, 6.2, and 6.5, respectively. In California, the overall rates of pediatric TB have been falling, and since 1992, this decline has been greatest in children born overseas.[4] Similarly, in low-prevalence countries in Europe, such as the United Kingdom, notification rates for TB have declined over the past 20 years.[5] National survey data from the United Kingdon show a decrease in TB rates in all age groups from 1978/1979, reaching their lowest levels in the mid-1980s before beginning to rise again. Rates in children and young people overall have remained relatively constant over the past 5 years.[6] In contrast to many other developed countries, TB notifications have increased substantially in London, which accounts for 40% of U.K. national

*In thousands.
†Per 100,000 population.

cases. Some areas have recorded rates of greater than 40 per 100,000 in children.[7] The proportion of black African children with TB in 1998 (44%) has increased substantially from 1993 (23%), whereas the proportion of pediatric cases from the Indian subcontinent (ISC) had fallen (21% in 1998 compared with 50% in 1993). Similar patterns have been reported in other low-prevalence countries in Europe, such as Sweden and Denmark.[8,9] In Australia, the majority of TB infection and disease also occurs in those born overseas. Humanitarian refugees, particularly from sub-Saharan Africa, account for many cases.

Accurate data from high-prevalence countries are less readily available. In South Africa, only 55% of children younger than 14 years with TB meningitis were notified.[10] The proportion of childhood TB to the total cases in South Africa is estimated to be 20%.[11] A study in an urban community in the Western Cape Province of South Africa (overall TB incidence estimated at 1149 per 100,000) found that 39% of the caseload occurred in children younger than 14 years.[12] In Botswana, 12% of all reported TB cases occurred among children younger than 15 years in 2000, although these accounted for only 2% of all smear-positive cases. In Malawi, the largest increases in cases in Blantyre from 1985 through 1995 occurred among children aged 1 to 5 years.[13] Because sub-Saharan Africa also has the highest burden of HIV infection, this will no doubt have a major impact on TB epidemiol-

ogy in this region. It has been estimated that based on contact with a smear-positive adult, 700,000 to 800,000 children would develop TB disease over 5 years.[14]

RISK FACTORS FOR TUBERCULOSIS IN CHILDREN

There have been several factors that have been associated with the resurgence of TB in children:

1. Increased travel and migration, particularly from countries with high rates of TB to resource-rich nations, has had a major impact on the epidemiology of TB in those nations. In North America, Australasia, and Europe, high-risk groups include immigrants as well as ethnic minorities, where higher rates of disease are observed in those born overseas compared with low rates in the nonimmigrant population.[15-21] Molecular epidemiologic studies undertaken in Norway and the United Kingdom both suggest that many of the new TB cases in immigrants are due to reactivation of infections acquired abroad.[20,22,23] Immigrant children born in regions with high prevalence who migrate to low prevalence countries are at much higher risk of developing TB for several reasons. First, they are more likely to be exposed to TB in their home country, often through an infectious adult within their household but also within refugee camps. One study of internationally adopted children in the United States found that 19% were TST positive.[24] Humanitarian refugees arriving in Western Australia, mainly from sub-Saharan Africa, have a TST positivity rate of approximately 25% (unpublished data).
2. Socioeconomic risk factors including poverty and crowding continue to be associated with a greater risk of children developing both latent infection and active TB.[25] In South Africa, a significant correlation was found between TB case notification rates in childhood and crowding, economic status, and parental education.[12] Similarly, the overall risk of TB was linked to deprivation, population density, and ethnicity in the United Kingdom.[26]
3. The HIV pandemic has had a profound effect on the incidence of TB, particularly in sub-Saharan Africa, where up to a quarter of the population are HIV infected. HIV is known to greatly increase the annual risk of progression from TB infection to active TB and is thought to be one of the principal causes of the resurgence of TB in this region. The average annual case rates for TB after 1985 have increased approximately twice as fast in countries with high versus low or intermediate HIV seropositivity rates.[27] In children, the association between HIV and infection is not as well characterized, with coinfection rates of 11% to 64%.[28] A multicenter U.S. study found a high annualized TB case rate (51 to 478 per 100,000) among HIV-exposed and HIV-infected children younger than 5 years compared with the 1992 overall U.S. case rate of 5.5 per 100,000 for children this age.[29] In Brazil, the numbers of children with TB with HIV coinfection increased from 23.5% to 31.4%.[30] Similarly high rates have been noted in South Africa, where in one study almost half of children under 12 years of age with culture-proved pulmonary TB were also HIV infected.[31] Despite the high rates of coinfection with HIV and TB in these children, it is still unclear whether HIV-infected children are more vulnerable to TB infection or more likely to progress to disease than HIV-negative children. An important risk factor for TB in HIV-infected children is that they are more likely to be a close contact of a smear-positive adult than HIV-uninfected children. Because TB is the most common opportunistic infection in HIV-infected adults in the developing world, children in this setting are more likely to be exposed to TB irrespective of their HIV status. In New York, Thomas and colleagues[32] found that HIV-infected children were at higher risk of TB than uninfected children born to HIV-infected mothers. Both groups had higher rates than other children in New York, suggesting that increased exposure to TB may also be a contributing factor irrespective of the child's HIV status. The difficulty of diagnosing TB in children, coupled with the difficulty of diagnosing HIV-associated pulmonary infections in children, may have important confounding effects on assessing the epidemiology of TB and TB/HIV coinfection in children. The outcome is also worse for children who are HIV infected with a higher mortality than those who are HIV negative when they develop TB. In Ethiopian children who were HIV positive, there was a 6-fold increased risk of death during an episode of TB compared with an HIV-negative child.[33] In a study of childhood TB in Cote d'Ivoire, Mukadi et al.[34] noted 50% mortality over the 6-month treatment period for HIV coinfected children who had $CD4^+$ percentage of less than 10%. In HIV-negative children, the mortality rate was 4%.
4. Drug-resistant TB is of great importance worldwide as it reflects TB control in the population. Cost of drug therapy, especially for multidrug-resistant (MDR) TB, is more expensive and treatment in many cases is more difficult to implement. However, there are limited data available on drug-resistant TB in children. In most children, definite confirmation of drug-resistant TB will not be possible, due to lower rates of microbiological identification from pediatric samples. Often, the diagnosis of drug-resistant TB will be made on the basis of confirmation of drug resistance in the adult index case. In high-prevalence communities, however, children may have multiple exposures within the same household, so even if close contacts have drug-sensitive disease, the possibility of resistant disease in the child still exists. Resistance patterns in children have generally been found to be similar to those of adults from the same areas and similar backgrounds. Children most often have primary resistance that has been transmitted to them by an adult with new or retreatment-resistant TB.[35] A large South African study, conducted between 1994 and 1998 in TB culture-positive children, found 5.6% had isoniazid (INH) resistance and 1% had MDR (defined as resistance to both INH and rifampicin).[36] These results were essentially the same as surveillance data from adults with TB during the same time period, with 3.9% INH resistance and 1.1% MDR. In the United Kingdom, the rate of INH resistance in pediatric cases is 6.5%, and that for MDR TB is 0.5%, again similar to the rates in adults of 6.4% and 1.2%, respectively.[6] Treatment outcome has also been poorly studied in children, with treatment completion of only 45% in children in Malawi.[37]

IMMUNE RESPONSE AND SUSCEPTIBILITY TO TUBERCULOSIS

The immunologic response to MTB is complex and reviewed only briefly here. The risk of developing TB infection or disease following exposure is influenced by the genetics of both the host and the pathogen.[38-40] Certain individuals appear to have enhanced innate resistance; at least 50% of heavily TB-exposed individuals do not develop infection, but the immunogenetic basis of the differential susceptibility is unclear. Most adults with TB disease have reactivation of previously contained latent TB infection (LTBI) due to increasing age, acquired immunodeficiency, alcoholism, or unknown factors. Reactivation of primary infection may also be seen in children, but they are also at risk of uncontrolled primary infection and hematogenous dissemination to extrapulmonary sites.

Investigation of individuals with disseminated infection due to low virulence nontuberculous mycobacteria have indicated that the interleukin (IL)-12–interferon (IFN)-γ pathway is central to host defense.[41] Bronchoalveolar lavage specimens from household contacts of TB demonstrate an increased frequency of IFN-γ producing cells that may contribute to local protection.[42] However, the immunologic basis of the development of LTBI is not well understood. It is thought that in the immunologically naïve host who lacks innate resistance, intracellular multiplication of MTB continues, leading to cell necrosis and release of bacilli into the alveolar space. T cells lacking immunologic memory migrate to this site of inflammation and may mediate monocyte- and macrophage–mediated killing of MTB, possibly through the local generation of nitric oxide and reactive nitrogen intermediates.[43] Bacilli released by lysed pulmonary cells spread to local draining lymph nodes and may spread to more distant sites hematogenously. Acquired resistance, generated by the initial interaction between the bacillus and the host, mediates the protection in the 90% of individuals who control their TB infection and do not develop TB disease.

The balance of Th1 and Th2 cytokines appears critical in controlling TB infection. In adult patients with progressive TB, there is a relative overexpression of Th2 cytokines IL-10 and transforming growth factor (TGF)-β, which suppress IFN-γ production.[44] $CD4^+$ T cells are clearly important, as depletion in animal models and in HIV infection is associated with greatly increased risk of TB disease. In those who develop protective immune responses to their initial TB infection, the primary focus usually heals with fibrosis and possibly caseation in older children. Regional lymph nodes also heal over several months, but lymphadenopathy may persist for years despite adequate therapy. Healed lesions may contain small numbers of viable MTB, which may cause disease if immunity wanes. Once protective immunity has developed, exogenous reinfection appears rare, although this may be important in overcrowded conditions and in immunocompromised populations.

There have been a number of studies that have attempted to define the immunogenetic basis of resistance to TB (for review, see References 38, 45-47). TB is clearly a genetically complex disease and susceptibility is inherited in a non-Mendelian manner. Thus, the relative contribution of each genetic locus is likely to be small, making identification of individual loci difficult.[48] There are important considerations regarding phenotypic definitions, as the immunologic pathways (and thus associations with the genes that control them) are likely to vary with the various manifestations of TB—LTBI, localized pulmonary infection, disseminated disease—and with different populations—children, immunocompetent adults, HIV-infected adults. Despite these caveats, a number of important findings are emerging. Antigen presentation, not surprisingly, is key to the generation of protective immunity. The main receptor for MTB on dendritic cells, which present antigens to T cells, is DC-SIGN. Variation in the promoter region of the gene encoding DC-SIGN (CD 209) is associated with protection from TB.[49] Amino acid sequence variation in the HLA binding groove is associated not only with differential risk of TB but also in markedly different responses to TB-specific antigens in vitro.[44] Genetic studies have also highlighted the importance of macrophages. The macrophage activator *SLC11A1* (formerly known as *NRAMP-1*) was initially shown to offer protection against various intracellular pathogens in animal models.[50] *SLC11A1* appears to prime macrophages and upregulate protective responses, including cytokine and nitric oxide production. Variation of the *SLC11A1* gene has been associated with differential TB susceptibility in adults and recently children, although the effects are not identical.[51,52] It is possible that *SLC11A1* variants slow progression from infection to disease in children. Low levels of vitamin D, an important immunomodulatory molecule and macrophage activator, increase susceptibility, and variation of the vitamin D receptor gene has been associated with increased susceptibility to TB disease in Indian migrants to the United Kingdom, although this finding has not been confirmed in other populations.[53,54] It appears that TB exhibits a degree of genetic heterogeneity—with different genetic variants operating in different ethnic groups—which makes interpretation of the data more difficult.[55] Newer methodologies, including genome-wide association studies and adequately powered genetic epidemiologic studies are likely to continue to yield insights into the complex immune response to MTB.

CLINICAL FEATURES

It is important to distinguish TB *infection* (also referred to as LTBI, discussed subsequently) from TB *disease*. In both, there is evidence of TB infection (TST or blood-based immunologic assay), but in latent infection, the clinical, radiologic, or microbiological evidence of disease is lacking. The majority of children (>50%) with TB disease will be asymptomatic. Of those who develop symptoms, most will have pulmonary manifestations, while 25% to 35% of children will have extrapulmonary symptoms.[56] Systemic complaints such as fever, night sweats, anorexia, and decreased activity occur less often. The most common symptoms at presentation in children with TB disease are cough in the preceding 3 months, persistent fatigue, and weight loss.[57]

INTRATHORACIC DISEASE

Pulmonary Disease

Following initial exposure and infection, the primary complex is characterized by a lung parenchymal infiltrate (commonly

subpleural and consisting of a minute cluster of macrophages around tubercle bacilli reaching 1 mm at 2 to 3 weeks in which multinucleate giant cells may develop) and regional lymph node enlargement. Most children are asymptomatic at this stage; the infiltrate may necrose, caseate, and undergo gradual dissolution, and the lymphadenopathy will resolve spontaneously in the majority of cases. In some children, particularly infants, the lymph nodes continue to enlarge, causing pressure effects on surrounding structures such as the trachea and bronchi, which may result in partial or complete bronchial obstruction. This obstruction may result in wheeze either as a presenting symptom or in some instances after commencement of antituberculous therapy. The term *epituberculosis* has been used to describe bronchial compression by enlarging lymph nodes causing atelectasis and subsequent parenchymal destruction.[58] Endobronchial disease may also occur when encroaching, enlarged lymph nodes erode into the bronchi with extrusion of caseous material into the bronchial lumen.[59] The clinical presentation may be insidious or acute. The right middle lobe syndrome may result due to chronic lobar atelectasis secondary to postinflammatory bronchial stenosis.[60] In general, the most common pulmonary symptoms of primary infection, if any, include nonproductive cough and mild dyspnea. There may be few clinical signs on examination; however, some infants and young children may have localized wheezing or decreased breath sounds accompanied by increased respiratory rate or respiratory distress. Older children and adolescents are more likely to develop adult-type reactivation disease[61,62] and will present with the classic symptoms of fever, malaise, weight loss, night sweats, productive cough, chest pain, and hemoptysis. Again, there may be very few or no clinical signs on physical examination.

Tuberculous Pneumonia

Primary and often fulminant tuberculous pneumonia in both immunocompromised and immunocompetent individuals, including older children, is reported rarely.[63] It may be segmental or lobar or involve extensive areas of the lung bilaterally. It is often severe and has been associated with acute respiratory distress syndrome.[64]

Pleural Disease

Pleural involvement may occur in reaction to the release of a few mycobacteria into the pleural space from a subpleural focus. This may result in clinically significant pleural effusions, which are often unilateral. Pleural fluid is typically yellow with elevated protein and white blood cells. Microscopy and culture yields from pleural fluid are often low; however, pleural biopsy will demonstrate caseating granulomas in the majority of cases. Clinical symptoms include fever, chest pain, and reduced air entry on the side of the effusion.

Cardiac Disease

Pericarditis is the commonest cardiac manifestation of TB, occurring in 1% to 4% of children.[65] Pericardial fluid is serofibrinous or slightly hemorrhagic. Clinical symptoms may be nonspecific, including low-grade fever, malaise, and weight loss; chest pain is unusual in children. Auscultation of the cardiovascular system may reveal a pericardial friction rub or reduced heart sounds.

EXTRAPULMONARY DISEASE

Lymphohematogeneous spread following primary complex formation occurs more commonly in children and results in disseminated TB, including miliary TB, and extrapulmonary TB. Extrapulmonary TB includes peripheral lymphadenopathy (65%), TB meningitis (10% to 15%), bone and joint disease (4%), and miliary TB (5%).[66]

Peripheral Lymphadenopathy

Local spread from primary infection in the lungs results in peripheral tuberculous lymphadenopathy, particularly in the supraclavicular and paratracheal regions. Lymphohematogenous spread may result in more distant lymph node involvement. Peripheral TB lymphadenopathy commonly presents as slowly enlarging, firm, nontender lymph nodes with no overlying skin discoloration. There are often no systemic symptoms such as fever or weight loss. With time, the enlarged lymph nodes become fluctuant and may discharge with sinus formation. The lymph nodes most often involved are in the anterior or posterior cervical and supraclavicular regions.

Miliary Tuberculosis

Miliary TB is the most common form of disseminated disease and usually occurs early after the infection, within the first 2 to 6 months, and may represent uncontrolled primary infection in children. The median age at presentation is 10.5 months, with about half of cases occurring in those younger than 1 year. The clinical manifestations of miliary TB are protean, with involvement of the lungs, spleen, and bone marrow. The presenting symptoms are often nonspecific: cough (72%), fever (61%), loss of appetite and weight (40%), and diarrhea and vomiting (33%). The main presenting signs are hepatomegaly (82%), splenomegaly (54%), lymphadenopathy (46%), and pyrexia (39%).[67] Like adults with military TB, children are usually smear negative. With progressive pulmonary disease, respiratory distress, hypoxia, and pneumothorax/pneumomediastinum may occur. Signs or symptoms of meningitis or peritonitis are found in 20% to 40% of patients with advanced disease. Choroid tubercles occur in 13% to 87% of patients and are highly specific for TB (Fig. 39-2).

Central Nervous System Tuberculosis

Involvement of the central nervous system, particularly meningitis, is among the more common manifestations of extrapulmonary disease.[68-72] Tuberculous meningitis is the most serious complication in children and is almost invariably fatal without treatment. The brain stem is the most common focus with cranial nerve involvement (III, VI, and VII).[73] The clinical progression of tuberculous meningitis may be rapid or gradual. Rapid progression tends to occur more often in infants who may experience symptoms for only several days before the onset of acute hydrocephalus, seizures, or cerebral edema.

Table 39-2 summarizes the clinical stages of TB meningitis (modified from British Medical Research Council study[74]).

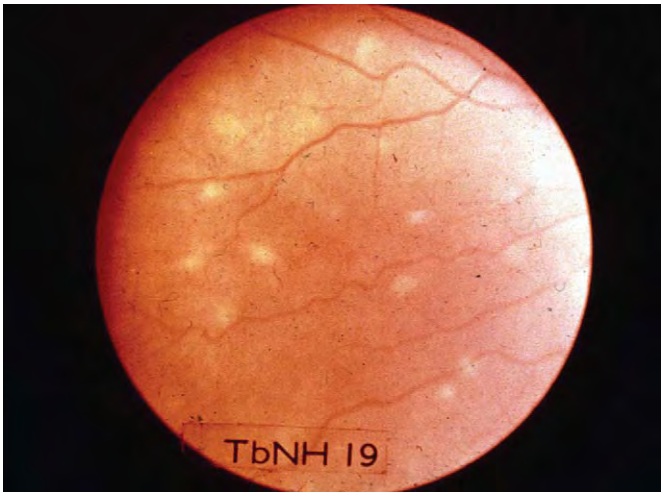

Figure 39-2 Choroid tubercles on retinal examination in patient with miliary tuberculosis.

Signs and symptoms may evolve and progress over time. Stage I (early) is characterized by nonspecific symptoms such as fever, headache, irritability, and malaise and usually lasts several weeks. There are few to no clinical signs, and at this stage, there is no reduction in consciousness. Infants may experience delay or loss of developmental milestones. Stage II (intermediate) is characterized by drowsiness and lethargy. Clinical signs are those of meningitis (including nuchal rigidity and positive Kernig or Brudzinski signs), cranial nerve palsies, vomiting, and seizures. This clinical picture usually correlates with the development of hydrocephalus and increased intracranial pressure. Stage III (advanced) is usually characterized by stupor or coma, often accompanied by gross paresis (hemiplegia or paraplegia), hypertension, and decerebrate posturing. Paresis most commonly reflects ischemic infarction from vasculitis, although it may be exacerbated by hydrocephalus. The prognosis of tuberculous meningitis correlates most closely with the clinical stage of illness at the time antituberculosis chemotherapy begins.[75] The majority of patients in the first stage have an excellent outcome, whereas most patients in the third stage who survive have permanent disabilities including blindness, deafness, paraplegia, and cognitive impairment.[76]

In children with TB meningitis, 40% to 80% will have abnormal chest radiographs, including hilar adenopathy (33%), infiltrates (33%), miliary pattern (20%), and pleural effusions (1%).[77] Cranial CT scans of the patients presenting with TB meningitis showed hydrocephalus in 80% to 90% and basilar enhancement in over 90% of cases. MTB may be cultured or identified by acid-fast stain from CSF or brain tissue from 63% of children. New tuberculoma may develop during treatment.[72] The Mantoux test is negative in 30% to 50% of all children on presentation with TB meningitis.[72,77]

Other Extrapulmonary Tuberculosis

Skeletal TB is a late complication of lymphohematogenous spread and usually presents many years following primary infection. The most common sites of involvement are the weight-bearing bones and joints such as the vertebral column (40% to 50%), hip, knee, and elbow. Vertebral TB may be very insidious, often presenting with referred pain, abnormal posturing, or paravertebral abscess formation.

Other extrapulmonary sites of TB are generally very rare in children, particularly genitourinary disease, which occurs many years after primary infection and hence is unlikely to occur in the pediatric age group.

Table 39-2
Stages of Tuberculous Meningitis[69]

Stage	Clinical Signs and Symptoms
I (early)	Nonspecific symptoms Few or no clinical signs of meningitis
II (intermediate)	Signs of meningitis Drowsiness or lethargy Cranial nerve palsies
III (advanced)	Stupor or coma Systemic toxicity Gross paresis or paralysis

DIAGNOSIS

Microscopy and Culture

Microscopic examination of clinical samples for acid-fast bacilli using the Ziehl-Neelsen (ZN) stain has been a standard diagnostic tool and is used globally for rapid TB diagnosis. Microscopy can detect 60% to 70% of culture-positive samples with a lower limit of detection of 5×10^3 organisms/mL. Newer fluorochrome stains, such as auramine and rhodamine, appear to have better detection compared with the ZN stain.[78] These tests have been widely adopted as they are easy to perform, cheap, and give rapid results. However, because younger children rarely produce sputum, early-morning gastric aspirate samples are often collected by aspiration of gastric contents via a nasogastric tube. The yield from microscopy of gastric aspirate samples in children with proved pulmonary TB is less than 20%, compared with 75% in adults.[79] The rates of detection on microscopy from other extrapulmonary samples, such as cerebrospinal fluid, are even lower.

Mycobacterial culture of gastric aspirates has provided a more useful method of diagnosis in children with suspected pulmonary TB. Three consecutive morning gastric aspirates yield MTB in 30% to 50% of cases and may be as high as 70% in infants.[80] The culture yield from other body fluids or tissues from children with extrapulmonary TB is usually less than 50% due to lower numbers of mycobacteria in these sites of disease.[81]

The role of bronchoscopy in evaluating children with pulmonary TB is controversial. Cultures from bronchoalveolar lavage fluid in children with suspected pulmonary TB has a low yield and does not significantly aid bacteriologic confirmation.[82] Indeed, the culture yield of a single bronchoscopic sample has been shown to be lower than that for three properly obtained gastric aspirates.[83] It has been suggested that bronchoscopy may, however, play a useful role in the diagnosis of endobronchial TB or bronchial obstruction, especially if transbronchial biopsy is performed.[84] Bronchoscopy may also be useful in excluding other causative agents such as opportunistic infections, particularly in immunocompromised children and those with HIV infection.

More recently, sputum induction with nebulized 5% saline has been used safely in young infants in resource-limited settings and found to be equivalent to the yield from three consecutive early-morning gastric aspirates.[85] The microbiological yield from sputum induction did not differ between HIV-infected and HIV-uninfected children with pulmonary TB, and all sputum induction procedures were well tolerated with only minor side effects, including increased coughing, epistaxis, vomiting, or wheezing.[86] However, there are concerns regarding spread of TB to other patients and staff, and it is recommended that sputum induction be performed with appropriate infection control procedures (e.g., negative pressured cubicles), and by appropriately trained staff. This technique may be difficult to use effectively in preschool-age children.

Regardless of the microbiological results, any sample should be cultured and susceptibility to antituberculous drugs determined. Bone marrow may be cultured in those with clinical disseminated disease.

Tuberculin Skin Test

A positive TST reaction is a hallmark of primary infection with MTB. In most children, tuberculin reactivity becomes apparent in 3 to 6 weeks with the associated onset of the immune response and, rarely, fever, erythema nodosum, or phlyctenular conjunctivitis, but occasionally can take up to 3 months after initial infection. Tuberculin reactivity due to MTB infection usually remains positive for the lifetime of the individual, even after treatment.[87]

The Mantoux test is the standard TST currently in use and uses 5 to 10 tuberculin units of purified protein derivative. The Mantoux test is the standard method used in many countries for detecting infection by MTB. This test involves the intradermal injection of purified protein derivative solution into the most superficial layer of the skin of the forearm, which raises an immediate wheal. The reaction is measured as millimeters of induration (not erythema) after 48 to 72 hours. Sometimes with strongly positive Mantoux tests, there may be marked induration, blister formation, and ulceration at the site of intradermal injection (Fig. 39-3). Percutaneous multipuncture devices, such as the Heaf test and Tine test, are no longer in common use. Interpretation of TST results differs around the world and is summarized in Table 39-3.

TST has both poor sensitivity (false-negative results) and specificity (false-positive results). The TST has the lowest sensitivity in younger children. Up to 10% of otherwise normal children with culture-proved TB do not react to tuberculin initially.[81] Most of these children will become reactive during treatment, suggesting that TB disease may itself contribute to immunosuppression. False-negative TST may also occur in children with severe TB disease and those with debilitating or immunosuppressive illnesses, malnutrition, or other severe infections. The rate of false-negative TST in children with TB

Figure 39-3 Strongly positive Mantoux test with marked induration and blistering.

Table 39-3
Summary of Interpretation of Positive TST Results for Mantoux Test in Children[145-148]

BTS Guidelines (UK)	WHO	American Academy of Pediatrics (USA)
Positive ≥6 mm (no bCG) ≥15 mm (bCG)	Positive >10 mm (no bCG) >15 mm (bCG)	Positive *>5 mm and one or more of the following:* Children in close contact with known or suspected contagious case of tuberculosis disease, i.e., households with active or previously active cases, if treatment cannot be verified as adequate before exposure, treatment was initiated after the child's contact or reactivation of latent tuberculosis infection is suspected *OR* Children suspected to have tuberculosis disease, i.e., chest radiograph consistent with active or previously active tuberculosis; or clinical evidence of tuberculosis disease *OR* Children receiving immunosuppressive therapy or with immunosuppressive conditions including HIV infection *>10 mm and one or more of the following:* Children at increased risk of disseminated disease, i.e., younger than 4 years of age or other medical condition, including Hodgkin's disease, lymphoma, diabetes mellitus, chronic renal failure, or malnutrition *OR* Children with increased exposure to tuberculosis disease, i.e., born or whose parents were born in high-prevalence regions of the world; or are frequently exposed to adults who are HIV-infected, homeless, users of illicit drugs, residents of nursing homes, incarcerated or institutionalized, and migrant farm workers *>15 mm* Children 4 years of age or older without any risk factors

who are infected with HIV is unknown, but it is certainly higher than 10% and is dependent on the degree of immunosuppression, particularly the $CD4^+$ count.

The converse problem may also occur, namely false-positive TST results. bCG (bacille Calmette-Guerin) vaccination may transiently cause a reactive TST, but most children who received bCG as infants have a nonreactive TST at 5 years of age.[88] A recent meta-analysis suggests that the effect of bCG on TST measurements was less after 15 years, and induration greater than 15 mm was more likely to be due to TB infection than bCG.[89] Among older children or adolescents who receive bCG, most develop a reactive TST initially; however, by 10 to 15 years postvaccination, the majority will have lost tuberculin reactivity.[90] Recent studies have shown that bCG vaccination had little impact on the interpretation of TST in children being tested as part of a contact investigation.[91] There have been concerns that false-positive TST may arise through antigenic cross-reactivity from asymptomatic infection by environmental nontuberculous mycobacteria.[92] Skin reactivity can also be boosted, probably through antigenic stimulation, by serial testing with TST in many children and adults who received bCG.[93]

Radiology

Radiologic evidence of pulmonary TB on chest radiography usually includes lymphadenopathy (hilar or mediastinal) (Fig. 39-4) and lung parenchymal changes. The latter include segmental hyperinflation, atelectasis, alveolar consolidation, pleural effusion/empyema (Fig. 39-5), and, rarely, a focal mass. Cavitation is rare in young children but is more common in adolescents (Fig. 39-6), who may develop adult-type postprimary disease and are more likely to be infectious.[94] Miliary TB is characterized by fine bilateral reticular shadowing, sometimes called a "snowstorm" appearance (Fig. 39-7). There is some evidence that lateral chest radiography improves the diagnostic yield.[95]

Figure 39-7 Chest radiograph showing miliary tuberculosis with pneumomediastinum.

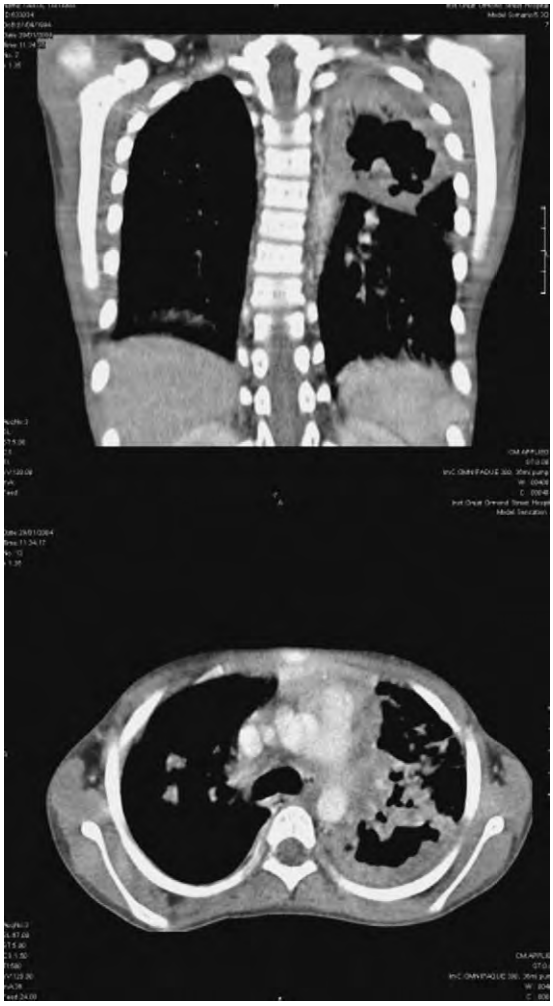

Figure 39-8 CT scans of chest showing left upper lobe cavitation.

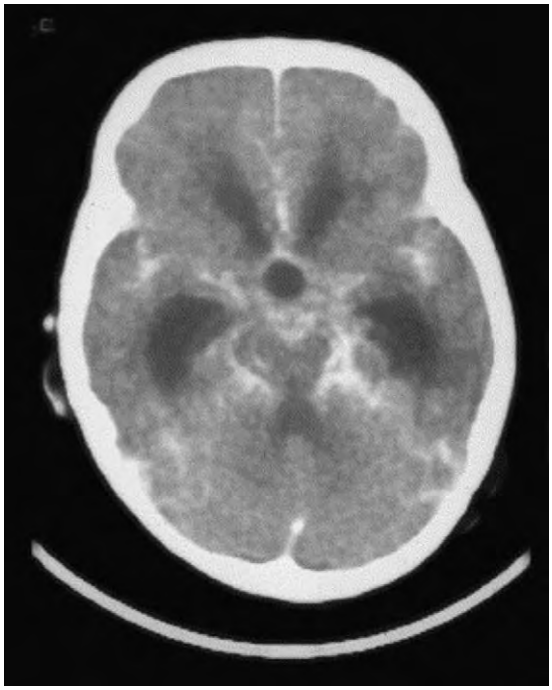

Figure 39-9 Head CT scan showing hydrocephalus and basal enhancement consistent with TB meningitis.

Computed tomography (CT) scanning has been useful in demonstrating early pulmonary disease such as cavitation (Fig. 39-8). CT imaging is also better than chest radiography in demonstrating bronchial involvement such as bronchial compression and bronchiectasis. CT may also be useful in detecting intrathoracic hilar lymphadenopathy, even in those with normal chest radiographs.[96-98] Furthermore, there is interobserver variability in the detection of mediastinal and hilar lymph nodes on CT in children with suspected pulmonary TB, and diagnostic accuracy might be improved by refining radiologic criteria for lymphadenopathy.[99]

CT has also been used for evaluation of pericardial effusions and is strongly suggestive of tuberculous disease when associated with mediastinal lymphadenoapthy and a positive TST.[100] Central nervous system disease, such as TB meningitis or tuberculoma, may also be identified on CT, especially as contrast demonstrates meningeal enhancement (Fig. 39-9).

Magnetic resonance imaging (MRI) has been found to be useful for musculoskeletal TB, particularly involving bones and joints.[101] Figure 39-10 shows a Pott's fracture of the spine that was identified on MRI.

Figure 39-10 MRI of spine showing Pott's fracture of upper thoracic vertebra.

Diagnostic Approaches in Childhood Tuberculosis

The diagnosis of TB in children is based mainly on a combination of history of contact with an adult infectious case, clinical signs and symptoms, and investigations mentioned earlier, particularly chest radiograph and tuberculin skin testing. However, symptoms may often be nonspecific, with over half of children being asymptomatic with early disease.[94] A positive history of contact with a case of TB, especially if the source case was a parent or other member of the household who was also bacteriologically positive, has been strongly associated with disease in a child.[102] These epidemiologic, clinical, and diagnostic parameters have been used to devise simple, inexpensive, and reliable tests to enable accurate diagnosis of TB in children, especially in low-income countries. Several diagnostic approaches exist, and most are grouped broadly into four families based on point scoring systems, diagnostic classifications, diagnostic algorithms, or combinations of these.[103] An example of a diagnostic approach is that recommended by the WHO, which relies on stratified categories of suspected, probable, and confirmed TB[104] (Table 39-4). Most of these diagnostic approaches have not been standardized, making comparison difficult, and few have been properly validated.[103] Some diagnostic approaches have been modified for populations where HIV is prevalent; however, only one diagnostic approach has been specifically designed to diagnose TB in such a population.[13] In a high HIV prevalent population, clinical scoring systems have been found to have low specificity (25%), resulting in overdiagnosis of TB.[105] Further studies are needed to develop standardized diagnostic approaches that are relevant to developing countries with limited resources with a high burden of TB, malnutrition, and HIV/AIDS.

MOLECULAR DIAGNOSTICS

Due to the slow growth of most pathogenic mycobacteria, investigations have been developed for microbial detection directly from clinical specimens. Most have involved amplification of small amounts of bacterial nucleic acid using techniques such as polymerase chain reaction (PCR). PCR has been used successfully in identifying many infectious agents, allowing early diagnosis and institution of therapy. Although the specificity of a well-developed PCR can be high, the sensitivity is significantly less than that of the use of culture. The sensitivity of a good-quality PCR would be expected to be 90% to 100% and 60% to 70% on smear-positive and smear-negative culture-positive respiratory samples, respectively.[106-108] However, there are several problems with applying this technique to routine clinical care, including variations in methodology, high cost, and high risk of contamination resulting in false positives.

Several studies in children have found the PCR test on clinical samples to have a sensitivity of 40% to 60% compared with clinical diagnosis.[109-112] This compares favorably to standard cultures, which have a sensitivity of 30% to 40%. The specificity of PCR ranges from 80% to 96% but is dependent on the type of assay used. Furthermore, up to 39% of children with no radiographic or clinical evidence of tuberculous disease may also have positive PCR results.[113] With the limitations that exist, the results of PCR alone are insufficient to diagnose TB in children. PCR detection in other body fluids or tissues, such as cerebrospinal fluid, appears to have been even less successful.

In view of the problems highlighted above, PCR methods have a limited role in the diagnosis of TB in children; however, they may be useful where the diagnosis is not easily established using standard clinical, microbiological, and epidemiologic methods. PCR may also have a future role in the diagnosis of TB in immunocompromised children, or those with extrapulmonary TB.

Molecular methods have also been used for species confirmation, detection of rifampicin resistance and for molecular typing as part of epidemiologic investigation. Species confirmation will allow differentiation between MTB complex organisms (MTB, *M. bovis*, and *M. africanum*) and environmental mycobacteria. These tests are most effective when applied to samples in which mycobacteria have been detected microscopically. They may also be important in confirming TB before a large contact-tracing exercise is conducted. Molecular probes looking for mutations of the *rpoB* gene may be useful, particularly as a marker of MDR TB. Molecular typing of MTB strains, using techniques such as restriction fragment length polymorphism (RFLP), may be a useful epidemiologic tool to identify potential links between patients and impact on diagnosis and transmission of TB in a community.[114]

Table 39-4
WHO Provisional Guidelines for the Diagnosis of Pulmonary Tuberculosis in Children[99]

Suspected Tuberculosis
An ill child with a history of contact with a confirmed case of pulmonary tuberculosis
Any child:
Not regaining normal health after measles or whooping cough
With weight loss, cough, and wheeze not responding to antibiotic therapy for respiratory disease
With painless swelling in a group of superficial nodes
Probable Tuberculosis
A suspected case and any of the following:
Positive (>10 mm) induration on tuberculin testing
Suggestive appearance on chest radiograph
Suggestive histologic appearance on biopsy material
Favorable response to specific antituberculosis therapy
Confirmed Tuberculosis
Detection by microscopy or culture of tubercle bacilli from secretions or tissues
Identification of tubercle bacilli as *Mycobacterium tuberculosis* by culture characteristics

SEROLOGIC DETECTION

Serology has so far found little place in the routine diagnosis of children with TB, despite several assays that have been developed. ELISA has been used to detect antibodies to a host of MTB antigens including protein-purified derivative, killed MTB, and antigen A60.[115-117] However, none of these methods has adequate sensitivity, specificity, or reproducibility for use in the diagnosis of children with TB.

IMMUNODIAGNOSIS

The TST has poor specificity due to cross-reactivity with BCG immunization and environmental mycobacteria. Fur-

thermore, false negatives may occur in individuals with altered immunity such as HIV infection, immunodeficiency or immunosuppression, advanced TB, and malnutrition. New diagnostic tests have been developed based on in vitro T-cell–based IFN-γ assays. These tests rely on IFN-γ production by sensitized T cells to specific TB antigens. While initial tests used PPD as the stimulating antigen, newer assays use specific antigens, such as the early secretory antigenic target-6 (ESAT-6) antigen and culture filtrate protein 10 (CFP10). These antigens are present in MTB complex but absent from all strains of *M. bovis* bCG and almost all environmental mycobacteria. Two commercial IFN-γ assays, the Quanti FERON-TB Gold assay (Cellestis Limited, Carnegie, Victoria, Australia), and the T SPOT-TB assay (Oxford Immunotec, Oxford, UK), are currently available. Both tests measure IFN-γ release from T cells in response to using methods such as ELISA and enzyme-linked immunospot (ELISPOT) assay.[118] The QuantiFERON-TB Gold cultures whole blood with the TB-specific assays and measures IFN-γ in the culture supernatant, whereas the ELISPOT cultures peripheral blood mononuclear cells and directly counts the number of IFN-γ-secreting cells. The QuantiFERON-TB Gold test has been approved by the U.S. Food and Drug Administration (FDA) for diagnosis of TB infection and disease. The T SPOT-TB test is currently approved for use in Europe and is awaiting FDA approval.

Current evidence suggests that IFN-γ assays have the potential to become useful diagnostic tools in clinical and public health settings. Studies in different populations suggest that these tests have greater specificity (>90%) compared with TST, although sensitivity may be equivalent or less, especially for latent infection. Furthermore, there are limited data from specific populations, particularly children and immunosuppressed individuals. Nevertheless, new guidelines have incorporated IFN-γ testing as an alternative and/or adjunct to TST. However, the cost-effectiveness and utility of these tests, especially in certain population groups, remains unclear.

LATENT TUBERCULOSIS INFECTION

Although two thirds of the world's population is infected with TB, only about 1 in 10 overall will develop active TB disease. The remainder are latently infected, with no clinical or radiographic evidence of active TB disease, but with a positive immunologic investigation (TST or blood-based assay), indicating exposure to and immunologic memory of MTB. Such diagnostic tests are increasingly insensitive with decreasing age, but it is younger children and infants who are most at risk of developing TB disease, and life-threatening dissemination of infection outside the respiratory tree is common; up to 45% of children present with advanced pulmonary, miliary, or meningeal disease.[119] Thus empiric prophylactic treatment for LTBI may be commenced in younger children if there is a significant history of exposure to an infectious adult or evidence of exposure within the household, irrespective of the immunologic investigations. In general, the decision to initiate prophylactic therapy for LTBI is based on an assessment of the risk of transmission and the risk of LTBI progressing to TB disease. These include the age of the exposed individuals, their immunocompetence (particularly HIV infection), the nature and degree of exposure to TB, as well as clinical, radiographic, and laboratory findings.

Children younger than 10 years with TB disease who typically have paucibacillary disease are rarely infectious, as cavitating disease and sputum positivity are extremely unusual in children. With a few exceptions, it is almost invariably adults with pulmonary or laryngeal TB who infect children.[120] Smear-positive adults are generally more infectious than are those who are sputum positive on culture alone.[121] Thus, adults with cavities on chest radiographs are more infectious than those without, although severely immunocompromised adults may be highly infectious with initially normal or atypical chest radiographs. Although adults coinfected with TB and HIV infection are no more contagious than those without HIV infection, the often-delayed diagnosis increases the risk of transmission.[122] Once TB treatment is initiated, a contagious adult becomes noninfectious within a few weeks, although the exact time frame varies.[120]

The identification and treatment of a child with LTBI provide a cornerstone of TB control, and the identification of LTBI in a child is considered a sentential event, indicating recent and on-going transmission, often within a household.[123] LTBI in a child should prompt an investigation for the infecting adult index case, although identification of the source is successful in less than 50% of source-case investigations.[124,125] In those from a refugee-like background, whose LTBI is often identified on routine screening on arrival in a developed country, the epidemiology is more complex. Families have often spent prolonged periods in large overcrowded refugee camps, with ample opportunity for transmission from outside the household, and an adult infective source is less commonly identified.

The diagnosis of LTBI is made by exclusion of TB disease in a child with a positive TST or blood-based assay or, in a younger child, on a history of exposure to an infectious adult. The diagnosis of LTBI in children is often difficult. As discussed, the symptoms of TB disease in children are notoriously variable and often subtle; up to 50% of children with TB disease have no symptoms at presentation.[57] Weight loss and malaise are the most sensitive symptoms, whereas chronic cough is specific but not sensitive in high-incidence populations.[57] A history of drenching night sweats is rarely elicited. It is reasonable to actively investigate any child with a positive contact history or TST/blood-based assay and a clinical or radiographic suggestion of TB disease. Empiric treatment is often warranted in children with evidence suggestive of TB diseases, rather than LTBI. In children younger than 2 years, in whom diagnostic investigations are insensitive, most guidelines advocate commencing empiric therapy for LTBI on the basis of a history of exposure alone.[122,126] Some guidelines advocate retesting (with Mantoux or blood-based assay) these younger children after 8 to 10 weeks of preventive therapy and discontinuing LTBI treatment if the results are negative.[122] However, given the insensitivity of the investigations and lack of data to support this approach in young children, it may be more prudent to continue a full course of treatment for LTBI in those younger than 2 years, regardless of the results of investigations.[127]

The rationale for treating LTBI is the significant risk of progression to TB disease in untreated infection, especially in

children. The risk is greatest in younger children (<5 years of age), but the exact age-related risk is difficult to ascertain from the available data, which are historical and include studies of both adults and children. The highest risk is in infants and young children, where a risk of disease progression of 40% to 50% is widely quoted.[128,129] The risk decreases gradually through childhood to adult levels of about 10%. The risk of disease progression is greatest in the 12 to 18 months following exposure.

Treatment of LTBI is highly effective in reducing the risk of TB disease, especially in children, where efficacy is well over 90%. A study of over 4000 children with tuberculin reactivity showed a 60-fold increased risk of developing TB disease if prophylactic therapy was not given, equivalent to a number needed to treat (NNT) of 50 LTBI cases to prevent one case of TB disease.[127,130] A meta-analysis of over 73,000 adults and children exposed to MTB in various settings indicated that prophylactic therapy gave a relative risk of TB disease of 0.4, compared with no prophylaxis; a NNT of approximately 90.[131]

Various regimens have been suggested for LTBI treatment, but most have not been subjected to randomized controlled trials in children. Six months of isoniazid therapy is the cornerstone of prophylactic therapy and the current recommendation for LTBI in many countries, including the United States, United Kingdom, and Australia.[132] The main issue in children, in whom side effects are less common than in adults, is compliance, which is inadequate in up to a quarter of patients.[133] Poor compliance diminishes the efficacy of prophylactic therapy. Isoniazid suspension, which may be necessary in younger children who do not tolerate crushed tablets or whose weight precludes available tablet doses, has a short shelf-life and is not available commercially.

Alternative regimens for LTBI are widely used in children, but without a sound evidence base. Isoniazid and rifampicin for 3 months is well tolerated and generally more acceptable to children and families.[134] This combination has a potential advantage if drug resistance is suspected. A meta-analysis in adults showed that this combination was equally efficacious as 6 months isoniazid monotherapy.[135] Rifampicin monotherapy for 4 months is also used infrequently in children.[136] In adults with silicosis, who have a high risk of disease progression from LTBI, 3 months of rifampicin was as efficacious as 6 months of isoniazid,[137] but there are no studies in children. Data, again only from adults, indicate that the combination of rifampicin and pyrazinamide potentially causes fatal hepatotoxicity and is best avoided.[138,139]

As with treatment for TB disease, LTBI therapy should be supervised and undertaken from a centralized TB service, where community workers can monitor compliance and assist families. It is good practice to dispense medication a month at a time and to review children regularly. Treatment with isoniazid alone or in combination with rifampicin is generally well tolerated and side effects are rare in children compared with adults. The main concern is hepatotoxicity, which is more likely in the presence of viral hepatitis or preexisting liver dysfunction. Pretreatment liver function testing is reasonable, but repeated testing or pyridoxine supplementation is unnecessary in asymptomatic children.[140] Vitamin D status should also be assessed prior to therapy for LTBI and supplemented as necessary. Both rifampicin and isoniazid can depress vitamin D levels, which are often already low or deficient in migrant populations.[141]

TREATMENT OF TB DISEASE

Treatment of children can be divided broadly into treatment of TB infection and treatment of TB disease. As mentioned, the distinction between these different categories may be unclear in some patients, particularly young children.

Several controlled and observational trials of 6-month therapy in children with pulmonary TB caused by organisms known or presumed to be susceptible to the first-line drugs have been published.[142-149] Although 6 months of therapy with INH and RIF has been shown to be effective for treatment of hilar adenopathy and pulmonary TB, a three-drug regimen (isoniazid, rifampicin, and pyrazinamide) has been shown to have success rates of greater than 95% and low adverse reaction rates. In general, extrapulmonary TB in children can be treated with the same regimen as pulmonary disease; however, there are no data from children and extrapolations have been made from studies in adults. Meningitis and disseminated TB, however, may not be adequately treated with 6 months' duration, and longer treatment durations of 9 to 12 months are recommended. The optimal treatment of TB in children and adolescents with HIV infection is unknown. Treatment durations of at least 9 months have been suggested.[150] Treatment schedules, policies, and drug doses as advocated by a number of national and international bodies often differ. Tables 39-5 and 39-6 compare drug regimens and dosages recommended in the United Kingdom, United States, and the WHO.[150-153] Traditionally, antituberculous regimens have included bactericidal and bacteriostatic drugs that have required treatment for long periods, between 18

Table 39-5
Recommended Dosages of First-Line Standard Antituberculous Drugs for Children[145-148]

	British Thoracic Society		American Thoracic Society		World Health Organization	
Drug	**Daily**	**Intermittent**	**Daily**	**Intermittent**	**Daily**	**Intermittent**
Isoniazid	5-10 mg/kg	15 mg/kg 3 times weekly	10-15 mg/kg	20-30 mg/kg twice weekly	5 mg/kg	10 mg/kg 3 times weekly

TB meningitis	2 months of RHZE then 10 months of RH	2 months of RHZE then 9-12 months of RH	2 months of RHZS then 4 months of RH
HIV	2 months of RHZE then 4-7 months of RH	2 months of RHZ then 7 months of RH	2 months of RHZE then 4 months of HR or 6 months of HE

R, rifampicin; E, ethambutol; H, isoniazid; S, streptomycin; Z, pyrazinamide.
*If resistance is suspected.

and 24 months. More recently, multidrug regimens have been used with more rapid microbiologic cure rates that allow shorter durations of therapy (short-course chemotherapy). Isoniazid, rifampicin, and pyrazinamide are mainstays of antituberculous therapy. Other agents often used in children include streptomycin and ethambutol.

Adverse reactions to antituberculosis therapy occur in children on anti-TB therapy, but generally the drugs are well tolerated. Gastrointestinal reactions such as nausea, vomiting, and abdominal pain are common, particularly in the first few weeks of therapy. In most cases, these reactions can be managed symptomatically. Isoniazid and rifampicin may both be hepatotoxic, causing elevation of serum aminotransferase levels (considered significant if three or more times the upper limit of normal). These hepatotoxic abnormalities are rarely severe in children, and modest increases in aminotransferases generally resolve spontaneously. All drugs used in treating TB can cause skin rash, which is usually minor and may be managed symptomatically. Isoniazid has also been associated with symptomatic pyridoxine deficiency, particularly in severely malnourished children. Supplemental pyridoxine is indicated in these malnourished children as well as in breastfeeding infants (dose is 5 mg in infants from birth to 1 month, 5 to 10 mg in infants and children less than 12 years, and 10 mg in children 12 to 18 years). Both isoniazid and rifampicin may cause suppression of vitamin D metabolism, which may result in symptoms of hypocalcemia.[141] Pyrazinamide is generally well tolerated in children and rarely causes hepatic dysfunction. Ethambutol has been associated with retrobulbar neuritis, which presents with blurred vision, central scotoma, and color blindness. Trebucq reviewed the literature regarding recommendations for ethambutol use in children and concluded that ethambutol was safe in children older than 5 years at a dosage of 15 mg/kg/day and also in younger children without undue fear of side effects.[154] It is often appropriate to obtain a baseline ophthalmologic assessment in younger children before starting ethambutol therapy. This should be repeated after 1 to 2 months.

Compliance by the patient and monitoring by the physician are major determinants of the success of drug treatment. Compliance in children is further compounded by the fact that children may have mechanical difficulties in taking medications, many of which are not specifically packaged or produced in pediatric formulations. Difficulties with taste, consistency of formulations, and gastrointestinal toxicity may be important factors in children that may dramatically affect treatment compliance.

DOTS (which stands for "directly observed therapy, short course" or "direct observation of therapy") has become a cornerstone for TB control across the globe. However, DOTS is only one of five key elements; these include government commitment to sustained TB control activities, case detection by sputum smear microscopy, standardized treatment regimens of 6 to 8 months for all confirmed smear-positive cases with DOTS for at least 2 months, a regular uninterrupted supply of essential antituberculosis drugs, and a standardized recording and reporting system. DOTS has been adopted by 148 of 210 countries worldwide and almost 55% of the world's population lives in countries providing DOTS. The WHO recommends that the DOTS strategy be applicable to all patients with TB, including children in whom high success rates (over 95%) can be achieved.[104] Many countries have adopted a universal DOTS policy, whereas others such as the United Kingdom use a selective policy for those who may be unreliable in taking their therapy.[151]

Respiratory Tuberculosis Including Hilar Adenopathy

In most cases, there is usually a history of contact with a smear-positive patient, commonly a family member. Treatment should consist of rifampicin and isoniazid for 6 months, supplemented by pyrazinamide for the first 2 months. Ethambutol should also be included in the first 2 months in children who are at high risk of isoniazid resistance. This includes those who are known or suspected to be HIV positive and those who are from other ethnic groups or are recent arrivals such as immigrants and refugees. For children aged 5 years or more, ethambutol is recommended for routine treatment without taking any more precautions than for adults. A routine ophthalmology review is recommended in young infants.

Central Nervous System Tuberculosis (Meningitis and Tuberculoma)

Quadruple therapy with rifampicin and isoniazid, with an initial 2 months of pyrazinamide and ethambutol or strepto-

mycin, is recommended for central nervous system TB. Both ethambutol and streptomycin cross the blood-brain barrier rather poorly, and only when the meninges are inflamed. Nevertheless, streptomycin is recommended by the WHO and the American Thoracic Society for TB meningitis. An alternative drug that achieves good cerebrospinal concentrations in children with TB meningitis is ethionamide, particularly when a dosage of 20 mg/kg/day is used.[155] A total duration of 12 months is generally recommended, although the WHO recommends a minimum of 6 months of therapy. Adjunctive steroid therapy is often given at the start of treatment. Advice from an infectious diseases specialist should be sought.

Other Extrapulmonary Tuberculosis

There are no clinical efficacy trials for the treatment of extrapulmonary TB in children. Present recommendations are based on trials in adults, which show favorable responses to 6 months of three or four drug combinations for non–life-threatening extrapulmonary disease. Treatment of TB adenitis, bowel disease, pericarditis, bone and joint disease, and other end-organ disease should be with the standard 6-month regimen. However, some authorities recommend longer courses of between 9 and 12 months for bone and joint disease.[150]

Multidrug-Resistant Tuberculosis

Single, multiple, and multidrug resistance is increasing worldwide. Isoniazid resistance has been found in 6.8% to 7.2% of isolates in children less than 15 years old in England and Wales from 1995 through 1999. MDR (defined as resistance to both isoniazid and rifampicin) over the same period was 0.5% to 0.7%. Higher levels of resistance occur in ethnic minority groups, especially those from the Indian subcontinent and sub-Saharan Africa. As children have lower rates of TB isolation, MDR TB is often initially identified only in the adult index case or in other contacts.

Treatment of patients with drug-resistant TB should be carried out only by specialists with appropriate experience in the management of such cases. The most common isolated drug resistance is to isoniazid. It is particularly important to add ethambutol as a fourth agent where isoniazid resistance is suspected or in those patients at higher risk of resistance. Treatment should be continued for 9 to 12 months, initially with rifampicin, pyrazinamide, and ethambutol for 2 months, followed by rifampicin and ethambutol for the complete duration of therapy. Isolated resistance to other first-line drugs is unusual and appropriate therapy must begin based on recommended guidelines.[151] Rifampicin resistance most commonly occurs in conjunction with isoniazid resistance (called MDR TB). Treatment should be carried out by a specialist with substantial experience in managing complex resistant cases and only in hospitals with appropriate isolation facilities. Such treatment should also be monitored closely not only for drug toxicity but, more important, to ensure compliance. Treatment will in most cases involve five or more drugs and for durations of at least 2 years. Several alternative antituberculosis drugs may need to be used, although the efficacy of these drugs has not been evaluated in children. The drugs that have been used previously include aminoglycosides (streptomycin, amikacin, capreomycin, kanamycin), ethionamide/prothionamide, cycloserine, quinolones (ciprofloxacin, ofloxacin), rifabutin, macrolides (azithromycin, clarithromycin), and *para*-amino salicylic acid.

Recently, *extensively drug-resistant tuberculosis* (XDR TB) has been reported in a number of countries.[156-158] XDR TB isolates are resistant to at least isoniazid and rifampin (MDR TB), and also exhibit additional resistance to at least three of the six classes of second-line drugs used to treat MDR TB. XDR TB is of particular concern among HIV-infected or immunocompromised individuals. Individuals are more likely to develop TB disease once they become infected with MDR and have a much higher mortality than those with other forms of TB.[157] The greatest concern is that XDR TB leaves some patients virtually untreatable with currently available drugs. To date, XDR TB has not been reported in children, but pediatric infection is probably inevitable in high-incidence populations, which often have high rates of HIV coinfection.

Corticosteroids

Corticosteroids have been found to be beneficial in situations where the host response to MTB contributes to significant tissue damage. Corticosteroids have been shown to significantly decrease mortality and long-term neurologic sequelae in patients with TB meningitis.[159,160] Children with bronchial obstruction due to enlarged lymph nodes may also benefit from corticosteroid therapy.[161] Corticosteroids may also be of benefit in extensive pulmonary TB, pericardial effusion, and pleural effusion. A dosage of 1 to 2 mg/kg (maximum of 60 mg) for 4 to 6 weeks is recommended, followed by a period of weaning doses.

PREVENTION AND CONTROL

The control of TB requires collaboration between health care professionals and public health departments in an effort to identify individuals who are contagious, provide effective and timely treatment to them, and also identify and investigate contacts of these individuals. Epidemiologic investigation of contacts of infectious individuals is aimed at identifying those with evidence of infection so that they may receive chemoprophylaxis to prevent future development of disease (see section on latent infection). WHO has focused on a DOTS strategy to ensure that TB control is effective particularly in high prevalence areas. The five key components of DOTS include the following:

- *Sustained political commitment* to increase human and financial resources and make TB control a nationwide activity and an integral part of the national health system
- *Access to quality-assured TB sputum microscopy* for case detection among persons presenting with symptoms of TB, screening of individuals with prolonged cough by sputum microscopy and special attention to case detection among HIV-infected people and other high-risk groups, such as people in institutions

- *Standardized short-course chemotherapy to all cases of TB under proper case-management conditions* including direct observation of treatment; proper case management conditions imply technically sound and socially supportive services
- *Uninterrupted supply of quality-assured drugs* with reliable drug procurement and distribution systems
- *Recording and reporting system enabling outcome assessment* of each patient and assessment of the overall program performance

bCG Vaccine

The WHO recommends neonatal bCG vaccination in countries with a "high prevalence" of TB, even in those with a high prevalence of HIV infection. bCG vaccine is also recommended for children at particular risk of TB exposure in low-endemic countries and for those exposed to MDR MTB.[162] bCG is used in over 150 countries and is mainly given in the neonatal period. However, there are some countries with low prevalence, such as the United States and Australia, that do not routinely vaccinate with bCG, based on the uncertain efficacy against pulmonary TB in adolescents and adults, as well as the need to maintain the utility of tuberculin testing as a diagnostic test in the population.

The protective efficacy of bCG remains controversial, varying from 0% to 80% in different populations and geographic regions.[163] Meta-analysis of prospective trials has shown a combined relative risk (RR) for TB of 0.49 (95% confidence interval, 0.34 to 0.70); that is, a protective effect of 51%.[164] Another meta-analysis has shown that the combined protection against meningeal and miliary TB was 86%.[165]

For the first time, after 80 years of widespread use of bCG, evaluations of new vaccine candidates in humans are available. Alternative approaches in vaccine development include subunit vaccines based on MTB antigens, recombinant bCG vaccines, and attenuated MTB vaccines. Another approach has been a prime-boost strategy, which may be relevant in populations already heavily vaccinated with bCG.[166] While vaccines are in different stages of development and use in humans, bCG remains the only vaccine currently available for the prevention of TB.

Nontuberculous Mycobacteria

Nontuberculous mycobacteria (NTM) include mycobacterial species associated with human infection, excluding those belonging to the MTB complex (MTB, *M. bovis*, and *M. africanum*) and also excluding *M. leprae*. NTM are also referred to as atypical or environmental mycobacteria, and only a fraction of the many species cause human disease. Apart from cervical lymphadenitis, infection in immunocompetent children is relatively unusual, and most NTM are weakly pathogenic. Disseminated NTM infections in children with previously unrecognized immunodeficiencies have highlighted crucial immunologic mechanisms in the host defense to mycobacteria in general.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

The classification of NTM has historically been made based on their microbiological characteristics, such as pigment production and rate of growth,[167,168] but this classification does not correlate well with clinical significance and disease. The most common species causing disease in children are two very closely related species, *M. avium* and *M. intracellulare*, which have been grouped taxonomically as *M. avium* complex (MAC). MAC infection is also common in adults with HIV/AIDS and is commonly isolated from the sputum of those with cystic fibrosis. Other common pathogenic species are *M. kansasii*, *M. fortuitum*, and *M. marinum*. Unlike most NTM, *M. fortuitum*, together with *M. chelonae* and *M. abscessus*, grow quickly (days rather than weeks) in vitro and are collectively known as "rapid growers."

NTM are ubiquitous in the environment, particularly in water, soil, and some animals. MAC is found in brackish warm water and poultry. The rapid-growing mycobacteria are relatively resistant to sterilization procedures and have been commonly reported to cause nosocomial infections as a result of contamination of fluids or devices in hospitals.[169] *M. marinum* is found in fish tanks and swimming pools and causes cutaneous infections by direct inoculation through broken skin (called "fish tank" or "swimming pool" granuloma).[170] *M. ulcerans*, which is found in fish, water insects, and snails, causes necrotic and often progressive skin lesions (Buruli ulcer), particularly in tropical countries, where it is extremely prevalent.[171] Significant outbreaks have also been reported from temperate countries.[172] Most infection with NTM is acquired through the oropharyngeal mucosa (the presumed portal of entry for cervical lymphadenitis) or, more rarely, through the respiratory and gastrointestinal tracts. Iatrogenic inoculation, for example, via central venous catheters or tympanostomy tubes, also occurs.

Given their wide distribution, exposure to NTM is ubiquitous, but clinical disease is relatively rare. Infection is acquired predominantly from environmental sources, and person-to-person transmission does not usually occur. In immunocompetent hosts, infection is usually limited to the portal of entry and regional lymph nodes. Dissemination of infection to distal sites is usually seen in those with immunodeficiency, particularly T cell–deficiency states such as advanced HIV/AIDS; MAC infection is an AIDS-defining illness. Detailed genetic analysis of a Maltese pedigree with previously unexplained and frequently fatal NTM infection identified a rare functional mutation of the IFN-γ receptor,[173] highlighting the importance of protection by this immunologic pathway. Deficiencies of key determinants of IFN-γ secretion, such as IL-12, also predispose to overwhelming infections with weakly pathogenic NTM and other intracellular organisms.[174] The pathogenesis of NTM infection is poorly understood. NTM may act as saprophytes as well as true pathogens, and distinguishing low-level infection from colonization may be problematic.

CLINICAL MANIFESTATIONS

The common manifestations of NTM are shown in Table 39-7.[175,176] Cervical lymphadenitis, predominantly caused by

Table 39-7
Clinical Manifestations of Nontuberculous Mycobacteria Infections

Predominant NTM species	Site of infection	Comments
MAC *M. kansasii* *M. fortuitum*	Cervical lymph nodes	Usually less than 6 years Subacute infection Usually unilateral
M. ulcerans *M. marinum* *M. chelonae* *M. fortuitum*	Cutaneous infection	Buruli ulcer Fish tank or swmming pool granuloma
MAC *M. kansasii* *M. abscessus*	Pulmonary infection	Usually immunocompetent host May be seen in CF May resemble MTB
MAC *M. kansasii* *M. abscessus* *M. chelonae* *M. marinum*	Skeletal infection	Usually direct inoculation Often associated with disseminated disease
MAC (other species rarely)	Disseminated infection	May be recovered from blood, bone marrow, reticuloendothelial system Implies immunodeficiency state

MAC, is the most common presentation seen in children, although globally Buruli ulcer is the third most common mycobacterial disease after MTB and leprosy.[5]

PULMONARY DISEASE

NTM infection of human lung tissue either follows primary invasion or secondary infection of previously damaged or abnormal lung parenchyma. Among the conditions reported in association with pulmonary NTM disease are cystic fibrosis, recurrent aspiration, lipoid pneumonia, and ciliary dyskinesia.[177,178] NTM isolation in children with cystic fibrosis is well recognized but often exemplifies the difficulties in distinguishing infection from colonization. The presence of a heavy growth of a single NTM species on repeated specimens with clinical and radiographic deterioration and no other clear etiology suggests true NTM infection.[179]

In general, NTM pulmonary infection may present as air-space filling processes or "pneumonia," as obstructing endobronchial lesions,[180] or as a compressive peribronchial lymphadenopathy.[181] Intrathoracic lymphadenitis without airway involvement has also been described. NTM secondarily invades regions of bronchiectasis caused by other disorders, and NTM may also be the primary cause of bronchiectasis. The radiographic signs of pulmonary NTM infection are usually nonspecific but may mimic MTB.

Unlike in adults, pulmonary NTM infection in infants and children is more likely to be associated with marked lymphadenitis and less likely to cause focal, destructive parenchymal disease. This pattern of disease is closely analogous to infection with MTB. Pleural disease in children caused by the NTM, as with adults, is uncommon. The tissue response typically has granulomatous features. Noncaseating granulomas, necrotizing granulomas, or, less commonly, caseation necrosis may be present. The rapid growing mycobacteria may elicit a dimorphic response with both granulomatous and pyogenic features.

DIAGNOSIS

Diagnosis is often problematic because of the wide distribution of the NTM in the environment, the saprophytic (rather than pathogenic) abilities of NTM and their relatively frequent contamination of laboratory cultures. Thus, establishing a specific pulmonary diagnosis should include (1) characteristic signs and/or symptoms; (2) representative radiographic abnormalities; (3) isolation, preferably repeatedly, of the mycobacteria from secretions or tissues; (4) granulomatous features on histopathology, if tissue is available; (5) absence of evidence for other potential pathogens; and (6) inferential evidence including plausible histories of exposure (where applicable), skin test reactivity (if available), and occasionally responses to therapeutic trials. Clearly isolation of NTM from a sterile site strongly suggests disseminated infection. Unlike other bacteria, isolates of NTM from a draining sinus are often clinically significant. Culture of NTM (rapid growers notwithstanding) can take several weeks. Newer liquid culture media have reduced culture times to days. Molecular techniques, such as PCR, can differentiate NTM from MTB,[182] but, as with MTB, diagnostic PCR sensitivity falls if the mycobacteria are not present in large numbers.

Skin testing for NTM infection is difficult to interpret because of the lack of sensitivity and specificity of available antigens. Although PPD derived from MAC is available, it is not routinely used in most centers and its use has not been standardized. The Mantoux test will generally discriminate between TB and NTM infection despite antigenic cross-reactivity.[176,183] The newer blood-based immunologic diagnostic methods that are gaining popularity for the diagnosis of TB use only predominantly TB-specific antigens and therefore largely distinguish between MTB and NTM responses.

DIFFERENTIAL DIAGNOSES

For many young children, even with careful evaluation, it may be difficult to exclude MTB infection, and empiric anti-TB treatment (possibly with additional treatment for NTM infections) may be warranted. This is particularly true in the cases of infants or young children in whom TB may rapidly progress to life-threatening or disabling forms of TB, including miliary, meningeal, or spinal disease. Disseminated NTM infection implies an underlying immunodeficiency.

TREATMENT

Prevention of NTM disease is limited to prophylactic antibiotics against MAC in HIV-infected individuals older than 6 years with significant immunodeficiency.[176] Typically, clarithromycin or (if MTB is definitely excluded) rifabutin is used. With highly active antiretroviral therapy, such anti-MAC prophylaxis is indicated infrequently in children with HIV.

Simple cervical lymphadenitis, especially that caused by MAC, is treated with complete surgical excision; adjunctive antibiotic therapy is only used where excision is incomplete. Other NTM infections are treated with combinations of antimicrobials for protracted periods. Many NTM are resistant to standard anti-TB medications. The choice of anti-NTM therapy is guided by the causative species, the site of infection, the in vitro susceptibilities, any underlying conditions, and the need to presumptively treat MTB infection until this can be excluded. In general in vitro susceptibility testing of NTM correlates poorly with clinical response.[184]

Combination therapy to prevent acquired drug resistance is an essential component of the treatment of TB and a principle that is also applied to NTM. Single drugs, no matter how efficacious, are subject to selection of drug-resistant variants, leading to clinical resistance to the individual agent. As in TB, therapy is generally extended well beyond the time of initial bacteriologic and clinical improvement. This is necessary to prevent recurrence by eliminating persistent, slow-growing, or semidormant bacilli that may reactivate if chemotherapy is prematurely terminated. Recommended drugs and drug regimens for the common NTM diseases include newer macrolides (clarithromycin or azithromycin), cefoxitin, rifabutin or rifampicin, trimethoprim-sulfamethoxazole, amikacin, and ciprofloxacin. Various drug combinations are recommended for different clinical scenarios (Table 39-8), often for prolonged periods.[176] Specialist advice should be sought prior to commencing therapy. It should be emphasized that these drug regimens represent generally uncontrolled experience rather than appropriate randomized trials. Surgical treatment for NTM disease may be useful, including resection of localized and refractory pulmonary disease associated with irreversible damage to the airways or lung parenchyma.

Immunologic interventions may be appropriate in selected instances. Where NTM disease occurs as a result of immunosuppressive therapy given for other disorders, it is desirable to stop or minimize the predisposing immunosuppressive treatments. Despite aggressive drug therapy, cures are seldom achieved if there is significant immunosuppression. Underlying immunodeficiency states, such as HIV, should be treated if possible. Recent case reports suggest a possible role for exogenous IFN-γ in selected patients with disseminated NTM disease, many of whom had non–HIV-related abnormalities of T-cell and/or macrophage function.[185]

Table 39-8
Suggested Antibiotic Regimens for Nontuberculous Mycobacteria Infection

	Suggested Drug Regimen	Additional or Alternative Agents	Comments
M. avium complex	Clarithromycin or azithromycin, plus ethambutol plus rifampicin	Ciprofloxacin Amikacin Rifabutin	Excision is usually curative for cervical lymphadenitis. Usual duration: up to 24 months for disseminated disease. Rifabutin lowers bioavailability of macrolides
M. kansasii	Rifampicin, ethambutol, and isoniazid		Usual duration: 12 to 18 months. Amikacin may be used initially for 2 to 4 months for more extensive disease. Debridement is necessary for osteomyelitis
M. abscessus	Clarithromycin plus amikacin plus cefoxitin		Otitis media may require only initial triple therapy and then prolonged clarithromycin. Surgical debridement may be necessary. Pulmonary disease (e.g., in CF) may require surgical resection. Most strains are resistant; treatment is rarely curative.
M. chelonae	Clarithromycin plus amikacin	Cefoxitin, ciprofloxacin	Usual duration: 6 to 12 weeks for palliation.
M. fortuitum	Initial therapy cefoxitin and amikacin, followed by a macrolide, doxycycline,* or ciprofloxacin	Trimethoprim-sulfamethoxazole may be used as follow-on therapy for catheter infections	Choice of oral therapy depends on susceptibilities. Usual duration: 4 to 6 months, attempting cure.
M. marinum	None if minor Trimethroprim-sulfamethoxazole, clarithromycin, doxycycline, or rifampicin		Surgical debridement may be necessary if extensive.

*Doxycycline should only be given to those older than 8 years.

PITFALLS AND CONTROVERSIES

- TB in children is often overlooked, especially in settings where it is relatively rare. The signs and symptoms are often subtle and are generally nonspecific (e.g., chronic cough) or insensitive (e.g., night sweats). Weight loss or lack of adequate weight gain is probably the most predictive symptom.
- Although children with TB disease are rarely infectious, their family or household members may well be the source of their infection. Timely assessment of household contacts and appropriate infection control measures are therefore needed following diagnosis of TB in children.
- Microbiological diagnosis of LTBI is not possible because in this situation MTB is never isolated from the sputum. Furthermore, in up to half of the cases of TB disease in children, a microbiological confirmation of TB (either by microscopy or culture) is not made.
- Children with TB disease should be investigated for HIV coinfection.
- The TST has been used in the diagnosis of TB for close to a century. However, this test is both nonspecific (it cross-reacts with both bCG and environmental nontuberculous mycobacteria) and insensitive, especially in younger children and immunocompromised individuals. Newer immunologic diagnostic methods, which measure IFN-γ responses following incubation with MTB-specific antigens, have shown great promise in improving the accuracy of TB diagnosis. Their comparative utility in children is largely unknown. It is likely that further developments in these methods, incorporating additional MTB-specific antigens, will eventuate. However, these methods need to be affordable, easy to use, and cost-effective, particularly in populations with high TB incidence and with limited resources.
- The optimal treatment of LTBI in children is unknown. Although most recommendations suggest 6 months of INH monotherapy, treatment completion may be poor, especially in children. There is a large, and largely anecdotal, experience of using INH and RIF combination for three months as an alternative, but there have been no trials of comparing compliance, acceptability, or outcome for this regimen.
- Treatment of XDR TB highlights the lack of development of novel anti-TB therapies that are urgently needed in the face of increasing and essentially untreatable MTB in several parts of the world.
- The current and only vaccine against TB (bCG) has variable efficacy (0% to 80%) and on average reduces the risk of TB disease by just over 50%. Newer vaccines are currently being developed using a variety of strategies and will hopefully be more effective in preventing TB.

CHAPTER 40 *Mycoplasma* Infections

Ziad M. Shehab

TEACHING POINTS

- While community-acquired pneumonia is commonly due to *Mycoplasma pneumoniae*, the most common manifestation of this infection is tracheobronchitis.
- Severe pneumonia secondary to *M. pneumoniae* is uncommon except in individuals with sickle cell disease or immunodeficiencies.
- The mainstay of diagnosis for *M. pneumoniae* infections is serological testing. Specific IgM antibodies appear in 80% of patients 9 or more days after onset of symptoms. PCR is a more sensitive detection method but is not yet widely available.
- Agents effective in therapy of *M. pneumoniae* infections are the macrolides, tetracyclines, and the newer quinolones.
- *Ureaplasma urealyticum* is associated with bronchopulmonary dysplasia in premature newborns but its causality has not been demonstrated. Empiric therapy of infants colonized with *U. urealyticum* for the prevention of chronic lung disease is not supported.

Mycoplasma pneumoniae has long been recognized as the agent of primary atypical pneumonia, especially in children. It is one of 17 *Mycoplasma* species infecting humans. In addition to *M. pneumoniae*, the genital mycoplasmas, which include *Mycoplasma hominis*, *M. fermetans*, *M. genitalum*, *Ureaplasma urealyticum*, and *Ureaplasma parvum*, have been recognized as agents of human disease.[1]

Mycoplasmas are the smallest self-replicating organisms that are able to live outside the host cell. Because they have no cell wall, these agents are pleomorphic, do not stain well with the usual bacteriologic stains such as Gram stain, are susceptible to drying, and are not killed by cell wall–active agents such as penicillins and cephalosporins. Like bacteria, they multiply by binary fission. The genome, which was completely sequenced in 1996, is very small and accounts for the saprophytic nature of this organism and its fastidious growth requirements.[2]

MYCOPLASMA PNEUMONIAE INFECTIONS

Epidemiology

Our understanding of the epidemiology of mycoplasma infections is the result of population-based studies done over the past four decades as well as improved diagnostic tools that have become available more recently. Infections occur endemically in urban settings, although epidemics occur periodically at irregular intervals of about 4 years. Although these outbreaks can occur at any time of the year, they are more commonly seen in the autumn, and they last several months.[3-17] These infections occur throughout life and are commonly manifested as respiratory infections, particularly in school-age children and adolescents.[3,9,10]

Infection and disease with *M. pneumoniae* are common. In the daycare center study by Fernald and associates,[18] the yearly risk of infection was estimated to be 12%, and most infections were asymptomatic (74%) or mildly symptomatic, manifesting with coryza and cough. In subjectively healthy individuals, the isolation rate of *M. pneumoniae* ranged from 4.6% to 13.5%.[13]

Seroepidemiologic studies show antibody prevalence rates rising from 28% in 7- to 12-month-old infants to 55% in 13- to 24-month-old infants, 67% in 25- to 60-month-old infants, and 97% in people over the age of 17 years.[20]

The rate of infection is highest in 5- to 9-year-old children. The rate is double that in children under 5 years of age or in adolescents and is about 4 times higher than that in adults; most infections in children under 5 years of age occur in 2- to 4-year-olds, with very few infections occurring in patients under 6 months of age, presumably because of transplacentally derived immunity.[21] Clinical disease secondary to *M. pneumoniae* infections is manifest mostly in those 5 to 9 years of age, followed by those 10 to 14 years of age. Recent studies show that *M. pneumoniae* is responsible for up to 23% of community-acquired pneumonias in children under 4 years of age and that infections may be just as common in very young children as in older age groups.[9,16]

In volunteer studies, the incubation period is 1 to 2 weeks and may be up to 3 weeks in community or family outbreaks, presumably because of the potentially higher inocula encountered in volunteer studies.[22-24] Intrafamilial spread occurs slowly but extensively, yielding an infection attack rate of 65% of families, including 84% of children and 41% of adults. Of the secondary cases, 71% had lower respiratory tract involvement, 14% had otitis media, 10% had pharyngitis, and 15% were asymptomatic. The progression of the disease in communities is slow, although rapid epidemics can occur. Recurrent infections are usual.[19,20,25]

Pathogenesis of Pulmonary Infection

Mycoplasmas are primarily mucosal pathogens living a parasitic existence on the epithelial cells of their host. *M. pneumoniae* is an exclusive pathogen of humans.[2] Infections with *M. pneumoniae* are acquired via the respiratory route from small-particle aerosols or more likely from large droplets. The organism attaches to a receptor on respiratory epithelia via a terminal structure containing an electron-dense core representing a cluster of adhesins. The P adhesin that is concentrated in the attachment tip is the major adhesin involved in attachment of *M. pneumoniae* to its host cell.[26,27] Recent experimental evidence has shown that it can replicate in vitro for 6 months.[28] Once adherence occurs, the organism remains extracellular. Cellular damage occurs primarily in the epithelium of the bronchi and bronchioles.[29,30] Injury to the cell is accompanied by ciliostasis.[31] It renders the host cell more susceptible to the action of catalases making the cell more susceptible to oxidative stress.[32] It is not known to produce exotoxins.

Specific serum antibody develops after infection, as does secretory antibody in respiratory secretions. After opsonization, macrophages release cytokines such as tumor necrosis factor α (TNF-α), interleukin (IL)-1, -5, and -6, and a mononuclear cell inflammatory response is seen.[1] Specific cell-mediated immune responses increase with age and are likely the result of repeated infections. It has been postulated that primary infection may sensitize the young infant so that more severe disease develops on reinfection. Only 11% of children younger than 4 years of age with documented prior infection had specific cell-mediated immunity compared to 58% of children older than 4 years and 87% of adults.[18]

Clinical Manifestations

RESPIRATORY DISEASE

M. pneumoniae infections involve the upper and/or lower respiratory tracts. The manifestation of tracheobronchitis is more commonly seen than that of pneumonia.

Pneumonia. Mycoplasmal pneumonia is a common form of community-acquired pneumonia that occurs after only 3% to 10% of infections and accounts for up to 40% of episodes of pneumonia in the general population.[1,4,33] The illness typically presents with a gradual onset of malaise, headache, and fever to 100° to 103° F (38° to 39° C) occurring over several days to 1 week.[34] Cough presents 3 to 5 days after the onset of symptoms and is initially nonproductive but may become productive of mucoid or mucopurulent sputum that can sometimes be blood tinged.[35] Associated symptoms may include chills, hoarseness, sore throat, chest pain, headache, nausea, vomiting, and diarrhea. Dyspnea can develop in more severe cases. The cough can sometimes be paroxysmal, mimicking that of pertussis. Coryza is an unusual finding except in young children, and its presence as a prodrome suggests a different diagnosis.[36] Pneumonia is rare in children under 5 years of age. School-age children are more likely to develop a bronchopneumonia involving one or more lobes.

Findings on physical examination are relatively minimal and include crackles in 78% of patients, wheezes on auscultation in 32%, and bronchial breathing in 27%.[36] However, early in the course of the illness, the chest examination may be entirely normal. Audible wheezing is described in up to 40% of children, including patients who do not have asthma.[37] Nonexudative pharyngitis, cervical lymphadenopathy, conjunctivitis, otitis media, and rash have also been noted.[38] The severity of the clinical symptoms often exceeds that of the physical signs detected.[4] Recovery is the rule in *M. pneumoniae* pneumonia. Although the clinical course is quite variable, the fever typically lasts for about 1 week and the illness usually resolves within 3 to 4 weeks. The duration of symptoms may be shortened by early antimicrobial use.[1,4,35] It is important to note that the presentation of *M. pneumoniae* pneumonia may be similar to that of other atypical agents, especially *Chlamydophila pneumoniae*, respiratory viruses, and *Streptococcus pneumoniae*. Coinfections with other respiratory pathogens are not uncommon.[9,11,13,14,16]

Pulmonary function abnormalities in the form of decreased lung diffusion capacity and abnormal lung function may persist up to 3 years.[37,39,40] In a noncontrolled study of children without asthma, the mean forced vital capacity, 1-second forced expiratory volume, and forced expiratory flow were significantly reduced.[37] Radiologic abnormalities observed by CT scans persist for months to years in 37% of children.[41] Abnormal lung diffusion is observed in 50% of children.[39]

Severe pneumonia is uncommon and may occur in healthy children and adults of all ages,[8,11,36,42-47] but especially in those with sickle cell disease,[48-50] immunodeficiency,[51] drug-induced immunosuppression,[52] and preexisting cardiopulmonary dysfunction.[53] Massive lobar consolidation, pleural effusions,[42,45,49] pneumatoceles, lung abscesses,[54,55] adult respiratory distress syndrome,[56,57] and the evolution of obliterative bronchiolitis and diffuse interstitial fibrosis have all been observed but are rare.[58]

The radiologic findings are highly variable and are usually unilateral (87%) and involve the lower lobes, the midlung fields (less frequent), and the upper lobes (least frequent).[59] In the early stages, the pattern is reticular and interstitial; patchy and segmental areas of consolidation are noted later. Lobar involvement is occasionally seen. Hilar adenopathy occurs in 34% of patients, and effusions are seen in 20% when lateral decubitus films are used.[60] A hallmark of *M. pneumoniae* infections is the often poor correlation among the degree of clinical symptoms, pulmonary physical findings, and findings on chest radiographs.[3,45,52] Using high-resolution CT scanning of the lungs, Kim and colleagues[41] demonstrated abnormal findings 1 to 2 years after their infection in 37% of children with a history of *M. pneumoniae* compared to 12% in the group with Mycoplasma upper respiratory tract infection. The changes consisted of mosaic perfusion, bronchiectasis, bronchial wall thickening, decreased vascularity, and air trapping.

The differential diagnosis of community-acquired pneumonia includes that of viral pneumonia (caused by influenza virus, parainfluenza virus, respiratory syncytial virus, and adenovirus) as well as infection caused by *Chlamydophila pneumoniae* and *Legionella pneumophila.* One of the characteristics that helps identify mycoplasmal pneumonia is the generally mild course of the illness with a progressive onset. The fever tends to be low grade, and constitutional symptoms are prominent. Ear, throat, and skin involvement are common, but coryza is not. Adenoviral and mycoplasmal pneumonias share clinical and radiologic features and may not be separable clinically.[17] Hoarseness is more likely to occur with

C. *trachomatis* infections than with mycoplasmal pneumonias.[61]

Respiratory Disease Other Than Pneumonia. *M. pneumoniae* infections have been associated with a variety of clinical syndromes. Pharyngitis was present in 32% of children with lower respiratory infection in one series but was not a major manifestation of the infection.[36] Glezen and associates[62] found that only 3% of children and adolescents with pharyngitis had *M. pneumoniae* infections, with a peak incidence in the 12- to 14-year age group. Serologic evidence of infection was demonstrated in 11% of adults with pharyngitis.[63]

Otitis media was noted in 27% of children in the series by Stevens and colleagues[36]; however, no attempt was made to establish the etiology of the otitis. The body of evidence would suggest a minimal role for Mycoplasma organisms in the etiology of otitis or bullous myringitis.[64] Radiographic evidence for sinusitis is commonly detected, but attempts at isolating the organism from middle ears and sinuses have largely been unsuccessful. Approximately 2% of cases of laryngotracheobronchitis,[3,65,66] 10% to 20% of cases of acute bronchitis,[3,15,17] 4% to 5% of cases of bronchiolitis, and 2% to 5% of cases of nonspecific upper respiratory infection[3,67] are due to *M. pneumoniae*. Mycoplasmas may also be associated with wheezing illnesses in children with asthma.[68] They are detected more commonly by culture and/or PCR from the airways of children and adults with asthma than from matched controls.[68,69] Some studies suggest that treatment of Mycoplasma infections in asthmatics results in improved lung function, and it is unclear whether this improvement is the result of the macrolide's antibacterial or anti-inflammatory effects.[70,71]

NONRESPIRATORY DISEASE

A variety of extrapulmonary complications have been described. Such complications commonly occur 1 to 21 days after the onset of respiratory illness, although concomitant respiratory symptoms are absent in some patients. Most of the diagnoses have been based on the results of serologic testing, mostly 4-fold rises in complement fixation titers, rather than on culture confirmation.

Neurologic Manifestations. The incidence of neurologic disease has been estimated at 0.1%; in selected populations such as hospitalized patients, it may be as high as 7%.[72] Onset occurs 3 to 23 days after respiratory illness, which itself was demonstrated in 79% of patients.[73] A variety of syndromes has been described, the most frequent of which is meningoencephalitis. Others include transverse myelitis, cranial neuropathy, myeloradiculopathy, a poliomyelitis-like syndrome, cerebellar ataxia, a brainstem syndrome, psychosis, cerebral infarction, focal encephalitis, and Guillain-Barré syndrome. The prognosis has been variable, and the mortality rate is estimated at about 10%. Recovery is slow and is often associated with permanent sequelae.[74,75]

Dermatologic Manifestations. Erythematous maculopapular or vesicular exanthems are the most common cutaneous manifestations of *M. pneumoniae* infection, although vesiculopustular, bullous, urticarial, and petechial lesions can occur. The most serious manifestations are erythema multiforme and Stevens-Johnson syndrome.[76,77] Ninety percent of patients between 4 and 20 years of age had clinical or radiographic evidence of pneumonia.[76] The duration of the rash typically exceeds 1 week.

Cardiac Manifestations. Cardiac involvement may occur in up to 4.5% of patients. Pericarditis and myocarditis are most frequent; congestive heart failure, heart block, and infarction have also been described.[38,78]

Gastrointestinal Manifestations. Nonspecific gastrointestinal complaints often accompany *M. pneumoniae* infections. Occasionally, hepatic dysfunction and, rarely, jaundice develop with increases in transaminase levels.[79,80]

Hematologic Manifestations. Hemolytic anemia is a common manifestation of mycoplasmal infection. The results of the direct Coombs test are usually positive. Other reported manifestations include bone marrow suppression, thrombocytopenia, and disseminated intravascular coagulation.[38]

Musculoskeletal Manifestations. Myalgias and arthralgias occur in 15% to 45% of patients. These manifestations have generally been transient and have resolved during the acute phase of the illness. Occasionally, frank arthritis may be severe and may last up to 18 months.[81]

Genitourinary Manifestations. Both glomerulonephritis and interstitial tubulonephritis have been described.[38]

Diagnosis

CULTURE

M. pneumoniae can be cultured from the throat or nasopharynx of infected individuals. The culture systems are not widely available and require 2 to 3 weeks before identification can be accomplished. Culture-based diagnosis is insensitive, expensive, and laborious and has been replaced by serologic- or molecular-based diagnostic approaches.[82]

ANTIGEN DETECTION AND DNA PROBES

Antigen detection techniques are generally insensitive and are not recommended for diagnostic purposes. DNA probes also suffer from a lack of sensitivity and are not available in the United States.[82]

SEROLOGY

Serologic assays are the mainstay of diagnosis of mycoplasmal infections because cultures and molecular diagnostic methods are not widely available.

Cold Agglutinin Identification. Cold agglutinins usually appear by the end of the first week or the beginning of the second week of illness and disappear by 2 to 3 months. Cold agglutinin responses are nonspecific and consist mostly of immunoglobulin M (IgM). They occur in association with half the cases of *M. pneumoniae* infection. A 4-fold rise in antibody or a titer greater than 1:64 suggests a recent *M. pneumoniae* infection. Cold agglutinins may become positive with a variety of viral infections and collagen vascular diseases and are not recommended for diagnosis.[82]

Specific Serologic Tests. The most widely available serologic assay is the complement fixation (CF) test, which has been used as the standard. Sera from patients in the acute and convalescent stages are run in pairs, and a 4-fold rise or fall in antibody titer is diagnostic of infection. A titer greater than 1:32 in a single serum sample is also considered diagnostic. The test measures primarily IgM antibodies and, to a lesser extent, IgG. Therefore, a negative test does not

exclude reinfection. The glycolipid antigen used in the assay cross-reacts with other plant and human antigens and has been reported in some investigations to cross-react in patients with Legionnaires' disease. In a recent 12-year study, the sensitivity and specificity of this test were 90% and 94%, respectively, in patients with pneumonia.[83]

Although the CF test used to be the gold standard, it has largely been replaced by immunofluorescent[84,85] and enzyme-linked immunosorbent assays,[86] which are more sensitive and specific. The diagnosis of primary infection is best made by detection of IgM antibody to *M. pneumoniae;* IgG levels remain elevated for several weeks and are not useful diagnostically. Whereas children and adolescents show primarily an IgM response, patients older than 40 years often do not. Thus, the absence of an IgM response does not necessarily indicate the absence of infection, especially in adults. Specific IgM antibodies are detectable in 80% of persons with *M. pneumoniae* pneumonias if sera are sampled 9 days or more after the onset of symptoms; only 40% of sera have detectable IgM antibodies 7 to 8 days after the onset of symptoms, and rarely does a sample have IgM when tested earlier.[87] The antibody peaks at 10 to 30 days and falls to undetectable levels in 12 to 26 weeks. A major limitation of serologic methods is that antibody responses may not be apparent in immunocompromised children or in infants under 12 months of age.[88] One should also note that there is a lot of variability in the sensitivity and specificity of commercially available serological assays when their performance is measured against a PCR gold standard.[89]

POLYMERASE CHAIN REACTION

Throat swabs have a higher yield than nasopharyngeal swabs for the detection of *M. pneumoniae* by the PCR and are the preferred specimens.[90] The PCR is highly sensitive and can be applied to a variety of body fluids, including cerebrospinal fluid. Nucleic acid amplification methods are the preferred methods in diagnosing *M. pneumoniae* infections. A large number of in-house PCR assays have been published, but there has not been large-scale validation and standardization of these assays.[82,91,92]

NONSPECIFIC LABORATORY DATA

The white blood cell count is usually normal, but there may be an absolute neutrophilia. The white blood cell count and erythrocyte sedimentation rate may be elevated in one third of patients with lower respiratory tract infections.

Therapy

M. pneumoniae is susceptible to the macrolides, tetracyclines, and the newer quinolones. Because it has no cell wall, it is resistant to beta-lactam antibiotics including penicillins, cephalosporins, and other cell wall–active agents. Sulfonamides, trimethoprim, and rifampin are also ineffective. Macrolides are the drugs of choice in children as tetracyclines are not indicated for children under 8 years of age, and the quinolones are not generally indicated in children under 18 years of age. The preferred macrolide is azithromycin because of its high level of activity against *M. pneumoniae* and its prolonged half-life (Table 40-1). The treatment is most effective when initiated within 4 days of the onset of symptoms,[93] but the evidence regarding efficacy of antibiotics in lower respiratory tract infections in children is not conclusive.[94] A positive culture in the absence of symptoms is not an indication for antimicrobial therapy. Similarly, upper respiratory tract illnesses or acute bronchitis caused by *M. pneumoniae* are not indications for therapy. The treatment does not appreciably affect the culture positivity. There are no good data on the benefit of steroids in the treatment of severe pulmonary or extrapulmonary infections, although some advocate their use in severe central nervous system infections.[95] Newer macrolides such as azithromycin have shown efficacy when used for a 3- to 5-day course.[1,96,97] Prophylaxis can be considered in the setting of outbreaks in institutional settings.[98]

Table 40-1
Recommended Antimicrobial Treatment for Mycoplasmal and Ureaplasmal Infection, by Age Group

Age Group	Primary Agents			Alternate Agent
	Azithromycin	Erythromycin	Clarithromycin	Tetracyclines
<1 mo	**Recommended** 10 mg/kg/day as a single dose for 5 days	Associated with pyloric stenosis. Use if azithromycin unavailable 40-50 mg/kg/day in 4 divided doses for 14 days	Not recommended	Not recommended except for severe CNS infections because of staining of dental enamel
1-5 mo	10 mg/kg/day as a single dose for 5 days	40-50 mg/kg/day in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses for 7 days	Not recommended
Infants (≥6 mo) and children	10 mg/kg/day in a single dose on day 1 then 5 mg/kg/day (max 250-500 mg) on days 2-5	40-50 mg/kg/day (max 2 g/day) in 4 divided doses for 14 days	15 mg/kg/day in 2 divided doses (max 1 g/day) for 7 days	Contraindicated for children <8 yr of age or during pregnancy Doxycycline: 4 mg/kg/day divided in 2 doses for 10-14 days (maximum 100 mg per dose) Tetracycline: 40-50 mg/kg/day (max 2 g/day) in 4 divided doses for 10-14 days.

UREAPLASMA AND GENITAL *MYCOPLASMA* INFECTIONS

Epidemiology

The main reservoir of human *Ureaplasma urealyticum* is the genital tract of sexually active men and women. It is a very common isolate in the lower genital tract. *Ureaplasma* spp. can be found in 40% to 80% of lower genital tract specimens of adult women, whereas *M. hominis* may be detected in 21% to 53%.[99] Infection of the chorioamnion is less common and is associated with chorioamnionitis, premature birth, and perinatal morbidity and mortality. *M. hominis* rarely invades the chorioamnion and amniotic fluid.

Pathogenesis of Pulmonary Infection

U. urealyticum and *M. hominis* can be transmitted to the fetus or neonate by way of an ascending intrauterine infection, by the hematogenous route through placental infection, or by passage of the newborn through an infected birth canal. Vertical transmission rates for *U. urealyticum* have been reported to be 18% to 88%, with isolation rates inversely proportional to gestational age. While *Ureaplasma* spp. can be detected in the lower respiratory tract of premature neonates for prolonged periods of time, colonization of full-term infants is transient and declines beyond 3 months of age.[100] The organisms attach to mucosal surfaces and release inflammatory cytokines that can cause damage to the respiratory epithelium. They are able to incite an inflammatory response in the bloodstream and respiratory tract. Indeed, colonized neonates who had *Ureaplasma* in their tracheal secretions in the first 24 hours of life are more likely to have neutrophils in their tracheal aspirates on day 2 compared to noncolonized newborns. Increased inflammatory cells are also a feature of bronchopulmonary dysplasia. *Ureaplasma* spp. colonization of the airways of neonates is associated with increases in proinflammatory tracheal cytokines (TNF-α, IL-1β, and IL-8) and sometimes blockage of IL-6 and/or IL-10.[100] These cytokine changes are thought to occur in association with a coinflammatory stimulus such as bacterial infection or hyperoxia.[101] In the neonatal mouse model, Crouse[102] has demonstrated that hyperoxia leads to persistence of *U. urealyticum* in the lungs and potentiates the inflammatory response leading to lung damage. A recent pooled analysis of observational studies demonstrates the association between *Ureaplasma* colonization and bronchopulmonary dysplasia but not its causation.[103]

Clinical Manifestations

Ureaplasma spp. may cause congenital and neonatal pneumonia. Maternal vaginal colonization is associated with wheezing up to the fifth year of life but not with asthma.[104] They can also cause lower respiratory tract infections in immunocompromised children. They have been associated with the development of bronchopulmonary dysplasia in preterm neonates. Bacteremia has been described and can occur in association with pneumonia and/or meningitis. Central nervous system infections are sometimes associated with the development of hydrocephalus with or without cerebrospinal fluid pleocytosis.[100] It is unlikely that genital mycoplasmas are a significant cause of systemic infection in healthy infants outside the neonatal period.[105] Genital mycoplasmas have been isolated from brain abscesses, osteomyelitis, pericardial fluid, and soft tissue abscesses.[100] Antibody is critical in host defenses against systemic ureaplasmal infections. Indeed, arthritis, subcutaneous abscesses, persistent urethritis, and cystitis occur in hypogammaglobulinemic patients.[106]

Diagnosis

Culture remains the standard for detection of genital mycoplasmas. The organisms typically grow in 2 to 5 days on specialized media. Specimens should be inoculated in special transport media at the bedside.[82,107] The PCR assay is not commercially available and remains a research tool. Serologic assays have not been standardized and are not recommended for diagnosis. Cultures of blood, cerebrospinal fluid, and respiratory secretions should be considered for sick neonates with pneumonitis or central nervous system disease, especially those with hydrocephalus with or without cerebrospinal fluid pleocytosis.

Therapy

Ureaplasmas are generally susceptible to macrolides and the tetracyclines. They are resistant to the lincosamides. In contrast, *M. hominis* is inherently resistant to the macrolides and is susceptible to the lincosamides. Both tend to be susceptible to the quinolones, but their use in children is limited by potential damage to the cartilage.

The macrolides are the preferred agents for treatment of these infections. Erythromycin is used less commonly now because of concerns about the risk of pyloric stenosis. Azithromycin and clarithromycin allow for easier dosing and better tolerability. The use of tetracyclines may be indicated for central nervous system infections. Generally, a course of 10 to 14 days is recommended for serious systemic infections (see Table 40-1). Treatment with macrolides will sometimes eradicate ureaplasmas from the lower respiratory tract, but no significant effect on respiratory outcome has been demonstrated.[108]

PITFALLS AND CONTROVERSIES

Our understanding of the contribution of *M. pneumoniae* infections to chronic lung disease remains incomplete. The need for the development of rapid sensitive assays for diagnosis that are reasonably priced is acute. Presently, serology is the only means by which *M. pneumoniae* infections are diagnosed routinely and suffers from lack of sensitivity and specificity. A reliable, widely applicable method of detection of the organism or its nucleic acids is needed for diagnosis and management as well as understanding the impact of this infection on chronic lung disease and for evaluation of antimicrobial therapies.

The association between *U. urealyticum* infections and bronchopulmonary dysplasia is well supported, but evidence of causality is lacking. To know whether antimicrobial therapy of colonized infants will result in eradication of the organism and decrease the risk of chronic lung disease will require a large-scale trial.

CHAPTER 41 Chlamydial Infections

Margaret R. Hammerschlag and Swati Kumar

TEACHING POINTS

- Chlamydiae comprise a diverse group of obligate intracellular organisms capable of causing respiratory disease in humans. Chlamydial infections are frequently subclinical and of long duration. Epidemiology and presentation vary from species to species.
- *Chlamydia pneumoniae* causes a variety of respiratory disease including pneumonia and bronchitis in adults and children and is transmitted person to person. Clinically, pneumonia due to C. *pneumoniae* cannot be readily distinguished from community-acquired pneumonia caused by other organisms, especially *Mycoplasma pneumoniae*.
- *Chlamydia trachomatis* is primarily a sexually transmitted infection, which can cause a distinctive pneumonia in infants born to women with active genital infection.
- *Chlamydia psittaci* is the causative agent of psittacosis, which is usually acquired from exposure to sick birds.

Chlamydiae are obligate intracellular pathogens that have established a unique niche within the host cell. Chlamydiae cause a variety of diseases in animal species at virtually all phylogenic levels. Recent taxonomic analysis using the 16S and 23S rRNA genes has suggested a new classification of species belonging to the order *Chlamydiales*.[1] The genus *Chlamydia* would be split into two genera, *Chlamydia* and *Chlamydophila* (Table 41-1). The genus *Chlamydia* would contain C. *trachomatis* and two new species, *Chlamydia muridarum* (formerly the agent of mouse pneumonitis, MoPn) and C. *suis*. The second genus was named *Chlamydophila* and would contain C. *pecorum*, C. *pneumoniae*, C. *psittaci*, and three new species split out from C. *psittaci:* C. *abortus*, C. *caviae* (formerly C. *psittaci* guinea pig conjunctivitis strain), and C. *felis*. The new classification scheme remains controversial the division into two genera has not been universally accepted. However, most experts on the field accept the splitting up of C. *psittaci* into separate species, given its biological and genetic heterogeneity. The species capable of causing respiratory disease in humans are C. *pneumoniae*, C. *trachomatis*, and C. *psittaci*.

The new classification scheme of Chlamydiales also identified two additional families of chlamydia-like organisms, Parachlamydiaceae and Simkaniaceae. Parachlamydiaceae was further subdivided into two genera, *Parachlamydia* with *Parachlamydia acanthamoebae* (Hall's coccus) as a type species and the genus *Neochlamydia* with *Neochlamydia hartmanellae* as the type species. These organisms appear to be endosymbionts of free-living ameba. Recent studies have suggested that they may be a cause of respiratory disease in humans, especially nosocomial pneumonias.[2]

Chlamydiae have a gram-negative envelope without detectable peptidoglycan, although recent genomic analysis has revealed that both C. *pneumoniae* and C. *trachomatis* encode proteins forming a nearly complete pathway for synthesis of peptidoglycan, including penicillin-binding proteins.[3] Chlamydiae also share a group-specific lipopolysaccharide antigen and use host adenosine triphosphate for the synthesis of chlamydial proteins. Although chlamydiae are auxotrophic for three of four nucleoside triphosphates, they do encode functional glucose-catabolizing enzymes that can be used for generation of ATP. As with peptidoglycan synthesis, for some reason these genes are turned off. All Chlamydiae also encode an abundant protein called the major outer membrane protein (MOMP, or OmpA) that is surface exposed in C. *trachomatis* and C. *psittaci* but apparently not in C. *pneumoniae*. The MOMP is the major determinant of the serologic classification of C. *trachomatis* and C. *psittaci* isolates.

Chlamydiae are characterized by a unique developmental cycle with morphologically distinct infectious and reproductive forms: elementary body (EB) and reticulate body (RB).[3] Following infection, the infectious EBs, which are 200 to 400 μm in diameter, attach to the host cell by a process of electrostatic binding, and are taken into the cell by endocytosis that does not depend on the microtubule system. Within the host cell, the EB remains within a membrane-lined phagosome. The phagosome does not fuse with the host cell lysosome. The inclusion membrane is devoid of host cell markers, but lipid markers traffic to the inclusion, which suggests a functional interaction with the Golgi apparatus. The EBs then differentiate into RBs that undergo binary fission. After approximately 36 hours, the RBs differentiate into EBs. At about 48 hours, release may occur by cytolysis or by a process of exocytosis or extrusion of the whole inclusion, leaving the host cell intact. Chlamydiae may also enter a persistent state after treatment with certain cytokines such as interferon-γ, treatment with antibiotics, or restriction of certain nutrients.[4] While Chlamydiae are in the persistent state, metabolic activity is reduced. The ability to cause prolonged, often subclinical, infection is one of the major characteristics of Chlamydiae.

Table 41-1
Classification of *Chlamydiales*

Genus	Species	Host(s)	Major Diseases
Chlamydia	*C. trachomatis*	Man	Trachoma, urethritis, cervicitis, PID, neonatal conjunctivitis and pneumonia, LGV
	C. suis	Pigs	Gastrointestinal disease
	C. muridarum	Mice	Pneumonia
Chlamydophila	*C. pneumoniae*	Man Koalas Bandicoots Amphibians Reptiles	Pneumonia, bronchitis
	C. psittaci	Birds Man	Gastrointestinal disease Pneumonia
	C. abortus	Cattle Sheep	Abortion
	C. pecorum	Cattle Sheep Koalas	Pneumonia, gastrointestinal disease Genital infections, conjunctivitis
	C. felis	Cats	Keratoconjunctivitis
	C. caviae	Guinea pigs	Conjunctivitis, genital infections

INFECTIONS DUE TO *CHLAMYDIA PNEUMONIAE*

C. *pneumoniae* is a common cause of lower respiratory tract diseases, including pneumonia in children and bronchitis and pneumonia in adults.[5,6] The first isolates of C. *pneumoniae* were obtained during studies of trachoma in the 1960s.[5] Subsequent serologic studies demonstrated that the organism caused an outbreak of mild pneumonia among school children in Finland in 1978.[7] In 1986, the organism was isolated from the respiratory tract of college students with acute respiratory disease (bronchitis and pneumonia) seen in Seattle.[5]

Epidemiology

C. *pneumoniae* is primarily a respiratory pathogen in humans. The organism has also been isolated from nonhuman species, including horses, Australian marsupials (koalas and bandicoots), reptiles, and amphibians, where it can cause symptomatic and asymptomatic respiratory infection. The potential role these infections may play in transmission to humans is unknown. C. *pneumoniae* appears to affect individuals of all ages.[5,6,8] The proportion of community-acquired pneumonias associated with C. *pneumoniae* infection has ranged from 2% to 19%, varying with geographic location, the age group examined, and the diagnostic methods used (Table 41-2). Several studies of C. *pneumoniae* in lower respiratory tract infection in pediatric populations have found evidence of infection from none to more than 18%; however, most of these studies have relied entirely on serology for diagnosis.[9-12] Results of a large U.S. multicenter study of community-acquired pneumonia in children 3 to 12 years of age found evidence of C. *pneumoniae* infection, based on culture, in 14% and of *Mycoplasma pneumoniae* in 22%.[9] The prevalence of C. *pneumoniae* infection in children 6 years of age or younger was 15%; in those older than 6 years of age, it was 18%. Almost 20% of the children with C. *pneumoniae* infection were coinfected with *M. pneumoniae*. C. *pneumoniae* may also be responsible for 10% to 20% of episodes of acute chest syndrome in children with sickle cell disease, 10% of episodes of bronchitis, and 5% to 10% of episodes of pharyngitis in children.[13,14] Transmission probably occurs from person to person through respiratory droplets. Spread of the infection can occur among members in the same household or individuals in enclosed populations such as military recruits and in nursing homes.[15]

Clinical Manifestations

Infections caused by C. *pneumoniae* cannot be readily differentiated from those caused by other respiratory pathogens, especially *M. pneumoniae*.[9,10,16] The pneumonia usually presents as a classic atypical (or nonbacterial) pneumonia characterized by mild to moderate constitutional symptoms

Table 41-2
Selected Studies of *Chlamydia pneumoniae* Acute Lower Respiratory Tract Infection in Children

including fever, malaise, headache, cough, and frequently pharyngitis. However, severe pneumonia with pleural effusions and empyema has been described.[17] C. *pneumoniae* may serve as an infectious trigger for asthma.[18,19] C. *pneumoniae* has been isolated from middle ear aspirates of children with acute otitis media but is usually associated with bacterial otitis media.[20] Asymptomatic respiratory infection has been documented in 2% to 5% of adults and children and may persist for a year or more.[18,21]

Diagnosis

As previously stated, it is not possible to differentiate C. *pneumoniae* from other causes of atypical pneumonia on the basis of clinical and laboratory findings.[6,16] Auscultation reveals the presence of crackles and often wheezing. The chest radiograph often appears worse than the patient's clinical status would indicate and may show mild, diffuse involvement or lobar infiltrates with small pleural effusions. The complete blood count may be elevated with a left shift but is usually unremarkable.

Specific diagnosis of C. *pneumoniae* infection is based on identification of the organism by isolation in tissue culture or by polymerase chain reaction (PCR).[22] C. *pneumoniae* grows best in cycloheximide-treated HEp-2 and HL cells.[23] The optimum site for culture is the posterior nasopharynx; the specimen is collected with wire-shafted Dacron-tipped swabs. The organism can be isolated from sputum, throat cultures, bronchoalveolar lavage fluid, and pleural fluid, but few laboratories perform culture.

PCR appears to be the most promising technology in the development of a rapid, specific, nonculture method for detection of C. *pneumoniae*. Numerous in-house PCR assays for detection of C. *pneumoniae* in clinical specimens have been reported and some are currently offered by laboratories.[22,24] However, none of these assays are commercially available or have Food and Drug Administration (FDA) approval. None are standardized or have been extensively validated compared with culture for detection of C. *pneumoniae* in respiratory specimens. Recent data have demonstrated major problems with both interlaboratory and intralaboratory reproducibility, even when the same assay is used with the same specimens.[25] Real-time PCR may be the method of choice.

Serologic diagnosis can be accomplished using the microimmunofluorescence (MIF) or the complement fixation (CF) tests.[22] The CF test is genus-specific and is also used for diagnosis of lymphogranuloma venereum and psittacosis. Its sensitivity in hospitalized patients with C. *pneumoniae* infection and children is variable. The Centers for Disease Control and Prevention (CDC) has proposed modifications in the serologic criteria for diagnosis.[22] Although the MIF test was considered to be the only currently acceptable serologic test, the criteria were made significantly more stringent. Acute infection, using the MIF test, was defined by a fourfold increase in IgG titer or an IgM titer of 16 or greater; use of a single elevated IgG titer was discouraged. An IgG titer of 16 or greater was thought to indicate past exposure, but neither elevated IgA titers nor any other serologic marker was thought to be a valid indicator of persistent or chronic infection. As accurate diagnosis would require paired sera, this would be a retrospective diagnosis. The CDC did not recommend the use of any enzyme immune assay (EIA) test for detection of antibody to C. *pneumoniae*.[22] However, a number of studies have documented a very poor correlation between serology, using MIF or EIA and detection of the organism by culture and/or PCR, especially in children.[9,10,18] Several studies of C. *pneumoniae* infection in children with pneumonia and asthma show that more than 50% with culture-documented infection have no detectable MIF antibody, even after more than 6 weeks of follow-up.[9,10,18,26]

Treatment

The optimum dose and duration of antimicrobial therapy for C. *pneumoniae* infections remain uncertain.[27] Most treatment studies have relied on serology only for diagnosis, thus the microbiologic efficacy cannot be assessed.[27] Prolonged therapy (≥2 weeks) may be desirable because recrudescent symptoms, and persistent positive cultures have been described following 2 weeks of erythromycin and 30 days of tetracycline or doxycycline.[5] Tetracyclines, macrolides (erythromycin, azithromycin and clarithromycin), and quinolones have excellent in vitro activity. Like C. *psittaci*, C. *pneumoniae* is resistant to sulfonamides.[28] The results of several treatment studies have shown that erythromycin (40 mg/kg/24 hr divided twice daily orally for 10 days), clarithromycin (15 mg/kg/24 hr divided twice daily orally for 10 days), and azithromycin (10 mg/kg/24 orally on day 1, 5 mg/kg/24 hr orally on days 2 to 5) are effective for eradication of C. *pneumoniae* from the nasopharynx of children with pneumonia in approximately 80% of cases.[29-32] Persistence has not been associated with the development of antibiotic resistance.

Prognosis

Clinical response to antibiotic therapy varies. Most patients improve clinically even if the organism persists. Coughing often persists for several weeks even after therapy.

INFECTIONS DUE TO *C. TRACHOMATIS*

C. *trachomatis* is subdivided into two biovars: lymphogranuloma venereum (LGV) and trachoma (the agent of human oculogenital diseases other than LGV). Although the strains of both biovars have almost complete DNA homology, they differ in growth characteristics and virulence in tissue culture and animals. In developed countries, C. *trachomatis* is the most prevalent sexually transmitted disease, causing urethritis in men, cervicitis and salpingitis in women, and conjunctivitis and pneumonia in infants.[33-36] C. *trachomatis* is a very rare cause of any respiratory infection in older children and adults.

Epidemiology

There are an estimated 3 million new cases of chlamydial sexually transmitted infections each year in the United States.[35] C. *trachomatis* is a major cause of epididymitis and is the cause of 23% to 55% of all cases of nongonococcal urethritis, although the proportion of chlamydial nongonococcal urethritis has been gradually declining. As many as

50% of men with gonorrhea may be coinfected with C. *trachomatis*.[34] The prevalence of chlamydial cervicitis among sexually active women is 2% to 35%. Rates of infection among adolescent girls, 15 to 19 years of age, exceed 20% in many urban populations but can be as high as 15% in suburban populations as well.[35] C. *trachomatis* genital infection has been reported in 5% to 30% of pregnant women with a risk of vertical transmission at parturition to newborn infants of about 50%.[37] The infant may become infected at one or more sites including the conjunctivae, nasopharynx, rectum, and vagina. Transmission is rare following cesarean section with intact membranes. The introduction of systematic prenatal screening for C. *trachomatis* infection and treatment of pregnant women has resulted in a dramatic decrease in the incidence of neonatal chlamydial infection in the United States.[38] However, in countries where prenatal screening is not done, such as the Netherlands, C. *trachomatis* remains an important cause of neonatal infection, accounting for over 60% of neonatal conjunctivitis.[39]

Pneumonia

Pneumonia due to C. *trachomatis* develops in 10% to 20% of infants born to women with active, untreated chlamydial infection. Only about 25% of infants with nasopharyngeal chlamydial infection develop pneumonia.[37] C. *trachomatis* pneumonia of infancy has a very characteristic presentation.[40-42] Onset is usually between 1 and 3 months of age and is often insidious with persistent cough, tachypnea, and absence of fever. Auscultation reveals crackles; wheezing is uncommon. The absence of fever and wheezing helps to distinguish C. *trachomatis* pneumonia from respiratory syncytial virus (RSV) pneumonia. A distinctive laboratory finding is the presence of peripheral eosinophilia (>400 cells/mm^3). The most consistent finding on chest radiograph is hyperinflation accompanied by minimal interstitial or alveolar infiltrates.

Diagnosis

Definitive diagnosis of C. *trachomatis* infection in infants and children is by isolation of the organism by cultures of specimens obtained from the conjunctiva or nasopharynx.[43] Several nonculture methods, specifically direct fluorescent antibody staining (DFA) and EIAs, are approved for diagnosis of chlamydial conjunctivitis in infants.[43] These tests have sensitivities of greater than 90% and specificities of greater than 95% for conjunctival specimens compared with culture. Their accuracy for nasopharyngeal specimens is not as good. The current method of choice for detection of C. *trachomatis* from genital specimens from adults and adolescents are nucleic acid amplification tests (NAATs).[43] However, data on use of NAATs in infants and children or from respiratory specimens are limited. There are currently three FDA-approved, commercially available NAATs for detection of C. *trachomatis:* PCR (Amplicor Chlamydia test; Roche Molecular Diagnostics, Nutley, NJ); strand displacement amplification (SDA) (ProbeTec; BD Diagnostic Systems, Sparks, Md); and transcription mediated amplification (TMA) (Amp CT; Gen-Probe, San Diego, Calif).[43] PCR and SDA are DNA amplification tests that use primers that target gene sequences on the cryptogenic C. *trachomatis* plasmid, which is present at approximately 10 copies/cell. TMA is an rRNA amplification assay. All three assays are also available as coamplification tests for simultaneously detecting C. *trachomatis* and *Neisseria gonorrhoeae*. The currently available commercial NAATs have FDA approval for cervical swabs from adolescent and adult women, urethral swabs from adolescent and adult men, and urine from adolescent and adult men and women. The latest version of TMA was recently approved for use with vaginal swabs in adolescents and adults. Currently, none of these assays has FDA approval for use with respiratory specimens. Preliminary data suggest that PCR is equivalent to culture for detection of C. *trachomatis* in the conjunctiva and nasopharynx of infants with conjunctivitis.[44]

Treatment

The recommended treatment regimen for C. *trachomatis* conjunctivitis or pneumonia in infants is erythromycin (base or ethylsuccinate, 50 mg/kg/24 hr divided four times daily orally for 14 days).[34] The rationale for using oral therapy for conjunctivitis is that 50% or more of these infants have concomitant nasopharyngeal infection or disease at other sites, and studies have demonstrated that topical therapy with sulfonamide drops and erythromycin ointment is not effective. The failure rate with oral erythromycin remains 10% to 20%, and some infants require a second course of treatment. The results of one small study suggest that a short course of azithromycin (20 mg/kg/24 hr once daily orally for 3 days) was as effective as 14 days of erythromycin.[38] Mothers (and their sexual contacts) of infants with C. *trachomatis* infections should be empirically treated for genital infection. An association between treatment with oral erythromycin and infantile hypertrophic pyloric stenosis has been reported in infants younger than 6 weeks of age who were given the drug for prophylaxis after nursery exposure to pertussis.[45,46]

Prevention

Neonatal ocular prophylaxis with topical erythromycin or tetracycline ointment, or silver nitrate, does not appear to prevent chlamydial ophthalmia or nasopharyngeal colonization with C. *trachomatis* or chlamydial pneumonia. Silver nitrate is no longer available in the United States. The most effective method of controlling perinatal chlamydial infection appears to be screening and treatment of pregnant women.[34] For treatment of C. *trachomatis* infection in pregnant women, the CDC currently recommends azithromycin (1 g orally as a single dose) or amoxicillin (500 mg orally three times daily for 7 days) as first-line regimen. Erythromycin base (500 mg orally four times daily for 7 days or 250 mg orally four times daily for 14 days) and erythromycin ethylsuccinate (800 mg four times daily for 7 days, or 400 mg orally four times daily for 14 days) are listed as alternative regimens.[34] Reasons for failure of maternal treatment to prevent infantile chlamydial infection include poor compliance and reinfection from an untreated sexual partner.

PSITTACOSIS (*CHLAMYDOPHILA PSITTACI*)

Chlamydophila psittaci, the agent of psittacosis (also known as parrot fever and ornithosis), is primarily an animal

pathogen and causes human disease infrequently.[47] In birds, C. *psittaci* infection is known as avian chlamydiosis.[47]

Etiology

The known host range of C. *psittaci* includes 130 avian species. C. *psittaci* affects psittacine birds (parrots, parakeets, macaws, etc.) and nonpsittacine birds as well (ducks, turkeys).[47,48] Strains of C. *psittaci* have been analyzed by patterns of pathogenicity, inclusion morphology in tissue culture, DNA restriction endonuclease analysis, and monoclonal antibodies, which indicate that there are seven avian serovars.[48] Two of the avian serovars, psittacine and turkey, are of major importance in the avian population of the United States. Each is associated with important host preferences and disease characteristics.

Epidemiology

From 1988 to 2003, there were 935 cases of psittacosis in the United States reported to the CDC.[47] Eighty-five percent of cases were associated with exposure to birds; 70% of these reported cases were the result of exposure to caged pet birds, which were usually psittacine birds including cockatiels, parakeets, parrots, and macaws. Among caged nonpsittacine birds, chlamydiosis occurs most frequently in pigeons, doves, and mynah birds. Persons at highest risk of acquiring psittacosis include bird fanciers and owners of pet birds (43% of cases) and pet shop employees (10% of cases).

Inhalation of aerosols from feces, fecal dust, and nasal secretions of animals infected with C. *psittaci* is the primary route of infection.[47] Source birds are either asymptomatic or have anorexia, ruffled feathers, lethargy, and watery green droppings. Psittacosis is uncommon in children, in part because children may be less likely to have close contact with infected birds. Cleaning the cage is an important high-risk activity. Several major outbreaks of psittacosis have occurred in turkey processing plants; workers exposed to turkey viscera are at the highest risk of infection.

Clinical Manifestations

Infection with C. *psittaci* in humans ranges from clinically inapparent to severe infection involving multiple organ systems as well as pneumonia.[49-51] The mean incubation period is 15 days after exposure, with a range of 5 to 21 days. Onset of disease is usually abrupt with fever, cough, headache, and malaise. The fever is high and often is associated with rigors and sweats. The headache can be so severe that meningitis is considered. The cough is usually nonproductive. Crackles may be heard on auscultation. Chest radiographs are usually abnormal with variable infiltrates, and pleural effusions may be present. The white blood cell count is usually not elevated, but a mild leukocytosis may be present. Elevated levels of aspartate aminotransferase, alkaline phosphatase, and bilirubin are common.

Diagnosis

The diagnosis of psittacosis can be difficult because of the varying clinical presentations. A history of exposure to birds or association with an active case are important clues, but as many as 20% of patients with psittacosis have no known contact.[47] Person-to-person spread has been suggested but not proved. Other infections that cause pneumonia with high fever, unusually severe headache, and myalgia include C*oxiella burnetii* (Q fever), *Mycoplasma pneumoniae*, C. *pneumoniae*, tularemia, tuberculosis, fungal infections, legionnaires' disease, and, most commonly, bacterial and viral respiratory infections.

The mainstay of diagnosis remains serology using the complement-fixation (CF) test, which is genus-specific. According to recommendations from the CDC, a confirmed case of psittacosis requires a compatible clinical illness, usually with a reliable history of avian exposure. Laboratory confirmation may be by one of the three following methods: (1) culture of C. *psittaci* from respiratory secretions; (2) a 4-fold or greater increase in CF or MIF titer in sera collected at least 2 weeks apart; or (3) a single MIF IgM titer greater than or equal to 1:16.[47] A probable case should be epidemiologically linked to a confirmed case or have a single CF or MIF antibody titer of 1:32 or more in at least one serum sample obtained after onset of symptoms. As with use of the MIF for diagnosis of C. *pneumoniae* infections, cross-reactions with other C*hlamydia* species and bacteria can occur.[51] Early treatment of psittacosis with tetracycline may abrogate the antibody response.

The organism can also be isolated by culture from sputum or pleural fluid. Although C. *psittaci* will grow in the same culture systems used for isolation of C. *trachomatis* and C. *pneumoniae*, very few laboratories culture for C. *psittaci*, mainly because of the potential biohazard.

Treatment

Recommended treatment regimens for psittacosis are doxycycline (100 mg orally twice daily) or tetracycline (50 mg/kg/day to maximum of 500 mg orally four times daily) for at least 10 to 14 days after the fever abates.[47] The initial treatment of severely ill patients is doxycycline hyclate (4.4 mg/kg/24 hr divided every 12 hours intravenously; maximum: 100 mg/dose). Erythromycin (500 mg four times daily orally in an adult) is an alternative drug if tetracyclines are contraindicated (e.g., children younger than 9 years of age and pregnant women), but may be less effective. Remission is usually evident within 48 to 72 hours. Initial infection does not appear to be followed by long-term immunity. Reinfection and clinical disease can develop within 2 months of treatment; there are two well-documented cases of reinfection reported.

Prognosis

The mortality of untreated psittacosis is 15% to 20% but is less than 1% with appropriate treatment. Severe illness leading to respiratory failure and fetal death has been reported among pregnant women.

Prevention

Several control measures are recommended to prevent transmission of C. *psittaci* from birds. Bird fanciers should be cognizant of the potential risk. C. *psittaci* is susceptible to most disinfectants and detergents as well as heat, but is resistant to acid and alkali.[47] Accurate records of all bird-

related transactions aid in identifying sources of infected birds and potentially exposed persons. Newly acquired birds, including birds that have been to shows, exhibitions, fairs, or other events, should be isolated for 30 to 45 days, or tested or treated prophylactically before adding them to a group of birds. Care should be taken to prevent transfer of fecal material, feathers, food, or other materials between birdcages. Birds with signs of avian chlamydiosis (e.g., ocular or nasal discharge, watery green droppings, or low body weight) should be isolated and should neither be sold nor purchased. Their handlers should wear protective clothing and a disposable surgical cap and use a respirator with an N95 or higher-efficiency rating (not a surgical mask) when handling them or cleaning their cages. Infected birds should be isolated until fully treated, which is generally 45 days.

INFECTIONS DUE TO OTHER *CHLAMYDIALES* SPECIES

The most studied member of this group of organisms has been *Simkania negevensis*, which was first identified as a contaminant in tissue culture in Israel.[2,52] The *S. negevensis* 16S and 23S ribosomal DNA each have 80% to 87% sequence identity with members of the *Chlamydiales*. The organism has been associated with a variety of respiratory illnesses including bronchiolitis in infants from Canada and Israel, community-acquired pneumonia and COPD in adults from Israel and respiratory tract infection in children and adults from Cornwall, UK. *S. negevensis* has a life cycle similar to *Chlamydiales* with a biphasic intracellular morphology with electron dense non-replicating EBs and replicating RBs of comparable sizes. There are distinct differences in that the growth cycle is longer, 12 to 15 days compared to 48 to 72 hours for *Chlamydiaceae*. Unlike *Chlamydia*, *S. negevensis* is totally resistant to penicillin. *S. negevensis* has been found to be present in drinking water and reclaimed waste water in the Negev, Israel. The organism has also been shown to be able to replicate in amebae and survive for long periods in amebal cysts, which would allow it to survive in water. Based on this, it has been proposed that *S. negevensis* may be transmitted to humans via drinking water. *Simkania* and related organisms are also called environmental chlamydiae.

P. acanthamoebae, previously called Hall's coccus, is an endosymbiont of *Acanthamoeba*. The organism was first described as bacteria-like structures in trophozoites of *Acanthamoeba* isolated from patients with fever and pneumonia associated with use of humidifiers.[2] The bacteria-like structures were subsequently identified as *P. acanthamoebae*. The organism has been isolated from nasal mucosa of healthy human volunteers and a BAL specimen from a patient with a diagnosis of viral pneumonia. However, it appears that *P. acanthamoebae* is a rare cause of pneumonia in humans. Greub and colleagues[53] were able to identify *P. acanthamoebae* DNA by PCR in only 1 of 1200 BAL specimens from patients with pneumonia of unknown etiology. This patient was a 31-year-old man who was HIV positive who presented with cough, fever, and bilateral infiltrates on chest radiograph. No other pathogens including *C. pneumoniae*, *Legionella pneumophila*, *Pneumocystis carinii*, and mycobacteria were detected. A subsequent study from the same group using serology suggested that *P. acanthamoebae* might be responsible for approximately 8% of pneumonias seen in a series of patients with head trauma and suspected aspiration pneumonia.[54] The in vitro susceptibilities of *P. acanthamoebae* appear to be similar to those of chlamydia except that they are constitutively resistant to quinolones.[55]

CHAPTER 42 Fungal Infections

Jay M. Lieberman and Felice C. Adler-Shohet

TEACHING POINTS

- In a patient with pneumonia, a history of travel to or residence in an endemic area should raise suspicion for the diagnosis of an endemic mycosis, such as coccidioidomycosis, histoplasmosis, or blastomycosis.
- The likelihood of clinical manifestations of histoplasmosis is determined by the intensity of the exposure and the host's immune status.
- Coccidioidomycosis and histoplasmosis usually cause self-limited infections—specific antifungal therapy is indicated only for disseminated, progressive, or severe disease.
- Invasive pulmonary aspergillosis is a potentially lethal infection in immunocompromised patients; the diagnosis requires a high degree of clinical suspicion and therapy must often be initiated before the diagnosis is confirmed.
- Effective therapy of invasive aspergillosis requires aggressive antifungal therapy and withdrawal or reduction of immunosuppressive therapy; surgical intervention is sometimes needed as well.

Fungi that cause pulmonary infections can be divided into endemic mycoses, which commonly occur in people, usually immunocompetent, who live in certain geographic areas, and opportunistic fungi that cause infection in high-risk, usually immunocompromised, hosts. The endemic mycoses discussed in this chapter include coccidioidomycosis, histoplasmosis, blastomycosis, and paracoccidioidomycosis, whereas the opportunistic mycoses include aspergillosis and cryptococcosis.

COCCIDIOIDOMYCOSIS

Coccidioides immitis, the primary etiologic agent of coccidioidomycosis, usually produces a self-limited pulmonary infection in otherwise healthy individuals. Extrapulmonary dissemination occurs rarely in normal hosts but is more common in infants and immunocompromised patients. Because of its variable clinical course and protean manifestations, coccidioidomycosis presents challenges in diagnosis and treatment.

The disease was first described in an Argentinian soldier with skin lesions in 1892. It was originally thought to be a protozoan organism until the fungal etiology was established in 1900. In 1936, primary and secondary forms of the disease were described—the primary form is commonly known as San Joaquin Valley or Valley Fever.

Until recently, C. *immitis* was considered the sole etiologic agent of coccidioidomycosis. However, a second species, C. *posadasii,* has been proposed based upon genotypic differences.[1] C. *immitis* is a dimorphic fungus that exists as a mycelium (mold) in nature and the laboratory and as a spherule containing endospores in host tissues at 37° C. When spherules rupture, they can release up to 10^5 endospores into the surrounding tissues (Figs. 42-1 and 42-2).

Epidemiology, Risk Factors, and Pathogenesis

Coccidioidomycosis is endemic to the southwestern United States and parts of Central and South America, including northwestern Mexico (Fig. 42-3). C. *immitis* naturally occurs in the soil of these areas, where the climate is arid to semiarid with low annual rainfalls. In the United States, where an estimated 150,000 people are infected annually, the disease is endemic in certain parts of Arizona, California, New Mexico, Texas, and Utah.[2] In Arizona, there has been a substantial increase in the number of cases, which is postulated to be due to environmental and climactic changes, namely hot, dry conditions.[3] Sporadic, nonendemic cases occur as a result of travel through endemic areas, inhalation of contaminated fomites, or laboratory exposure.

A history of dust exposure in endemic areas is of particular significance. Outbreaks of coccidioidomycosis have been associated with construction, archaeological digs, and other causes of soil disruption, including earthquakes.[4] During windstorms, construction work, or farming, the arthroconidia (spores) break from the parent mycelium in the soil and become airborne; even a single fungal spore can result in infection.

When arthroconidia are inhaled, primary pulmonary infection occurs. Spherules develop and grow in the lung, fill with endospores, and a polymorphonuclear reaction occurs around them. The infection remains confined to the respiratory tract in most healthy people, but extrapulmonary dissemination may occur in immunocompromised patients and, rarely, in healthy people. The incubation period is usually 10 to 16 days depending on the quantity of arthroconidia inhaled. In immunocompromised patients, reactivation of primary infection can occur months to years later.[5]

The annual risk of infection in endemic areas is about 3% based on repeated skin testing. Although primary coccidioidomycosis affects all age groups and races equally,

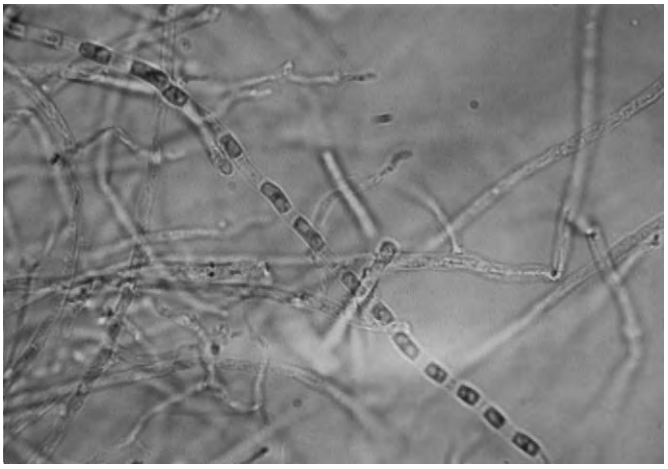

Figure 42-1 Mycelial form of *Coccidioides immitis* showing arthroconidia at 25° C (original magnification, ×400).

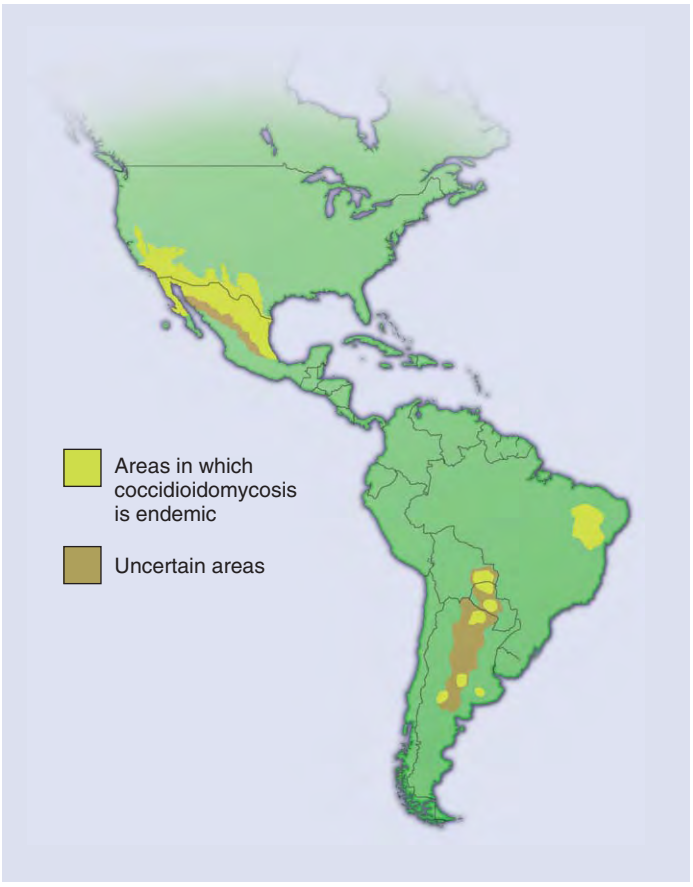

Figure 42-3 Map showing areas endemic for coccidioidomycosis.

the risk of dissemination is higher in certain groups, including infants and the elderly, Filipinos, Hispanics, African Americans, immunocompromised patients, and pregnant women.[2,6]

Person-to-person transmission does not occur and no special isolation precautions are recommended for a person with coccidioidomycosis. The spherule form of the fungus has very low infectivity, and the infective arthroconidia are generally not expelled in high numbers, even in patients with cavitary disease. Nonetheless, care should be taken when handling dressings or wounds that may contain infectious material.

Clinical Features

The majority of infections are asymptomatic, but approximately 40% of infected children develop an influenza-like illness with headache, fever, cough, and malaise. Children may also experience pleuritic chest pain and night sweats. Other clinical manifestations include arthralgias and myalgias, and a variety of rashes, including erythema multiforme or erythema nodosum.[6,7]

In patients with acute pulmonary infection, chest radiographs are abnormal in approximately half of patients. Lobar or segmental consolidation may be seen, often with ipsilateral hilar adenopathy (Fig. 42-4). Pleural effusions occur, and can be quite large. Cavities are rare in children—when they occur, they are usually solitary and have distinctive thin walls. In more than half of patients, they resolve spontaneously within 2 years. Rarely, however, they can result in hemoptysis or can rupture into the pleural space.[6]

More than 90% of primary infections resolve spontaneously. Although dissemination or severe pulmonary disease is seen mostly in immunocompromised patients, severe respiratory disease leading to respiratory failure can occur in immunocompetent children. Such severe disease, which can result in diffuse pulmonary involvement, may occur after a large magnitude exposure leading to multiple sites of infection or because of hematogenous dissemination.[6]

Chronic pulmonary lesions are rare, but approximately 5% of adults and older children develop adenopathy or residual lesions such as cysts, nodules, calcifications, cavities, fibrosis, and bronchiectasis. Solitary nodules are not uncommonly found in asymptomatic patients, which can pose a diagnostic dilemma in a patient not known to have had prior infection with coccidioidomycosis. In patients with fungemia, the chest radiograph often demonstrates a miliary or reticuloendothelial pattern and mediastinal adenopathy.

In about 0.5% of cases, disease spreads beyond the respiratory tract. Symptoms of extrapulmonary disease usually manifest a few months after the primary infection.[6] The

Figure 42-4 Chest radiograph of a 4-year-old girl with disseminated coccidioidomycosis.

most common site of dissemination is the skin, where verrucous, papular, and nodular lesions occur that can form sinuses and abscesses. The next most frequent site of spread is the skeletal system. The bones most commonly involved are the vertebrae, skull, ribs, and long bones. Arthritis is monoarticular in 90% of cases and occurs most frequently in the knees, ankles, and elbows. Meningitis is the most serious form of disseminated coccidioidomycosis; although transient remissions occur, it is fatal if not treated.

Diagnosis

A history of travel to or residence in an endemic area should raise suspicion for the diagnosis. However, cases of fomite transmission have been reported in nonendemic areas. A travel history in HIV-infected patients years before active disease might be relevant because, in these patients, there can be a reactivation of prior dormant infection. Laboratory data associated with, but nonspecific for, coccidioidomycosis include leukocytosis, an elevated erythrocyte sedimentation rate, and eosinophilia.

Demonstration of C. *immitis* in tissues indicates infection. Histopathologic features include acute suppuration around arthroconidia, and granulomatous inflammation and possibly caseating necrosis around developing spherules. Spherules may be identified freely or within macrophages.

The diagnosis can be confirmed by culture, but C. *immitis* poses a significant risk to laboratory personnel, and the laboratory should be notified when C. *immitis* is suspected. Although the fungus is fast growing and cultures may be positive as early as 2 days, cultures should be kept for 4 weeks before being discarded as negative.

Serologic testing can play an important role in diagnosing and managing patients with coccidioidomycosis.[8] Acute infection can be diagnosed by measuring IgM antibodies against tube-precipitin by latex agglutination, enzyme immunoassay, or immunodiffusion. The latex agglutination test is rapid and sensitive but not specific and, therefore, a positive test needs to be confirmed by another means. An IgM response can be detected in approximately 75% of patients with primary disease, appears between 1 and 3 weeks after the onset of clinical symptoms, and lasts 3 to 4 months.[7]

The IgG response can be measured by enzyme immunoassay, complement fixation (CF), or immunodiffusion tests that use a heat-labile antigen isolated from the spherule phase of C. *immitis*. Clinical laboratories use different diagnostic test kits and, therefore, positive results should be confirmed at a reference laboratory. These antibodies are usually detected 1 to 2 months after infection.[8] They provide both diagnostic and prognostic information, as CF titers >1:16 are associated with severe pulmonary disease or dissemination.[7] With therapy, these titers fall, and with resolution of the infection, CF antibodies usually disappear. Therefore, serial CF titers should be followed to assess the response to therapy. Low or negative titers in immunocompromised patients must be interpreted with caution.

Skin tests were used in the past, but are no longer available in the United States. Skin testing had value as an epidemiological tool, but was not helpful in the diagnosis of acute disease because a positive skin test did not differentiate between acute and past infection and because a negative skin test did not rule out disease.

Treatment

Primary coccidioidomycosis usually resolves spontaneously in healthy children and adults, and antifungal therapy is generally not indicated for uncomplicated primary infection.[7] There is no evidence that treatment of the primary infection reduces the morbidity of the infection or the likelihood of the development of more serious complications.[2,5] Patients who might benefit from treatment are those in whom symptoms persist for several weeks and those who have or are at high risk for dissemination, such as immunocompromised patients. Treatment is also indicated for patients with enlarging or spreading infiltrates or CF titers greater than 1:16.[2]

The azole antifungals, primarily itraconazole and fluconazole, have supplanted amphotericin B as therapy of choice for most patients with coccidioidomycosis. For uncomplicated acute pneumonia, therapy can be initiated with an oral azole and continued for 3 to 6 months[2] (Table 42-1). There is some evidence that patients treated with itraconazole may be less likely to relapse than patients treated with fluconazole.[9]

Whether or not antifungal therapy is given, the patients must be reassessed every month or so to be sure their symptoms, radiograph, and serologies are improving and that there is no evidence that they are developing disseminated disease.

For more severe disease, therapy should be initiated with amphotericin B, although the patient can be changed to an oral azole after he or she has clinically improved. Treatment should be continued for at least a year if the patient has diffuse or miliary disease.

For immunocompromised patients, it is reasonable to continue suppressive therapy with fluconazole or itraconazole for life. However, suppressive therapy with oral azoles has not been 100% effective in preventing relapses.

Table 42-1
Recommended Doses of Selected Antifungal Drugs in Children

Drug	Route	Dose
Amphotericin B deoxycholate	IV	0.5-1.5 mg/kg once daily
Amphotericin B lipid complex	IV	5 mg/kg once daily
Amphotericin B cholesteryl sulfate complex	IV	3-6 mg/kg once daily
Liposomal amphotericin B	IV	3-5 mg/kg once daily
Anidulafungin	IV	0.75-1.5 mg/kg once daily
Caspofungin	IV	70 mg/m^2 loading dose, then 50 mg/m^2 once daily
Fluconazole	IV/PO	6 mg/kg once daily (up to 12 mg/kg per day divided twice daily for serious infections)
Itraconazole	IV/PO	5-10 mg/kg per day divided into 2 doses
Ketoconazole	PO	3.3-6.6 mg/kg once daily
Micafungin	IV	4-12 mg/kg once daily (higher dose needed for patients <8 yr of age)
Voriconazole	IV/PO	8 mg/kg every 12 hr for 1 day, then 7 mg/kg every 12 hr

IV, intravenous; PO, oral.
Higher doses of some of the drugs are sometimes used in patients with invasive aspergillosis or mucormycosis. Experience with some of the drugs in children is limited.
Adapted from American Academy of Pediatrics: Antifungal drugs for systemic fungal infections. In Pickering LK, Baker CJ, Long SS, McMillan JA (eds): Red Book: 2006 Report of the Committee on Infectious Diseases, ed 27. Elk Grove Village, IL, American Academy of Pediatrics, 2006, pp 774-784.

Surgical intervention may be required for symptomatic patients with persistent cavities or a parapneumonic process.

HISTOPLASMOSIS

Histoplasmosis is the most common mycosis in the United States, although fewer than 5% of infected individuals become symptomatic. Children younger than 2 years of age and immunocompromised patients are among those most likely to develop disseminated disease.

Histoplasma capsulatum was first described in 1906 on autopsy of a patient with disseminated disease. For many years, histoplasmosis was described as a rare and uniformly fatal disease. In 1946, it was demonstrated that a large number of pulmonary calcifications resulted from *H. capsulatum* infection.

H. capsulatum is a dimorphic fungus that exists in mycelial form in the environment at 25° C and in yeast form in tissues at 37° C (Fig. 42-5). The organism is slow growing, requiring 2 to 4 weeks for colonies to appear. However, isolates have been identified in less than 7 days when a large number of infecting cells have been present.

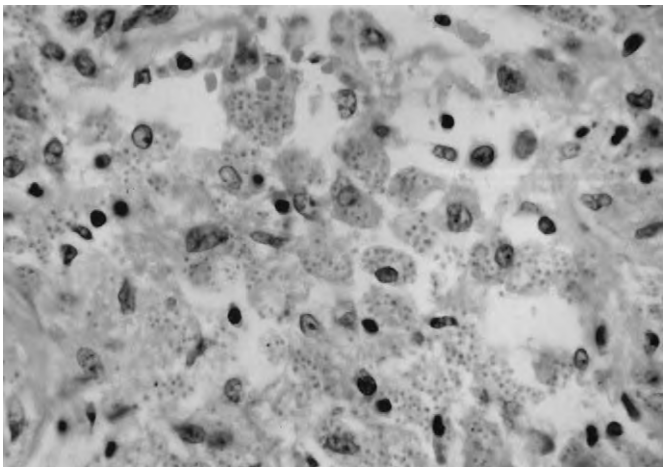

Figure 42-5 Tissue form of *Histoplasma capsulatum* at 37° C (original magnification, ×100).

Epidemiology, Risk Factors, and Pathogenesis

Histoplasmosis has a worldwide distribution but is more prevalent in parts of North and Central America.[10] Histoplasmosis is endemic to the midwestern United States, particularly the Ohio and Mississippi River valleys (Fig. 42-6). The natural habitat of *H. capsulatum* is soil, particularly soil that has been contaminated by bat or bird droppings, which creates an environment of high nitrogen content that enhances the organism's growth by accelerating sporulation. Infection occurs by inhalation of spores, causing a localized or patchy pneumonitis.

Outbreaks have been reported among pigeon or chicken breeders, explorers of caves with bats, and in populations living close to construction that causes the fungus to become airborne. A large outbreak occurred among high school students in Indiana after the soil in the school courtyard, which was known to be a bird roosting site, was tilled.[11]

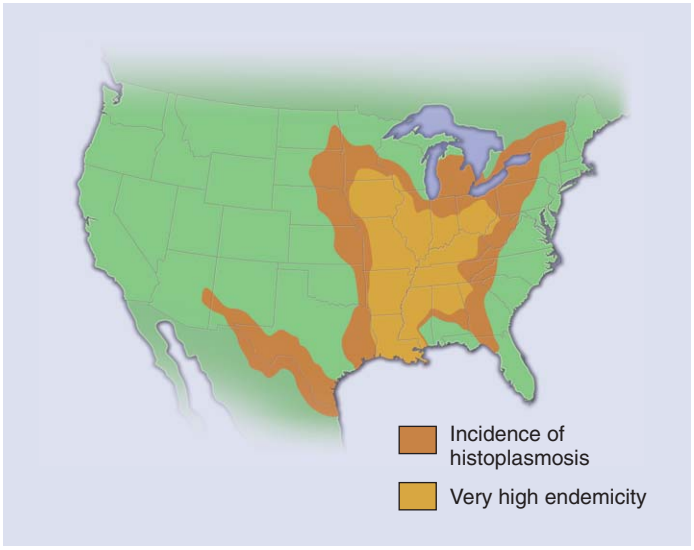

Figure 42-6 Map showing areas endemic for histoplasmosis.

The incubation period is variable but is usually no more than a few weeks after exposure. Person-to-person transmission does not occur.

After inhalation of *H. capsulatum* spores, they undergo transition to a yeast phase in the lower respiratory tract. Hematogenous dissemination, when it occurs, does so within the first two weeks after inhalation, before the development of specific immunity. The ability of the organism to cause clinical symptoms depends on the host's immune status and the magnitude of the inhaled inoculum.[10] Decreased cellular immunity of the host enhances the likelihood of dissemination. *H. capsulatum* yeast cells are phagocytosed by human macrophages, but killing does not occur. The yeast cells replicate inside macrophages and spread via the lymphatic or hematogenous route, where new foci of infection develop. These lesions eventually develop caseating necrosis or heal with fibrosis and calcification.

Reactivation of dormant infection can occur during periods of immunosuppression. Reinfection can occur in the setting of a high inoculum exposure, although it usually results in less severe symptoms than a primary infection with a high inoculum.

Clinical Features

The likelihood of clinical manifestations of histoplasmosis is determined by the intensity of the exposure and the host's immune status. Although approximately 90% of infections are asymptomatic, symptoms develop in more than 75% of normal individuals after heavy exposure.[10] Following infection, symptomatic patients often develop an acute flu-like illness with headache, fever, fatigue, dry cough, and myalgias. Other symptoms, more common after high inoculum exposures, may include chest pain, chills, arthralgias, night sweats, and shortness of breath.

Approximately 10% to 20% of patients with acute pulmonary disease develop pericarditis, a symmetric polyarticular arthritis, or erythema nodosum. Chest radiography in acute pulmonary histoplasmosis is characterized by enlarged hilar or mediastinal lymph nodes and patchy infiltrates. Pulmonary effusion occurs in about 10% of adults and fewer than 5% of children with acute disease.[12] These clinical manifestations usually resolve within a few weeks without antifungal therapy.

Progressive dissemination or cavitary disease develops after heavy exposure to *H. capsulatum* in about 1 of 2000 infected individuals. Risk factors for dissemination include old or very young age, chronic debilitating disease, and impaired cellular immunity. Notably, otherwise healthy infants younger than 2 years of age can develop progressive, disseminated histoplasmosis.[13]

Patients with disseminated histoplasmosis usually have prolonged fever, malaise, cough, and weight loss. Hepatosplenomegaly is found in 30% of adults and 89% of infants.[14] Patients may have shock, disseminated intravascular coagulation, respiratory failure, renal failure, endocarditis, and adrenal insufficiency. Thrombocytopenia and anemia are common laboratory findings. Chest radiographs are characterized by lobar or diffuse reticulogranular infiltrates, cavitation, hilar adenopathy, or any combination thereof. However, 40% to 50% of immunocompromised patients with disseminated histoplasmosis have normal chest radiographs.[14,15]

Chronic histoplasmosis resembles tuberculosis and usually occurs in patients with chronic obstructive lung disease or in immunocompromised patients. They may have a chronic cough, fevers, night sweats, hemoptysis, and weight loss. Calcified lesions, fibrosis, cavitation, and nodules may be seen on chest radiography.

Diagnosis

Isolation of *H. capsulatum* by culture is the definitive method of diagnosis, although growth requires 1 to 6 weeks on standard mycologic media. Cultures are positive from bronchoscopy or lung biopsy in approximately 85% of cases of disseminated or chronic pulmonary histoplasmosis and are often positive in patients with acute pulmonary disease following high inoculum exposure.[10] However, they are usually negative from patients with the more common acute pulmonary disease. Blood and bone marrow cultures are especially useful for the diagnosis of disseminated histoplasmosis, and should be done by the lysis centrifugation method for optimal yield.[10,13] Silver stain of the peripheral blood, particularly the buffy coat, may reveal the diagnosis in disseminated disease.

In tissues, areas of caseous necrosis with a surrounding fibrous capsule that prevents the spread of the organism are characteristic. The fungus may also be seen in tissues inside macrophages.

The standard serologic tests are an immunodiffusion assay and complement fixation test.[10] Serologic tests are positive in greater than 90% of patients with symptomatic disease, and approximately 80% of patients with disseminated disease, but 2 to 6 weeks are required for seroconversion. The CF and immunodiffusion tests peak 2 to 3 months after infection and decline over 2 to 5 years. The sensitivity of serologic testing is increased by performing both complement fixation and immunodiffusion. Although complement fixation is more sensitive, especially early in disease, the immunodiffusion test remains positive longer and is more specific. CF titers of 1:32 and 4-fold increases in titer provide the best evidence of acute infection. However, the height of the titer does not correlate with the severity of infection.

There are a number of potential pitfalls of serologic tests. Immunocompromised patients with disseminated disease may have low or negative titers, which can delay the diagnosis.[16] False-positive results can occur in patients with other infections, such as blastomycosis, coccidioidomycosis, paracoccidioidomycosis, and tuberculosis.[17] Moreover, patients with a history of histoplasmosis who have other illnesses may have borderline titers, as do about 1% to 3% of residents from endemic areas.

H. capsulatum polysaccharide antigen detection by radioimmunoassay or enzyme immunoassay from blood, urine, cerebrospinal fluid, or bronchoalveolar fluid provides a rapid means of diagnosing disseminated or extensive acute pulmonary disease. Antigen is often negative in immunocompetent patients with acute pulmonary disease. Antigen can be detected in the urine or blood of 50% to 80% of patients with disseminated histoplasmosis and in the bronchoalveolar lavage fluid of 70% of AIDS patients with pulmonary disease.[18]

False-positive results have been reported in patients with blastomycosis and paracoccidioidomycosis. Antigen levels decline in response to treatment and may be a useful tool for the follow-up of patients with histoplasmosis.[19]

Skin testing is not useful for diagnostic purposes because the skin test is positive in 80% to 90% of people without evidence of active disease in endemic areas. Furthermore, up to 50% of immunocompromised patients with disseminated disease have negative skin test results. The histoplasmosis skin test is not available in the United States.

Treatment

In the majority of immunocompetent children with uncomplicated primary pulmonary histoplasmosis, disease is self-limited and therapy is not required.[13,20] No controlled trials have been performed to evaluate the effect of antifungal therapy on the course of disease for patients with nonprogressive pulmonary disease. Pericarditis and rheumatologic manifestations including arthritis and erythema nodosum typically do not require antifungal therapy because they are probably immune mediated—nonsteroidal anti-inflammatory agents are often prescribed. If corticosteroids are used for patients with pericarditis, concurrent antifungal therapy is recommended.

Antifungal treatment is recommended for patients with progressive pulmonary disease, disseminated disease, symptoms persisting more than 2 to 4 weeks, or acute pulmonary disease complicated by adult respiratory distress syndrome or obstruction.[13,20]

Oral itraconazole is generally considered the drug of choice for most patients with histoplasmosis, although amphotericin B remains the mainstay of therapy for severe, progressive, and disseminated disease (see Table 42-1). The lipid-based amphotericin B agents may have a role—in a controlled clinical trial in adult AIDS patients with disseminated histoplasmosis, patients treated with liposomal amphotericin B had improved survival compared to those treated with conventional amphotericin B.[21]

Therapy with amphotericin B should be initiated in children with life-threatening, progressive, disseminated disease or those with chronic cavitary histoplasmosis. Once the patient's clinical condition has stabilized, therapy can be switched to itraconazole. Immunocompetent patients should receive at least 6 months of therapy, whereas immunocompromised patients require life-long suppressive therapy after the acute course is completed.

Fluconazole appears to be less effective than itraconazole for pulmonary histoplasmosis, but may be useful as follow-up therapy for meningitis or as suppressive therapy if the patient does not tolerate itraconazole.[13,20]

Corticosteroids may be helpful in conjunction with antifungal therapy in patients with pulmonary histoplasmosis complicated by obstruction or adult respiratory distress syndrome.

BLASTOMYCOSIS

Blastomycosis is an endemic mycosis of the central, midwestern, and southeastern United States (Fig. 42-7). It can cause a chronic granulomatous and suppurative disease that occurs primarily in young and middle-aged men who work or recreate outdoors. Blastomycosis was once thought to be restricted to North America, but the disease has also been described in Africa and India.

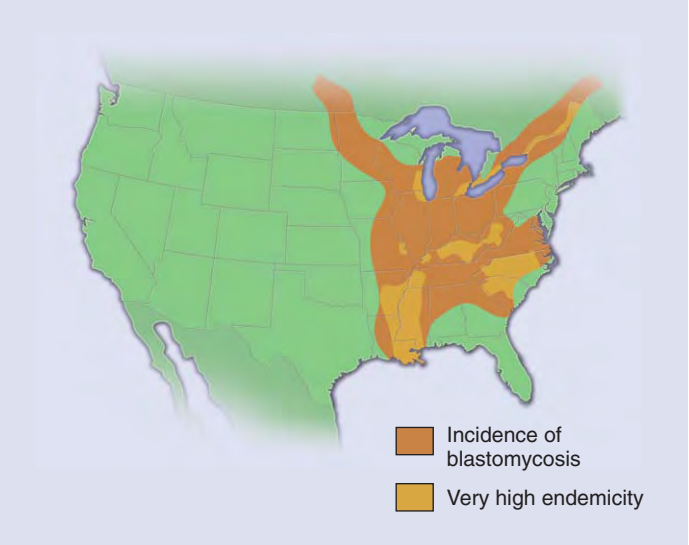

Figure 42-7 Map showing areas endemic for blastomycosis.

Blastomyces dermatitidis, the etiologic agent of blastomycosis, is a dimorphic fungus that exists in yeast form at 37° C and in infected tissues and in a mycelial form at room temperature and in soil. Microscopically, the mycelial form is characterized by pyriform conidia produced on long to short conidiophores that resemble lollipops. The yeast form is thick walled and usually produces a single bud with a broad base (Figs. 42-8 and 42-9).

Epidemiology, Risk Factors, and Pathogenesis

Isolation of *B. dermatitidis* from nature has proved difficult, and so the precise ecology of the fungus is not well known, although it has been isolated on rare occasions from soil and decaying wood. Pulmonary infection occurs after inhalation of conidia. Those conidia that escape ingestion by alveolar macrophages and killing by neutrophils and monocytes

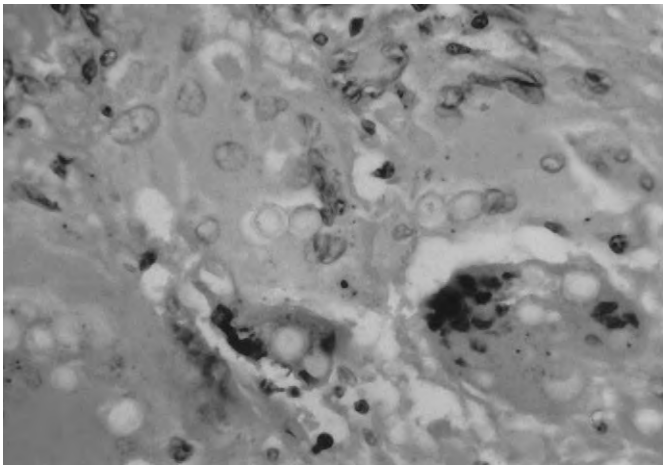

Figure 42-8 Thick-walled spherical yeast form of *Blastomyces dermatitidis* (*arrow*) (original magnification, ×400).

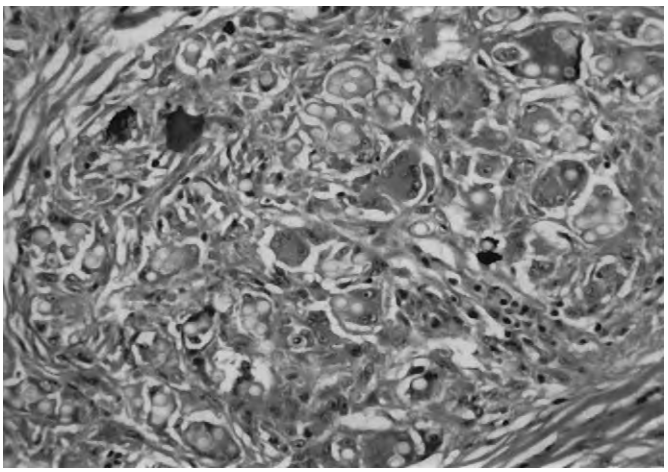

Figure 42-9 Cutaneous blastomycoses illustrating tissue form at 37° C (original magnification, ×100).

undergo conversion to the yeast form, which is more resistant to phagocytosis and killing. A granuloma forms as a result of an inflammatory response consisting principally of macrophages and neutrophils. The fungus may spread hematogenously to other organs.

Clinical Features

The two most common forms of disease are pulmonary and chronic cutaneous blastomycosis, although the clinical presentation is highly variable.[22] Patients with primary pulmonary blastomycosis typically have nonspecific symptoms including fever and malaise. The primary pulmonary form can resolve spontaneously, disseminate to other organs, or develop into a chronic pulmonary disease. The chest radiograph in acute pulmonary disease is characterized by alveolar infiltrates often involving the lower lobes or mass-like infiltrates. Diffuse miliary or reticulonodular patterns can occur in neonates[23] or in patients with the chronic form. Chronic pulmonary disease is characterized by cavitation or fibronodular lesions predominantly of the upper lobes, although cavitary disease is not seen as commonly with blastomycosis as it is with histoplasmosis. Acute lung disease may mimic bacterial pneumonia, whereas chronic disease may resemble tuberculosis or lung cancer.

Cutaneous blastomycosis is the most common form of extrapulmonary disease and can occur with or without lung involvement.[22] Skin lesions can be nodular, verrucous, or ulcerative and subcutaneous lesions may be found. Lesions occur most frequently on the face, hands, wrists, and lower extremities. Other sites of dissemination include bones, the genitourinary system, and the central nervous system (as meningitis or abscesses).

Diagnosis

Because blastomycosis is rarely encountered in children, the diagnosis is often not considered. The key to making a diagnosis is to include blastomycosis in the differential diagnosis in appropriate patients and to send specimens for histopathology and fungal culture. Growth of the organism in culture is relatively easy if an appropriate specimen is submitted for fungal culture. Growth usually occurs within 2 to 4 weeks of incubation and provides a definitive diagnosis. The organism has characteristic features that distinguish it from other yeast, including a thick refractile cell wall that suggests the diagnosis when seen by microscopy in a tissue specimen.

Serologic methods such as complement fixation and immunodiffusion are not helpful because of their low sensitivity and specificity. There is significant cross-reactivity with histoplasmosis. Up to 80% of patients with blastomycosis develop precipitins to antigen A of *B. dermatitidis* and enzyme immunoassay is more sensitive than immunodiffusion in detecting antibodies to antigen A, but is not routinely available.

Treatment

Blastomycosis in immunocompetent patients is often self-limited, but most experts advocate antifungal therapy for all cases of acute pulmonary disease.[22,24] Chronic disease generally does not resolve without treatment. There are no therapeutic studies in children, but based upon the experience in adults and anecdotal data in children, amphotericin B remains the drug of choice for the treatment of life-threatening and central nervous system infections (see Table 42-1).

Children with mild to moderate infections can be treated with itraconazole,[25] which can also be used as step-down therapy for non–central nervous system infections after a patient's condition has stabilized on amphotericin B. Fluconazole has also been shown to be effective and may be appropriate therapy for children with central nervous system infections after initial therapy with amphotericin B. The total duration of therapy is usually at least 6 months for pulmonary and nonpulmonary disease, although some experts recommend 12 months of therapy for osteomyelitis.[26]

Children treated with azoles should be monitored closely, as a review of pediatric blastomycosis cases at Arkansas Children's Hospital suggested that the response to azoles was limited.[27] Immunocompromised patients should generally be placed on suppressive therapy with fluconazole or itraconazole after the primary course of therapy for the duration of their immunosuppresson.[22,24]

PARACOCCIDIOIDOMYCOSIS

Paracoccidioidomycosis, sometimes called South American blastomycosis, is caused by the dimorphic fungus *Paracoccidioides brasiliensis*. The disease is endemic to parts of Latin America, primarily Brazil, Colombia, and Venezuela. Disease occurs mostly in adults and is rare in children.

Clinical Features

Paracoccidioidomycosis is classified into acute and chronic types.[28] The acute form occurs in children and young adults; most commonly, it involves the reticuloendothelial and skeletal systems—patients have lymphadenopathy, and involvement of the liver, spleen and bone marrow as well as bones, joints, skin, and mucous membranes. The fungus can remain dormant within lymph nodes for years. The chronic form is more common, occurs in adults, and can be limited to the lungs or disseminate to other organs. The chest radiograph in pulmonary paracoccidioidomycosis is characterized by nodules, cavities, and lobar or diffuse infiltrates.

Diagnosis

P. brasiliensis grows as a yeast at 37° C and as a mold at 25° C. Direct examination of a clinical specimen is the best method to establish the diagnosis. The yeast form frequently has a pilot-wheel appearance with multiple buds. The organism grows on culture fairly easily. Serologic tests are of both diagnostic and prognostic value. Complement fixation, enzyme immunoassay, and immunodiffusion are the most widely used serologic tests.

Treatment

Amphotericin B remains the therapy of choice for disseminated or progressive disease, but is not curative by itself and itraconazole or a sulfonamide is usually used in combination. Itraconazole is the drug of choice for less severe or localized infections and for patients whose condition has been stabilized after a course of amphotericin B therapy. Therapy should continue for at least 6 months to reduce the likelihood of relapse.[29]

ASPERGILLOSIS

There are three major clinical syndromes associated with pulmonary aspergillosis—aspergilloma, allergic bronchopulmonary aspergillosis, and invasive aspergillosis. Invasive pulmonary aspergillosis is a major cause of morbidity and mortality in patients with hematologic malignancies and in transplant recipients.

There are more than 180 species of *Aspergillus*, but the majority of invasive infections are caused by *A. fumigatus*.[30,31] *A. flavus*, *A. terreus*, *A. niger*, and *A. nidulans* are other significant pathogens in immunocompromised patients. The mold reproduces asexually, and its conidia are readily aerosolized, which can be inhaled by a susceptible host and result in pulmonary infection. Growth into filamentous forms, which have the propensity to invade blood vessels, leads to pulmonary inflammation and the potential for hematogenous dissemination.

Aspergillus organisms rarely cause disease in the normal host unless they are inhaled at high concentrations. Bronchopulmonary colonization occurs most frequently in patients with asthma, bronchiectasis, cystic fibrosis, and primary ciliary dyskinesia syndrome.

Epidemiology, Risk Factors, and Pathogenesis

Aspergillus species are ubiquitous in the environment and are especially common in soil and decaying vegetation. Infection occurs primarily through inhalation of spores, although the fungus can also be acquired via aerosolization from a contaminated water source. Person-to-person transmission does not occur.

Macrophages and neutrophils are the main host defenses against *Aspergillus* infection. Patients with impaired macrophage function, such as those treated with prolonged corticosteroids or transplant recipients, and patients with neutropenia or neutrophil dysfunction (e.g. chronic granulomatous disease) are at risk for invasive pulmonary aspergillosis. Prolonged neutropenia is the most important risk factor for patients with hematologic malignancies or after transplantation—in patients with chemotherapy-induced granulocytopenia, the risk of infection increases progressively after the sixth day of neutropenia.[32]

A retrospective cohort study estimated that more than 650 cases of invasive aspergillosis occurred among immunocompromised children in the United States in 2000. The highest incidence was seen in children who had undergone allogeneic bone marrow transplantation and those with acute myelogenous leukemia, each of which had an approximately 4% risk of invasive disease.[33]

Invasive aspergillosis is frequently a hospital-acquired infection, and outbreaks have occurred among immunocompromised patients during hospital construction. Reactivation of an endogenous organism has also been reported to cause disease.

Clinical Features

Allergic bronchopulmonary aspergillosis results from a hypersensitivity reaction to the fungus—this clinical entity is discussed in Chapter 46.

Aspergillomas, or "fungal balls," occur most frequently in patients with pre-existing cavities or congenital pulmonary cysts that become secondarily infected with *Aspergillus*. The chest radiograph is characterized by an ovoid opacity surrounded by a halo that usually involves the upper lobes or the superior segment of a lower lobe. The lesion is typically unilateral, although bilateral involvement occurs in 5% to 10% of cases. Fungal balls also sometimes occur in patients with mild to moderate immunosuppression who do not have preexisting cavities. In contrast to classic aspergillomas, these subacute or "semi-invasive" infections can progress and lead to hemorrhagic complications.[30]

Clinical signs of invasive pulmonary aspergillosis can be nonspecific. Patients usually have fever, but may or may not have respiratory tract symptoms, such as cough or pleuritic chest pain. A common clinical scenario is the child who has persistent fever after resolution of prolonged neutropenia. Hemoptysis sometimes occurs as a result of the propensity for *Aspergillus* to invade blood vessels. Patients may also present with signs and symptoms related to dissemination of the infection to other sites, such as the brain, liver, or kidneys. Patients with documented invasive pulmonary aspergillosis should be evaluated for other sites of infection.

Findings on chest radiography are variable, ranging from patchy infiltrates in any lobe of the lungs to classic nodular or cavitary lesions. The chest radiograph can even be normal while the patient is neutropenic because of the lack of inflammatory response. A CT scan of the chest may reveal lesions suggestive of aspergillosis not appreciated on chest radiograph. As the disease progresses, pulmonary infarction occurs, and wedge-shaped densities with the crescent sign are seen on the chest radiographs (Figs. 42-10 and 42-11).

Aspergillus can also cause infection in immunocompromised hosts at other sites along the respiratory tract,[30] including invasive sinusitis or tracheobronchitis. Invasive sinusitis is a life-threatening infection and the presenting findings can be subtle. Infection of the tracheobronchial tree can present with symptoms of fever, airway obstruction, cough, or hemoptysis.

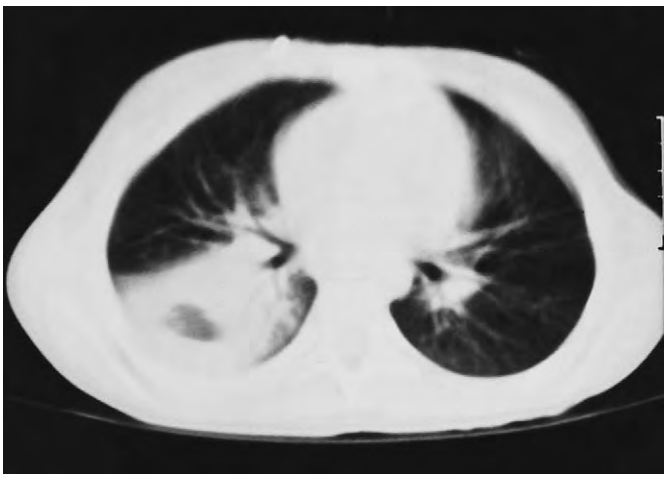

Figure 42-10 Computed tomography scan of the chest in a 6-year-old child with acute nonlymphocytic leukemia and aspergillosis in the right lower lobe.

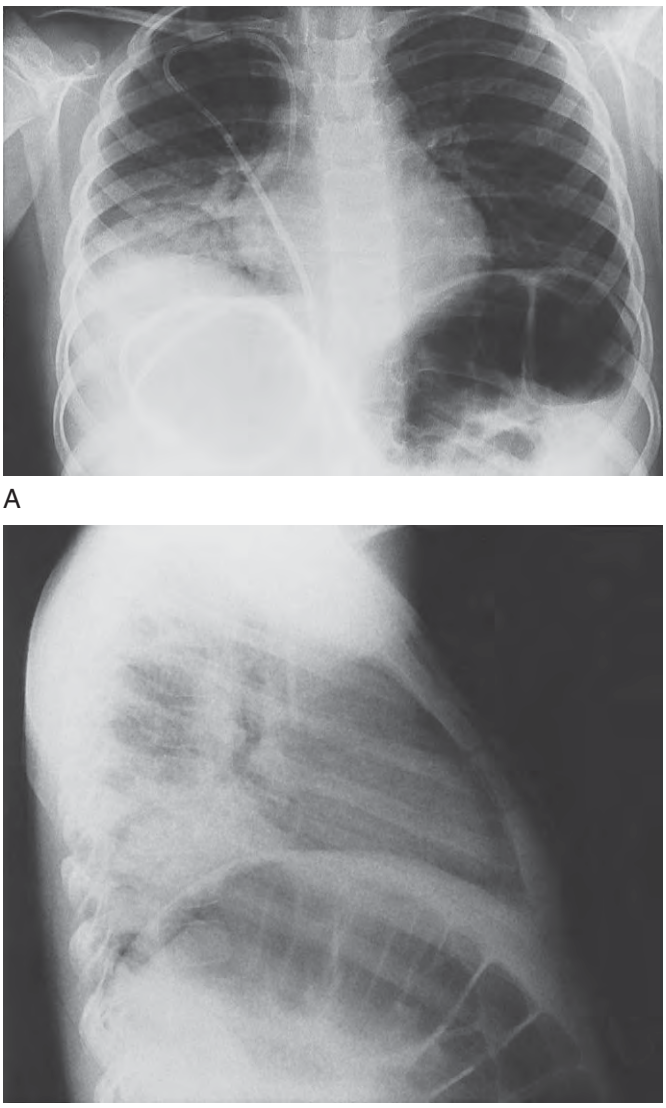

Figure 42-11 Posteroanterior **(A)** and lateral **(B)** chest radiographs of a 6-year-old child with acute nonlymphocytic leukemia and aspergillosis.

Diagnosis

The diagnosis of invasive aspergillosis can be challenging. The most effective diagnostic approach combines a high degree of clinical suspicion with radiologic studies and subsequent cultures and histopathology obtained from the lower respiratory tract.

Demonstration of tissue invasion on histologic examination is highly suggestive of invasive aspergillosis, but other fungi, including *Fusarium* spp. and *Pseudoallescheria* spp. can be indistinguishable on tissue samples, and mucormycosis can also be confused with aspergillosis.[30,34] Therefore, isolation of the organism by culture from biopsy specimens is essential to confirm the diagnosis and determine the species. However, the potential risks of invasive procedures in immunocompromised patients should be weighed against the benefits. Although *Aspergillus* can colonize the respiratory tract, its isolation from sputum or bronchoalveolar lavage fluid in an immunocompromised patient with pneumonia is highly suggestive of invasive disease.

A serologic assay to detect galactomannan, a molecule found in the *Aspergillus* cell wall, is commercially available for diagnosing invasive disease, but almost all studies have been done in adults. False-positive tests occur more commonly in children than adults,[31,35] and a negative test does not exclude the diagnosis. Polymerase chain reaction may prove to be a useful diagnostic tool for rapid, noninvasive diagnosis, although its role has not yet been determined.[36]

Treatment

Invasive aspergillosis is a potentially lethal infection in immunocompromised patients and, therefore, aggressive therapy must often be initiated before the diagnosis is confirmed. The overall in-hospital mortality of immunocompromised children with invasive aspergillosis in a large retrospective study was 18%,[33] which is much better than historical data.

Effective therapy requires both antifungal therapy and withdrawal or reduction of immunosuppressive therapy; surgical intervention is sometimes needed as well.[30] Unfortunately, there have not been any large-scale clinical trials evaluating the treatment of invasive aspergillosis in children. Therefore, treatment decisions must be extrapolated from data in adults (see Table 42-1).

For decades, high-dose amphotericin B (1 to 1.5 mg/kg/day) was the standard of care for patients with invasive pulmonary aspergillosis, although response rates were suboptimal. With the availability of lipid formulations of amphotericin B, many clinicians prefer their use because higher doses of amphotericin B can be administered (5 to 10 mg/kg/day) with less toxicity.[37] There are no controlled clinical trials showing that the lipid formulations have superior efficacy.[38]

Itraconazole has good activity against *Aspergillus* organisms in vitro and has often been used as sequential oral therapy after initial therapy with amphotericin B. For oral therapy, the suspension is preferred because absorption is better than with the capsules. An intravenous formulation is also available.

Voriconazole is a broad-spectrum triazole agent with activity against *Aspergillus*. Among pediatric patients with invasive

aspergillosis who were intolerant to amphotericin B or failed to respond, 45% had a complete or partial response to voriconazole.[39] In a large clinical trial in adults, voriconazole showed superior efficacy compared to amphotericin B for primary therapy of invasive aspergillosis.[40] Voriconazole is now approved for first-line therapy of invasive aspergillosis, and many experts consider it the drug of choice. The recommended dose for adults is 4 mg/kg/dose every 12 hours, although pharmacokinetic data suggest that higher doses, up to 8 mg/kg/dose, may be needed in children to achieve adequate concentrations.[31]

Posaconazole is another extended spectrum triazole with activity against *Aspergillus*. Clinical trials have documented efficacy as prophylaxis in patients with neutropenia[31a] and as salvage therapy for patients with invasive aspergillosis.[31b] Data researching the use of posaconazole in children are limited. The echinocandins are fungistatic against *Aspergillus*, and caspofungin is approved for patients with invasive aspergillosis who are refractory to or intolerant of other therapies.[41] Caspofungin is dosed in children at 50 mg/m^2/day.[31,42] Anidulafungin and micafungin have in vitro activity against *Aspergillus*, but there are very limited clinical data.[43] There also are limited data regarding the use of micafungin[44] and anidulafungin[45] in children.

Because of the high mortality associated with invasive aspergillosis, combination antifungal therapy has been considered (e.g. voriconazole and caspofungin), but there are no definitive data to support its use.[30,34]

The duration of treatment depends on the patient's clinical and radiographic response, immune status, and the severity of infection, but it should be at least 12 weeks.[34]

The role of surgical intervention in critically ill patients with invasive pulmonary aspergillosis is limited. Surgical resection should be considered for patients with well-defined lesions or those with an aspergilloma that does not respond to conventional antifungal therapy.

The definitive therapy for an aspergilloma is surgical resection, but surgery may be associated with significant morbidity and even mortality. The major threat of the aspergilloma is life-threatening hemoptysis; therefore, the risks and benefits of potential curative surgery must be considered.

CRYPTOCOCCOSIS

Cryptococcus neoformans is an encapsulated yeast with a worldwide distribution. It can be isolated from trees, fruits, and soil contaminated with bird droppings, especially those of pigeons. The disease is acquired through the inhalation of airborne particles containing the yeast. Infection is typically subclinical or is limited to the lungs. Dissemination to other organs, such as the central nervous system, bones, and skin, is rare in children unless they are immunocompromised. Although cryptococcosis is a frequent opportunistic infection in adults with AIDS, it is rare in pediatric AIDS patients.

Clinical Features

The lungs and the central nervous system are the two primary sites of infection with C. *neoformans*.[46] At least one third of patients with pulmonary cryptococcosis are asymptomatic. Symptomatic children present with headache, fever, chest pain, and cough. The chest radiograph is variable and may reveal a solitary nodule, multiple nodules, cavities, hilar adenopathy, or focal or diffuse infiltrates usually involving the lower lung fields.

In the immunocompromised patient with cryptococcal pneumonia, disease can progress rapidly. The chest radiograph can show a variety of features as with normal hosts, but can also reveal diffuse or focal interstitial infiltrates that may be confused with *Pneumocystis* pneumonia.

Diagnosis

The diagnosis of cryptococcosis is often made by the demonstration of budding, encapsulated yeast in India ink or wet-mount preparations of clinical specimens (Figs. 42-12 and 42-13). C. *neoformans* can be isolated from culture of blood, body fluid, or tissue specimens. The lysis centrifugation method should be used for blood cultures.[47] The latex agglutination test for detection of cryptococcal capsular antigen remains highly sensitive and specific, especially in patients with meningitis or disseminated forms of cryptococcosis, but serum cryptococcal antigen is generally negative if disease is limited to the lungs.

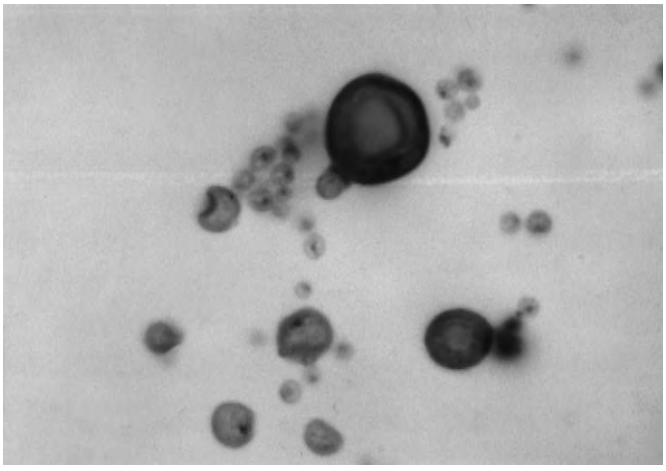

Figure 42-12 *Cryptococcus neoformans* isolated from cerebrospinal fluid (original magnification, ×400).

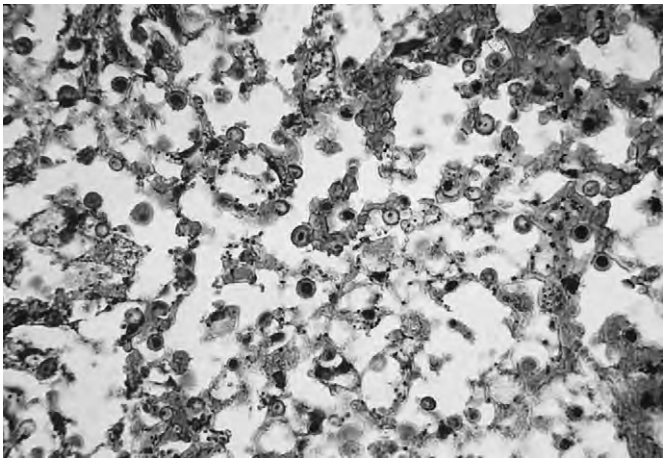

Figure 42-13 Pulmonary cryptococcosis (original magnification, ×100).

Treatment

For severe infections and meningitis, amphotericin B (or one of the lipid based amphotericin B preparations) in combination with oral flucytosine, is the initial therapy of choice.[46] After two weeks of combination therapy, fluconazole can be used as continuing therapy if the response is adequate (see Table 42-1).

The azole antibiotics, such as fluconazole or itraconazole, are probably the drugs of choice for pulmonary cryptococcosis. Children with HIV infection should be continued on lifelong suppressive therapy with fluconazole after completing treatment.[47]

UNCOMMON PULMONARY MYCOSES

In severely immunocompromised patients, a variety of fungi can cause invasive disease, including *Candida* species, the Zygomycetes, *Sporothrix schenckii*, *Fusarium* species, and *Pseudallescheria boydii*.

Pulmonary candidiasis as a primary disease is extremely rare, although it sometimes occurs as one manifestation of disseminated candidiasis. Patients with disseminated candidiasis can appear septic with various degrees of dyspnea. The chest radiograph may show multiple septic emboli or interstitial or lobar disease. Isolation of *Candida* species from the sputum or bronchoalveolar lavage fluid almost always reflects oropharyngeal colonization. Therefore, histologic demonstration of invasive disease is required to confirm the diagnosis.

Mucormycosis (or zygomycosis) most commonly occurs in immunocompromised patients, such as those with malignancies, those receiving immunosuppressive therapy including long-term corticosteroids, or those with diabetes mellitus. The clinical picture is similar to that of aspergillosis and it can be confused with *Aspergillus* on histologic examination of tissues. Therefore, cultures are important to distinguish between the fungi. As mucormycosis is not susceptible to voriconazole, high doses of a lipid-based amphotericin B drug should be used if there is any question whether the diagnosis is mucormycosis or aspergillosis.

Pulmonary sporotrichosis is probably underdiagnosed because its radiographic and clinical courses are similar to those of other granulomatous lung infections (such as tuberculosis) and because it is difficult to diagnose. Pulmonary sporotrichosis can occur as a primary infection or secondary to disseminated disease. The most reliable method of diagnosis is by culturing the organism from infected tissues. Amphotericin B or itraconazole are the drugs of choice and surgical resection is important in well-localized disease.

CHAPTER 43 Other Infectious Agents

Geoffrey A. Weinberg and Ann M. Buchanan

TEACHING POINTS

Pneumocystis carinii

- This is an opportunistic atypical fungus that causes pneumonia in immunodeficient hosts.
- Risk factors include T-lymphocyte deficiencies (HIV infection, cancer chemotherapy, organ transplantation, primary immunodeficiency, connective tissue disorders, marked protein-calorie malnutrition), and, rarely, humoral immunodeficiency (hypogammaglobulinemia).
- Typical manifestations are tachypnea, dyspnea, fever, nonproductive cough, and hypoxemia, all in association with relatively normal auscultation of the chest. There are diffuse interstitial infiltrates on chest radiography.
- Diagnosis is best made by silver staining or immunologic staining of bronchoalveolar lavage fluid or lung tissue.
- Antibiotic therapy of choice is trimethoprim-sulfamethoxazole for 14 to 21 days (plus adjunctive prednisone for moderate to severe pneumonia).
- Prophylactic therapy of choice is trimethoprim-sulfamethoxazole for 3 to 7 days per week.

Legionella pneumophila

- This is a rare cause of pediatric community-acquired pneumonia requiring hospitalization.
- Risk factors are organ transplantation and immunodeficiency.
- Typical manifestations include acute fever, patchy alveolar pneumonia unresponsive to β-lactam antibiotics, progressive lung consolidation, diarrhea, mental status changes, hyponatremia, and elevated transaminase levels.
- Diagnosis is best made by culture of bronchoalveolar lavage fluid, lung tissue, or pleural fluid; urinary antigen test is available for *L. pneumophila* serogroup 1.
- Antibiotic therapy of choice is azithromycin for 14 to 21 days (with or without adjunctive rifampin) or a fluoroquinolone.

A number of infectious agents of several types (beyond those discussed in other chapters of this textbook) can cause infections of the lung in childhood. Perhaps the most commonly considered unusual infectious etiologies for pediatric pneumonia in children in the developed world are *Pneumocystis carinii* and *Legionella pneumophila*. Less commonly, pulmonary infections caused by *Toxoplasma gondii*, *Echinococcus*, *Paragonimus westermani*, *Ascaris lumbricoides*, hookworms, *Toxocara*, *Strongyloides stercoralis*, *Schistosoma*, and other parasites might be encountered. It is beyond the scope of this chapter to include full sections on each of these unusual pediatric pulmonary pathogens, but *P. carinii* and *L. pneumophila* are addressed in detail, and salient features of several of the parasitic causes of pneumonia are summarized.

PNEUMOCYSTIS CARINII

P. carinii is one of the most common causes of pneumonia in the immunocompromised host, whether the immunocompromise results from a congenital defect (e.g., severe combined immunodeficiency syndrome), an acquired defect (e.g., human immunodeficiency virus [HIV] infection), or an iatrogenic cause (e.g., immune suppression associated with therapy of malignancy or prevention of organ transplant rejection).[1-11] Recognized infection with *P. carinii* was once uncommon, but as the prevalence and survival of immunocompromised hosts have increased over the past several decades, so has the incidence of *Pneumocystis* disease. The occurrence of several consecutive cases of *P. carinii* pneumonia among apparently healthy young men in Los Angeles and New York City led to the rapid recognition of acquired immunodeficiency syndrome (AIDS) as a new diagnostic entity in the early 1980s. With the spread of the HIV pandemic, the importance of accurate diagnosis of and effective therapy for *P. carinii* disease has greatly increased.

Epidemiology, Risk Factors, and Pathogenesis

ORGANISM

P. carinii is an extracellular eukaryotic pathogen whose taxonomic classification has been a matter of controversy since its description in 1909. Chagas originally thought that the organism was a variant form of *Trypanosoma cruzi* infecting animals, but by 1912 this assignment was shown to be incorrect.[1,6] In the 1950s the organism was found to be the cause of interstitial plasma cell pneumonia in infants and children, most of whom were malnourished residents of orphanages and foundling homes following World War II.[1,6] Over the past 50 years, the pathogen has been classified alternately as a protozoan because of its morphologic structural properties and susceptibility to antiprotozoal agents or as a fungus because of its subcellular organelle structure, cell wall biochemistry, and staining characteristics.[1] Molecular biologic studies have shown that *P. carinii* exhibits the greatest genomic homology with fungal rather than protozoal lineages at a number of loci (ribosomal RNA, β-tubulin, folate metabolism pathway, and mitochondrial enzyme genes, among others); thus, the organism is best classified as an unusual

fungus that infects both humans and animals, yet retains many biologic features more typical of protozoa.[1,6,8-12] Recent attempts at synthesizing both phenotypic and genotypic data have led to a trinomial system of names to distinguish among *P. carinii* from human and animal hosts,[13] and some investigators have suggested renaming the human form of *P. carinii* as *P. jiroveci*.[14,15] However, the renaming of the organism is controversial and not universally accepted.[16-19] For the sake of simplicity, here we refer to all *P. carinii* organisms with the older binomial system.

Three developmental stages of *P. carinii* have been identified: trophozoites, cysts, and precysts.[1,2,8] Trophozoites are small (1 to 5 μm), are pleomorphic, and commonly exist in large clusters in lung tissue or respiratory secretions. This form is identified on Giemsa stain, rapid Giemsa stain variants such as the Diff-Quik stain, or Wright stain, by its dot-like reddish nucleus with surrounding blue cytoplasm[1,6] (Fig. 43-1). It is thought that trophozoites reproduce via binary fission. Cysts appear as spherical or crescent-shaped structures about 5 μm in size, often with a fold that gives them a parentheses-like or cup-shaped appearance. The cyst wall will not be visualized with Giemsa stain, but up to eight round or spindle-shaped intracystic bodies may be seen, surrounded by a clear halo. The cyst wall is readily stained by the Gomori methenamine silver nitrate procedure (Fig. 43-2), the more rapid Grocott silver stain, or other cell wall stains such as toluidine blue O, cresyl echt violet, or calcofluor white.[1,6] The precyst is an intermediate stage of reproduction, about 4 to 6 μm in size, which may represent a parent cell undergoing encystment. All three *P. carinii* forms reside in the alveoli.

Attempts at long-term or continuous cultures of rat *P. carinii* or short-term culture of *P. carinii* from humans have not been successful, although a few laboratories have successfully propagated rat and mouse *P. carinii* for a short period (7 to 14 days) in cell culture using epithelial or fibroblast cells such as HEL and WI-38 cells.[1,20]

EPIDEMIOLOGY

Many questions about the natural habitat, modes of transmission, and attack rates of *P. carinii* remain unanswered. It is well established that *P. carinii* infects a wide variety of wild, domestic, and laboratory animals, as well as humans, in a worldwide distribution.[2] Airborne transmission of infection has been shown to occur among infected rats in the laboratory,[21,22] and *P. carinii* DNA has been amplified by the polymerase chain reaction (PCR) from filtered ambient air samples.[23] Thus, while circumstantial evidence indicates that *P. carinii* might be an opportunistic zoonosis in humans, no firm evidence of animal-to-human transmission has been found, and the substantial chromosomal and DNA sequence diversity among *P. carinii* recovered from humans, rats, mice, and ferrets makes zoonotic transmission seem unlikely.[24,25] In addition, attempts to produce experimental infections between different mammalian species have been unsuccessful.[26] It is currently thought that several *P. carinii* lineages (perhaps distinct species of the genus *Pneumocystis*) infect different mammals, perhaps with transmission only to homologous hosts.

It is generally accepted that most children and adults have been asymptomatically infected with *P. carinii*, based on seropositivity rates of 75% in children and 90% in adults.[1,2,27] Reactivation of latent organisms when the host becomes immunosuppressed was thought to explain subsequent disease appearance.[3] However, animal studies question the existence of *P. carinii* latency.[28] The transmission of new infection from one animal to another (within the same host species),[29] and the occurrence of apparent outbreaks of *P. carinii* pneumonia in some (but not all) nurseries and orphanages in central and eastern Europe after World War II, in some children's hospitals in the United States, and in outpatient clinics for immunocompromised patients in Europe,[6] suggests that transmission of *P. carinii* from person to person, even if uncommon, is more likely than reactivation as a source of disease among immunosuppressed hosts.

RISK FACTORS

Whether *P. carinii* disease is manifested after acquisition of new infection or after reactivation of latent infection, it is clear that the infection is opportunistic, occurring in patients with immunodeficiency disorders, especially those involving cell-mediated immunity. Before the beginning of the HIV pandemic, the disease was rare and was found almost exclusively in hosts with malnourishment, malignancy, or primary immunodeficiency disorders or those undergoing immunosuppressive therapy for malignancies, connective tissue disease, or organ transplantation.[30] In contrast, without che-

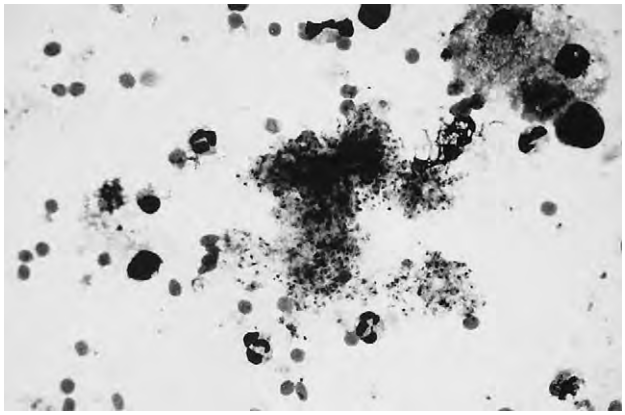

Figure 43-1 *Pneumocystis carinii* trophozoites in bronchoalveolar lavage fluid (Giemsa stain, original magnification ×1000).

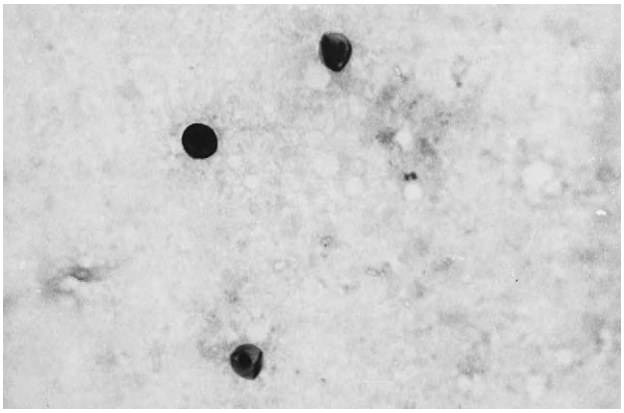

Figure 43-2 *Pneumocystis carinii* cysts in bronchoalveolar lavage fluid (modified Gomori methenamine silver stain, original magnification ×1000).

moprophylaxis, *P. carinii* pneumonia will affect about 75% of adults with AIDS and at least 50% of children with AIDS.[3,4] Initially, *P. carinii* pneumonia was said to be much less common in patients with AIDS in central Africa than in North America and Europe;[6] however, when modern diagnostic techniques are applied, the infection is found globally.[31,32]

PATHOLOGY AND PATHOGENESIS

After the presumed airborne acquisition of organisms, *P. carinii* adheres to type I alveolar cells via binding to fibronectin, vitronectin, or other host components.[33,34] Reproduction of the organisms takes place in the alveolus. Malnutrition, hypogammaglobulinemia, and severe combined immunodeficiency (SCID) have all been associated with *P. carinii* disease, although $CD4^+$ T-lymphocyte immune defects appear to be most important in the pathogenesis of *P. carinii* pneumonia, as manifested by its prominent occurrence in patients with AIDS. The central role of T cells is borne out by the resolution of *P. carinii* pneumonia in nude mice and SCID mice after adoptive transfer of splenic helper T cells from normal heterozygote mice.[1,28] However, the humoral immune system does seem to play a role in protection against *P. carinii*, because the disease has been found in hypogammaglobulinemic children, and experimental animal studies show that passive protection can be afforded by monoclonal antibodies and also that $CD4^+$ T cells alone are not required for protection in previously immunized animals.[1,35] The $CD8^+$ T-cell subset is postulated to contribute more to host pulmonary inflammation than protection against *P. carinii*.[36,37]

Alterations in both amount and distribution of pulmonary surfactant occur during *P. carinii* pneumonia.[4,9,38] Surfactant protein A binds to *P. carinii* surface glycoproteins, which could possibly enhance attachment of the organisms to the alveolus and retard phagocytosis by alveolar macrophages. The alteration in surfactant phospholipids might contribute to ventilation-perfusion mismatches and altered lung compliance.[1,4,9,39] Pulmonary surfactant is inactivated also by $CD8^+$ T-lymphocyte–mediated inflammation.[38]

In children and adults alike, the classic histopathologic appearance of *P. carinii* pneumonia is a prominent eosinophilic foamy intra-alveolar exudate with a mild interstitial pneumonitis[1] (Fig. 43-3). Upon staining with Giemsa or silver stains, organisms are seen within the exudate. Organizing diffuse alveolar damage with interstitial fibrosis is commonly seen (63%) in HIV-infected patients with *P. carinii* pneumonia. Less common findings include absence of foamy exudate (20% of patients with AIDS, nearly 50% in those without AIDS), granuloma formation (5% to 10%), calcification (2%), and cyst formation (2%).[1] Extrapulmonary disease is uncommon (1% to 3%) but well described in adults with AIDS; dissemination in pediatric AIDS patients and in non-AIDS patients appears to be much rarer.[1,40]

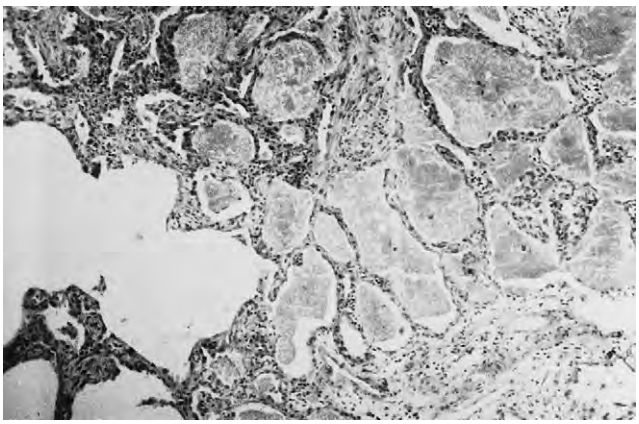

Figure 43-3 Foamy alveolar exudate and mild interstitial fibrosis characteristic of *P. carinii* pneumonia (hematoxylin and eosin stain, original magnification ×450).

Clinical Manifestations

P. carinii pneumonia is characterized by tachypnea, dyspnea, fever, and nonproductive cough.[1] The course of the disease is variable, however, and symptoms distressing enough to bring the patient to medical attention may not occur until late in the infection. This is particularly true in patients with HIV infection, in which the onset of disease is more insidious (over several weeks) than in the pediatric cancer patient, in whom fever and respiratory distress occur over a period of days.[41,42] Crackles are conspicuously absent in most cases (60% to 70%) of *P. carinii* pneumonia; few abnormalities on physical examination are evident beyond tachypnea and respiratory distress.[3,4,41] The mortality of *P. carinii* pneumonia among immunosuppressed patients approaches 100% without therapy.[3] Most infants with perinatally acquired HIV infection (not receiving antimicrobial prophylaxis) have onset of *P. carinii* pneumonia between 3 and 6 months of age.[43,44]

Epidemic interstitial plasma cell pneumonia in malnourished babies, now a rarely recognized condition, was associated with an even more insidious onset, often following weight loss and chronic diarrhea. Fever was less prominent to absent; the mortality rate was at least 50%.[1]

RADIOLOGY

Chest radiographs typically show interstitial infiltrates, beginning in the perihilar regions and spreading to the periphery, becoming more homogeneous and alveolar as the disease progresses[1] (Fig. 43-4). The apices are usually spared until late in the disease. Less commonly, atypical lesions are found, such as asymmetric lobar or segmental consolidation (Fig. 43-5), cavitary, nodular, or upper lobe disease (the latter is especially noted in patients receiving aerosolized pentamidine chemoprophylaxis).[1]

Computed tomography (CT) scans of the chest have shown diffuse interstitial and alveolar consolidation in some cases in which chest radiographs appeared normal, but CT has limited added diagnostic value in most children. Similarly, gallium nuclear imaging has been suggested to be of value in the diagnosis of *P. carinii* in adults with AIDS, but the sensitivity and specificity of the test have varied between 50% and 90%, and the test takes up to 72 hours to perform. In addition, data among pediatric populations (who might have other conditions yielding abnormal gallium uptake, such as lymphoid interstitial pneumonia) are limited, making gallium imaging much less useful.[3]

LABORATORY DIAGNOSIS

The most important indirect marker of *P. carinii* pneumonia is hypoxemia (i.e., a PaO_2 in room air of <80 mm Hg or an

Figure 43-4 Chest radiograph showing diffuse interstitial infiltrates in a 7-month-old child with AIDS and *Pneumocystis carinii* pneumonia.

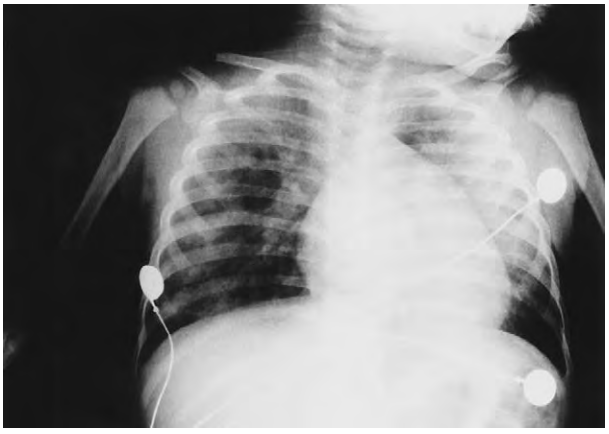

Figure 43-5 Chest radiograph showing right lung interstitial infiltrates and left lung consolidation in an 18-month-old child with AIDS and *Pneumocystis carinii* pneumonia.

alveolar-arterial oxygen gradient of >35 mm Hg).[4] Although more difficult to measure, carbon monoxide diffusion capacity is below 70% of predicted values in nearly all patients with *P. carinii* disease. Serum lactate dehydrogenase (LDH) levels are elevated in both children and adults with AIDS and *P. carinii*, but the finding has limited specificity (75%).[3,4] Serum antibody tests for *P. carinii* are useful in epidemiologic work but not for diagnosis, because low antibody titers are found in normal hosts, and the immunosuppressed host may not be competent enough to show increases in antibody titers.[2] Serum antigen tests were studied at one time but were prohibitively nonspecific.[2] Detection of serum (or sputum) *P. carinii* DNA, which has been amplified by PCR in several laboratories, may become a useful diagnostic technique when better standardized.[45-47]

When an immunocompromised child has tachypnea, cough, dyspnea, fever, and diffuse interstitial infiltrates on chest radiographs, *P. carinii* disease must be considered, along with a number of other etiologies, including cytomegalovirus, *Mycobacterium tuberculosis*, *M. avium-intracellulare*, *Histoplasma capsulatum*, and lymphoid interstitial pneumonitis. Effective therapy depends on definitive tissue diagnosis, which in turn currently depends on demonstration of organisms in lower respiratory secretions or lung tissue.

A staged approach is useful to maximize diagnostic information and minimize patient risk. Techniques that have been advocated include sputum induction, bronchial biopsy, bronchial wash, bronchoalveolar lavage (BAL), and open lung biopsy.[1,3,4] Sputum induced by ultrasonic nebulization and then subjected to Giemsa staining, silver staining, and immunologic staining has been useful for adults with HIV infection/AIDS at medical centers familiar with the technique. However, the procedure is labor intensive when done correctly, experience with children has been limited, and the predictive values have ranged widely (between 40% and 90%). Bronchial washes (suctioning secretions through the bronchoscope) increase sensitivity somewhat, and transbronchial biopsy can be very sensitive if 20 to 25 alveoli are obtained without crushing; however, the risk of bleeding and pneumothorax approaches 10%.

The cornerstone of diagnostic procedures in adults and children is the BAL.[3,4,10,11] In this procedure, aliquots of sterile, preservative-free saline are instilled in a peripheral nondependent airway (e.g., right middle lobe) after the bronchoscope is wedged. After a few seconds, the saline is aspirated and the procedure repeated several times. The yield of BAL is often 85% to 95%. Some success has been achieved with non–bronchoscopic lavage via a small feeding tube placed through the endotracheal tube in patients already undergoing mechanical ventilation.

When the BAL is nondiagnostic, when controlled hemostasis is desirable because of bleeding disorders or when diffuse nodular infiltrates are present that may not yield a diagnosis by BAL, the open lung biopsy is performed. This procedure remains the most sensitive and specific, but it involves the most risk, requiring general anesthesia and the risk of some impairment of pulmonary function. It is possible that open lung biopsy might even be superior to BAL for the non-AIDS patient, because the organism load in this case is lower than that seen in the AIDS patient.[42]

Once BAL fluid or lung tissue is obtained for diagnosis, the material should be examined by experienced personnel, ideally using multiple staining techniques to detect both cysts and trophozoites, although many laboratories will feel most comfortable with careful examinations of specimens for cysts alone.[1,3,4,6] The Gomori or Grocott methenamine silver stain for cysts is widely used. It has sensitivity and specificity exceeding 95%, and the cysts are relatively easy to see.[1,4] Disadvantages include a more intensive procedure, which can take 6 to 24 hours to perform. However, several rapid modifications exist that can cut down the preparation time to a few hours and utilize a microwave oven rather than boiling water baths. Other cyst stains used less widely include toluidine blue O, crystal echt violet, and calcofluor white.[1,4]

Trophozoites are stained by the Giemsa stain and its derivatives such as Diff-Quik. The cost of these stains is minimal, and they require only a few minutes to an hour to perform. However, the sensitivity and specificity are slightly less than silver stains (perhaps 85% to 90% each), and more experience

is needed to recognize the trophozoites among the stained host cells and debris.[1,4] Papanicolaou stain can be useful but is more labor intensive and slightly less sensitive in detecting trophozoites.

Immunologic stains (direct and indirect immunofluorescent antibodies) are now commercially available and may be a reasonable choice for some laboratories. The diagnostic sensitivity exceeds 90% in BAL fluid, and these stains may be useful for induced sputum as well. However, the kits are costly and require considerable experience to discern false positives from true positives.[1,4] Molecular techniques (PCR amplification and oligonucleotide probing) have the potential for exquisite sensitivity, but possibly at the cost of decreased specificity, depending upon the laboratory's experience.[10,11,45-47]

Treatment

ANTIMICROBIAL THERAPY

A number of agents are currently available for the therapy of *P. carinii* pneumonia[1-4,48-54] (Table 43-1). Most have been tested only in adults with *P. carinii* disease, and substantially fewer controlled data are available to provide guidelines for appropriate pediatric use. Thus, the published pediatric experience primarily concerns trimethoprim-sulfamethoxazole (TMP-SMX), pentamidine, and, to a lesser extent, dapsone. Because the incidence of *P. carinii* infection in children and adults with HIV infection has fallen so remarkably in the era of highly active antiretroviral therapy, it is doubtful that further randomized comparative therapy trials will be forthcoming.

Table 43-1
Therapy of *Pneumocystis carinii* Pneumonia*

Medication	Total Daily Dosage
Trimethoprim-sulfamethoxazole	IV: 15-20 TMP + 75-100 SMX mg/kg/day divided q6h-q8h PO: 15-20 TMP + 75-100 SMX mg/kg/day divided q8h
Prednisone (adjunctive)†	PO or IV: 2 mg/kg/day divided q12h for 5 days, followed by 1 mg/kg/day q24h for 5 days, followed by 0.5 mg/kg/day q24h for 11 days
Pentamidine	IV: 4 mg/kg/day q24h, infused over 60 min
Atovaquone	PO: 30-45 mg/kg/day divided q12h administered with food (maximum dose 750 mg PO q12h)
Trimetrexate and leucovorin	IV: trimetrexate 45 mg/m^2 body surface area/day divided q24h plus leucovorin (IV or PO) 20 mg/m^2 body surface area/day divided q6h (leucovorin must be continued for 3 days following completion of trimetrexate)
Primaquine and clindamycin	PO: primaquine base 0.3 mg/kg/day q24h plus clindamycin (IV or PO) 40 mg/kg/day divided q6h (maximum dose primaquine 30 mg/day and clindamycin 600 mg IV or 300-450 mg PO q6h)
Dapsone and trimethoprim	PO: dapsone 2 mg/kg/day q24h (maximum dose 100 mg) plus trimethoprim (IV or PO) 15 mg/kg/day divided q8h)

*Duration of therapy: 21 days for HIV-infected patients, 14 days for non–HIV-infected patients, generally followed by suppressive therapy (secondary prophylaxis); see text and Tables 43-2 and 43-3. Medications are listed roughly in order of choice—see text.
†Prednisone adjunctive therapy suggested for patients with moderate to severe disease, as defined by room air Pa_{O_2} < 70 mm Hg or $P(A-a)_{O_2}$ gradient >35 mm Hg.

The mortality rate of *P. carinii* pneumonia has been strongly correlated (in adults) with the degree of hypoxemia at presentation. Patients with either Pa_{O_2} values less than 70 mm Hg or alveolar-arterial $[P(A-a)_{O_2}]$ gradients greater than 35 mm Hg while inspiring room air experience 20% to 30% mortality rates even with rapid, aggressive therapy, whereas those who have less severe hypoxemia experience a 5% or less mortality rate. Thus many authorities differentiate moderate to severe disease [room air Pa_{O_2} < 70 mm Hg or $P(A-a)_{O_2}$ gradient >35 mm Hg] from mild to moderate disease [room air Pa_{O_2} > 70 mm Hg or $P(A-a)_{O_2}$ gradient <35 mm Hg] in planning therapy.[4,10,11,53,54]

For the initial therapy of moderate to severe disease, parenteral TMP-SMX remains the drug of first choice, and parenteral pentamidine is the most suitable alternative for those intolerant of or not responding to TMP-SMX.[3,4,10,11,53,54] For initial therapy of mild to moderate disease in adults and older adolescents, a number of alternatives exist, including oral or intravenous TMP-SMX, oral TMP-dapsone, oral atovaquone, and intravenous or oral clindamycin with oral primaquine.[4,10,11,53,54] Experience with therapy of mild disease in younger children and infants is limited to TMP-SMX for the most part.[3,54]

It is often noted that the response to therapy seems delayed for 4 to 8 days, and that patients may in fact worsen initially (presumably from pulmonary inflammation incited by dying organisms). Thus determining whether a patient has failed initial therapy, is simply slow to respond, or whether antibiotic resistance has developed, is difficult, and further therapeutic options ("salvage therapy") are uncertain.[48,53,54] For those patients failing TMP-SMX, intravenous pentamidine is generally added or used as a single replacement agent. For those given pentamidine initially, TMP-SMX is used if tolerated. For those patients failing or intolerant to both TMP-SMX and pentamidine, the next best studied agent is parenteral trimetrexate in combination with leucovorin rescue; the combination of clindamycin and primaquine may also have a role in salvage therapy.[4,48]

Therapy for *P. carinii* pneumonia in patients with HIV infection is given for 21 days. In non–HIV-infected individuals, 14 days of therapy generally will suffice.

Specific Agents (see Table 43-1)

TMP-SMX remains the preferred drug for all patients (children and adults) who can tolerate it, because it is the most effective agent, is generally safe, is inexpensive, and is available in both oral and intravenous formulations.[4,48,52-55] The drug combination inhibits two sequential steps in *P. carinii* folate metabolism; TMP inhibits the enzyme dihydrofolate reductase and SMX inhibits dihydropteroate synthetase. Therapy is given intravenously at the onset for all but very mild disease; oral therapy can be used to finish a course of parenteral therapy for those who have responded well. The intravenous infusion should be infused over at least 60 minutes, and the dose must be adjusted for renal failure. It

is possible (but not established) that holding the dose to 15 mg/kg/day (to provide trough serum levels of 5 to 8 μg/ml of TMP and 100 to 150 μg/ml of SMX) may reduce toxicity while providing efficacy.[4,48] TMP-SMX is generally well tolerated, although adult patients with HIV infection (and, to a lesser extent, children with HIV infection) have a much higher rate of adverse effects than do other patients.[3,4] Many of the adverse effects are thought to be due to the SMX component or its metabolites; desensitization of individuals with a history of adverse reactions has been advocated by some authorities but has not been studied in a controlled manner.[3,4,48] Mild adverse effects are not necessarily contraindications for further therapy, because they can be managed with antihistamines or antipyretics, or may even resolve and not recur if the drug is temporarily withdrawn.[4,49,50] Such side effects include transient maculopapular rashes, itching, nausea, and fever; neutropenia can also occur. Urticaria, the Stevens-Johnson syndrome, or hepatitis may contraindicate further therapy.

Pentamidine isethionate is the most commonly used alternative to TMP-SMX.[3,4,48,52-54] It is an antiparasitic agent whose mechanism of action is not well established. For moderate to severe *P. carinii* disease in children or adults, pentamidine is best administered once daily as a slow (60 to 120 minutes) intravenous infusion. In the past, intramuscular injections were used, but these led to the development of painful sterile abscesses. Pentamidine is a toxic drug in both patients with and without coexisting HIV infection. Nephrotoxicity, pancreatitis, hypotension, and hypoglycemia can develop during therapy or even days to weeks later. Azotemia and hypoglycemia tend to occur in the second and third weeks of therapy; the latter is thought to be due to pancreatic injury with subsequent release of insulin. Some patients develop insulin deficiency resulting in hyperglycemia. An aerosolized form of pentamidine was developed in an attempt to deliver medication to the lung while reducing toxicity. Aerosolized pentamidine is an effective agent for prophylaxis but is less effective for therapy of established disease than intravenous pentamidine or TMP-SMX, and thus it can be used for therapy of only very mild disease.[4,48] Aerosolized pentamidine has rarely been associated with pancreatitis, nephrotoxicity, and hypoglycemia, but it is commonly associated with cough due to bronchospasm.

Trimetrexate is a powerful inhibitor of *P. carinii* dihydrofolate reductase. It is perhaps 1500 times more avid in binding the enzyme than is TMP but is far less selective for the *P. carinii* protein than the mammalian protein.[4] Thus, trimetrexate must be given with leucovorin (folinic acid, which *P. carinii* cannot use as an extrinsic source for folate metabolism) to attenuate potentially severe trimetrexate-induced hematologic toxicity. When careful attention is paid to adjustment of the trimetrexate dosing and leucovorin dosing depending on observed hematologic toxicities, trimetrexate can serve as a better tolerated (but somewhat less effective) agent for severe *P. carinii* pneumonia than TMP-SMX.[56] It is critical to extend the leucovorin administration for 3 days beyond the last administered dose of trimetrexate. A few children have been treated using this protocol as well, but data are limited.

Dapsone, like SMX, is a dihydropteroate synthetase inhibitor that is reportedly somewhat better tolerated than SMX. The drug is potentially useful because it is orally bioavailable, is inexpensive, and has a long half-life. However, it is not clear whether dapsone's efficacy when administered with TMP equals that of TMP-SMX or whether it is indeed less toxic.[4,48] Dapsone can cause methemoglobinemia (almost uniformly, but rarely to a treatment-limiting degree), anemia (especially if glucose-6-phosphate dehydrogenase deficiency is present), rash, and vomiting. Dapsone has been used in adults as daily therapy for mild *P. carinii* pneumonia in combination with daily TMP (dapsone is not acceptable as single-agent therapy).[4] Perhaps a better role for dapsone is as a prophylactic agent (see discussion later in this chapter).

Atovaquone is an antimalarial hydroxynaphthoquinone. It inhibits protozoan mitochondrial electron transport, but the mechanism of action against *P. carinii* is unknown. The drug has a long serum half-life and is bioavailable orally (especially if ingested with fat-rich food, and if no diarrhea or gastrointestinal disease is present), lending itself to use in mild to moderate *P. carinii* pneumonia. In a randomized, double-blind study of oral atovaquone versus oral TMP-SMX conducted in 322 adults with mild to moderate *P. carinii* pneumonia, there were more therapeutic failures with atovaquone (20% versus 7%, $p = 0.002$), but fewer patients required change of therapy because of treatment-limiting side effects (7% versus 20%, $p = 0.001$).[57] Overall success rates were similar between the two groups. Thus atovaquone might serve as an alternative agent for mild *P. carinii* pneumonia in those patients who cannot tolerate TMP-SMX. Limited pharmacokinetic data in children suggest that 30 mg/kg/day of the suspension yields serum concentrations comparable with those found in adults given 750 mg twice daily Palatability of atovaquone suspension has been problematic for some children and adults.

The combination of clindamycin and primaquine shows excellent activity in cell culture and experimental animal models of *P. carinii* infection, although neither agent is effective if used alone.[58] This alternative regimen is attractive because of the relative inexpense of the drugs, their oral bioavailability, and the fact that each appears to concentrate in lung tissue. Several studies have been performed in adults using clindamycin-primaquine as either salvage therapy for patients not responding to or intolerant of conventional agents (TMP-SMX or pentamidine) and as primary therapy in mild to moderate *P. carinii* disease.[4] In one prospective noncomparative study, 20 (91%) of 22 patients given intravenous clindamycin and oral primaquine, followed by oral clindamycin and primaquine responded to therapy, and 16 (73%) completed therapy.[59] In a follow-up trial, 38 adults were treated for the entire course with oral medication; 92% responded and 79% completed therapy.[59] In these and other studies, the primary toxicity was a macular or maculopapular erythematous rash developing in about 60% of patients around day 10 of therapy, which often subsequently regressed, rarely necessitating limitation of therapy. About 10% of patients experienced diarrhea; because clindamycin has been associated with pseudomembranous colitis, therapy may need to be altered if severe diarrhea occurs. Like dapsone, primaquine causes methemoglobinemia (40% incidence in the previously mentioned study, but none requiring treatment or with serum methemoglobin >20%), and it can cause hemolytic anemia in patients with glucose-6-phosphate dehy-

drogenase deficiency. Although there is no theoretical reason why the combination should not also be effective in children, few data are available to guide its use.

Several classes of experimental therapeutic agents for *P. carinii* have been studied, including inhibitors of dihydrofolate reductase,[60,61] novel pentamidine analogs,[62] echinocandin antifungal agents,[1,63] inhibitors of enzymes or proteins required for *P. carinii* growth,[64,65] antimalarials,[64,66] and iron chelators.[67-69] None of these agents, however, has been shown to be safe and effective for *P. carinii* therapy in humans.

ADJUNCTIVE THERAPY

Anti–*P. carinii* therapy is often associated with a decline in PaO_2 of 10 to 30 mm Hg during the first few days, especially in patients with AIDS. Such a decline may be tolerated in those with mild disease, but it can be harmful in moderate to severely ill patients who already have PaO_2 values below 70 mm Hg. It is not certain whether the decline in oxygenation is part of the natural progression of *P. carinii* pneumonia, or whether dying organisms incite further pulmonary inflammation. The possibility that pulmonary inflammation might significantly contribute to lung damage in *P. carinii* pneumonia, along with the observation that *P. carinii* pneumonia in cancer patients often developed while corticosteroids were being tapered, suggested that corticosteroid therapy could serve as a useful adjunct to antimicrobial therapy.

Five controlled trials assessing the efficacy of adjunctive corticosteroid therapy in reducing pulmonary morbidity and mortality in adults with moderate to severe *P. carinii* pneumonia have been reviewed by a National Institutes of Health–University of California Expert Panel.[70] All four trials in which steroids were begun within 72 hours of anti–*P. carinii* therapy showed improved outcome, as documented by (in various combinations) prevention of initial decline in oxygenation, reduced need for mechanical ventilation, and reduced mortality rate (from 22% to 11% overall mortality rate in the largest trial).[53,70] Adverse effects of steroid therapy were uncommon, but included an excess of oral thrush and development of mucocutaneous herpes; there was no observed increase in Kaposi's sarcoma or life-threatening opportunistic fungal or mycobacterial infections.

The Expert Panel consensus, now recommended as standard by most experts, was that for adults and adolescents over 13 years of age with moderate to severe *P. carinii* pneumonia, as defined by PaO_2 below 70 mm Hg or $P(A-a)O_2$ gradient above 35 mm Hg, adjunctive corticosteroid therapy should be begun as soon as possible after anti–*P. carinii* therapy is instituted.[70] The dosage regimen recommended for adults was that used by the largest published study, as follows: on days 1 through 5 of therapy, 40 mg of oral prednisone twice daily; on days 6 through 10, 40 mg of prednisone once daily; and on days 11 through 21, 20 mg of oral prednisone once daily.[10,11,53,70]

Four reports have described the use of steroids in children with *P. carinii* pneumonia to be beneficial, but each study has been an open, nonrandomized trial without concurrent controls, using different dosages of medications among a combined study population of fewer than 50 children.[71-74] Despite these statistical limitations, it seems reasonable to consider using steroids as adjunctive therapy for children with moderate to severe *P. carinii*.

Other supportive measures are to maintain the PaO_2 greater than 70 mm Hg and, if possible, to limit the FIO_2 to <50%. Assisted ventilation, packed red blood cell transfusion, and parenteral alimentation are frequently indicated in severe infection.

ANTIMICROBIAL PROPHYLAXIS

Antimicrobial prophylaxis is highly effective in preventing the development of *P. carinii* pneumonia and is indicated for any group of patients with a high incidence of the disease resulting from immunosuppressive therapy or primary immune dysfunction.[2-4,10,11,48-52] Such groups include children with T-lymphocyte dysfunction, such as those with acute lymphocytic leukemia, those with severe combined immunodeficiency syndromes, children undergoing intensive chemotherapy for lymphomas or solid tumors, and recipients of solid organ and bone marrow transplants.[2,30,48] A few children with humoral immune defects have also developed *P. carinii* pneumonia and may warrant prophylaxis, as have children with connective tissue diseases such as rheumatoid arthritis or systemic lupus erythematosus who are undergoing high-dose corticosteroid therapy.[2,30] Finally, the most susceptible group of immunodeficient patients recognized is the HIV-infected population, who require chronic primary and secondary prophylaxis against *P. carinii* pneumonia during advanced immunosuppresson.[10,11,52] Primary prophylaxis refers to the use of medication to prevent the initial episode of *P. carinii* pneumonia; secondary prophylaxis refers to the use of medication to prevent recurrences of disease.

Seminal controlled studies by Hughes and colleagues[75] in 1977 showed that the incidence of *P. carinii* pneumonia in children with acute lymphocytic leukemia undergoing chemotherapy could be reduced from 21% to 0% by daily oral administration of TMP-SMX (150 mg/m^2 TMP and 750 mg/m^2 SMX divided in two daily doses). Subsequent studies by the same workers showed that TMP-SMX could be given on three consecutive days per week rather than daily, with equivalent efficacy.[76] These results now have been generalized to other groups of patients. Although controlled studies are lacking in other groups of patients, a number of retrospective analyses and a large body of clinical experience have indicated that a number of different dosage regimens of TMP-SMX (once or twice daily, 3 or 7 days per week) effectively prevent the development (primary prophylaxis) and recurrence (secondary prophylaxis) of *P. carinii* pneumonia in children and adults with both primary and acquired immunodeficiency, including those with HIV infection.[3,4,48-52]

Prophylaxis with TMP-SMX is simple, safe, inexpensive, and highly effective in patients with immunosuppression of any cause. Unfortunately, in the HIV-infected individual, the incidence of adverse effects is much higher than in other immunocompromised patients, especially in the HIV-infected adult.[3,4] Thus, many adults and some children cannot tolerate TMP-SMX because of the development of substantial pruritus, rash, leukopenia, transaminase elevation, and nausea. For these individuals, the development of aerosolized pentamidine was an important advance. Aerosolized pentamidine delivered by the Respirgard II nebulizer at a monthly dose of 300 mg was shown to be effective in two controlled trials in

Table 43-2
Indications for Prophylaxis of *Pneumocystis carinii* Pneumonia*

Indication	Begin Prophylaxis	Discontinue Prophylaxis
Any immunosuppressive therapy for cancer or connective tissue disease	With immunosuppression	After immunosuppressive therapy ends
HIV infection, no previous history of *P. carinii*	0-1 yr: From 1 mo through 12 mo of age 1-5 yr: Begin if $CD4^+ < 500$ cells/μL or <15% 6-18 yr: Begin if $CD4^+ < 200$ cells/μL or <15%	Prophylaxis may be discontinued for adolescents and adults undergoing highly active antiretroviral therapy whose $CD4^+$ counts are ≥200 cells/μL or ≥15% for ≥3 mo; prophylaxis is restarted if cell counts again fall below these levels. The safety of discontinuing prophylaxis in children has not yet been adequately studied.
HIV infection, previous *P. carinii* disease, any age	As soon as therapy for primary infection ends	Prophylaxis may be discontinued for adolescents and adults undergoing highly active antiretroviral therapy whose $CD4^+$ counts are ≥200 cells/μL or ≥15% for ≥3 mo; prophylaxis is restarted if cell counts again fall below these levels. The safety of discontinuing prophylaxis in children has not yet been adequately studied.
Infants born to HIV-infected women	From 1 mo until 4-6 mo or longer (until time that HIV infection is reliably excluded)	Discontinue at 12 mo, unless HIV excluded earlier by serially negative HIV PCR tests (i.e., negative PCR tests at a minimum of 1 mo and 4-6 mo of age)

*Choice and dosages of prophylactic medications in Table 43-3.

adults with HIV infection (one trial was a primary prophylaxis study and the other a secondary prophylaxis study).[4,49,50] Two other controlled trials in Canada also demonstrated the effectiveness of aerosolized pentamidine, 60 mg every 2 weeks delivered by the Fisoneb ultrasonic nebulizer (a product not currently available in the United States).[4,49,50] The toxicity of aerosolized pentamidine is primarily limited to bad taste and bronchospasm and coughing. The latter complications can be reduced by administration of β-agonists such as albuterol, but they are of concern because of the possibility of coughing increasing the transmission of other coinfecting opportunistic pathogens (such as *M. tuberculosis*). Systemic toxicity of aerosolized pentamidine is rare, but it has been described. In addition, a limitation of aerosolized pentamidine is the development of atypical *P. carinii* disease (upper lobe pneumonia, extrapulmonary disease, etc.), complicating diagnosis and management. Finally, the medication is expensive and requires a source of compressed air.

Controlled trials in adults with AIDS have shown that aerosolized pentamidine is less effective than TMP-SMX for primary and secondary prophylaxis.[77,78] Thus, when TMP-SMX is tolerated, it is the first choice for both children and adults. A randomized controlled trial of TMP-SMX, aerosolized pentamidine, and oral dapsone as primary prophylaxis in adults with advanced HIV infection showed that all three regimens were similarly effective for patients with 100 to 200 $CD4^+$ lymphocytes/μL, but that aerosolized pentamidine was inferior for those patients with fewer than 100 $CD4^+$ lymphocytes/μL. Aerosolized pentamidine was better tolerated than systemic therapy.[79] If TMP-SMX, pentamidine, and dapsone are not tolerated, many theoretical options exist, but few have been subjected to large controlled trials. Dapsone with pyrimethamine, dapsone with TMP, sulfadoxine with pyrimethamine, and intermittent parenteral pentamidine also have been tried in adults with HIV infection.[4] Limited data exist on the use of dapsone in children. Atovaquone and clindamycin-primaquine have theoretical attractiveness for children, but no data allow firm conclusions about their use in primary or secondary prophylaxis; in addition, atovaquone is substantially more expensive.[52]

The U.S. Public Health Service/Infectious Diseases Society of America Prevention of Opportunistic Infections Working Group issues periodically updated comprehensive guidelines on therapy and prevention of opportunistic infections, including those caused by *P. carinii*, in adults and children with HIV infection.[52-54] These important documents (and any future publications from the groups) should be consulted for detailed recommendations on therapeutic and prophylactic agents, choice of regimens, monitoring of patients, and treatment of breakthrough *P. carinii* disease. A summary of the guidelines is presented below and in Tables 43-2 and 43-3.

Because of the recognized advantages of TMP-SMX (efficacy against pulmonary and extrapulmonary *P. carinii*, low cost, cross-protection against toxoplasmosis and bacterial infections), the guidelines call for consideration of rechallenge with TMP-SMX in case of non–life-threatening adverse effects, because many patients seem to tolerate rechallenge and can thus be continued on TMP-SMX.[50,52,53] Preliminary data suggest that TMP-SMX is better tolerated by HIV-infected children than adults and that TMP-SMX prophylaxis is better tolerated than therapy.[3]

In the HIV-infected adolescent and adult, the $CD4^+$ lymphocyte count below 200 cells/μL or the previous occurrence of *P. carinii* disease indicates high susceptibility to infection and mandates primary prophylaxis[50,52] (see Table 43-2). The preferred regimen for both primary and secondary prophylaxis is TMP-SMX for those who can tolerate it.[50,52] Similar recommendations, utilizing age-appropriate $CD4^+$ T-lymphocyte levels, are made for HIV-infected children.[52] Prophylaxis against *P. carinii* is often given for the lifetime of an immunosuppressed patient, but recent guidelines suggest that prophylaxis may be discontinued for certain patients with HIV infection, i.e., adults and adolescents receiving highly active antiretroviral therapy whose $CD4^+$ T-lymphocyte counts have increased and remained greater than 200

Table 43-3
Medications for Prophylaxis against *Pneumocystis carinii* Pneumonia*

Medication	Dosage
Trimethoprim-sulfamethoxazole	150 TMP + 750 SMX mg/m^2 body surface area/day divided q12h administered PO 3 times weekly on consecutive days. (Acceptable alternative regimens include the above dosage given as a single dose 3 times weekly on consecutive days; given as 2 divided doses daily; or given as 2 divided doses 3 times weekly on alternate days. The standard adult dose, which should not be exceeded for children, is 1 DS tablet [160 TMP + 800 SMX mg] once daily.)
Dapsone	2 mg/kg/day as a single dose (maximum dose 100 mg/day)
Aerosolized pentamidine	300 mg by inhalation via Respirgard II nebulizer (Marquest, Englewood, CO) once monthly
Atovaquone	30-45 mg/kg/day as a single dose (maximum dosage 1500 mg/day)

*Medications are listed roughly in order of choice—see text.

cells/μL for longer than 3 months.[52] Prophylaxis is restarted if CD4$^+$ T-lymphocyte counts decrease to less than 200 cells/μL. The safety of discontinuing *P. carinii* prophylaxis in HIV-infected children is less certain but might be considered if age-appropriate CD4$^+$ T-lymphocyte reconstitution has taken place for 3 to 6 months[52] (see Table 43-2).

Universal prophylaxis for HIV-exposed infants is provided until such time that HIV infection is reasonably excluded.[51,52] The preferred regimen is TMP-SMX in two divided doses, three times weekly; acceptable alternatives include once-daily TMP-SMX three times a week or twice-daily TMP-SMX seven times a week[51,52] (see Table 43-3). Aerosolized pentamidine, oral dapsone, and (least desirable) intravenous pentamidine are suggested alternatives for TMP-SMX–intolerant patients.[51,52]

The prophylactic drug regimens shown in Table 43-3 may be used for the primary prophylaxis of *P. carinii* disease in children with non–HIV-related immunocompromise (e.g., cancer and cancer chemotherapy, congenital immunodeficiency, transplant recipients) as well. All children and adults with a previous episode of *P. carinii* disease likely require secondary prophylaxis, although again, discontinuation in immune-reconstituted, HIV-infected adults and adolescents may be considered.[52]

LEGIONELLA PNEUMOPHILA

A number of species of genus *Legionella* of the family Legionellaceae are responsible for causing infection in humans.[80] *Legionella pneumophila*, the cause of legionnaires' disease, was the first species to be associated with fatal pneumonia and is the one most commonly implicated in human legionellosis.[81] Legionnaires' disease is uncommon in children. The illness is often grouped with the "atypical pneumonias" caused by *Chlamydia* or *Mycoplasma*, but this classification is unsatisfactory because the clinical features of legionellosis are much more variable.

Epidemiology, Risk Factors, and Pathogenesis

ORGANISM

Legionella organisms are pleomorphic, thin, faintly staining gram-negative rods that are aerobic, motile, and nutritionally fastidious. Growth of *Legionella* depends on the presence of L-cysteine and iron in specialized growth media, which often results in unsuccessful bacterial isolation unless the laboratory is forewarned that *Legionella* infection is suspected; this most likely plays a role in the underdiagnosis of *Legionella* infection. Similar to other gram-negative rods, the outer membrane of *Legionella* is primarily lipopolysaccharide, and the serogroup-specific antigen of the lipopolysaccharide is used for serotyping of the organism. *Legionella* species are saprophytic aquatic microorganisms that rarely become human pathogens. Most cases of *Legionella* infection are caused by only a few of the 70 or so serogroups among the nearly 50 known species.[82,83] The *L. pneumophila* serogroup 1 is responsible for up to 85% to 90% of *Legionella* infection in healthy individuals, and *L. pneumophila* serogroups 4 and 6, along with *L. longbeachae* and *L. bozemanii*, are responsible for much of the rest.[82,83]

EPIDEMIOLOGY

Legionella organisms are most commonly found in water sources; the natural reservoir may be freshwater amebae.[84] The organism has been isolated both from natural (freshwater streams and lakes, water reservoirs) and artificial (cooling towers, potable-water distribution systems) aquatic habitats. The optimal temperature for growth is between 28° C and 40° C, a range present in both natural and artificial habitats.

RISK FACTORS

In the initial period after the recognition of *Legionella* as a cause of pulmonary disease, the infection was most often identified in point-source epidemics. Sporadic individual infections often went unrecognized. However, more recent data from studies performed in adults suggest that *Legionella* may be responsible for up to 15% of community-acquired pneumonias and 40% of nosocomial pneumonias in some areas.[85-88] Immunodeficiency, corticosteroid and other immunosuppressive therapy, old age, chronic obstructive pulmonary disease, and cigarette smoking have been considered risks for *Legionella* infection in adults. Surgery also appears to be a risk factor in nosocomial infection,[89,90] and transplant patients are among the patients at the highest risk for *Legionella* infection.[91-93]

In children, immunologic and pulmonary compromise have also been considered risks for *Legionella* infection, but sound data regarding the actual incidence of pediatric *Legionella* are lacking. Most of the information has been obtained by serologic surveys of specific groups of patients under medical care and therefore may be biased. In one study from Iceland, 14% of children showed serologic evidence of previous *Legionella* infection.[94] Legionnaires' disease has been documented in children with immunosuppression, but large

studies of this population have not been completed.[95-99] Nevertheless, as in adults, immunosuppression must be considered one of the most important factors assumed to increase the risk of *Legionella* infection in childhood.

PREVALENCE

Legionella infection in children appears to be uncommon, being responsible for only about 1% of cases of pneumonia in seven surveys involving a total of 742 children (range, 0% to 6% in individual studies).[100-106] In contrast, at least 2% of community-acquired pneumonia in adults, 5% of pneumonia in adults causing hospitalization, and 8% of pneumonia in adults requiring ICU admission are thought to be due to legionnaires' disease.[82] A number of reports of nosocomial transmission of *Legionella* infection in children have been published.[107-109] These reports have most often been linked to contaminated water supplies, and aerosol-generating respiratory equipment has been implicated in outbreaks. Sporadic infection in infants younger than 2 weeks has been associated with contaminated water both at home and in the hospital.[110,111] Person-to-person transmission probably does not play a role in the nosocomial spread of *Legionella*.

PATHOLOGY AND PATHOGENESIS

Legionella organisms are facultative intracellular pathogens that cause acute fibrinopurulent pneumonia with alveolitis and bronchiolitis. Histologically, organisms can be seen both intracellularly and extracellularly along with inflammatory cells in the purulent exudate. Besides the lungs, *Legionella* has also been found in the lymph nodes, brain, kidney, liver, spleen, bone marrow, and myocardium.[112] *Legionella* is cleared from the upper respiratory tract by the mucociliary action. Therefore, any process that compromises mucociliary clearance (such as tobacco smoke) will increase the risk of legionellosis. It is phagocytosed by local pulmonary macrophages but is not actively killed, and macrophages may actually support the growth of *Legionella* (thereby allowing the organism to evade one of the first lines of pulmonary host defense). *Legionella* multiplies intracellularly and kills infected macrophages, and then spreads to infect other macrophages. Cell-mediated immunity appears to be the primary protective host defense mechanism, although the roles of neutrophils and humoral immunity have not yet been well characterized. The mode of acquisition of original infection in humans is uncertain but is likely to be airborne inhalation of contaminated aerosols, or perhaps aspiration of contaminated water or oropharyngeal secretions.

Clinical Features

Most of the information regarding the classic clinical features of *Legionella* infection is from studies of adults, because of the rarity of documented pediatric legionellosis. *Legionella* infection in adults has a wide spectrum of clinical manifestations ranging from serious and fatal pneumonia to a self-limiting viral-like illness, but typically the infection manifests as one of two clinical syndromes: Pontiac fever or legionnaires' disease.

Pontiac fever is a viral-like illness with high fever, headache, malaise, and myalgia. The illness is self-limiting, with a short incubation period (24 to 48 hours) and recovery in 7 to 10 days, usually without sequelae. Pneumonia is not usually a part of Pontiac fever, although nonproductive cough may be present. Antibiotic therapy is not necessarily required.

Legionnaires' disease is a multisystem disease that primarily affects lungs. The onset of illness may be acute or insidious. Although pneumonia is the predominant feature of this disease, respiratory symptoms may be absent initially. After an incubation period (which can be as short as 48 hours or as long as 10 days) patients have weakness, lethargy, fatigability, myalgia, and malaise. High fevers (>40° C) and chills are not uncommon. Almost all patients are febrile, although initially fever may be absent or low grade.[80] Relative bradycardia may be present in febrile patients. A dry cough is present in almost all patients. Most adults develop purulent sputum and sometimes hemoptysis. Patients may complain of pleuritic chest pain and shaking chills. Neurologic and gastrointestinal symptoms may also be prominent in some patients, including headache, lethargy, confusion, cerebellar ataxia, agitation, mental status changes, encephalopathy and watery, nonbloody diarrhea. Anorexia may be present, and some patients may complain of abdominal cramps.[90] Hyponatremia and elevated serum transaminase levels are seen more commonly with *Legionella* than pneumonias caused by other organisms. A number of extrapulmonary sites of *Legionella* infection occur as a result of bacteremic dissemination. Although isolation of *Legionella* from the cerebrospinal fluid (CSF) has not been successful, CSF pleocytosis and elevated protein concentrations have been described.[113]

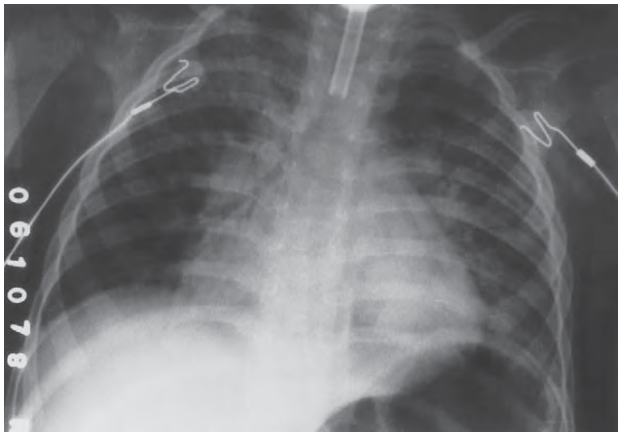
In short, the triad of pneumonia, confusion, and diarrhea, especially if accompanied by hyponatremia and elevated serum transaminase levels, should raise the suspicion of legionnaires' disease. Unfortunately, several prospective studies have noted that it is not possible to distinguish between legionnaires' disease and other causes of pneumonia on the basis of one or more of these findings alone.

Radiographic findings of legionellosis are variable and nonspecific, from patchy alveolar infiltration to a consolidated pneumonia (Fig. 43-6). Pleural effusions may be seen, and cavitary lesions develop occasionally.[114] The usual progression is from patchy areas or nodules to multilobar, almost homogeneous infiltrates. A somewhat typical feature is the centripetal progression of *L. pneumophila* pneumonia. Initially the pneumonia is present in the peripheral lung regions and then becomes sublobar and finally lobar, involving contiguous lobes on the same side.[116-118] This progression may be complicated by adenopathy, abscess, or atelectasis.[119,120] The majority of patients with legionnaires' disease develop radiographic evidence of pneumonia.[114]

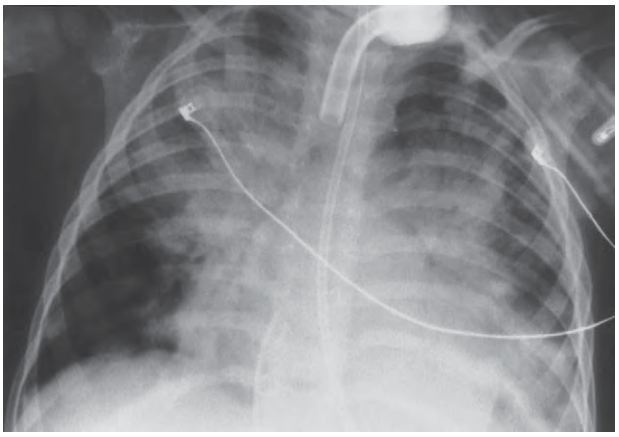
Patients who are healthy before the infection will most likely recover in 7 to 10 days. Immunocompromised or debilitated patients may develop multiorgan failure and die of respiratory failure. Some patients may have other complications of one of the organ systems involved (such as colitis or peritonitis) that may take weeks to resolve.

LABORATORY DIAGNOSIS

Various methods are available for laboratory diagnosis of *Legionella* infection, but the diagnosis of *Legionella* infection cannot be excluded on the basis of any single test.[82,115] However, diagnostic tests can be complementary, elevating



A



B

Figure 43-6 Serial radiographs of a 19-month-old who developed lipoid-like pneumonia after the ingestion of oil of cloves, followed by induced emesis and aspiration. Subsequently this child required a tracheostomy, steroid therapy, and multiple antimicrobial agents. One month after the aspiration the patient died from respiratory failure secondary to *Legionella pneumophila* serogroup 6 pneumonia. **A,** Chest radiograph 26 days after aspiration and 1 day after onset of fever and increasing respiratory distress. **B,** Chest radiograph 2 days later, showing increasing infiltrates. One day later the child died. (Radiographs courtesy of Leland L. Fan, MD, National Jewish Center for Immunology and Respiratory Medicine and Department of Pathology, Children's Hospital, Denver, CO.)

the diagnostic yield for the diagnosis of *Legionella* infection.

Culture is currently considered the gold standard but requires special media, as noted earlier. When *Legionella* is suspected, the clinical laboratory may also "decontaminate" the specimen with a brief acid treatment before inoculation of the specialized growth medium, again to reduce the overgrowth of other organisms. Even with these specialized techniques, it may take up to 5 days to isolate the slow-growing *Legionella*. Although the specificity of culture is 100%, its sensitivity ranges from 10% to 80%.

Direct fluorescent antibody (DFA) staining for *Legionella* is a rapid test requiring as few as 2 to 4 hours for results. However, the sensitivity of DFA can vary from 25% to 70%, depending upon the experience of the technician and quality of the specimen.[115] Therefore, a negative DFA does not exclude *Legionella* infection. Newer monoclonal antibody reagents appear more specific than the polyclonal anti-*Legionella* antibody preparations for diagnosis of *Legionella*, yielding 95% specificity; false positives result from cross-reaction with other bacteria or operator error in reading fluorescence.

Specimens for culture and DFA stain commonly must be obtained by bronchoscopy, because sputum specimens are usually not available from children. Bronchoalveolar lavage is the method of choice, because the yield of bronchial washings and induced sputum samples is low. Pleural fluid, if available, may be sent for culture and DFA stain for diagnosis of *Legionella* infection.

Serologic assays for *Legionella* antibodies are not generally useful in clinical decision making, although are valuable for epidemiologic research. The antibody detected by indirect immunofluorescence tests is produced against the lipopolysaccharide in the outer membrane of *Legionella*. Diagnosis is based on a 4-fold or greater rise in antibody titer, between acute and convalescent serum specimens, to at least 1:128. This seroconversion may take up to 4 to 8 weeks to develop. In epidemics, a single titer of 1:256 or greater, with supporting clinical illness, has been considered sufficient to make a presumptive diagnosis of legionellosis,[121] but this definition has been questioned.[122]

The urinary antigen test for the diagnosis of *Legionella* infection is commonly used in clinical practice because of its rapid turnaround time with high sensitivity (70% to 99%) and specificity (>99%).[115,122] The major disadvantage of the urinary antigen test is that it detects antigen only from serogroup 1 *Legionella*. However, this limited cross-reactivity is less of a problem clinically because serogroup 1 organisms are the cause of most clinical disease. Nucleic acid amplification tests (PCR, etc.) have been used to identify *Legionella* species in research laboratories; if these become commercially available, their theoretical sensitivity should be very high for many serogroups and species, but specificity will depend upon the characteristics of the tests and laboratories performing them.

At the present time, the best combination of diagnostic tests appears to be the urinary antigen test combined with culture of respiratory tract material (BAL fluid, lung tissue, or possibly pleural fluid), especially in geographic areas where *L. pneumophila* serogroup 1 infection is predominant.

Treatment

Many antibiotics inhibit the growth of *Legionella* in vitro, but only those that concentrate well inside cells are clinically useful to combat this intracellular pathogen.[123] Thus, only macrolides, fluoroquinolones, doxycycline, TMP-SMX, and rifampin should be considered as potential therapeutic agents; β-lactams and aminoglycosides will not be clinically effective, despite the in vitro activity of the latter.

Azithromycin (10 mg/kg/day in children, up to the adult dose of 500 mg/day) has replaced erythromycin as the antibiotic of choice for *Legionella* infection. This choice is not based on carefully controlled clinical trials, but rather on good in vitro and animal model activity against *Legionella*, and clinical experience in isolated legionellosis, nosocomial infections, and outbreaks of legionnaires' disease.[82,123] Addition of rifampin to azithromycin (or erythromycin) may be beneficial

in some patients with severe legionellosis.[82,123] In adolescents older than 18 years or in children younger than 18 years in whom the benefits of use outweigh the theoretical risks of cartilage toxicity, a fluoroquinolone such as levofloxacin, ciprofloxacin, moxifloxacin, or gatifloxacin may be used (some experts prefer to treat severely ill adults with fluoroquinolones rather than macrolides).[124-128]

The initial antibiotic therapy of severe *Legionella* infection should be given intravenously, and when clinical improvement occurs antibiotic administration may be changed to the oral route to complete at least 14 days of therapy. Azithromycin and several of the fluoroquinolones are available for intravenous use and are also well absorbed by mouth. Severely ill patients, as well as those who are immunosuppressed, may require longer courses of antibiotic therapy, up to 21 days. Length of the antibiotic therapy should not be gauged solely by radiologic manifestations, because the radiograph may show progression, even when the patient is receiving adequate antibiotic therapy (similar to what occurs during the therapy of pneumococcal pneumonia).

Alternative drugs for legionellosis, if neither macrolides nor fluoroquinolones are used, include TMP-SMX and doxycycline, although experience is limited, and doxycycline may not be suitable for therapy of children younger than 7 to 9 years of age.

PREVENTION

Potable water systems in hospitals and clinics should be maintained in such a fashion to minimize nosocomial *Legionella* (generally a combination of superheating, hyperchlorination, or copper-silver ionization treatment followed by periodic routine water culturing and patient surveillance).[82]

PARASITIC INFECTIONS

Parasitic infections are common worldwide, but pulmonary complications are relatively rare. This section reviews notable pulmonary disease caused by intestinal, tissue, and blood protozoa; helminthic pulmonary infections will be discussed individually. Table 43-4 presents the antiparasitic drugs of choice and suggested dosages for the most common parasitic infections of the lungs.

Table 43-4
Therapy of Selected Pediatric Parasitic Pulmonary Infections

Parasite	Therapy of Choice (maximum daily adult dose shown in [brackets]; all given by mouth)
Protozoa	
Entamoeba histolytica	Metronidazole 35-50 mg/kg/day divided q8h × 7-10 days [750 mg PO q8h] ***Or*** Tinidazole 50 mg/kg/day q24h × 5 days [2 g once daily × 5 days]
Toxoplasma gondii	Pyrimethamine 2 mg/kg/day × 3 days, then 1 mg/kg/day × 4 wk [25-100 mg/day × 4 wk] **plus** sulfadiazine 100-200 mg/kg/day divided q6h × 4 wk [1-1.5 g q6h × 4 wk] **plus** leucovorin 10-25 mg/day [all ages; combination therapy for congenital infection prolonged to 12 mo]
Helminths	
Echinococcus species	Albendazole 15 mg/kg/day divided q12h × 1-6 mo [400 mg q12h × 1-6 mo] (and/or surgery; see text)
Paragonimus species	Praziquantel 75 mg/kg/day divided q8h × 2 days [all ages]
Schistosoma species	Praziquantel 40-60 mg/kg/day divided q8h × 2 days [all ages; exact dose depends on infecting species]
Ascaris lumbricoides	Mebendazole 200 mg/day divided q12h × 3 days [all ages] **OR** Albendazole 400 mg once [all ages]
Hookworm	Mebendazole 200 mg/day divided q12h × 3 days [all ages] **OR** Albendazole 400 mg once [all ages]
Strongyloides stercoralis	Ivermectin 0.2 mg/kg/day × 2 days [all ages] ***or*** Albendazole 400 mg q12h × 7 days [all ages]
Toxocara canis	Albendazole 400 mg q12h × 5 days [all ages] ***or*** Mebendazole 200 mg q12h × 5 days [all ages]

Intestinal, Blood, and Tissue Protozoa

INTESTINAL PROTOZOA

Entamoeba histolytica. Amebiasis is endemic worldwide, but the prevalence of disease is highest in areas with poorer sanitation systems, including nearly all developing countries. Although a large number of species infect humans, most human disease is associated with *E. histolytica*. Recent evidence suggests that even most organisms identified as *E. histolytica* are not actually pathogenic; rather, a minority of strains that contain a number of virulence genes cause nearly all clinical disease. Cysts are shed in the stools of individuals with intestinal infection (90% of which is asymptomatic) and are ingested by others via contaminated food or water. Direct person-to-person transmission can also occur. Although intestinal amebic disease causes dysentery, most patients with the less common extraintestinal disease do not have dysentery. The most common extraintestinal manifestation is amebic liver abscess, which typically causes fever, abdominal pain or tenderness, and leukocytosis.

Pleuropulmonary involvement is seen in only 0.1% of cases of amebiasis and usually represents a complication of amebic liver abscess.[129] An inflammatory reaction may develop adjacent to an abscess in the liver or subphrenic space, causing pleural effusion or pneumonitis. Hepatic abscesses can also rupture into the pleural space, causing localized empyema, pneumonitis, or lung abscess.[129,130] Erosion into the airways may lead to chocolate-colored sputum or even to a bronchobiliary fistula. Pericardial involvement is rarely noted. Only rarely are *E. histolytica* trophozoites identified in aspirated or expectorated material. Thus diagnosis is usually based on demonstration of serum antibodies. Extraintestinal amebiasis usually responds to treatment with antiparasitic agents such as metronidazole or tinidazole, followed by therapy with an agent directed at cysts such as paromomycin or iodoquinol to clear intestinal cyst carriage. Surgical drainage may be used as an adjunct to therapy in some cases of hepatic abscesses.

BLOOD PROTOZOA

***Plasmodium* species.** Malaria is a common infection worldwide, with more than 300 million persons infected and at least 1 million deaths per year. Uncomplicated malaria is characterized by fever, chills, and hemolysis. Malaria can be complicated by involvement of the central nervous system, kidneys, or lungs. Pulmonary involvement is thought to result from a combination of cytokine-associated damage and perhaps localized ischemia caused by vessels occluded with adherent parasitized erythrocytes.[131] The clinical picture of bilateral infiltrates and hypoxia resembles that seen in other causes of noncardiac pulmonary edema, such as the adult respiratory distress syndrome. Management involves aggressive therapy for the parasitemia with chemotherapeutic agents and possibly exchange transfusion. In addition, ventilatory support is often required.

TISSUE PROTOZOA

Toxoplasma gondii can cause clinically and radiologically discernible pneumonia, or it can be found as a silent component in patients with clinical toxoplasmosis of other organ systems.[132] Pulmonary toxoplasmosis is rare among infections in immunocompetent hosts (probably much less than 1%), but it is increasingly reported among immunosuppressed adults with malignancy or advanced AIDS.[132,133] The symptoms, signs, and radiographic findings provide few clues to the diagnosis and may easily be confused with those of *P. carinii* or cytomegalovirus disease (dyspnea, cough, fever, crackles, and interstitial infiltrates). Serologic diagnosis can be difficult in immunocompromised hosts who may not produce antibody, and thus BAL or lung biopsy may be required. Pyrimethamine combined with sulfadiazine is the standard therapeutic regimen for severe toxoplasmosis, as summarized elsewhere.[134-136] Both the mortality rate and the relapse rate among survivors have been reported to be high,[132] although the lack of prospective contemporary data may have biased these estimates.

Leishmania donovani and ***Cryptosporidium parvum*** have been identified in pleuropulmonary infections in a few cases.[129] Most of these patients had depressed immunity, most often from advanced AIDS.

Helminthic Infections

ECHINOCOCCOSIS

Epidemiology, Risk Factors, and Pathogenesis

Echinococcosis, also known as hydatid disease, is caused by the cestode parasites of the genus *Echinococcus*. The two major species that infect humans, *Echinococcus granulosus*, and *E. multilocularis*, differ in geographic location, host specificity, and disease manifestations.[137,138]

Different genetic strains of *E. granulosus* have separate domestic and wild animal (sylvatic) life cycles.[137-138] In the domestic cycle, the definitive host (i.e., the host harboring the intestinal tapeworm form) is the domestic dog. The most common intermediate host (i.e., the host harboring the tissue cyst) is sheep. Other intermediate hosts include goats, swine, cattle, buffalo, horses, and camels. In the sylvatic cycle, wild carnivores, such as wolves, coyotes, jackals, and dingoes, are the normal definitive hosts. The intermediate hosts include moose, elk, and deer. Thus, both domestic and sylvatic hydatid disease is usually acquired from domestic dogs, which are in turn infected by ingestion of either contaminated mutton/lamb/beef or game, respectively.

Human disease caused by *E. granulosus* is termed *cystic hydatid disease*. Cystic hydatid disease has a wide geographic distribution and is endemic in most areas where sheep are raised. Highly endemic areas include eastern and southern Europe, the Middle East, North Africa, Australia, and southern portions of South America. There are also endemic foci in North America. The domestic cycle has been described in sheep-raising areas of the American Southwest, such as Navajo and Zuni Indians in Arizona and New Mexico, among Mormons in Utah, and among Basque shepherds in California. The sylvatic cycle most often occurs in Alaska and Canada.

Human disease caused by *E. multilocularis* is termed *alveolar hydatid disease*. Alveolar hydatid disease is a more serious, but somewhat more geographically limited, infection in the colder portions of the Northern Hemisphere, including most of the arctic and subarctic regions, the alpine regions of central Europe, and much of Russia and central Asia. In North America, endemic areas include the subarctic tundra and scattered areas in the north central plains. The usual definitive hosts are foxes. Dogs and cats can serve as definitive hosts as well. The most important intermediate hosts are small rodents such as mice and voles.

Rarely, human hydatid disease is caused by two other species, *E. vogeli* and *E. oligarthrus*, and is known as *polycystic or multicystic hydatid disease*. These species are limited to parts of lower Central America and upper South America. The normal definitive hosts are wild dogs or cats (e.g., bush dogs, ocelots, or pumas) and the intermediate host is the paca.

After a person is infected by ingestion of parasite eggs from infected dogs, the eggs hatch in the intestines, and the larvae penetrate the intestinal mucosa into the portal veins and lodge in the liver or in some cases the lung. The cysts do not cause symptoms until they have enlarged to several centimeters in diameter. Symptoms usually result from mass effects of the expanding cyst. The rate of cyst expansion is determined in part by the tissue infected. Cysts in the liver typically expand at a rate of 1 to 5 cm in diameter per year and require years to decades before causing symptoms; thus, symptomatic pediatric disease is uncommon. Lung tissue offers less resistance than liver, such that pulmonary cysts may expand more rapidly and cause clinical symptoms earlier in life. In one recent series, one third of patients with pulmonary cysts were 20 years of age or younger.[139] Cyst rupture is associated with localized inflammation, allergic manifestations, and the formation of daughter cysts. Bacterial superinfection of the cyst may lead to symptoms suggestive of bacterial infections, such as fever and leukocytosis.

Clinical Features

Most patients with intact pulmonary hydatid cysts are asymptomatic and are discovered incidentally at autopsy or by radiographic studies. Signs and symptoms vary with the location, number, and size of cysts. Typical cystic hydatid disease causes solitary cysts in the lungs (25%), liver (60% to 70%), and rarely in other organs including muscle, spleen, brain, and bone (<5%). Isolated pulmonary disease has been reported

to be more common in children and in adults with sylvatic disease, but this finding is likely confounded by genetic strain variation among *E. granulosus*.[137,140,141] Cough, hemoptysis, and chest pain are the most common symptoms in patients with hydatid disease of the lungs. In the case of cyst rupture, patients may note abrupt onset of cough and expectoration of cyst fluid, parasite membranes (described as "grape skins"), or even scolices. Cyst rupture may also be associated with allergic manifestations, including urticaria, pruritus, and anaphylactic shock, and may lead to pneumothorax or empyema. Secondary bacterial infection is common and causes fever and purulent sputum.

One fourth of patients with pulmonary hydatid cysts also have liver involvement. Symptoms of liver disease include epigastric pain, bloating, and indigestion, and signs include hepatomegaly and obstructive jaundice. If cysts are secondarily infected, patients may have signs and symptoms of liver abscess.

Alveolar hydatid disease (caused by *E. multilocularis*) invariably involves the liver; pulmonary disease, when present, is due to metastatic lesions. Clinical disease generally is limited to adults.[142]

Radiographic Features

Pulmonary cysts are unilateral in 80% and bilateral in 20% of cases. There is a predilection for the lower lobes and the right lung over the left. Intact cysts appear as well-defined, rounded masses on chest radiographs (Fig. 43-7). Cysts adjacent to the pleura may conform to the shape of adjoining structures. On CT scan the cyst fluid is at water density, and the cyst wall may vary in thickness. Daughter cysts are occasionally seen within the cyst. If the cysts have eroded into bronchioles, air can be introduced between the pericyst and the parasite membrane, resulting in the appearance of a thin lucent crescent in the upper portion of the cyst: the "air meniscus" or "crescent" sign.[137,143-145] When the cyst has collapsed, the collapsed endocyst membrane may appear floating freely in the remaining fluid, producing an irregular air-fluid level ("water lily sign")[137,143-145] (see Fig. 43-7). Ruptured cysts may be associated with surrounding bronchopneumonia or may be secondarily infected, appearing as a lung abscess with thickened walls and an air-fluid level. Collapsed or detached endocysts or daughter cysts are more readily visualized by CT scan.[146] The role of magnetic resonance imaging (MRI) in pulmonary hydatid disease is as yet undefined.

Laboratory Diagnosis

Laboratory findings in all forms of hydatid disease are nonspecific. Only 30% or less of patients manifest eosinophilia. Serologic tests can be used to confirm a clinical diagnosis of hydatid disease. Indirect hemagglutination and enzyme-linked immunosorbent assay (ELISA) techniques are about

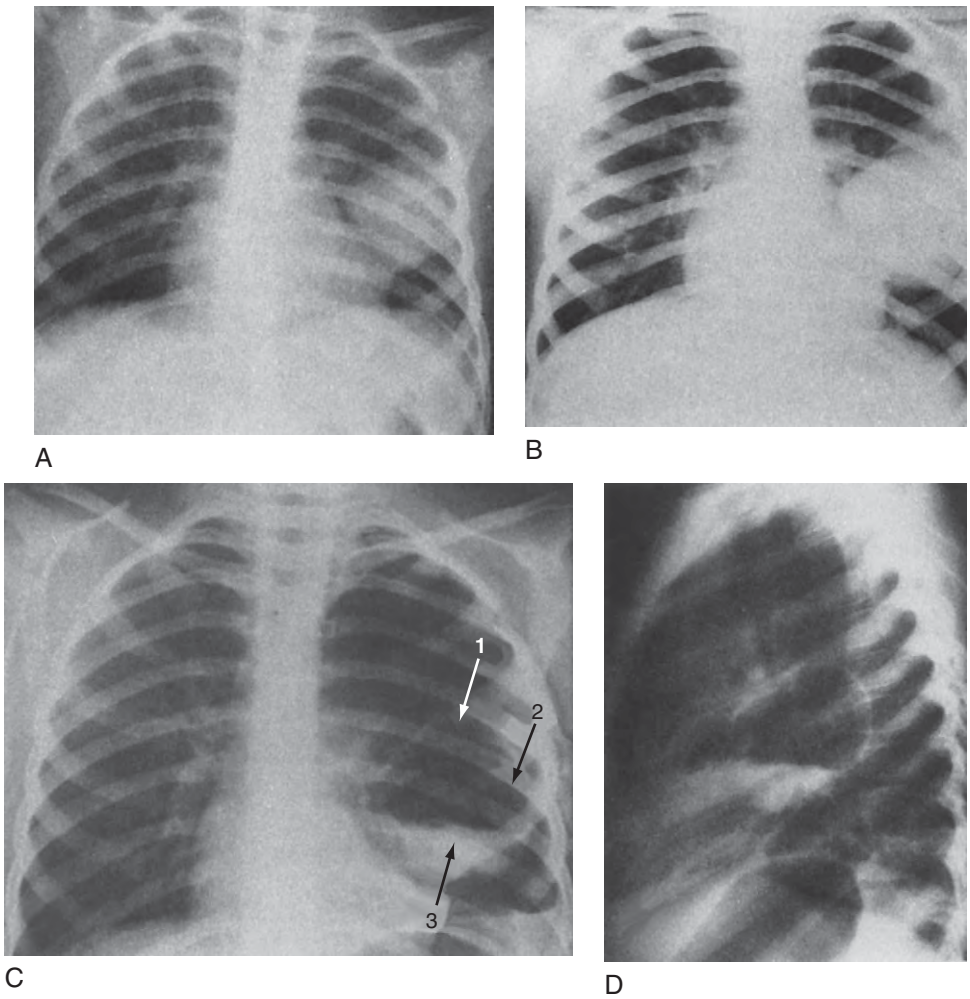


Figure 43-7 Serial chest radiographs of a 4-year-old girl with cystic hydatid disease caused by *Echinococcus granulosus*. **A,** Chest radiograph taken during asymptomatic period reveals large solitary left-lung lesion. **B,** Subsequent film taken 1 year later shows growth of cyst. **C,** The cyst has now ruptured, producing a left hydropneumothorax; the characteristic "air meniscus" or "crescent" sign is seen when air is introduced between the cyst and the host adventitia (arrow 1). The remnants of the cyst (arrow 2) appear inside the pericyst, and the irregular air-fluid level caused by the floating collapsed endocyst membrane ("water-lily sign") is also seen (arrow 3). **D,** Lateral view of the chest corresponding to **C.** (Figure reproduced from Reeder MM, Palmer PES [eds]: The Radiology of Tropical Diseases with Epidemiological, Pathological, and Clinical Correlation. Baltimore, Williams & Wilkins, 1981.)

90% sensitive.[137,147] The sensitivity of these assays is lower for isolated pulmonary disease.[137,138] Specificity can be improved by employing multiple simultaneous antigens, but currently there is no standardized highly sensitive and specific antibody test for cystic hydatid disease. For alveolar hydatid disease, assays employing semipurified antigens from *E. multilocularis* (e.g., Em2 ELISA) are suggested rather than using tests employing *E. granulosus* antigens.

In the setting of a ruptured or carefully aspirated pulmonary cyst, parasite membranes or hooks may be visualized in unstained sputum or fluid; hooks also stain well with the Ziehl-Neelsen acid-fast stain. Cyst aspiration solely for confirmation of diagnosis should not be performed in most cases of hydatid disease because of the potential risks of producing metastatic infection from, and anaphylactic reactions to, leaked fluid. In some patients, however, a definitive diagnosis may be possible only at surgery or by employing percutaneous aspiration under ultrasound or CT guidance (PAIR procedure, see later).[137,141,148,150]

Treatment

Surgical resection is the best-established therapy for pulmonary cystic hydatid disease when treatment is necessary. Until recently, all cases were believed to require radical surgery to avoid spillage of cyst contents and associated risk of anaphylaxis or the development of metastatic cysts. However, many authorities are now using a combined approach to therapy involving surgery, preoperative and postoperative antiparasitic chemotherapy, or even careful monitoring with time alone, depending on the presumed *Echinococcus* organism strain, the number and location of lesions, symptomatology, and underlying health of the patient.

If surgery is indicated (either at the onset of therapy or after a trial of chemotherapy to reduce worm viability), care is taken to avoid rupture and release of cyst contents.[151-154] For pulmonary cysts, the usual approach is to remove the entire cyst, pericyst, and a margin of normal lung. Scolicidal agents such as 70% to 90% ethanol or 10% to 15% (hypertonic) saline may be instilled into cysts before completing resection. Preoperative and perioperative chemotherapy with antiparasitic agents (e.g., albendazole) may be used to kill the scolices and prevent intraoperative spread from spillage of cyst contents.[137,138,155] *P*ercutaneous *a*spiration, *i*nstillation of scolicidal agents, and *r*e-aspiration (known as the *PAIR procedure*) has been very useful for the therapy of isolated hepatic cysts.[148,149] At present, however, there are too few data to comment on the safety or efficacy of the PAIR procedure for therapy of pulmonary cysts in adults and children, or hepatic cysts of children or pregnant women.[148,149]

The benzimidazole antiparasitic drug albendazole (and, to a lesser extent, mebendazole) is active against *Echinococcus*. Most patients will respond to antiparasitic agents, although many of the responses are only partial (i.e., reduction in size of the cysts rather than disappearance).[137,156-158] Albendazole therapy is indicated as an adjunct to surgery, or as sole therapy for those patients with inoperable, widespread, or numerous cysts, as well as for those patients who are judged to be unsuitable for surgery because of complicated medical problems.[137,155]

Alveolar hydatid disease caused by *E. multilocularis* is probably best managed by prolonged albendazole chemotherapy, because only a minority of cases of this metastatic infection can be cured by radical surgery.[137,138,142,155]

PARAGONIMIASIS

Human paragonimiasis is caused by infection with trematode lung flukes of the genus *Paragonimus*, most commonly *P. westermani*. Infection is acquired by ingesting undercooked crustaceans. Eastern Asia is the primary endemic region, but there are also foci in western Africa and, less commonly, in Latin and North America.[159,160] In endemic areas, paragonimiasis is a common cause of bronchitis and hemoptysis, and it must be differentiated from tuberculosis, which may cause similar clinical and radiographic findings.

Epidemiology, Risk Factors, and Pathogenesis

The adult parasites live within cystic lesions in the lung parenchyma.[159] The eggs are passed via tunnels into the bronchi and are either expectorated in sputum or swallowed and eventually passed in the stools. In fresh water, the eggs embryonate, hatch into miracidia, and invade snails (the first intermediate host). After a cycle of asexual reproduction, the cercarial form can either emerge from the snail and invade freshwater crabs (or sometimes crayfish) or be ingested with the snail by the crab. Infectious metacercariae form in the tissues of the crabs. Mammalian hosts are infected by ingesting raw or undercooked crab (or crayfish). In humans, the metacercariae excyst and penetrate the duodenum and, after a period of further development in the liver, penetrate the diaphragm into the lung. Over 5 to 6 weeks the parasites mature into adults, which can begin to lay eggs as early as 8 to 10 weeks after infection. The adult worms may persist in the lungs for up to 20 years.

In the lung, the parasite cysts are 1 to 4 cm nodules, typically located within a few centimeters of the pleura, adjacent to bronchi or bronchioles. The cysts consist of a pseudocapsule of host granulation tissue and contain one or two adult worms (7 to 12 mm × 4 to 7 mm). Parasite eggs and Charcot-Leyden crystals are also present within the cyst. Associated pathology may include bronchopneumonia, bronchitis and bronchiectasis, fibrosis, or angiitis. There are often tunnels, egg granulomas, and calcified eggs in the vicinity of the cysts.

Each of the three endemic regions for paragonimiasis is associated with different species of parasite and minor differences in epidemiology and clinical manifestations. The major factors necessary for transmission include the presence of large numbers of the snail and crustacean intermediate hosts and local customs in which raw or lightly cooked crustaceans are ingested. The prevalence of infection has been estimated to range from 15% to 45% in endemic regions in China and 0.3% to 78% in Korea.

Clinical Features

Acute infection is typically asymptomatic, but it may be associated with abdominal pain, diarrhea, urticaria, cough, fever, or chest pain.[159,160] Chronic pulmonary infection usually follows an incubation period of about 6 months; chronic infections may be asymptomatic or associated with symptoms of bronchitis (cough, sputum production, and chest discomfort). Many patients will complain of dyspnea and wheezing. Pleuritic chest pain and production of rusty brown ("golden flake") sputum or even frank hemoptysis are

typically present. Mild fever may be present also. Symptoms are usually episodic and are frequently associated with exertion. Some patients primarily manifest with pleural disease. Pleural effusions are exudative, frequently contain numerous eosinophils, and may be quite large. Ectopic worms sometimes can be found in the brain and abdominal cavity.

Radiographic Features

Up to 20% of patients with pulmonary paragonimiasis will have normal chest radiographs.[129] One third of patients have patchy infiltrates and one third have well-defined homogeneous densities. Many of the chest radiographs show either cystic lesions or streaks within the infiltrates, depending on the stage of the infection. Early in infection when the larvae first arrive in the lung, poorly defined cottonwool shadows are seen. Later, when the mature worms produce eggs, characteristic ring shadows with a corona (thin-walled cysts with crescent-shaped opacities along one edge) are noted.[161] Linear worm burrows may be seen adjacent to the cysts (Fig. 43-8). Pleural abnormalities are noted in up to half of all cases and may occasionally be the only abnormality.[161,162] The main CT feature of pleuropulmonary paragonimiasis is the presence of pulmonary nodules with poorly defined margins, frequently associated with adjacent areas of ground-glass consolidation and subpleural linear opacities.[163] Late in the infection after the death of the parasite, cysts often become calcified, simulating the radiographic appearance of tuberculosis (Fig. 43-8).

Laboratory Diagnosis

Laboratory tests often reveal eosinophilia. Sputum examination may reveal ova, necrotic tissue, erythrocytes, leukocytes, or Charcot-Leyden crystals. Definitive diagnosis requires demonstration of the operculated eggs in sputum or stools. Because the eggs are shed intermittently, multiple specimens or 24-hour collections are often required to demonstrate the eggs. Body fluids from involved sites, such as cerebrospinal fluid or pleural fluid, may occasionally contain eggs, but demonstration of eggs is usually not possible. A number of serologic assays have been employed and may be required to make a firm diagnosis in cases in which eggs cannot be identified, such as in extrapulmonary disease.

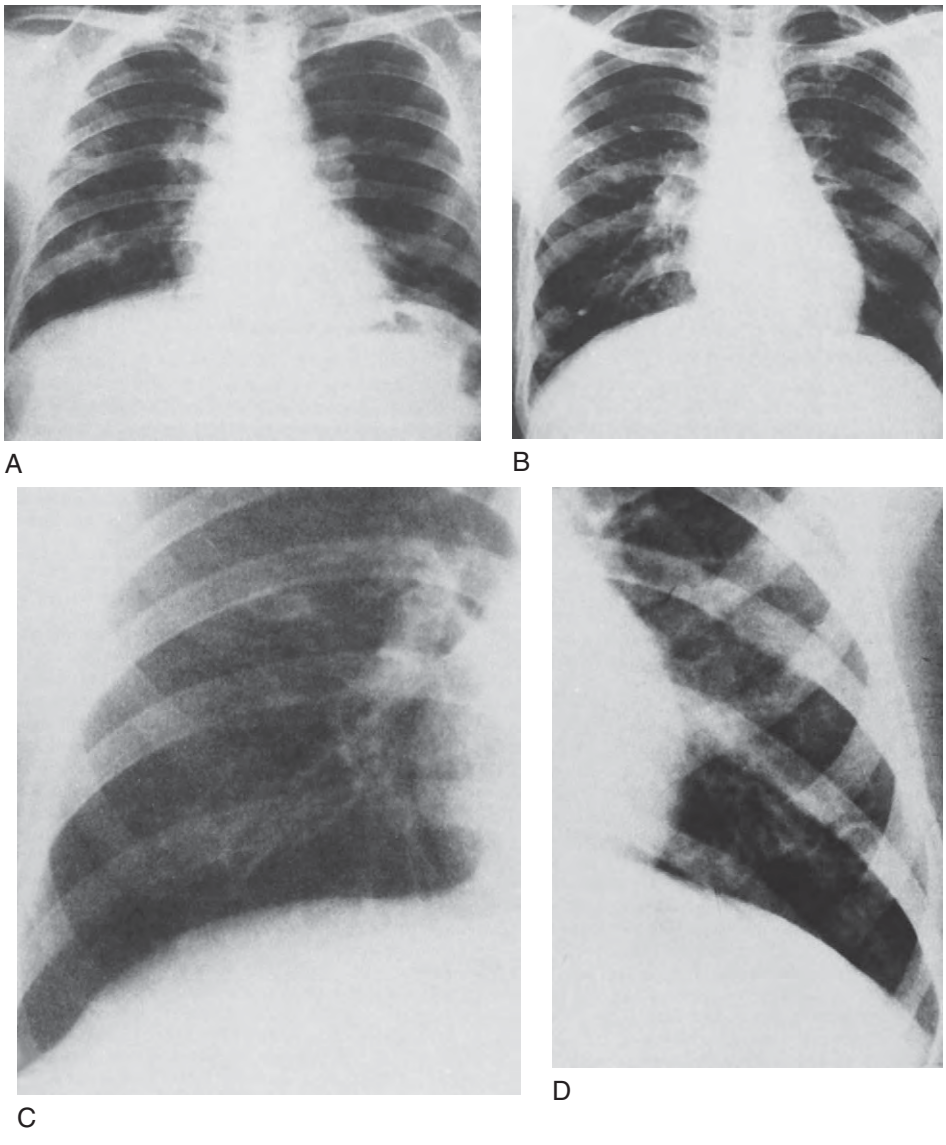

Figure 43-8 Chest radiographs from four different Korean adults with *Paragonimus westermani* infection. **A,** Multiple cystic cavities of 1 to 2 cm are seen in the right midlung and lower lung. **B,** Aggregates of 5-mm ringlike cysts appear in the right midlung, right base, and left upper lobe (especially under the left clavicle). Older calcified lesions appear in the right lung also. **C,** A single ring shadow with medial corona is seen in the right midlung. **D,** Numerous cystic cavities, some of which show coronas as well as adjacent linear tracts representing worm burrows. (Figure reproduced from Reeder MM, Palmer PES [eds]: The Radiology of Tropical Diseases with Epidemiological, Pathological, and Clinical Correlation. Baltimore, Williams & Wilkins, 1981.)

Treatment

Praziquantel is the drug of choice for treating paragonimiasis.[160,164] Symptoms improve rapidly, and eggs typically clear from the sputum in a matter of weeks, but radiographic clearing may be slower.

STRONGYLOIDIASIS

Strongyloides stercoralis is the cause of human strongyloidiasis. *Strongyloides* has a wide geographic distribution, including most of the developing world, parts of Europe, and scattered foci in the United States, especially in the Appalachian region.[165] The clinical presentation of strongyloidiasis can vary from asymptomatic infection and mild intestinal disease to fatal disseminated disease with multiple organ involvement. Unlike other nematode parasites, *Strongyloides* larvae can mature into free-living adults in the soil; furthermore, the worms also can multiply in humans without passing through the soil or any other host via an autoinfectious cycle. The *Strongyloides* hyperinfection syndrome continues to be found in immunosuppressed older adults who were infected decades earlier as a result of serving in the military in Asia during World War II, or who have immigrated from endemic areas of Asia.[166]

Epidemiology, Risk Factors, and Pathogenesis

The *Strongyloides* life cycle is more complex than that of other nematodes. It begins when infective filariform larvae in the soil penetrate intact skin. After passive migration (via the bloodstream) to the lungs, the parasites exit the capillaries into the alveoli. After further maturation in the lung, the larvae migrate up the trachea and are swallowed. The adult females attach to the small intestine and produce eggs, which are laid in the lamina propria. The eggs hatch within the lumen of the gut, and rhabditiform larvae are excreted into the soil, where they either molt into infective filariform larvae or mature into free-living adults. The free-living adults, unique among the pathogenic nematodes, can lay eggs in the soil that will hatch into rhabditiform larvae; these larvae will subsequently molt into infective filariform larvae. The "autoinfective cycle" of *Strongyloides* arises when some of the rhabditiform larvae in the intestines or perianal area molt into filariform larvae before reaching the soil. These filariform larvae can directly reinfect the host by penetrating either the colonic mucosa or the perianal skin. It is the autoinfective cycle that is thought to be responsible for chronic infection (which can last for many decades) as well as significant illness in the subsequently immunocompromised host.

Strongyloidiasis is primarily acquired by skin contact with contaminated soil. There is no clear evidence of direct person-to-person transmission. Fecal-oral spread is thought to occur rarely.[167]

In most cases, strongyloidiasis is only mildly symptomatic. Intestinal infection is associated with congestion and mononuclear cell infiltration. There are descriptions of rare cases with sprue-like malabsorption. Migration of the larvae through the lungs may stimulate a hypersensitivity response presenting as asthma and eosinophilia (Loeffler's pneumonia).

In uncomplicated cases of chronic infection, low numbers of parasites are in equilibrium with the host. Disease is primarily abdominal and cutaneous in nature; respiratory complaints are distinctly unusual, but asthma and chronic obstructive lung disease have been reported.

The symptomatic *Strongyloides hyperinfection syndrome* occurs primarily in immunocompromised hosts. Although the hyperinfection syndrome has been associated with various malignancies, renal disease, asthma, and autoimmune diseases, in industrialized countries the majority of cases occur after corticosteroid treatment.[168,169] In areas of the world in which the human T-cell lymphotrophic virus-1 (HTLV-1) and strongyloidiasis are co-endemic (much of Africa, the Caribbean, South America, and Asia), there is an increase in the prevalence of severe hyperinfection syndrome, refractory to treatment, among persons with HTLV-1 infection.[169,170] HTLV-1 infection appears to shift the immune response toward activation of Th-1 cells, with greater production of interferon-γ and decreased production of interleukins 4 and 13. This is the reverse of the Th-2 predominant profile thought important in controlling *Strongyloides* replication and inducing anti–*S. stercoralis*–specific IgE antibody.[170] Whether *Strongyloides* infection reciprocally worsens HTLV-1 clinical disease in addition is unclear from the current conflicting data.[170] In the past, it was thought that hyperinfection primarily resulted from failure of the host response (e.g., eosinophils, IgE, mast cells) to kill migratory larvae. More recently, it has been hypothesized that hyperinfection instead may result from a direct effect of corticosteroids or HTLV-1 infection on larvae, via acceleration of molting and parasite maturation.[168-170] This theory would explain why patients with HIV infection–induced immunocompromise living in endemic areas for strongyloidiasis do not commonly develop the *Strongyloides* hyperinfection syndrome, unless treated with corticosteroids or coinfected with HTLV-1.[168-170]

Patients with the *Strongyloides* hyperinfection syndrome have massive worm burdens, with hundreds of thousands of adult parasites in the intestines.[167] The lung is the primary extraintestinal organ involved. Damage to the lung is in part mechanical. Passage of larvae from the bloodstream to the alveoli causes microhemorrhages. When there are low numbers of larvae the microhemorrhages are of little consequence. With hyperinfection and dissemination, however, innumerable microhemorrhages may lead to massive pulmonary hemorrhage, manifested as hemoptysis, pulmonary infiltrates, and respiratory distress. Because alveolar hemorrhage may occur after treatment, some have speculated that immunologic mechanisms may also be involved. Larval migration from the intestines may be associated with invasion of the bloodstream by bacteria, either because of breaks in the mucosa or in association with the parasite cuticle.

Clinical Features

Chronic strongyloidiasis may be asymptomatic. When symptoms are present, they are often nonspecific: abdominal pain, bloating, heartburn, diarrhea, constipation, and chronic urticaria.[167,171] When the filariform larvae migrate through the skin, serpiginous urticarial lesions termed larva currens may be noted. These lesions appear to reflect both direct parasite migration and an associated hypersensitivity response. Cough, dyspnea, wheezing, and fleeting pulmonary infiltrates also have been described in association with larval migration, as have asthma and chronic obstructive lung disease. Although the role the parasite plays in the pathogenesis is not clear,

strongyloidiasis should thus be considered in patients with asthma and significant concomitant eosinophilia.

The *Strongyloides* hyperinfection syndrome, which may occur days to months after the initiation of immunosuppression, primarily causes gastrointestinal and pulmonary manifestations.[167,171] In contrast to uncomplicated disease, most patients with hyperinfection do not have eosinophilia. In addition to severe abdominal pain, nausea, vomiting, and diarrhea, hyperinfection may progress to intestinal obstruction, paralytic ileus, gastrointestinal bleeding, protein-losing enteropathy, peritonitis, and shock. The pulmonary symptoms of hyperinfection are nonspecific. A minority of patients will have only bronchospasm, but most patients will have pulmonary infiltrates (which may be focal or diffuse), opacities with or without cavitation, or consolidation. Common symptoms include cough productive of sputum, hemoptysis, dyspnea, and wheezing. Respiratory failure may develop in severe cases. In nearly one third of cases, hyperinfection is accompanied by severe bacterial infections.[166,167] These infections include pneumonia, lung abscess, sepsis, meningitis, and brain abscess. The most common bacterial isolates are enteric gram-negative bacilli and group D streptococci (including *Enterococcus*).[166] The source of enteric bacteria may be damaged intestinal mucosa, organisms associated with the surface of the filariform larvae, or even organisms from the parasites' intestinal tracts. Other systems commonly affected include skin, liver, and biliary tract.

Radiographic Features

The results of intestinal radiographs are typically nondiagnostic but may show gastritis, duodenitis, and mucosal thickening, spasm, and transverse folds in the duodenum. In hyperinfection, there may be disruption of the mucosa, ulcerations, or ileus.[167]

Chest radiographs are usually normal in uncomplicated disease. In contrast, hyperinfection is usually accompanied by changes on chest radiographs.[167] Pulmonary infiltrates are typically diffuse but may be focal. Lobar consolidation may occur with or without accompanying bacterial superinfection. Some patients have localized nodules. Cavitation and abscess formation have been associated with both infiltrates and nodules.

Laboratory Diagnosis

Uncomplicated strongyloidiasis is usually diagnosed by examination of three separate stool specimens for rhabditiform larvae. Because the burden of organisms is low, larvae may be difficult to detect, however, and a positive diagnosis cannot always be obtained even with multiple specimens.[167] Additional methods of diagnosing infection include sampling of duodenal fluid for larvae (string test), duodenal biopsy, and serologic assays for antibody. ELISA titers are available from the Centers for Disease Control and Prevention.

For patients with hyperinfection, demonstration of parasites is less difficult. The key is to consider the diagnosis of strongyloidiasis in immunocompromised hosts with nonspecific symptoms. The burden of parasites in the stool is high.

Treatment

Ivermectin is the drug of choice for the treatment of strongyloidiasis.[168-173] For nondisseminated strongyloidiasis, ivermectin is given on each of 2 days; for disseminated strongyloidiasis (hyperinfection syndrome), prolonged or repeated courses of therapy may be required (data are lacking to determine the optimal regimen). Albendazole, a broad-spectrum benzimidazole antiparasitic agent, is an alternative to ivermectin.[169,171,172] The older, more toxic alternative (thiabendazole) is generally no longer recommended if ivermectin or albendazole is available.

VISCERAL LARVA MIGRANS

Migration of larvae of several nematode species through the liver, lung, and central nervous system can give rise to the syndrome of visceral larva migrans, causing pulmonary manifestations such as asthma and eosinophilic pneumonitis. Although most of the infections are due to *Toxocara canis*, the canine roundworm, a similar clinical picture can be seen with *Toxocara cati*, the cat roundworm, *Ascaris suum*, a pig roundworm, and, rarely, *Baylisascaris procyonis*, a raccoon ascarid (although the latter is much more associated with severe meningoencephalitis rather than pulmonary disease).[174,175]

Toxocara is endemic worldwide, and human toxocariasis has been recognized in nearly every country. In the United States, most of the 52 million domestic dogs are infected with *Toxocara*, usually from perinatal exposure.[176] Up to one third of puppies and dogs at any one time pass *Toxocara* ova into the soil. The eggs can withstand a wide variety of environmental conditions and remain infective for years. *Toxocara* eggs can be recovered from yards of homes, parks, and playgrounds frequented by children. The seroprevalence of antibodies to *Toxocara* in the United States is 2.8%, with rates of 4.6% to 7.3% in children aged 1 to 11 years.[177] In contrast, seroprevalence rates in developing countries are typically 50% to 80%.[176] Infection is most associated with pica and geophagia.

Epidemiology, Risk Factors, and Pathogenesis

The life cycle of *T. canis* in dogs is similar to that of *Ascaris* in humans. After ingestion of the ova, the larvae hatch, migrate through the lungs, are swallowed, and develop into adult worms in the canine intestines. Ova are shed in the stool but must embryonate in the soil over a period of weeks before they are infectious. In general, humans are infected after ingesting embryonated eggs from the soil (e.g., young children with geophagia or pica). A recent report of an adolescent with pulmonary and abdominal visceral larva migrans after ingestion of an earthworm showed that *Toxocara* eggs can be transmitted by soil-contaminated objects as well.[178] The *Toxocara* ova hatch in the intestines and penetrate the intestinal wall. Humans are an abnormal host, however, and the larvae are unable to complete their migration and maturation into adult worms. Instead, the larvae continue to migrate through the tissues of the liver, the lungs, and, to a lesser extent, the eye and the central nervous system. The larvae can continue to migrate for years within the human viscera.

Migratory larvae and their excretory products induce a strong local inflammatory response, with eosinophils as the predominant cell. Most patients also have a prominent peripheral eosinophilia. Hemorrhages may be noted at sites where the larvae exit the host venules. Asthma and urticaria are associated with an elevated IgE response. When the larvae

become trapped in the host tissues, they typically induce an eosinophilic granulomatous response, which may subsequently lead to fibrosis and calcification. Thus disease is related to both parasite migration and host inflammation.

The pathogenesis of *Toxocara* infections is thought to be related to the number of infecting organisms.[179] Thus infections with low numbers of organisms evoke only a minimal immune response. In these cases, disease may not be apparent until the larvae migrate to the eye (causing the ocular larva migrans syndrome). Heavier infections elicit a stronger host response, with larvae trapped and destroyed in the liver and lungs causing symptoms of visceral larva migrans. Rarely, as the numbers of larvae increase still further (e.g., a large inoculum in a very young child), the host is unable to trap the migratory larvae, and patients may have both visceral and ocular larva migrans.

Clinical Features

The clinical presentation of visceral larva migrans varies with the number of larvae and the organs infected. Most infected patients are asymptomatic, but some have pulmonary symptoms and signs.[174,176,178-181] Cough is the most common symptom, and wheezing is reported in over half of cases. Examination may reveal wheezes, crepitations, or signs of consolidation. One third to one half of patients have pulmonary infiltrates. Visceral larva migrans should be considered in children with asthma of unknown cause, especially with a history of pica. Eosinophilia is usually present and may be pronounced. However, recent descriptions note normal eosinophil counts in up to 27% of patients with elevated *Toxocara* titers.[180] Other common clinical manifestations of visceral larva migrans relate to involvement of the abdomen: abdominal pain, hepatomegaly, anorexia, nausea, and vomiting. Lethargy and sleep and behavior disturbances are also common. Only a minority of patients have cervical lymphadenopathy or fever.

Ocular larva migrans is generally distinct from visceral larva migrans, and takes the form of leukocoria and posterior granulomas (mimicking retinoblastoma), chronic endophthalmitis, retinal detachment, and uveitis. It is distinctly unusual to see any visceral signs or symptoms in children with ocular disease, and such patients are generally older (mean age, 8 years versus 2 years for visceral disease) and have normal eosinophil counts and lower antibody titers.

Occasional involvement of the nervous system may take the form of seizures, eosinophilic meningitis, or one of a variety of focal neurologic symptoms.[181]

Radiographic Features

The chest radiograph will be abnormal in 30% to 50% of cases of visceral larva migrans. Abnormalities are described as alveolar, interstitial, or miliary. The infiltrates may be unilateral or bilateral, patchy or diffuse. Infiltrates are often migratory. Hilar adenopathy may be present.

Laboratory Diagnosis

It is difficult to make a definitive specific diagnosis of visceral larva migrans. Definitive diagnosis requires the demonstration of larvae in biopsy specimens, especially from the liver. A presumptive diagnosis, however, can be made based on a consistent clinical picture in a child with a history of soil, grass, or feces pica. Because the human host does not allow the worms to mature, no ova are found in the stool.

Eosinophilia, hyperglobulinemia (IgG, IgM, and IgE), and elevated isohemagglutinin titers (due to worm surface components that cross-react serologically with blood-group antigens) are often found in children with visceral larva migrans. Anti-*Toxocara* antibody tests also aid in diagnosis. An ELISA assay employing *Toxocara* larval excretory-secretory antigens has been shown to be a specific indicator of *Toxocara* infection (using a cutoff of 1:32, sensitivity in visceral larva migrans of 73% to 78%, and specificity >90%).[174,179] Many of the "negative" specimens nonetheless showed low but detectable titers of antibody (1:8 to 1:16). There are some cross-reactions to other species of ascarids. A positive ELISA does not ensure that a patient's illness is due to *Toxocara*, because a small percentage of normals will also have antibody titers.

Treatment

The symptoms usually regress spontaneously over a period of months to years such that mild disease may not require specific treatment. Treatments include measures aimed at decreasing the host inflammatory response in addition to antihelminthic drugs. Antihistamines have been used to diminish symptoms in some cases. Corticosteroids may dramatically reduce pulmonary inflammation and are indicated in life-threatening infection, including severe bronchospasm and disease of the myocardium or central nervous system.

A course of oral albendazole for 5 to 21 days, often supplemented by prednisone for symptomatic children, is generally suggested for therapy of visceral larva migrans. Older alternative agents include the less bioavailable mebendazole, and the more toxic (and perhaps less effective) agents thiabendazole and diethylcarbamazine.[174,176,182,183]

OTHER HELMINTHIC INFECTIONS

Tropical pulmonary eosinophilia is one of the causes of the syndrome of pulmonary infiltrates with eosinophilia.[129,184] The disease is thought to represent an unusual immunologic reaction to the microfilariae of parasites more commonly associated with lymphatic filariasis (*Wuchereria bancrofti* and *Brugia malayi*). The clinical presentation includes cough, wheezing, and peripheral blood eosinophilia. Patients have a gradual onset of cough and paroxysms of wheezing and breathlessness mimicking asthmatic attacks. Systemic complaints can include fever, weight loss, and fatigue. Chest radiographs show increased vascular markings, diffuse interstitial nodular lesions, and mottled opacities. Pulmonary function tests usually show restrictive defects, although obstructive defects are also noted. Antifilarial antibodies are present and can be used to confirm the diagnosis. Patients usually respond to treatment with diethylcarbamazine given for 3 weeks, although several courses may be required.

Pulmonary symptoms can also be identified during larval migration through the lungs for *Ascaris lumbricoides*, hookworm, and other roundworms.[129,185] The symptoms and pathogenesis are similar to those seen with *Toxocara* infection. However, because the larvae are able to complete their normal migration, symptoms are self-limited (i.e., there is no chronic larva migrans stage), and ova do later appear in the stool. *Ascaris* infections with low numbers of organisms are usually asymptomatic. Symptoms may develop 9 to 12 days

after ingestion of large numbers of ova and include cough, chest discomfort, wheezing, and hemoptysis. Some patients have urticaria or pruritic skin lesions. Low-grade fever is common. On examination, there may be wheezing and crepitations, but signs of consolidation are absent. Chest radiographs may reveal oval infiltrates, which are migratory. Eosinophilia is characteristic. Symptoms resolve spontaneously in 5 to 10 days. Diagnosis at the time of chest symptomatology requires demonstration of the larvae in sputum or gastric aspirate, because ova passed in the stool are not produced until weeks after pulmonary symptoms resolve. Occasionally, coincidental worm migration through endotracheal tubes has been noted during induction of anesthesia in otherwise asymptomatic children (G. A. Weinberg, unpublished observations). Therapy of ascariasis is given with mebendazole for 3 days or albendazole once. After therapy, migrating worms may be expelled orally and adult worms rectally.

Schistosomiasis is caused by infection with the blood flukes *Schistosoma mansoni*, *S. japonicum*, *S. hematobium*, *S. mekongi*, and *S. intercalatum*.[129] Approximately 200 million people are infected worldwide, with endemic areas in Asia, the Middle East, Africa, and Latin America.[186] Schistosomiasis has become an infection noted in industrialized countries among returning travelers.[186-188] Human infection is acquired by penetration of the skin by cercaria released from freshwater snails. The adult worms live in the mesenteric (most species) or vesical (*S. hematobium*) venules. Disease results from a granulomatous reaction to the released, embolized eggs, resulting in portal hypertension or fibrosis of the urinary tract. Eggs may also migrate to the lungs, where chronic granulomatous inflammation may cause an obliterative arteriolitis that may result in pulmonary hypertension. Schistosomiasis is treated with praziquantel.

Rarely, the canine heartworm, *Dirofilaria immitis*, can cause solitary pulmonary nodules in humans (zoonotic filariasis), most of which are asymptomatic and often coincidentally discovered.[129,189] This infection has only been described in adults, despite the fact that pediatric contact with dogs is frequent. The clinical significance of these nodules is their frequent diagnostic confusion with malignancy; no specific antiparasitic therapy is required.

CHAPTER 44 Interstitial Lung Disease

Gregory J. Redding, Robin R. Deterding, and Leland L. Fan

TEACHING POINTS

- Many etiologies for interstitial lung disease in infants and young children do not produce inflammation or fibrosis by lung histology. In these cases, use of corticosteroid therapy may have no role.
- Genetic mutations in genes that influence surfactant metabolism, including surfactant proteins B and C and genes for ABCA3, can produce several forms of histologic interstitial lung disease.
- Noninvasive diagnostic techniques can identify a specific etiology of childhood interstitial lung disease (chILD) syndrome in up to one fourth of cases.
- Lung biopsy is the current standard for diagnosis of primary pulmonary etiologies for chILD syndrome.
- Mutations in the genes for surfactant protein C and ABCA3 proteins tend to produce severe lung disease in newborns but can also produce milder disease with onset later in childhood.

Concepts about pediatric interstitial lung disease (ILD) have undergone dramatic changes with new nomenclature and the recognition of new clinical entities not encountered in adults. In fact, the term ILD has become controversial because it includes a variety of rare and heterogeneous pulmonary disorders involving the lung parenchyma and not exclusively the pulmonary interstitium. Radiographic changes associated with ILD, including ground glass, reticular, nodular patterns, reflect alveolar, vascular, and interstitial involvement on histology. Changes in lung function associated with ILD are not specific to the pulmonary interstitium. As a result, a new term, "childhood interstitial lung disease" syndrome (chILD syndrome) has been coined to include pulmonary disorders involving the acinar regions of the lung.[1] Importantly, many of the entities included under the chILD syndrome do not result from interstitial inflammation or the propensity for fibrosis cited in adult literature.[2] Consideration of chILD syndrome is raised in children who present with acute or chronic respiratory symptoms, respiratory signs on physical examination, hypoxemia, and diffuse radiographic changes in the absence of known causes of lung disease. A combination of any three of these four features identified 91% of 336 children with ILD in a recent retrospective chart review.[3] Clinical algorithms for diagnostic evaluations have been expanded to include this broader group of disorders.

ILD in children is rare compared to other forms of pediatric lung disease and is less common in children than ILD in adults. A descriptive study from the United Kingdom estimated a prevalence of 3.6 cases per 1,000,000 children less than 16 years of age based on a survey among physicians.[4] However, the definitions and nomenclature are dated and may under-represent the true prevalence among infants and children. In contrast, Coultas and colleagues reported an incidence of ILD to be 31.5 and 26.1/100,000 per year in adult men and women, respectively, in a population-based study over a 2-year period.[5] The categories of etiologies that cause ILD in infants and children are listed in Box 44-1. This chapter focuses on primary pulmonary etiologies for pediatric ILD and chILD syndrome. It does not describe etiologies associated with known exposures such as hypersensitivity pneumonitis or radiation-induced injury, recurrent aspiration, drug responses, and pulmonary hemorrhage; nor does it address the pulmonary complications of systemic disease such as connective tissue disorders, sarcoidosis, histiocytosis, inflammatory bowel disease, or immunodeficiencies.

NOMENCLATURE AND CLASSIFICATION OF ILD IN CHILDREN

The American Thoracic Society (ATS)/European Respiratory Society (ERS) consensus statement in 2002 standardized common histologic patterns of ILD in adults.[6] However, these patterns often do not resemble pathologic features of lung tissue from infants and children with chILD syndrome. Consequently, a new histologic classification system is being developed based on review of 187 pediatric lung biopsies of children with diffuse lung disease by a pathology cooperative from 11 medical centers in North America.[7] This classification, pertaining to immunocompetent children <2 years of age, includes disorders of lung growth (e.g., pulmonary hypoplasia), lung development (e.g., alveolar capillary dysplasia), and genetic disorders of surfactant metabolism. Importantly, many of these conditions are not associated with inflammation or fibrosis, and underscore the need for a specific histologic diagnosis before considering anti-inflammatory therapy. A detailed version of this classification system is in preparation for publication. Over the last decade, conditions specific to infants and young children have been described and then

BOX 44-1 General Etiologies for ILD in Children

- Infections (viral, *Pneumocystis,* fungal)
- Inhalation injury
  - Aspiration
  - Hypersensitivity pneumonitis
- Exposures
  - Drug reactions
  - Radiation injury
- Congenital or acquired immunosuppression-associated disease
  - Post–bone marrow transplantation (noninfectious)
- Systemic diseases
  - Connective tissue disease
  - Storage and metabolic diseases
  - Post-transplantation disease
  - Leukemia, histiocytosis
  - Lymphoproliferative disorders
  - Sarcoidosis
  - Churg-Strauss vasculitis
  - Eosinophilic pneumonia
- Pulmonary hemorrhage syndromes
  - Pulmonary hemosiderosis
  - Pulmonary capillary hemangiomatosis
  - Diffuse capillaritis
- Cardiovascular disease
  - Post–pulmonary capillary obstructions, e.g., anomalous pulmonary venous return
- Structural abnormalities
  - Lymphangiectasia
  - Lymphangiomatosis
- Metabolic disease
  - Lysinuric protein intolerance
  - Lysosomal storage disease
  - Neurofibromatosis
  - Gaucher disease
  - Niemann-Pick disease
  - Farber lipogranulomatosis
  - Pulmonary alveolar microlithiasis
  - Inborn errors of surfactant metabolism

renamed after further study. Persistent tachypnea of infancy, described in 2001,[8] is likely the same condition as neuroendocrine cell hyperplasia (NEHI) syndrome, described in 2004.[9] Cellular interstitial pneumonitis (1992)[10] represents pulmonary interstitial glycogenosis, described in 2002.[11] Chronic pneumonitis of infancy (1995)[12] includes some children with underlying genetic mutations in the gene for surfactant protein C and the ABCA3 gene.[13] Notably missing is usual interstitial pneumonitis (UIP), also known as cryptogenic fibrosing alveolitis or idiopathic pulmonary fibrosis. Katzenstien described fibroblastic foci within the leading edges of the fibrotic regions in UIP from adults, but these foci have not been identified in several case series of children previously diagnosed with UIP.[14-16] Although a recent large series identified 46 children with idiopathic pulmonary fibrosis, it is unclear if this represented UIP or other forms of ILD (e.g., nonspecific interstitial pneumonitis [NSIP]), that progressed to a fibrotic stage.[17] Further prospective and retrospective reevaluation of histology in children diagnosed with UIP should resolve this controversy.

Table 44-1
Clinical Presentation of 185 Infants and Children with Interstitial Lung Disease

	All Patients	Patients Aged <2 Yr
Patients (no.)	233	58
Symptoms		
Cough	78%	73%
Tachypnea/dyspnea	76%	84%
Failure to thrive	36%	62%
Fever	16%	29%
Physical Findings		
Cyanosis	26%	54%
Clubbing	16%	9%
Crackles	47%	57%

From Clement A: Task force on chronic interstitial lung disease in immunocompetent children. Eur Respir J 24:868-697, 2004; and Fan LL, Mullen ALW, Brugman SM, et al: Clinical spectrum of chronic interstitial lung disease in children. J Pediatr 121:867-872, 1992.

In addition, different histologic diagnoses of ILD can result from a single genetic abnormality. Surfactant protein C deficiency causes pediatric ILD that can appear on histology as DIP, UIP, NSIP, or chronic pneumonitis of infancy.[18-21] Conversely, the histologic pattern of pulmonary alveolar proteinosis can result from mutations in the genes encoding surfactant B or C proteins, the ABAC3 gene, a transmembrane protein and member of the ATP binding cassette family, or the beta c chain of the receptors for GMCSF/IL-3/IL-5.[22-24] Although pulmonary histopathology remains the standard for diagnoses of ILD in children, genetic diagnoses may prove to be a more cohesive classification system for some of these disorders in the future. Further understanding as to how specific genetic mutations produce different histologic patterns of ILD will also improve the current classification system of chILD syndrome.

CLINICAL PRESENTATION AND ASSESSMENT OF SEVERITY OF ILD IN CHILDREN

Clinical symptoms at presentation include nonproductive cough, fatigue, and dyspnea with exertion, such as during feeding in infants and exercise in older children.[17,25,26] Less common symptoms include fever, wheezing, anorexia, chest pain, and poor growth. In severe cases, cyanosis and dyspnea at rest may also be present. Symptoms of chILD syndrome can begin at any age. Onset of symptoms can be acute and life-threatening, particularly in the neonatal period. Although acute ILD occurs in older children, an insidious onset of symptoms is more common in this age group and the specific onset of symptoms may be difficult to ascertain. Consequently, children may present initially with severe disease because they have adapted to the gradual progression of disease over months and years.[25-27] "Chronic" ILD has been defined as greater than 1 and 3 months' duration by U.S. and European literature, respectively.[17,28]

Common physical findings in children with ILD in two case series are listed in Table 44-1 according to relative frequencies and age at diagnosis.[17,25] Infants in particular present

with failure to thrive and tachypnea. Other reported physical findings were chest wall retractions in 22 of 48 children (46%) and wheezes in 9 children (22%).[25]

Pulmonary function and lung imaging studies are abnormal in most children with chILD. The characteristic features produced by chILD syndrome in older children are restrictive lung mechanics and hypoxemia, first evident during exercise and later at rest. Vital capacity is reduced more than functional residual capacity and residual volume.[29] Total lung capacity is therefore reduced but less so than vital capacity. Lung compliance, measured as a rightward shift in the static expiratory pressure-volume curve, is also reduced.[30] Some children have mixed obstructive-restrictive abnormalities, with reduced flows or elevated FRC. Recent data using infant lung function tests showed that infants with neuroendocrine cell hyperplasia (NEHI) have significant air trapping and reduced forced expiratory flows, whereas infants with surfactant protein C deficiency and pulmonary interstitial glycogenosis (PIG) have reduced vital capacities with minimal air trapping.[31] Hypoxemia without hypercapnia is the most common gas exchange abnormality in children with chILD syndrome. Cardiopulmonary exercise testing is useful to establish baseline functional limitations in older children when disease is mild. In adults, a simpler and useful method is measurement of oxyhemoglobin saturation during a standardized 6-minute walk test.[32] Lung diffusion capacity corrected for hemoglobin and alveolar volume may be reduced if alveolar-capillary surface area is reduced, but it also can be normal or even increased if significant pulmonary parenchymal bleeding has occurred.

Typical chest radiographic abnormalities among children with chILD include hazy parenchymal densities in reticular, nodular, or ground-glass patterns. The densities are usually bilateral and often diffuse. Normal-appearing chest radiographs have been reported in symptomatic adults and children with ILD.[33,34] However, the plain chest radiograph has been replaced by high resolution computed tomography (HRCT) as the imaging technique of choice owing to improved sensitivity in detecting disease and more precise definition of the distribution and pattern of disease. Common pulmonary patterns by HRCT in children with chILD include ground-glass densities, nodules, cystic changes, and tissue consolidation—all of which can be either patchy or diffuse.[35] HRCT scans in young children and infants who cannot hold their breath are obtained at controlled lung volumes at full inspiration and passive expiration, often under anesthesia or sedation, and in some cases while patients are intubated.[36] HRCTs at low lung volumes identify areas of air trapping, suggesting the presence of airway disease. In children with radiographic densities in dependent regions, HRCTs are obtained in both the prone and supine positions. The use of helical or spiral HRCT tailored to the size of the child and performed only in regions of interest reduces the delivered radiation dose.[37]

Among infants with severe ILD, pulmonary hypertension can be life threatening and produce refractory hypoxemia because of right-to-left shunting through the ductus arteriosus or foramen ovale. In two case series of 74 infants and children presenting with ILD, 45% had evidence of pulmonary hypertension, reflecting the insidious progression of disease and severity at the time of diagnosis.[25,26] In older children, elevated pulmonary artery pressures, measured by echocardiography, may exist during and immediately after exercise before progressing to pulmonary hypertension at rest.[38] Pulmonary hypertension may reflect, in part, the involvement of the pulmonary vasculature with an underlying disease, as is seen in connective tissue disorders. Alternatively, it reflects the extent to which the lung is involved with the underlying process and represents a marker of severity.

Assessment

The pace of evaluation and choice of diagnostic tests depends on age at presentation, immunocompetence, chronicity and severity of disease, and trend over time toward improvement. These features particularly influence the choice to use invasive techniques (e.g., lung biopsies) early. Presentation of chILD in the newborn period mandates a more aggressive approach because many infants with chILD are extremely ill and may have lethal conditions. Given the broad range of clinical considerations, there is no universally accepted algorithm for diagnosis.

Laboratory evaluations are used for two purposes: (1) to quantify functional severity, changes in severity over time, and changes in response to therapy and (2) to identify an etiology for the chILD syndrome. Spirometry and total lung volumes, diffusion capacity, exercise tests, and hemodynamic assessments are more useful to assess functional severity than to identify a diagnosis. Imaging studies are used to diagnose and assess extent of disease, identify sites to biopsy, and monitor changes in patterns and extent of disease over time. Both imaging and lung function studies are used to monitor patients with chILD syndrome but trends in these studies do not necessarily correlate with one another or coincide over time.[17] This poses a challenge of defining responses to therapy.

In contrast to the manifesting clinical features of chILD syndrome, the characteristics that portend shortened survival are symptoms and hypoxemia at rest and pulmonary hypertension.[39] Aside from neonates, age of onset of symptoms and duration of symptoms do not predict longevity, nor do physical findings of crackles, clubbing, or weight less than 5% than predicted.[39] Specific histologic diagnoses clearly influence prognosis, and values for spirometry (FVC) and lung diffusion capacity associated with ILD in adults have been used to predict survival.[40] However, functional assessments, apart from gas exchange and pulmonary hemodynamics that predict longevity, have not been described in children.

Most children with chILD who present with symptoms after 1 month of age have features of a chronic pulmonary process. Exceptions include children with pulmonary hemorrhage, acute interstitial pneumonia, and acute eosinophilic pneumonia. Among both adults and children with chronic ILD, a noninvasive evaluation followed by selective invasive techniques usually yields a specific diagnosis and minimizes the use of unnecessary procedures.[41,42] Fan and colleagues reported that one fourth of children with ILD were successfully diagnosed without use of invasive procedures.[41] The initial choice of tests follows medical history of exposure, recurrent infections, known immunodeficiencies, known underlying conditions, such as rheumatologic or oncologic disease, and past medical treatments such as radiation or

organ transplantation. A family history should include any early infant deaths, use of prolonged oxygen by family members, and any chronic childhood or adult disease. A history of extrapulmonary organ involvement, such as renal disease (Goodpasture syndrome), inflammatory bowel disease (ulcerative colitis and Crohn disease), skin rash (Churg-Strauss disease), and sinus disease (Wegener granulomatosis), may lead to diagnosis by evaluating these affected organs. Gastroesophageal reflux with or without aspiration can represent either an etiology for chILD syndrome or the consequence of increased work of breathing associated with the underlying ILD, or both.

When a diagnosis is not suggested by history, certain screening procedures are necessary to address broad categories of etiologies of chILD syndrome. An echocardiogram will identify occult congenital heart disease and obstructed pulmonary veins. An evaluation for occult congenital or acquired immunodeficiency and a screen for rheumatologic and autoimmune diseases (in older children) are necessary, as the lung may be the first organ affected in some patients. The HRCT scan may be suggestive (e.g., subpleural cysts in association with connective tissue disorders [Fig. 44-1][43]) or sufficiently characteristic to avoid a lung biopsy. Examples of the latter are bronchiolitis obliterans, lymphangiectasia, and NEHI syndrome (Fig. 44-2).[9]

When these tests are not revealing, bronchoalveolar lavage (BAL) is used to sample the lung for infectious etiologies, parenchymal cell populations, and noncellular material, such as that found in pulmonary alveolar proteinosis. A few cell types in BAL, such as Langerhans cells staining for S100 and CD1a, are pathognomonic of histiocytosis.[44] Erythrocytes and hemosiderin-laden macrophages in BAL are very suggestive of pulmonary hemorrhage but do not indicate the nature of pulmonary bleeding (e.g., vasculitis versus idiopathic etiology). Lipid-laden macrophages in BAL may be found with aspiration events but also can reflect nonspecific lung injury due to other etiologies. BAL has been most useful in immunocompromised hosts to identify common and opportunistic infections, identifying infection in 50% to 75% of patients with HIV and pulmonary symptoms.[45,46] In the future, additional markers of lung pathology in BAL, such as cytokine profiles, may direct clinicians toward specific etiologies or pathologic pulmonary processes.[47]

Lung histology remains the gold standard to make a definitive diagnosis in most immunocompetent patients with chILD. That said, up to 40% of technically adequate biopsy specimens do not reveal diagnostic characteristics.[48] With the new classification of disorders and concomitant gene testing, this percentage may be lower. In addition, new standardized methods for lung tissue processing have been described that will reduce the technical reasons for nondiagnostic results.[49] This processing includes electron microscopy to assess for ultrastructural changes consistent with genetic diseases affecting lipid and surfactant protein function. The choice of optimal site(s) for lung biopsy by the surgeon has not been studied. Fan and associates reported that among 27 patients with lung biopsies, 7/12 (58%) with single sites biopsied were nondiagnostic compared to 5/15 (33%) who were biopsied in multiple sites.[48] This was not a statistically different proportion between the groups, but a larger series may have led to different statistical conclusions. Where to biopsy and how many sites to sample remain controversial.

Transbronchial biopsy has been used to assess organ rejection in lung transplant recipients, but its use in infants and older children with chILD syndrome is less common. Video-assisted thoracoscopic surgery (VATS) has become the procedure of choice to sample lung tissue for chILD syndrome. Lung biopsies using VATS are as safe and useful as the open

Figure 44-1 High resolution CT scan of 9-year-old girl with systemic sclerosis. The pattern is one of peripheral cystic changes in multiple lobes.

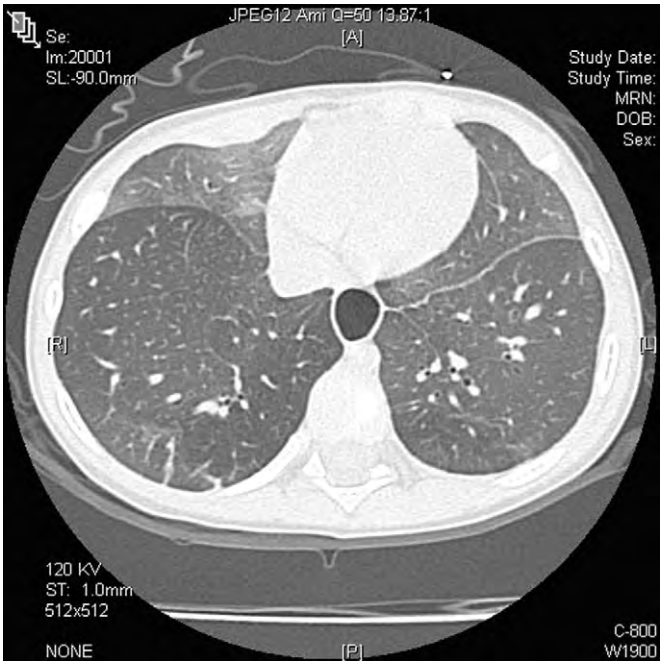

Figure 44-2 High resolution CT scan of lungs of a young child with neuroendocrine cell hyperplasia. Note the patchy nature of the ground-glass appearance characteristic of this condition.

mini-thoracotomy approach and carry less postoperative morbidity.[50] Children receiving VATS to obtain lung biopsies for chILD have reduced use of chest tube drainage and reduced length of hospital stay postoperatively compared to children undergoing open lung biopsies. The lung biopsy may transiently worsen pulmonary function as a result of the anesthesia, air leak, or bleeding in children who are severely ill.[51] However, the potential benefit, even in infants and children receiving ventilator support, may outweigh the risks.

EVALUATION OF THE NEONATE WITH chILD SYNDROME

The clinical presentation of chILD syndrome in the newborn period may be similar to that of common etiologies for neonatal respiratory distress, such as pneumonia or meconium aspiration. Some newborns develop mild to moderate chronic tachypnea and persistent pulmonary infiltrates in the first month of life, do not progress rapidly, and are diagnosed later in infancy. However, the typical neonate with chILD is a full-term neonate with persistent, severe parenchymal lung disease requiring oxygen, mechanical ventilation, or extracorporeal membrane oxygenation who does not improve. Pulmonary hypertension commonly coexists and may reflect either primary pulmonary vascular disease, the severity of the lung disease, or both. Evaluation should include family history, assessment for immunodeficiency, a search for pulmonary infection, and extrapulmonary manifestations of systemic disease. Specific entities causing severe neonatal onset of the chILD syndrome are listed in Table 44-2. Most of these entities require a lung biopsy for diagnosis despite the severity of the pulmonary disease.[52] Conditions such as surfactant B protein deficiency and alveolar capillary dysplasia are lethal newborn pulmonary entities, and early histologic diagnosis will influence philosophy of care and consideration for early lung transplantation. Tests for mutations in genes for surfactant protein B and ABCA3 should be performed early if they are to influence duration of supportive care.

Entities Producing chILD in Children Less Than 2 Years of Age

The common etiologies of chILD with onsets in children <2 years of age are listed in Table 44-2. Not all conditions are associated with an inflammatory process, and treatment of some of these disorders with steroids is neither effective nor indicated. Importantly, the prognosis varies greatly among these entities despite the fact that they are clinically similar. Gene analysis of ABCA3 and SPC mutations suggests that the age at clinical presentation may dictate the prognosis of the child, with more severe disease developing in the neonatal period. Currently there are no predictable genotype/phenotype relations, although cases with combinations of mutations in both SPC and ABCA3 genes reportedly lead to more severe disease.[13] The list also includes disorders of the pulmonary vasculature and pulmonary lymphatics. Brief summaries of some of the conditions producing chILD in neonates, infants, and children less than age 2 are listed subsequently.

Alveolar capillary dysplasia (ACD) with or without misalignment of pulmonary veins is a uniformly fatal condition manifesting in the newborn period with refractory severe pulmonary hypertension, diffuse radiographic infiltrates, and in some cases, with other congenital anomalies of the heart, duodenum, eye, and spleen.[53] In the more than 100 reported cases in the literature, this disorder has been uniformly fatal despite mechanical ventilation, inhaled nitric oxide, and extracorporeal membrane oxygenation (ECMO).[54] "Prolonged" survival of several months on intensive supportive care has been described.[55] Diagnosis is made at autopsy or with lung biopsy. In five reported families, multiple children have been born with ACD, suggesting a rare familial form.

Surfactant protein B deficiency manifests in the newborn period and is almost always fatal within the first few months of life despite intensive supportive care and exogenous surfactant replacement. The only current effective therapy is lung transplantation. There are many mutations of the gene

Table 44-2
Entities Causing chILD in Children <2 Years of Age

	Onset	Inflammatory Cells	Mortality*	Clinical Course
Neonatal Onset chILD				
Alveolar dysplasia	A	–	100%?	Pro
Alveolar/capillary dysplasia	A	–	100%	–
Surfactant protein B gene mutations	A	+/–	95%+	–
ABCA3	A/C	+/–	Variable	Per/Pro

on chromosome 2 that reduce its transcription or compromise intracellular transport of the gene product into lamellar bodies. The 121ins2 mutation is most common, accounting for 65% to 75% of mutations.[56,57] Surfactant protein B deficiency is transmitted as an autosomal recessive disorder. There are case reports of transient surfactant protein B deficiency and a mutation that did not reduce the protein enough to cause lung disease later in childhood.[58,59] However, the most common presentation is acute severe neonatal respiratory distress with diffuse ground-glass densities on chest radiographs similar to IRDS and, less frequently, neonatal pneumothoraces.[60] The histology includes extracellular material which stains positively with periodic acid–Schiff stain, consistent with alveolar proteinosis, type II pneumocyte hyperplasia, and interstitial inflammation and fibrosis.[22,61] Genetic testing for this disorder should be conducted on any neonate with a diagnosis of congenital alveolar proteinosis.

ABCA3 gene mutations are associated with severe neonatal chILD syndrome and also chronic ILD which can be either mild or severe in older children. The gene for ABCA3 on chromosome 16 contains 30 exons and encodes a large protein with 170 amino acids. The ABCA3 transmembrane protein is highly expressed in alveolar type II cells and localizes to lamellar body membranes. Missense, frame shift, insertion, and splice site mutations have all been described.[62] ABCA3 mutations are transmitted as an autosomal recessive trait. Disease onset in the neonatal period occurs hours to days after birth and progresses to death within a month despite intensive supportive care.[63] The clinical presentation in neonates is similar to surfactant protein B deficiency. One case out of 16 reported in the newborn period survived and was followed through age 6 years with chronic lung disease.[63] Histology in neonatal lungs includes hyperplasia of alveolar type II cells, accumulation of alveolar macrophages and proteinaceous material in the airspaces, and interstitial thickening—previously diagnosed as neonatal DIP or pulmonary alveolar proteinosis. Lamellar bodies are abnormal, small, and densely packed on electron microscopy of lung tissue.

In contrast to the neonatal presentation, Bullard and coworkers described 11 older children with ABCA3 mutations who had milder ILD.[64] Seven had symptoms as neonates, two within the first year of life, but two with onset of symptoms at 5 and 7 years of age. HRCT scans demonstrated nonspecific diffuse ground-glass densities. Four of the 11 had lung biopsies consistent with DIP. Ten of the children had a common missense mutation (E292V). Older children with chILD who have ABCA3 mutations or surfactant protein C deficiency present similarly.

Pulmonary interstitial glycogenosis (PIG) has been described in 12 infants presenting with radiographically diffuse infiltrates, chronic tachypnea, cough, and wheeze beginning between birth and 1 month of life in both premature and full-term infants.[11,10] Two of 12 children died but the others improved gradually over a period of 6 to 18 months. Three children assessed at age 6 years were asymptomatic with normal exercise tolerance but required intermittent inhaled therapy. PIG is also associated with neonatal lung injury such as bronchopulmonary dysplasia but is not encountered on lung biopsies after 6 months of age (C. Langston MD, personal communication). HRCT patterns have diffuse nonspecific densities. Previously described as *cellular interstitial pneumonitis of infancy,* Canakis and colleagues found abnormalities on lung biopsies consisting of spindle-shaped histiocytic immature interstitial cells containing mono-particulate glycogen, and diffuse interstitial thickening but no inflammation or collagen deposition.[11] Mature lymphocytes occur in small numbers within the interstitial spaces. The typical histologic appearance of PIG is depicted in Fig. 44-3. The condition may be a developmental adaptation to lung injury. Treatment is supportive, although bronchodilators and corticosteroids have been used empirically.

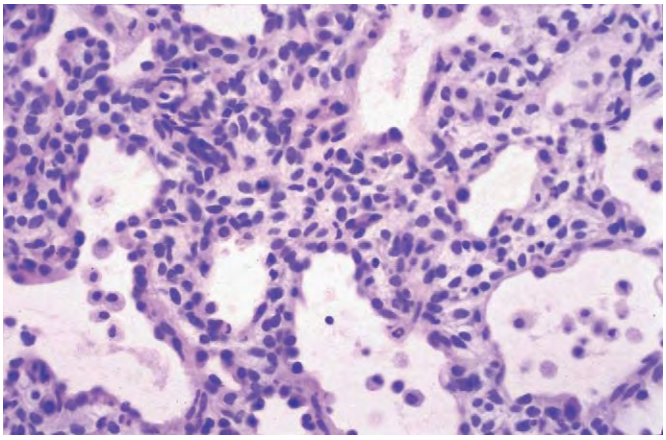

Figure 44-3 In pulmonary interstitial glycogenosis, alveolar walls are widened by a proliferation of glycogen containing bland interstitial cells with round to ovoid nuclei and clearing to bubbly cytoplasm on routine hematoxylin and eosin stain. The alveolar epithelium is not generally hyperplastic.

Chronic pneumonitis of infancy begins 2 weeks to 9 months after an uneventful birth and neonatal course. It produces chronic cough, tachypnea, and respiratory distress associated with ground-glass densities, consolidation, and hyperinflation on a chest radiograph.[12] HRCT findings, limited to a few case reports, show diffuse ground-glass appearance.[65] Lung biopsies in Katzenstein's original series were obtained at 2 to 16 months. Histologic features are portrayed in Fig. 44-4 and

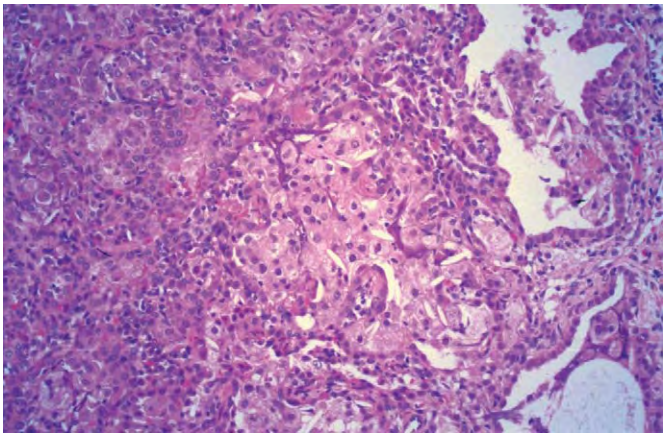

Figure 44-4 Chronic pneumonitis of infancy is one of the histologic patterns associated with surfactant dysfunction mutations in Sp-C and to a lesser extent in ABCA3 deficiency. It is characterized by diffuse alveolar epithelial hyperplasia and lobular remodeling with the addition of mild interstitial inflammation and occasional cholesterol clefts and eosinophilic hyaline globules in airspace. All of these features, except for the hyaline globules, are seen in this image.

include striking cellularity, with pneumocyte hyperplasia in the alveolar septa and macrophages in the air spaces. Multifocal alveolar proteinosis-like material also fills the airspace. Reported outcomes include 9 children in the original description, several individual case reports, and a series of 12 children with autopsy findings.[12,66,67] Mortality is at least 33% if not higher. Of the four children followed up to 3 years after biopsy, all had significant persistent respiratory impairment.[12] Genetic testing was not performed in the original series, but the pathology is similar to changes associated with ABCA3 and surfactant C protein gene mutations.

Neuroendocrine cell hyperplasia of infancy (NEHI) manifests in infancy with tachypnea, crackles, hypoxemia, and hyperinflation on physical examination and chest radiograph. It can manifest in the first week of life or within the first two years of life.[9] The HRCT of NEHI is almost pathognomonic (see Fig. 44-2). Biopsies of both the lucent and dense areas show remarkably normal lung, which may lead one to believe that diseased lung was missed at the time of sampling. However, with Bombesin staining, hyperplasia of neuroendocrine cells along the distal airways and in aggregates in the lung parenchyma are identified.[9] This is illustrated in Figure 44-5. NEHI persists over years and improves gradually, but is not responsive to prolonged steroid therapy. Fatalities have not been reported despite clinically severe pulmonary manifestations.[9] Supportive care with oxygen is indicated, particularly at night and with intercurrent illness. Previously called *persistent tachypnea of infancy*, the pathogenesis of NEHI is not understood.

Follicular bronchitis of infancy has been reported in 13 cases from two series of children.[68,69] Some investigators believe this is part of the continuum of lymphoproliferative disorders that include lymphocytic interstitial pneumonitis (LIP).[16] Symptoms of cough and tachypnea develop by 4 to 6 weeks of age in most cases and persist for years. Chest radiographs have diffuse infiltrates and hyperinflation. Lung biopsies show follicular lymphocytic infiltrates around and invading bronchial walls but no alveolar or interstitial cellularity or fibrosis. Children do not respond to steroid therapy despite the presence of lymphocytes on lung biopsy.[68] No one died in these two series and most children improved dramatically between 3 to 4 years of age. The longest reported follow-up in three patients, age 8 to 15 years, revealed mild to moderate obstructive lung disease by spirometry and persistent crackles on examination.[69]

Surfactant protein C deficiency results from missense and frameshift mutations in a 6 exon gene located on chromosome 8.[23,62] These mutations result in abnormal processing of the pro-SPC protein after transcription, leading to accumulation of pro-SPC within the cell and absent SPC production and secretion. SPC deficiency has produced ILD in all age groups including severe neonatal lung disease consistent with alveolar proteinosis.[22] Unlike surfactant protein B deficiency or mutations in the ABCA3 gene, surfactant protein C deficiency in newborns may not be as lethal a condition and the lung disease may clinically improve over time with chronic respiratory support (R. Deterding, personal communication); however, it is more commonly diagnosed in infants and older children than in newborns. SPC mutations are inherited as an autosomal dominant trait with variable penetrance. In one family kindred of 97 members, 14 people had ILD with a single mutation.[20] The lung disease on histology appeared as usual interstitial pneumonitis (UIP) in adults and nonspecific interstitial pneumonitis (NSIP) in two children who were 4 and 17 months old. Two adults in this kindred with the mutation had no respiratory symptoms, demonstrating incomplete penetrance. SPC deficiency has also been associated with lung histology in children consistent with DIP and chronic pneumonitis of infancy.[19,21] Clinical and radiographic features of SPC deficiency in infants and older children are indistinguishable from children with ABCA3 mutations and both gene studies should be obtained in this age group.

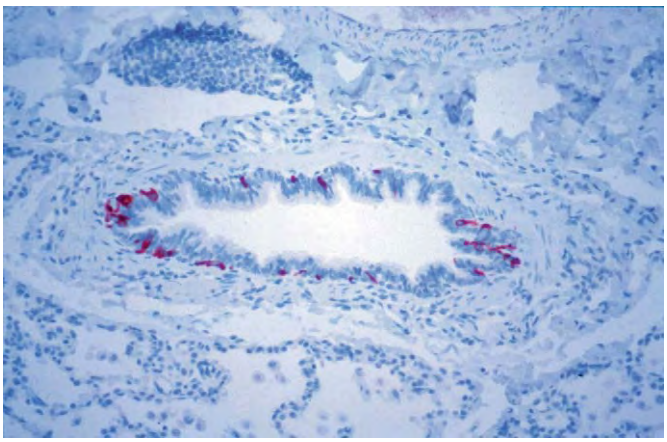

Figure 44-5 In neuroendocrine hyperplasia of infancy (NEHI) the lung histology is near normal; only immunostaining for neuroendocrine cells, here with immunostain for Bombesin, shows the increased numbers of neuroendocrine cells in clusters in bronchioles.

Interstitial Lung Disease Common to Adults and Children

Several forms of ILD described in the ATS/ERS Consensus Statement on ILD are common to both adults and children. They include lymphocytic interstitial pneumonitis, cryptogenic acute interstitial pneumonitis (Hamman-Rich syndrome), desquamative interstitial pneumonitis, organizing pneumonia, and nonspecific interstitial pneumonitis.[6] Despite identical histology, certain clinical characteristics differ between adults and children.

Lymphocytic interstitial pneumonitis (LIP) is a distinct form of ILD that can occur at any age alone or in conjunction with an underlying disorder. Familial forms of LIP have been reported.[70] LIP represents a form of lymphoproliferative pulmonary disease rather than a primary inflammatory or fibrotic process and it occurs in conjunction with congenital or acquired immunodeficiency, autoimmune disease, and dysproteinemia.[71] Clinical features of LIP are identical to other chILD conditions but are also associated with features of underlying conditions, for example,. weight loss and lymphadenopathy in HIV infection. Radiographic features on HRCT include ground-glass densities, reticulonodular or nodular densities, and (less often) bronchovascular thickening and thin wall cysts. Histologic features of the lung include diffuse infiltrates of B and T cell lymphocytes within the interstitial spaces, along lymphatics, and occasionally around airways.

Nodules of cells with germinal centers and noncaseating granulomas can also be seen. Pulmonary fibrosis rarely develops. The lymphocytes are usually polyclonal but oligo- and monoclonal populations can occur, suggesting malignant potential.[72]

LIP has been associated with Epstein-Barr virus in the lungs and by serology among children with HIV infection and following organ transplantation without HIV.[71,73] Among patients with HIV infection, noninfectious interstitial pneumonitis is presumed to be LIP and biopsy may not be necessary for diagnosis.[74] Whether EBV contributes to the lung pathology or dictates the clinical course of LIP is unclear.[73,75] LIP occurs in up to 30% of children with perinatal acquisition of HIV infection and manifests 5 to 60 months after birth.[76] LIP can improve, persist, or progress, and can be fatal. LIP is responsive to corticosteroids in many cases but controlled therapeutic trials have not been performed. The prognosis among children with LIP in the absence of immune defects has not been described.

Acute interstitial pneumonitis (AIP) is an acute and rapidly progressive form of parenchymal lung disease that results from diffuse alveolar damage. Very little has been published about AIP, specifically in children. It is strikingly similar to the fibrotic phase of adult respiratory distress syndrome (ARDS) but without a known inciting event (e.g., sepsis). Histologic features include temporally homogeneous lesions with hyaline membrane remnants, fibroblast proliferation, mononuclear cell infiltrates, and increased collagen deposition. It differs from acute eosinophilic pneumonia where eosinophils predominate.[77] Up to 25% of adults have a subacute course with symptoms developing over a period of more than 30 days—similar to the original case reports of Hamman and Rich.[78,79] Mortality is 70% for adults; similar data are not published in children. There are no proven therapies for this disorder.

Desquamative interstitial pneumonitis (DIP) has common histologic features among adults and children but different predisposing circumstances and different prognoses. The clinical presentation is similar to other etiologies of the chILD syndrome. Findings on HRCT are reticular or ground-glass densities that can be diffuse or regionally distributed, often in a basal or peripheral distribution.[80] Lung biopsies show a consistent pattern of airspaces filled with alveolar macrophages (previously considered epithelial desquamation [erroneously]), thickened alveolar septa, scattered mixed inflammatory cells, and minimal fibrosis.

In adults, DIP is associated with smoking and respiratory bronchiolitis-associated interstitial lung disease (RBILD).[81] Some experts consider these entities to represent a continuum of the same condition. DIP is considered relatively benign with a better prognosis than other etiologies of ILD in adults.[82] In contrast, DIP is not associated with smoking in children, can occur in families, and carries a high mortality rate, particularly in children with onset of symptoms in the first year of life.[26] The recent association of DIP with surfactant protein C deficiency and mutations in the ABCA3 gene may explain why DIP in infants is so much more severe.[21,64] Clinical improvement in response to corticosteroid therapy occurs short-term in almost one half of children.[25] However, mortality among children is 50% among 42 reported cases and higher among children with familial DIP.[83]

Cryptogenic organizing pneumonia (COP) was previously known as bronchiolitis obliterans and organizing pneumonia (BOOP). It occurs in both adults and children, and is usually associated with infections, drug exposure, myelodysplastic syndromes, bone marrow transplantation, or autoimmune disease.[84-86] In the largest series of 112 adults with COP, King and coworkers reported dyspnea, cough, and restrictive lung disease in one half of the patients. Fever and elevated erythrocyte sedimentation rate were common.[87] HRCT features are different from other radiographic features of the chILD syndrome, with patchy focal or bilateral consolidation that can migrate, ill-defined nodules, or a reticular pattern.[88] The histopathologic features include organization of the alveolar spaces and respiratory bronchioles with a fibromyxoid appearance and temporally uniform features, suggesting response to a single insult.[89] COG carries a good prognosis and is steroid responsive in adults and in the majority of case reports of children.[86,90]

Nonspecific interstitial pneumonitis (NSIP) was recognized by the ATS/ERS classification of interstitial lung disease as separate from UIP/IPF in 2002.[6] NSIP differs from UIP primarily because its histologic pattern is temporally homogeneous, unlike UIP, which has lesions in various stages of fibrosis. However UIP and NSIP have been diagnosed in the same patients with multiple biopsies.[91] NSIP has either cellular or fibrotic predominance on biopsy. The cellular form is associated with up to 80% improvement on therapy in adults; the fibrotic NSIP carries a progress of 45% survival over 5 years.[92] Both the cellular and fibrotic forms have been described in children.[16] NSIP is a prevalent form of ILD in adults. However, it is rare in children and there are insufficient numbers of cases to describe prognosis or responses to therapy. NSIP has been associated with surfactant protein C deficiency in several children but mutations have not been evaluated in most reported cases.[18] NSIP also occurs with a variety of underlying conditions, including occupational or drug exposure, and collagen vascular diseases (dermatomyositis, polymyositis, and systemic sclerosis).

THERAPY

Specific therapies for chILD syndrome clearly relate to the etiology identified for a particular patient, and vary from anti-infective and immunosuppressive agents to observation and supportive care. In patients with pulmonary alveolar proteinosis, lung lavage is still the treatment of choice with or without subcutaneous or aerosolized GM-CSF.[93,94] Interventions should also include alterations in the environment if the environment is contributing to the disease (e.g., hypersensitivity to bird antigens). Importantly, in those conditions where inflammation does not exist, the use of agents such as corticosteroids may create or increase rather than reduce morbidity.

In all cases, supportive care should include reducing irritant exposure (e.g., tobacco smoke, immunization against preventable infections, and assurance of adequate nutrition, sleep, and oxygenation). Models of care for idiopathic chILD should include a team approach to chronic severe lung disease in centers that can provide serial physiologic and radiographic assessments in addition to supportive care. Psychosocial support of families, genetic counseling, and

serial nutritional assessments are all necessary for most patients.

The most common treatment of ILD in children remains corticosteroids, administered orally or by monthly intravenous delivery.[95,96] The latter treatment was initially reported for treatment of adults with ILD in 1982 and has been extended to children with ILD using 15 to 30 mg/kg/day of methylprednisolone administered monthly. The period of time between intravenous treatments may be lengthened when improvement occurs.[95,96] There is some evidence that higher dose parenterally administered corticosteroids may more effectively reduce neutrophilia in the lung when inflammation is present.[96] In addition, intravenous intermittent steroid therapy may reduce the severity of side effects associated with prolonged use of high-dose oral corticosteroids. When oral steroids are used, an initial dose of 2 mg/kg/day twice daily is used for 3 to 6 months as a therapeutic trial, despite anticipated side effects. Choices about route, initial dose, and duration of therapy are at best empirical because no controlled studies of children with the chILD syndrome have been conducted to assess the efficacy of different regimens for different clinical entities.

In addition, the amount of improvement may be modest and slow in developing on corticosteroid treatment alone, and a choice between magnitude of improvement and development of therapy-induced side effects will influence considerations for further drug therapy. Reducing the dose of oral corticosteroids when improvement has reached a plateau is equally empirical. Equally important is a reduction in corticosteroid dosage when no improvement has occurred. There are reports in children of rapid steroid weaning leading to flares of disease activity that are not easily reversed.[27] Cautious reductions in steroid therapy are, therefore, prudent.

Hydroxychloroquine has been used as a second line agent when corticosteroids produce significant morbidity or minimal improvement and as a concurrent first line agent in children who are very ill.[97] Hydroxychloroquine is preferred to chloroquine to minimize the risk of retinopathy associated with both drugs.[98] As with corticosteroids, no placebo-controlled trials have been conducted and experience with this agent remains anecdotal, based on case reports.[99] The dose used initially is 5 to 10 mg/kg/day and trials of therapy usually last 3 to 6 months.[30] Additional anti-inflammatory immunosuppressive agents that have been used in selected cases include azathioprine, cyclophosphamide, methotrexate, cyclosporine, rituximab, and chlorambucil. All have been used empirically when corticosteroid therapy is ineffective and all produce unpredictable results.

Lung transplantation is a last treatment option when chILD syndrome is severe and disease is progressive or life threatening. It has been used successfully in neonates with otherwise lethal surfactant B protein deficiency and in children with progressive DIP and NSIP.[100,101] Survival is variable and is complicated by problems with recurrent infections, post-transplantation lymphoid proliferative disease, and bronchiolitis obliterans.[102] The report of the International Society for Heart and Lung Transplantation in 2005 noted that 6% of children less than 1 year of age and 9.6% of those 1 to 10 years of age who received lung transplantation did so as treatment for interstitial pneumonitis and/or pulmonary fibrosis.[103] The 50% survival time for all children with lung transplantation was 4.7 years and a 50% survival time after the first year of 7.5 years.[103] These figures have improved steadily over the last decade and are likely to improve in the future.

Acknowledgment

We wish to thank Dr. Claire Langston for providing the photographs of different histopathologic patterns included in the chapter.

CHAPTER 45 Eosinophilic Lung Diseases and Hypersensitivity Pneumonitis

Ariel Berlinski and John L. Carroll

TEACHING POINTS

- Nonparasitic eosinophilic lung diseases (ELDs) are rare in children.
- Diagnostic criteria include: peripheral eosinophilia and pulmonary infiltrates; eosinophilia on bronchoalveolar lavage (BAL); eosinophilia in lung biopsy (gold standard).
- Development of acute respiratory failure of unknown etiology should prompt early aggressive investigation
- Most ELDs respond well to corticosteroid therapy.

In hypersensitivity pneumonitis (HP)

- High degree of suspicion and thorough environmental exposure history are required to make the diagnosis.
- Pediatric HP is mainly due to exposure to avian and fungal antigens.
- Treatment consists of allergen avoidance and, in some cases, corticosteroids.
- Pediatric HP has an excellent outcome.

EOSINOPHILIC LUNG DISEASES

Eosinophilic lung diseases (ELDs) encompass a wide variety of disorders that feature eosinophilic infiltration of airways, alveoli, or the interstitium of the lung. These different entities can be diagnosed by (1) presence of peripheral blood eosinophilia and the presence of infiltrates on a chest radiograph; or (2) elevated percentage of eosinophils in bronchial lavage fluid; or (3) the presence of eosinophils on lung biopsy.[1,2] Although initially termed "pulmonary infiltrates with eosinophilia," the use of bronchoalveolar lavage (BAL) as a diagnostic tool broadened the spectrum of diseases, and subsequent reports described tissue infiltration with or without peripheral blood eosinophilia.[3] Therefore, a normal eosinophil count in peripheral blood does not exclude the diagnosis of ELD. Moreover, there are cases reported of tissue infiltration with normal radiologic findings.[4] The most common ELDs include simple pulmonary eosinophilia, chronic eosinophilic pneumonia, acute eosinophilic pneumonia, Churg-Strauss syndrome, idiopathic hypereosinophilic syndrome, asthma, allergic bronchopulmonary aspergillosis, bronchocentric granulomatosis, parasitic infections, and drug reactions.[2] Nonparasitic eosinophilic lung diseases are rare in childhood.[1]

Classification

Since its initial description by Löffler and subsequent reports by Crofton and colleagues and Reeder and associates in 1952, several classification schemes have been reported.[3,5,6] The fact that the presence of eosinophils either in blood or in lung tissue is the common denominator between all of these different diseases makes classification problematic. The initial classification by Crofton divided ELD as follows: (1) simple pulmonary eosinophilia; (2) prolonged pulmonary eosinophilia; (3) pulmonary eosinophilia–associated asthma; (4) tropical eosinophilia; and (5) pulmonary eosinophilia with asthma and polyarteritis nodosa.[6] More recently, Cottin and coworkers presented a classification that divided ELD into those of undetermined cause, those of a determined cause (mostly infectious and drug related) and a third group of miscellaneous with possible associated eosinophilia.[7] Alberts presented another classification based on the location of the disease; ELDs were classified as either airways or parenchymal disorders.[8] In Table 45-1 we present a combination of those two recent classifications.

Pathophysiology

To understand the eosinophilic lung diseases, it is necessary to understand the pathophysiological role played by eosinophils in these disorders. Eosinophils are derived from pluripotential $CD34^+$ precursors in the bone marrow. Several cytokines have been shown to be important in this process, including interleukin-3 (IL-3), interleukin-5 (IL-5), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Interleukin-5 is the most specific and is also known as eosinophil-differentiation factor.[9] Once released to the circulation in mature form, eosinophils migrate to the target organs. This process involves the adhesion of the eosinophils to the endothelial cells via the interaction with selectins and integrins. Chemoattractant mediators stimulate diapedesis to the tissues where IL-3, IL-5 and GM-CSF generated by T cells are critical for activation and survival. Eotaxin-1 and eotaxin-2 have been reported as being eosinophil-specific chemoattractant agents. Eosinophils can survive for extended periods of time, depending on the local conditions.[10] Once activated, eosinophils are responsible for the release of proinflammatory cytokines, arachidonic acid–derived mediators, enzymes, and reactive oxygen species. The activation in the

target tissue of the eosinophils results in the release of several proteins including major basic protein, eosinophilic cationic protein, eosinophil-derived neurotoxin, and eosinophil peroxidase. The eosinophilic response in the lungs may act as a double-edged sword; being beneficial during parasitic infestation but detrimental in other clinical situations, such as asthma. The antihelminthic killing properties are due to the release of cytotoxic granular contents. Interleukin-5 produced by Th2 lymphocytes plays a major role in this process.[11] A better understanding of the eosinophil physiology and the roles played by eosinophils in these disorders may allow for development of new therapeutic approaches.[10,12]

Eosinophilia is classified in different degrees of severity according to the absolute count (cells per cubic millimeter) as mild (351 to 1500), moderate (1500 to 5000) and severe (more than 5000).[10] Glucocorticoids act not only by suppressing the transcription of certain genes responsible for the synthesis of inflammatory mediators but also by inhibiting the cytokine dependent survival of the eosinophils.[13,14] Glucocorticoids are very effective in rapidly clearing eosinophils from the bloodstream. This should be kept in mind in the diagnostic process. Other therapeutic options will be discussed with each specific disease.

Table 45-1
Classification of the Eosinophilic Lung Diseases (ELDs)

ELD	Location
ELD of Known Etiology	
Eosinophilic pneumonias of parasitic origin	Parenchyma
Eosinophilic pneumonias of other infectious causes	Parenchyma
Allergic bronchopulmonary aspergillosis and related syndromes	Airways
Drug-, toxin-, radiation-induced eosinophilic pneumonias	Parenchyma
ELD of Unknown Etiology	
Idiopathic simple pulmonary eosinophilia	Parenchyma
Idiopathic chronic eosinophilic pneumonia	Parenchyma
Idiopathic acute eosinophilic pneumonia	Parenchyma
Churg-Strauss syndrome	Parenchyma
Hypereosinophilic syndrome	Parenchyma
Miscellaneous Lung Diseases with Possible Associated Eosinophilia	
Asthma and eosinophilic bronchitis	Airways
Idiopathic interstitial pneumonia	Parenchyma
Langerhans cell granulomatosis	Parenchyma
Lung transplantation	Parenchyma

Modified from Cottin V, Cordier JF: Eosinophilic pneumonias. Allergy 60(7):841-857, 2005; and Alberts WM: Eosinophilic interstitial lung disease. Curr Opin Pulm Med 10(5):419-424, 2004.

Specific Eosinophilic Lung Diseases

DRUG-, TOXIN-, AND RADIATION-INDUCED REACTIONS

Many drugs, including some drugs used to treat pulmonary conditions, can induce ELD. The mechanism is not completely clear. It is speculated that macrophages, after consuming the drugs, then act in their role of antigen-presenting cells. The antigen-receptor is then recognized by the lymphocyte CD4 and the Th2 lymphocyte T cell receptors. This leads to the release of IL-5 by Th2 lymphocytes, resulting in eosinophil production, chemotaxis to the lung, and degranulation.[15]

The following criteria are used to make a diagnosis of drug-associated ELD: (1) absence of other likely causes of lung disease; (2) presence of symptoms compatible with the suspected drug; (3) time course compatible with drug-induced ELD; (4) BAL or tissue findings consistent with drug-induced ELD; and (5) clinical improvement after discontinuation of the drug. Definite, probable, and suspected diagnoses are made when five, four, and three criteria, respectively, are met.[15,16] Bronchoalveolar lavage reveals in most cases a lymphocytic alveolitis associated with the eosinophilia.[17] The website www.pneumotox.com maintained by the Groupe d'Etudes de la Pathologie Pulmonaire Iatrogene is an invaluable resource of information of drug-associated lung disease.[18] Table 45-2 shows a list of drugs that have been reported to produce ELD.

The most common clinical presentation of drug- or toxin-induced ELD is simple pulmonary eosinophilia. Patients present with minimal or subacute symptoms, migrating infiltrates on the chest radiograph, and peripheral blood eosinophilia. In addition to cough and dyspnea, patients may also exhibit fever and/or rash. Discontinuation of exposure to the suspected offending drug or toxin results in resolution of the symptoms. On rare occasions, corticosteroids may be

Table 45-2
Drug-Induced Eosinophilic Lung Disease

More than 100 Cases Reported	Between 20 and 100 Cases Reported	About 10 Cases Reported	
Angiotensin-converting enzyme inhibitors	Acetylsalicylic acid	Beclomethasone	Mesalamine
Amiodarone	Anti-inflammatory drugs (nonsteroidal)	Chloroquine	Methylphenidate
Aurothiopropanosulfonate	Antidepressants	Cotrimoxazole	Para-(4)-aminosalicylic acid
Beta-blockers	Carbamazepine	Dapsone	Penicillins
Blood transfusions	Fenfluramine/dexfenfluramine	Desipramine	Phenylbutazone
Captopril	GM-CSF	Diclofenac	Procarbazine
Iodine, radiographic contrast media	Hydrochlorothiazide	Imipramine	Propranolol
L-tryptophan	Minocycline	Interleukin-2	Simvastatin
Methotrexate	Nilutamide	Isoniazid	Streptomycin
Nitrofurantoin	Penicillamine	Isotretinoin	Trimipramine
Phenytoin	Propylthiouracil		
	Sulfamides-sulfonamides

required. The prognosis associated with this type of ELD with eosinophilia is excellent.

Two episodes of historical interest are the "toxic oil syndrome" and "eosinophilia-myalgia syndrome," the latter associated with L-tryptophan.[19,20] Both cases illustrate how easily toxic elements can induce ELD.

New exposure to inhaled tobacco has been associated with the development of ELD,[21] as has illicit drugs such as heroin and cocaine. More recently Schorr and colleagues reported 18 cases of acute eosinophilic pneumonia in U.S. military personnel deployed in or near Iraq. Almost all were exposed to fine airborne sand or dust and all smoked tobacco but almost 80% had recently started smoking.[22] Another case of acute eosinophilic pneumonia was reported in a firefighter who participated in the rescue efforts at the World Trade Center area on September 11, 2001.[23] Radiation therapy has also been associated with the development of ELD.[24]

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS AND RELATED SYNDROMES

Allergic bronchopulmonary aspergillosis (ABPA) occurs mainly in patients with asthma and cystic fibrosis. The disease is the result of the immune response to the presence of the fungus in the airways. Patients present with worsening of lung function and increased pulmonary symptoms such as wheezing. Laboratory findings include peripheral blood eosinophilia, elevated IgE, precipitating antibodies to *Aspergillus fumigatus*, and elevated specific IgE. Radiologic findings include central bronchiectasis and presence of infiltrates. Pathology findings include dilated airways filled with mucus plugs containing macrophages, eosinophils, Charcot-Leyden crystals, and sometimes hyphae or hyphal fragments (Fig. 45-1). Although *A. fumigatus* is responsible for most of ABPA cases, other fungi have also been associated with the syndrome. These include other species of *Aspergillus (A. niger, A. flavus,*

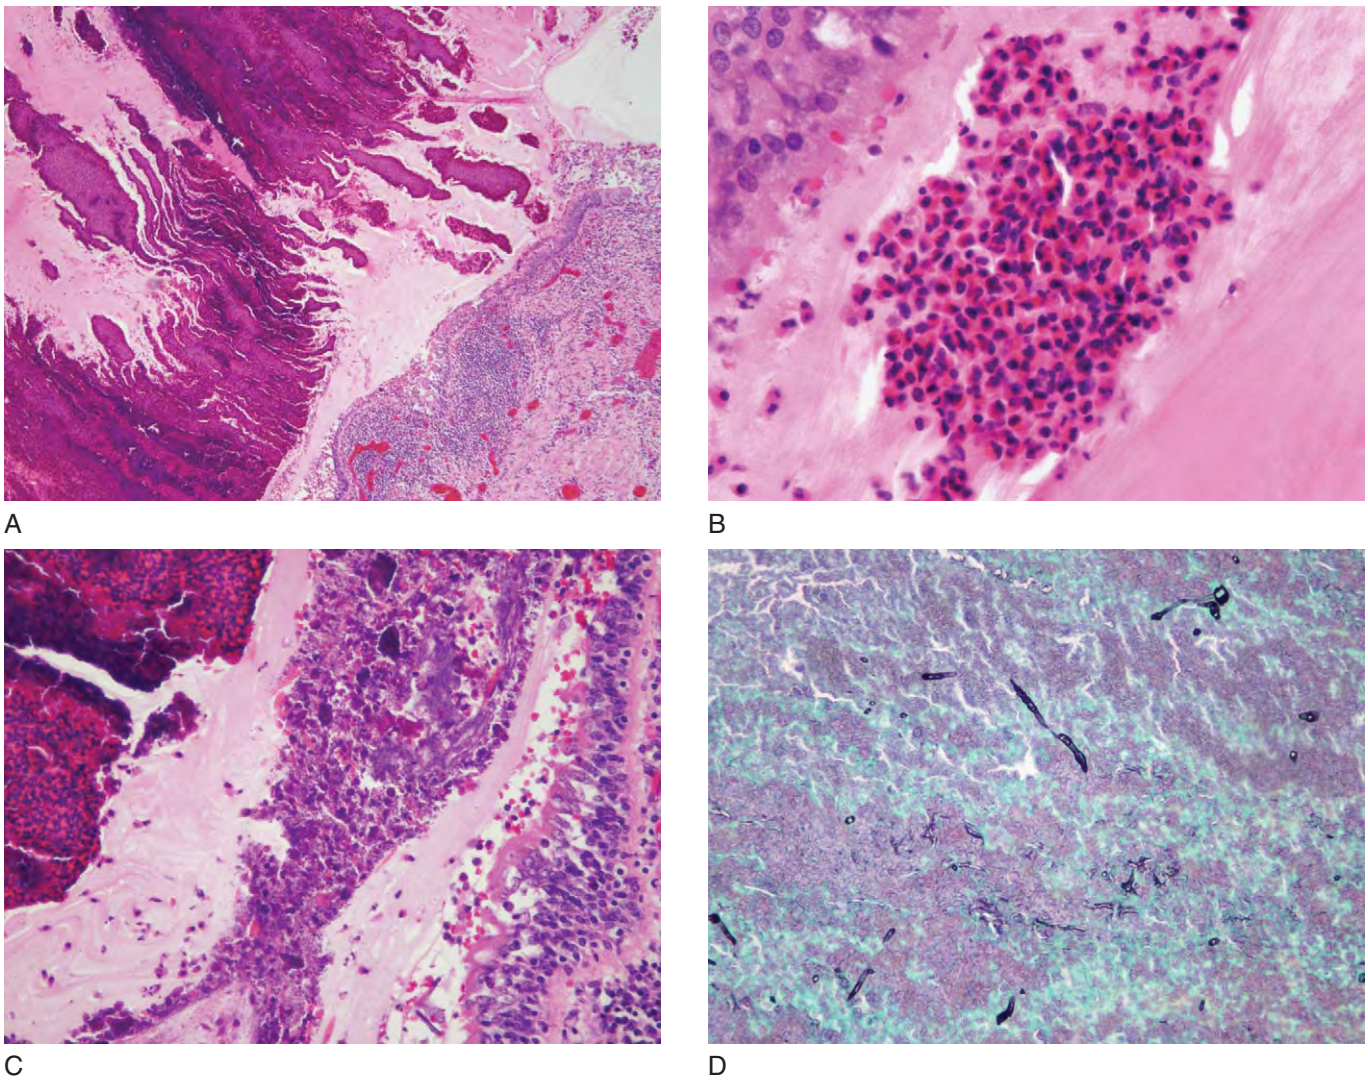

Figure 45-1 Pathology of ABPA: lung biopsy specimens. A, Eosinophilic material within the airways (hematoxylin-eosin stain). **B,** Cluster of eosinophils within mucous material in the airway at a higher power (hematoxylin-eosin stain). **C,** Mucus, cellular debris, and eosinophils within the airway lumen (hematoxylin-eosin stain). **D,** Fungal organisms within cellular debris (GMS stain). (Courtesy of Dr. Claire Langston, Texas Children's Hospital, Houston, Tex.)

A. nidulans, *A. oryzae*, or *A. glaucis)* and other fungi *(Stemphylium lanuginosum*, *Helminthosporium* species, *Candida* species, *Curvularia* species, *Schizophyllum commune*, *Drechslera hawaiiensis*, *Fusarium vasinfectum)*. Current therapy includes long-term corticosteroids and, more recently, itraconazole, which also has been shown to have steroid-sparing properties.[25] The use of itraconazole to treat ABPA in children remains controversial.

Bronchocentric granulomatosis is characterized by focal destructive granulomatous lesions that affect the bronchi and bronchioles.[26] The etiology is most commonly caused by fungi. Furthermore, some authors suggested that bronchocentric granulomatosis is a variant form of ABPA.[27] The clinical presentation is nonspecific and includes fever, cough, chest pain, and malaise. Nearly 50% are patients with asthma. There is no gender preference and the youngest case reported was 9 years of age.[27] Radiologic findings are generally unilateral and are confined to the upper lobes and include two patterns: masses and consolidation.[28] Treatment options include corticosteroids and surgical resection.

PARASITIC INFECTIONS

Many parasites have been identified as responsible for the development of ELD as a result of local action and host response. *Ascaris*, *Strongyloides*, and *Toxocara* frequently cause infection in the United States.[2] However, with the increasing ease of international travel to remote locations, a thorough travel history should be included in the evaluation of ELD.[29] Infection with more than one parasite is not uncommon. Clinical manifestations are nonspecific.

Ascaris lumbricoides infection is the most common helminthic infection in children. There have been reports of cases in the neonatal period. Symptoms are transient and usually include cough, wheezing, and fever; blood eosinophilia may last for a few weeks. The transmission takes place by ingestion of food contaminated with human feces containing parasitic eggs. Treatment is not necessary for asymptomatic patients because of the self-limiting nature of the disease. Symptomatic patients are treated with mebendazole.

Toxocara canis, a universally distributed parasite, is one of the etiologies for visceral larva migrans. The infection occurs after ingestion of eggs released by female worms in the feces of infected dogs. Children attending playgrounds where dogs are allowed and children with pica are at increased risk of infection. Most cases are asymptomatic, but some patients may present with cough, wheezes, or crackles on chest examination. Eosinophils are elevated in both peripheral blood and BAL fluid. The diagnosis is made by enzyme-linked immunosorbent assay.[30] Once the diagnosis is made, ophthalmic evaluation is warranted owing to ocular complications of *Toxocara* infection.[31] Symptomatic treatment is recommended and the use of antiparasitic agents (thiabendazole) for ELD is controversial.

Strongyloides stercoralis is acquired through the skin. The larva migrates to the airway and is then swallowed into the gastrointestinal tract where it matures into an adult worm. One unique characteristic of this parasite is its ability to remain in the host almost indefinitely—sometimes making it difficult to link the travel history with the symptoms. Patients may present with wheezing, bronchitis, and abdominal pain. Immunocompromised patients can develop a severe form characterized by gram-negative sepsis, respiratory failure, and a high mortality rate.[32] Diagnosis is made by serology and treatment is recommended with thiabendazole.

Tropical eosinophilia is caused by two filarial parasites: *Wuchereria bancrofti* and *Brugia malayi*.[33] Humans become infected through the skin by larva deposited by mosquitoes. The mature worm resides in the lymphatics, from which microfilariae are released to the lungs where an intense inflammatory reaction occurs. The interval between infection and development of symptoms may take 6 to 12 months. Patients present with fever, weight loss, malaise, cough, dyspnea, and wheezing. On physical examination crackles and wheezes are frequently heard and lymphadenopathy and hepatomegaly can be found. Diagnosis is made by serology and other laboratory findings, such as eosinophilia in peripheral blood and BAL, as well as very high IgE levels. Tropical eosinophilia is usually treated with the antifilarial antibiotic diethylcarbamazine. Corticosteroids may be required to treat allergic reactions that occur as microfilariae die.

OTHER INFECTIOUS NONPARASITIC CAUSES

Several infectious agents can cause an illness that manifests with ELD. This occurs infrequently and most of the time eosinophilic features are a minor component. Bacterial infections such as tuberculosis and brucellosis, fungal infections such as histoplasmosis and coccidiodomycosis, and viral infections have been reported in the literature to be associated with ELD.[34,35]

SIMPLE PULMONARY EOSINOPHILIA

Simple pulmonary eosinophilia was originally described by Löffler and is characterized by peripheral blood eosinophilia associated with migratory chest infiltrates and minimal symptoms.[5] Eosinophils are also elevated in BAL. The current thought is that most of the patients reported in the original series probably had a parasite-induced ELD. Currently, simple pulmonary eosinophilia is believed to be secondary to parasitic infections or drug reactions. However, in some cases, no etiology is found. Treatment is not necessary and clinical relapse is rare.[36]

IDIOPATHIC ACUTE EOSINOPHILIC PNEUMONIA

This eosinophilic lung disease was first described in 1989.[37] It manifests as an acute illness in a previously healthy individual with the potential development of respiratory failure and the acute lung injury syndrome or acute respiratory distress syndrome. Data from the largest case series reported in the literature show a mean age of 29 years, a slight male predominance, and a 40% smoking rate with most of them being recent smokers.[38-40] However, there have been cases reported of children as young as 10 months of age.[41] It has been suggested that the pathophysiology of this disease is an acute hypersensitivity reaction to an inhaled antigen.[42] The patient's previous activities should be elicited in the history-taking process including indoor renovation work, tank cleaning, smokehouse cleaning, and cave exploration. The clinical presentation includes 1 to 5 days of fever, cough, chest pain, and myalgias. This could develop into progressive respiratory distress and failure. Physical examination reveals tachypnea, tachycardia, and crackles. Chest radiograph shows bilateral infiltrates with both alveolar and interstitial opacities together

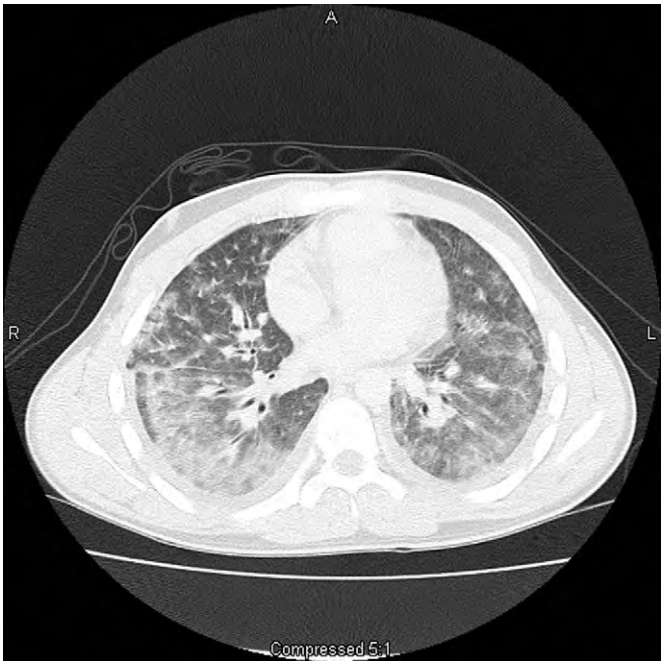

Figure 45-2 CT scan of the chest of patient with acute eosinophilic pneumonia. Note pleural effusion, ground-glass infiltrates, and alveolar opacities.

with interlobular septal thickening and pleural effusion.[43] High resolution computed tomography of the chest reveals ground-glass opacities, bilateral air space consolidation, interlobular septal thickening, nodules, and bilateral pleural effusions[44] (Fig. 45-2). Laboratory testing usually reveals a normal number of eosinophils in the peripheral blood, and a BAL with lymphocytosis, neutrophilia and eosinophilia (greater than 25%) (Fig. 45-3; Box 45-1). Patients may subsequently develop eosinophilia. The histology reveals interstitial edema and fibrin deposition, type II cell detachment from the alveolar walls but with an intact basal lamina.[45] Treatment is with corticosteroids for 2 to 4 weeks. The chest radiograph usually returns to normal after 4 weeks.[40] The disease is not characterized by a relapse, in contrast with chronic eosinophilic pneumonia.

BOX 45-1 Diagnostic Criteria for Acute Eosinophilic Pneumonia

Acute onset of fever and respiratory manifestations
Bilateral diffuse infiltrates on chest radiograph
Oxygen saturation on room air less than 90%
Lung eosinophilia with greater than 25% of eosinophils on BAL or eosinophilic pneumonia lung biopsy and absence of infection or exposure to drug that may cause eosinophilia

Modified from Cottin V, Cordier JF: Eosinophilic pneumonias. Allergy 60(7):841-857, 2005

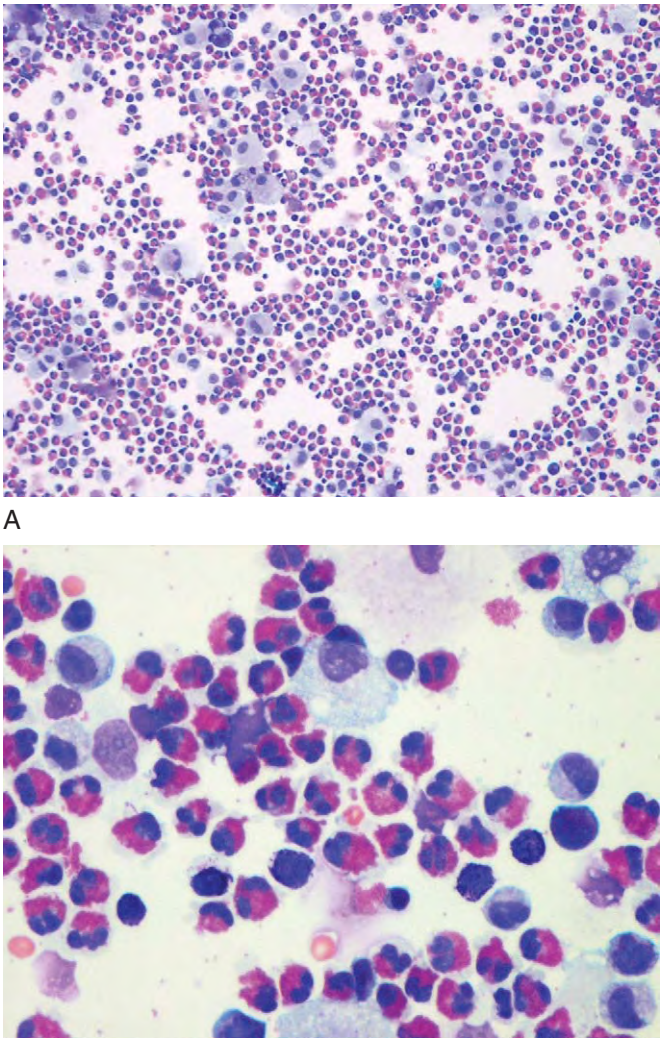

Figure 45-3 Acute eosinophilic pneumonia: BAL specimen (**A**) (Diff Quick stain). Note large amount of eosinophils surrounding alveolar macrophages. **B,** High power view of **A.** (Courtesy of Dr. Dale Ellison, Arkansas Children's Hospital, Little Rock, Ark.)

IDIOPATHIC CHRONIC EOSINOPHILIC PNEUMONIA

Idiopathic chronic eosinophilic pneumonia was first characterized in 1969 by Carrington and colleagues[46] The disease manifests more frequently in women with a 2 : 1 ratio and the mean age at presentation is 45 years. More than 50% have a diagnosis of asthma and more than 90% are nonsmokers.[47,48] However, biopsy-confirmed cases have been reported in 1- and 4-year-old children.[49,50] The clinical course is characterized by progressive onset of respiratory symptoms that include cough, dyspnea, asthenia, and weight loss. Less frequently, chest pain, malaise, and fever are seen. In adults, the mean time between onset of symptoms and diagnosis is 20 weeks. Physical examination reveals wheezes or crackles. Bilateral infiltrates were present in nearly 75% of patients with one half of them restricted to the upper lobes.[51] The classic radiographic pattern is that of a photographic negative of pulmonary edema; unfortunately this is seen in only around 25% of the patients.[48,52] The presence of migratory infiltrates increases the likelihood of making a diagnosis. High resolu-

tion computed tomography of the chest shows bilateral infiltrates mostly in the upper lobes with both peripheral ground-glass and consolidation opacities.[53] Laboratory findings include peripheral blood eosinophilia, elevated C reactive protein and erythrocyte sedimentation rate, and high levels of IgE. Markedly elevated eosinophils, usually greater than 45%, are present in the BAL. Lung biopsy shows eosinophilic infiltration of both alveoli and interstitium. Disruption of the basal lamina is present along with intraluminal fibrosis.[54] The treatment includes prednisone, which results in a dramatic resolution of clinical symptoms and radiologic findings. Patients may require long-term steroid therapy owing to the high rate of relapse during the weaning process or after corticosteroid therapy has been discontinued. Those with a diagnosis of asthma had a lower frequency of relapse than the nonasthmatics.[55] It should be kept in mind that very little is known about this disease in children.

CHURG-STRAUSS SYNDROME

This rare systemic vasculitis was originally reported in 1951 by Churg and Strauss.[56] It is characterized by eosinophilic and granulomatous inflammation of the respiratory system with necrotizing vasculitis affecting small to medium-sized vessels. Churg-Strauss syndrome manifests exclusively in subjects with asthma, usually in their fourth decade, and it has no sex preference.[57] However, children as young as 7 years of age and in infancy have been diagnosed.[58-60] Patients with Churg-Strauss syndrome frequently present with allergic rhinitis, sinusitis, and polyps. The clinical presentation of Churg-Strauss syndrome includes asthenia, weight loss, fever, and myalgias. Dermatologic findings such as purpura and subcutaneous nodules are common. Patients also frequently present with peripheral neuropathy, abdominal pain, and gastroenteritis.[61] Cardiac involvement is often insidious but may lead to severe dysfunction if treatment is not started.

The pathophysiology of the disease remains unclear, although eosinophils have been implicated. Kurosawa and coworkers reported high levels of serum eosinophilic cationic protein and urinary excretion of eosinophil-derived neurotoxin reflecting eosinophil degranulation.[62] Kiene and coworkers reported a Th0 $CD4^+$ cytokine production pattern in T cell lines in Churg-Strauss syndrome. In addition, they reported high production levels of IL-4 and IL-13, as well as a positive correlation between IL-4 production and the eosinophil count.[63] More recently, the National Institutes of Health led a workshop that reviewed the relation between different asthma medications and the development of Churg-Strauss syndrome.[64] They were unable to find conclusive data for any of the studied agents. They speculated that the clinical improvement achieved with any of the medications allowed a decrease in the corticosteroid dose, thereby unmasking the presence of the disease. Peripheral blood and BAL eosinophilia are present. Antineutrophil cytoplasmic antibodies (pANCA) are reported in 50% and 75% of the patients, although its diagnostic value is unclear.[65] Other laboratory findings include elevated IgE and normochromic normocytic anemia. Radiologic findings are characterized by migrating pulmonary infiltrates. Pathologic findings include tissue and vessel infiltration by eosinophils, necrotizing vasculitis, and extravascular granulomas[66] (Fig. 45-4). However, lung biopsy is obtained only on rare occasions because skin lesions provide the pathologic information. The treatment is similar to that of other vasculitides and includes medium- to long-term corticosteroids. If symptoms are not controlled with corticosteroids, cyclophosphamide can be added. Other medications such as methotrexate and azathioprine have been used.

Hypereosinophilic Syndrome

Hypereosinophilic syndrome is a term coined in 1968 to refer to a heterogeneous group of diseases characterized by persistent eosinophilia of unknown origin complicated by end organ damage.[67] The hypereosinophilic syndrome diagnostic criteria are (1) peripheral blood absolute eosinophil count greater than $1500/mm^3$ for at least 6 months; (2) lack of evidence of parasitic or other recognized causes of eosinophilia; and (3) symptoms and signs of organ system involvement.[68]

Katz and colleagues in a recent review reported an age of presentation ranging from $5^1/_2$ months to 16 years, with a mean of 8 years with a slight predominance of males (55%).[69,70] Symptoms included fever, arthralgias, fatigue, rash, and cough. The heart and the lungs were involved in 71% and 55%, respectively.[69] Of note, nearly 20% of the cases were associated with chromosomal abnormalities. Treatment modalities included corticosteroids, vincristine, 6-mercaptopurine, hydroxyurea, and others—with corticosteroids used in 84% of the patients.[69] More recently, two major disease variants have been described in the adult literature; these are termed *lymphocytic hypereosinophilic syndrome* (LHS) and the *myeloproliferative hypereosinophilic syndrome* (MPHS).[71] The MPHS variant is now viewed as a myeloproliferative disorder with overlap with chronic eosinophilic leukemia. In this group, some patients have been characterized by the presence of FIP1-L1-platelet derived growth factor receptor α chain mutation and good response to imatinib mesylate (tyrosine kinase inhibitor).[72] A pediatric case in a 6-year-old boy was recently reported.[73] The LHS variant is seen as a clonal expansion of $CD3^-CD4^+$ T cells associated with hyperproduction of IL-5.[74] The mean survival from diagnosis to death was reported as $10^1/_2$ months with an overall mortality of 60%.[69]

Clinical Approach to Eosinophilic Lung Disease

Most of the time clinicians are asked to see patients with ELD in consultation. We have shown the heterogeneity of the diseases that are included in the designation of ELD. Therefore, a more systematic approach to the evaluation should be taken (Fig. 45-5). If the patient presents with acute respiratory failure, BAL can lead to a diagnosis of idiopathic acute eosinophilic pneumonia. If the patient presents ambulatory, the evaluation starts with a thorough travel history (past and present), a detailed drug history (both prescription, over the counter and illicit) and an environmental (including pets) history. Any preexisting conditions should be noted (e.g., asthma, allergies, cystic fibrosis).

Minimal evaluation includes complete blood count, C-reactive protein, erythrocyte sedimentation rate, serology for *Toxocara* and *Strongyloides*, stool for ova and parasite, imaging studies (chest radiograph and HRCT of the chest). Other tests are performed based on any individual risk assessed by

history. Bronchoscopy with BAL constitutes an invaluable tool in the diagnosis of ELD.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP) is an under-recognized immune-mediated lung disease resulting from recurrent inhalation of organic antigens (Table 45-3). The disease has been mainly reported in adults with occupational exposure to antigens, whereas cases reported in children typically involve avian and fungal antigens resulting from residential exposures to pet birds (such as pigeons, parakeets, and cockatiels), and contaminated humidifiers with molds. Several cases have been reported in adults after exposure to hot tubs, indoor swimming pools, and water-damaged buildings.[75] Hypersensitivity pneumonitis, also known as extrinsic allergic alveolitis, was originally described by Ramazzini in 1713 in his book *Diseases of Workers*.[76] That was the first description of what is now called *farmer's lung*. In 1932, Campbell made the first report in modern medicine. Three decades later pigeon breeder's lung was reported in the United Kingdom and the United States.[77,78] The first pediatric case was reported by Stiehm and coworkers in 1967.[79] There has been a case report on an infant as young as 10 weeks old.[80] Since the initial report, 119 cases have been reported in children (Table 45-4).[80-124]

It is estimated that 5% to 15% of exposed persons will develop HP.[125] The development of the disease in exposed subjects is the result of a combination of host susceptibility, antigen characteristics (especially particle size), intensity and length of antigen exposure, host immune response, and modulatory factors.[126-129] The adult literature reports that HP occurs mostly in nonsmokers.[130]

Almost 300 years after the first clinical report, its pathophysiology is not fully understood.[126-128] After a sensitized subject inhales the antigen, immune complexes are formed with precipitating antibodies (IgG) (type III reaction of Gell and Coombs) and the complement cascade is activated. This

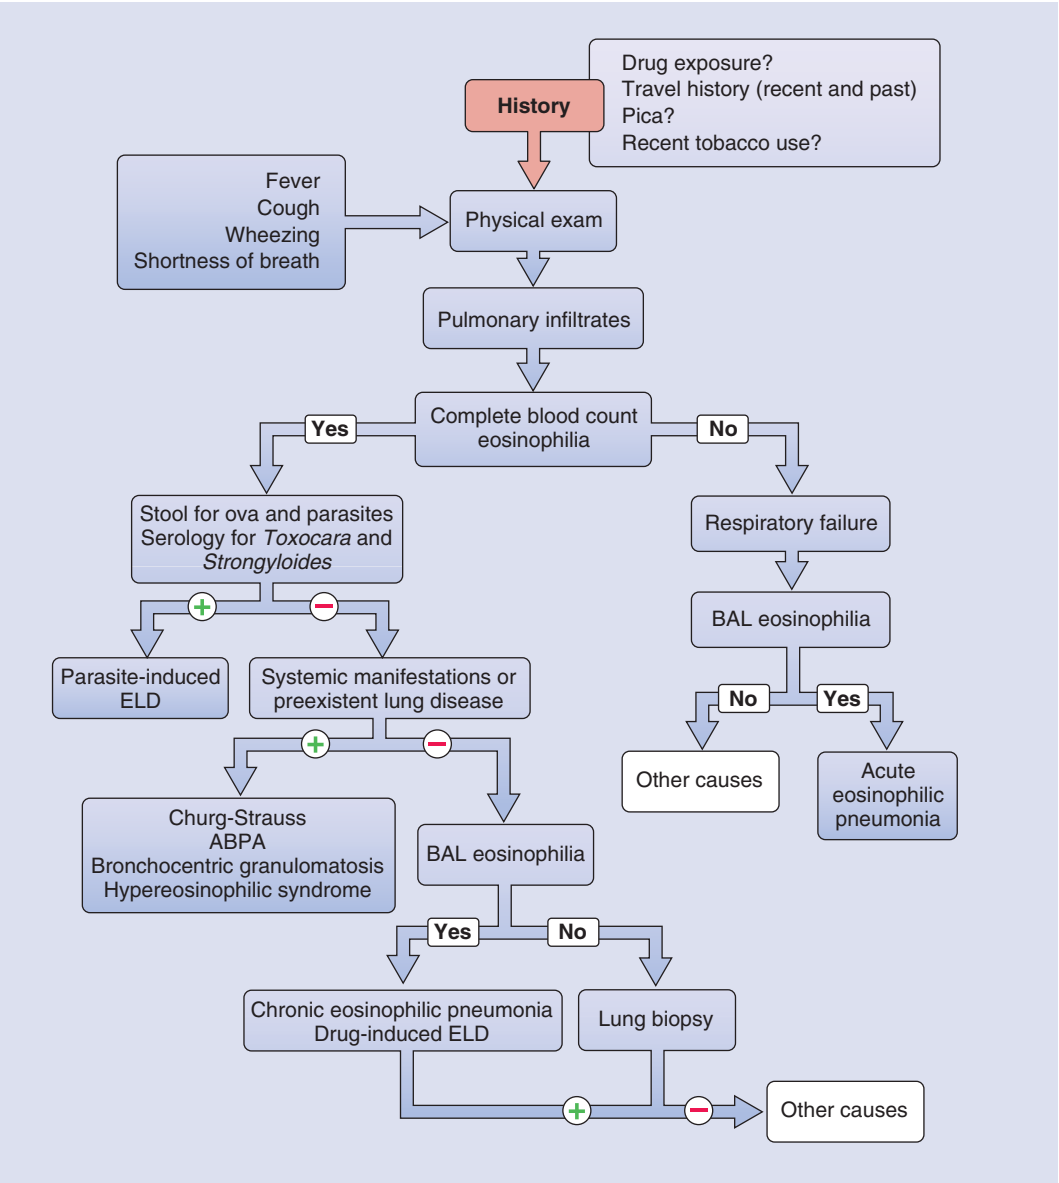

Figure 45-5 Clinical approach to eosinophilic lung disease (ELD). ABPA, allergic bronchopulmonary aspergillosis; BAL, bronchoalveolar lavage. (Modified from Oermann CM, Panesar KS, Langston C, et al: Pulmonary infiltrates with eosinophilia syndromes in children. J Pediatr 136[3]:351-358, 2000.)

leads to a transient neutrophilic alveolitis that is responsible for the acute respiratory symptoms.[131] This event is followed by an influx of activated $CD8^+$ T cells that is followed by an increase of $CD4^+$ T cells.[132] Activated macrophages produce proinflammatory cytokines such as TNF-α, IL-1, and IL-8. The lymphocytic reaction (type IV of Gell and Coombs) is also associated with granulomatous inflammation in the distal airways and alveoli. Although both acute and chronic forms of HP in adults are associated with NK lymphocytosis, the former manifests with $CD4^+$ and the latter with $CD8^+$ cells.[128]

In childhood, the mean age of presentation is approximately 9.7 years and there is a 1.4 : 1 male to female ratio.[79-124,133,134] Seventy-seven percent of reported pediatric cases are caused by exposure to bird antigens (pigeons, doves, parakeets, parrots, and others) and 22% are caused by exposure to molds (*Aspergillus*, *Penicillium*, *Micropolyspora faeni*, *Micromonospora vulgaris*, *Fusarium napiforme*, and others).[79-124]

In a recent study of adults with HP the following were found to be predictors of disease: (1) exposure to a known offending antigen; (2) positive precipitating antibodies to the offending antigen; (3) recurrent episodes of symptoms; inspiratory pulmonary crackles on physical examination; (4) symptoms occurring 4 to 8 hours after exposure; and (6) weight loss.[135] The exposure to a known offending antigen provided an odds ratio of nearly 40. These predictors were validated in 216 patients and retained their accuracy.

Radiologic findings have been found to correlate with pulmonary function in HP. Ground-glass opacification on HRCT correlates with lung restriction and reduction in lung compliance and diffusing capacity.[136-138] Mosaic perfusion patterns and air trapping correlate with increased residual volume.[127,136-138]

Table 45-3
Etiologic Agents in Hypersensitivity Pneumonitis

Antigen	Antigen Source	Typical Disorder
Animal Products		
Avian serum proteins: pigeon, dove, parrot, cockatiel, parakeet	Droppings	Bird-breeder's lung, pigeon breeder's lung, etc.
Duck proteins	Feathers	Duck fever
Turkey proteins	Turkey products	Turkey handler's disease
Chicken proteins	Chicken products	Chicken plucker's disease
Bovine and porcine proteins	Pituitary snuff	Pituitary snuff taker's disease
Rat serum proteins	Rat urine and droppings	Rat lung, laboratory animal worker's lung
Actinomycetes- and Fungus-Laden Vegetable Products		
Thermophilic actinomycetes *(Micromonospora faeni, Thermoactinomyces vulgaris), Aspergillus* species	Moldy hay	Farmer's lung
Thermophilic actinomycetes (*Thermoactinomyces)*	Moldy pressed sugar cane	*Bagassosis sacchari, T. vulgaris*
Thermophilic actinomycetes (*M. faeni, T. vulgaris*)	Moldy compost	Mushroom worker's disease
Penicillium frequentans	Moldy cork	Suberosis
Aspergillus clavatus	Contaminated barley	Malt worker's lung
Cryptostroma corticale	Contaminated maple logs	Maple bark disease
Alternaria species	Contaminated wood pulp	Woodworker's lung
Thermophilic actinomycetes (*Thermoactinomyces, Cephalosporium* species, amebas	Contaminated humidifiers, dehumidifiers, and air conditioners	Humidifier lung *Candida, T. vulgaris, Penicillium* species
Bacillus subtilis	Contaminated wood dust in walls	Familial hypersensitivity pneumonitis
Penicillium casei, Penicillium roqueforti	Cheese casings (mold)	Cheese washer's lung, cheese handler's lung
Rhizopus species, *Mucor* species	Contaminated wood trimmings	Wood trimmer's disease
Saccharomonospora viridis	Dried grasses and leaves	Thatched roof disease
Streptomyces albus	Contaminated fertilizer	*Streptomyces* hypersensitivity pneumonitis
Cephalosporium species	Contaminated basement (sewage)	*Cephalosporium* hypersensitivity
Pullularia species	Sauna water	Sauna taker's disease
B. subtilis enzymes	Detergent	Detergent worker's disease
Mucor stolonifa	Paprika dust	Paprika splitter's disease
Insect Products		
Acarus siro (mite)	Dust	–
Sitophilus granarius (wheat weevil)	Contaminated grain	Miller's lung (wheat weevil disease)
Chemicals		
Altered proteins or hapten protein conjugates	Toluene diisocyanate (TDI)	TDI hypersensitivity pneumonitis
	Trimellitic anhydride (TMA)	TMA hypersensitivity pneumonitis
	Diphenylmethane diisocyanate (MDI)	MDI hypersensitivity pneumonitis
	Heated epoxy resin	Epoxy resin lung
Other Agents		
Coffee dust	?	Coffee worker's lung
Hair dust	Animal proteins	Furrier's lung

Modified from Salvaggio JE: J Allergy Clin Immunol 79:558-571, 1987; and Fink JN: J Allergy Clin Immunol 74:1-10, 1984.

The disease manifests in three clinical forms: acute, subacute, and chronic. However, the reported pediatric literature does not clearly distinguish between these different clinical forms. Acute HP presents 4 to 6 hours after an intense exposure to the antigen. Patients develop a flu-like syndrome with fever, chills, cough, myalgias, and malaise. Acute HP is often initially misdiagnosed as infectious in nature. Physical examination reveals an ill-appearing child with dyspnea and bibasilar crackles. Symptoms usually subside after 24 hours, provided the patient is not re-exposed to the antigen. Laboratory results reveal leukocytosis with neutrophilia, elevated C-reactive protein, and erythrocyte sedimentation rate. The chest radiograph reveals bilateral reticulonodular infiltrates, more evident in the lower lung zones. High resolution CT of the chest shows ground-glass appearance and poorly defined centrilobular nodules.[139] Pulmonary function tests reveal hypoxemia and a restrictive lung disease pattern with increased elastic recoil and decreased diffusing capacity.[140] Radiologic abnormalities were found in 85% (100 out of 118) of reported pediatric cases.[79-124] Treatment of the acute form consists of avoidance of the offending antigen—although corticosteroids may be helpful in severe cases. Radiologic studies and pulmonary function tests should become normal after a few weeks, provided the subject is not re-exposed to the antigen

Subacute HP is the result of repeated low-dose exposures to an antigen, and is even more challenging to diagnose. Systemic (low-grade fevers, arthralgias, myalgias, and fatigue) as well as recurrent respiratory symptoms (exertional dyspnea, cough, sputum production, wheezes, crackles, rhonchi) are present.[141] This presentation is often misdiagnosed as asthma or bronchitis. Micronodular infiltrates and areas of mild fibrosis may be seen on radiographic and HRCT studies. Exertional hypoxemia may be present as well as restrictive changes in pulmonary function testing. Laboratory tests may show an elevated C-reactive protein and erythrocyte sedimentation rate. Lymphocytosis with a normal $CD4^+/CD8^+$ ratio, elevated natural killer cells, and increased expression of human leukocyte antigen-DR were found in BAL of children diagnosed with subacute HP.[119] Moderate abnormalities were also found in biochemical and physical surfactant properties.[142]

Table 45-4
Hypersensitivity Pneumonitis Reported in Children

Patient demographics	Mean age: 9.7 ± 4 years old (n = 103)
	Age range: 0.5 to 17 years old
	Male : female 1.4 : 1 (n = 117)
Etiology (n = 119)	Birds: 77%
	Mold: 22%
	Other: 1%
Signs	Crackles: 71% (n = 78)
	Clubbing: 33% (n = 36)
	Hypoxemia: 84% (n = 67)
Symptoms	Cough: 97% (n = 99)
	Exercise intolerance: 97% (n = 92)
	Weight loss: 89% (n = 64)
	Fever: 74% (n = 68)
Ancillary testing	Abnormal chest radiograph: 85% (n = 118)
	Precipitins: 91% (n = 115)
	Erythrocyte sedimentation rate: 34 mm (n = 53)
	FVC: 52 ± 20% predicted (n = 72)
	FEV_1: 54 ± 20% predicted (n = 44)
Treatment	Antigen avoidance: 99% (n = 111)
	Corticosteroids: 60% (n = 119)
Outcome (n = 114)	Improved: 98%
	Deteriorated: 2%

n, number of reported cases for which information was available.

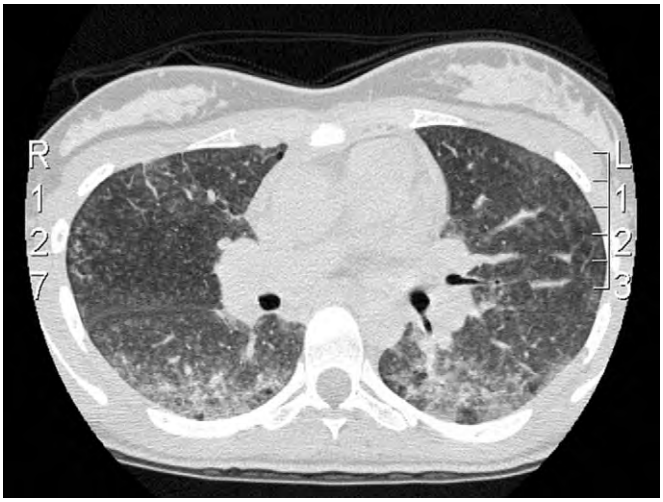

Figure 45-6 CT scan of the chest of patient with hypersensitivity pneumonitis. Note centrilobular nodules, patchy ground-glass infiltrates, and irregular linear opacities. (Courtesy of Dr. Leland Fan, Texas Children's Hospital, Houston, Tex.)

Approximately 5% of adult patients with HP will develop chronic HP,[143] which is characterized by progressive cough, dyspnea on exertion, anorexia, weight loss, and malaise. Physical examination shows crackles and clubbing in 71% and 33% of the affected children, respectively.[133] Chest imaging shows diffuse reticular infiltrates, fibrosis, patchy ground-glass opacities, and centrilobular nodules[144] (Fig. 45-6). Honeycombing is seen in advanced lung disease. Antigen avoidance remains the mainstay of treatment, but 60% of the patients were also treated with corticosteroids.[79-124,134] In patients with chronic HP, even with antigen avoidance and corticosteroid treatment, improvement in pulmonary function may require many months of treatment. The overall prognosis is excellent with only a few cases reporting worsening of clinical status or death.[95]

In summary, lack of standardized antigens, incomplete understanding of the pathophysiology of the disease, and lack of validated diagnostic criteria in the pediatric population make diagnosing HP a difficult task for which a high degree of suspicion and a thorough environmental/exposure history are needed.

CHAPTER 46 Allergic Bronchopulmonary Aspergillosis

Richard B. Moss

TEACHING POINTS

- Allergic bronchopulmonary aspergillosis (ABPA) exists as one manifestation of a spectrum of *Aspergillus*-induced lung diseases.
- ABPA is an allergic lung disease usually caused by *Aspergillus fumigatus* in immunocompetent individuals.
- ABPA occurs primarily in patients with underlying asthma or cystic fibrosis.
- ABPA is diagnosed by a combination of clinical, physiologic, radiographic, and immunologic criteria, which differ somewhat in patients with underlying asthma or cystic fibrosis.
- ABPA is a chronic relapsing condition in most patients that requires ongoing monitoring and at least episodic treatment.
- ABPA is treated by systemic glucocorticosteroids with use of adjunctive antifungals, primarily itraconazole, in many cases.

ASPERGILLUS IN NATURE AND AS PATHOGEN

The ubiquitous dimorphic fungal genus *Aspergillus* is the only known microbe to cause both invasive life-threatening infection and hypersensitivity respiratory illness in humans.[1] Most *Aspergillus* disease is due to *Aspergillus fumigatus* (Af), but at least 17 of some 175 other species such as *Aspergillus niger*, *A. terreus*, *A. nidulans*, and *A. flavus* have been reported to cause clinical infection or allergic disease.[2-4] Airborne sampling data suggest *Aspergillus* is the most prevalent of airborne fungal spores. Af conidia produce spores of 3 to 5 μm diameter that can penetrate to distal airways, allowing the possibility of inhalational sensitization to spore antigens and/or germination into mycelial growth—if not cleared by local host defense mechanisms.

Aspergillus species grow well at body temperature, and Af can also grow well at much higher temperatures and low oxygen environments, such as those found in compost piles.[5,6] *Aspergillus* spores germinate and grow in the mycelial phase by extension of 7 to 10 μm septate hyphae that branch at an angle of 45 degrees, with Af showing the most rapid growth rates (doubling time of <50 minutes and hyphal extension rate of up to 2 cm/hour). Interestingly, Af growth in vitro is augmented in the presence of hydrocortisone.[7] *Aspergillus* spores are robustly resistant to environmental degradation owing to a dense hydrophobic outer protein layer, the pigment of which confers antiphagocytic protection.[8] Af is usually sensitive to the antifungal agents amphotericin B and itraconazole, but resistance to both has been reported.[9]

ASPERGILLUS PULMONARY DISEASE SPECTRUM

A wide variety of lung disease secondary to *Aspergillus* has been noted—in which the elements of host response seem primarily to drive clinical manifestations—with three main categories of invasive, saprophytic (mycetoma), or allergic disease.[10,11] Box 46-1 lists distinct human pulmonary disease syndromes caused by Af in different host conditions. Host defenses against Af rely primarily on innate mechanisms of immunity such as mucociliary clearance, toll-like receptor bearing monocytes-macrophages, neutrophils, dendritic and natural killer cells, collectins, antimicrobial peptides, chemokines, and cytokines.[12-15] If innate mechanisms are breached, adaptive immunity is invoked leading to antibody and cell-mediated immune responses.[16,17] Immunocompromised hosts are susceptible to saprophytic and invasive forms of aspergillosis, whereas immunocompetent hosts with impaired mucociliary clearance and/or other host risk factors are susceptible to allergic and occasionally saprophytic disease (if there has been previous cavitation). The allergic disease spectrum includes atopic sensitization with development of mold-induced asthma, hypersensitivity pneumonitis, and the complex immunologic hypersensitivity lung disease known as allergic bronchopulmonary aspergillosis. Interestingly, there are numerous case reports of overlap syndromes, suggesting a spectrum of possible disease not only between but also within subjects—for example, development of saprophytic disease (aspergilloma or mycetoma) in patients with preexisting ABPA and vice versa (Fig. 46-1).[10,11,18]

Besides the antiphagocytic spore-coating pigment, *Aspergillus* produces a wide variety of virulence factors.[19] These include a variety of secretory enzymes which may protect it from host defenses and enhance pathogenicity, such as superoxide dismutase, catalase, phospholipase, alkaline protease and elastolytic and collagenolytic metalloproteases.[20] Af proteases in particular induce both respiratory epithelial cell shedding and activation resulting in proinflammatory cytokine secretion (Fig. 46-2)—likely mechanisms allowing penetration of Af antigens into the submucosa where the adaptive immune response may be induced or amplified.[21-23]

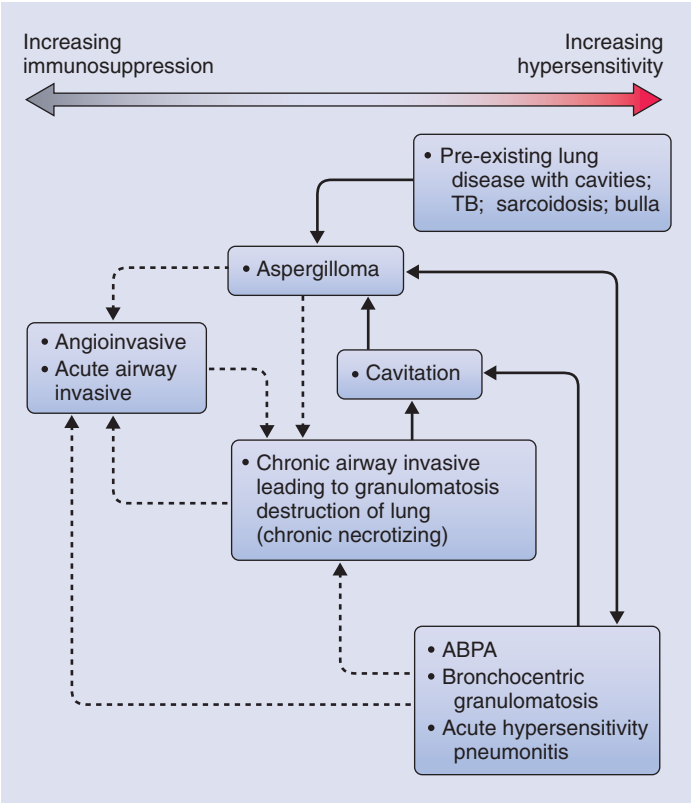

Figure 46-1 Relation of various, potentially coincident, forms of *Aspergillus* lung disease. ABPA, allergic bronchopulmonary aspergillosis. (Redrawn from Buckingham SJ, Hansell DM: Aspergillus in the lung: Diverse and coincident forms. Eur Radiol 13:1786-1800, 2003.)

BOX 46-1 Spectrum of Lung Diseases Caused by *Aspergillus* Species

Saprophytic: structurally damaged host (bronchiectasis, cavities, necrotic tissue)
- Aspergilloma (mycetoma): cavitary colonization and growth, IgG antibodies
- Chronic necrotizing aspergillosis: semi-invasive, intermediate between invasive and saprophytic; chronic disease or mild immunocompromised state

Allergic: immunocompetent host
- Asthma: exposure and IgE antibodies, immediate hypersensitivity
- Allergic bronchopulmonary aspergillosis: endobronchial growth, IgE and IgG antibodies, polyclonal IgE, Th2 cellular response, eosinophilia; asthma, CF, rarely CGD, hyper-IgE syndrome
- Hypersensitivity pneumonitis (allergic alveolitis): parenchymal contact, IgG antibodies, Th1 cellular response
- Bronchocentric granulomatosis
- Eosinophilic pneumonia

Invasive: immunosuppressed host
- Angioinvasive aspergillosis; usually systemic, rare localization in less compromised host
- Acute bronchopneumonia
- Pseudomembranous necrotizing tracheobronchitis: immunosuppressed or chronic lung disease
- Invasive pleural disease

CGD, chronic granulomatous disease

ALLERGIC BRONCHOPULMONARY ASPERGILLOSIS

A form of immunologic hypersensitivity lung disease, allergic bronchopulmonary aspergillosis (ABPA) is induced by Af or occasionally other *Aspergillus* species. Rarely, non-*Aspergillus* fungi have been implicated in allergic bronchopulmonary mycoses but the pathogenetic, pathophysiologic, clinical and radiologic features are similar (Box 46-2). The disease was described by Hinson and colleagues in 1952 in asthmatics as a distinct lung disease syndrome characterized by productive cough, fever, infiltrates, eosinophilia, and growth of Af from sputum.[24] It was later recognized as a complication of cystic fibrosis by Mearns and associates in 1965.[25] Early diagnostic criteria and therapeutic strategies were worked out in patients with asthma in the 1970s and 1980s, with more recent modifications in patients with cystic fibrosis. Pathologically ABPA is characterized by one or more of the following features: mucoid impaction of bronchi, bronchocentric granulomatosis, eosinophilic pneumonia, and exudative or obliterative bronchiolitis (Figs. 46-3 and 46-4).[2] Immunologically, ABPA is characterized by local and circulating IgE and IgG Af antibodies, immediate skin test reactivity to Af, local and peripheral eosinophilia, increased serum IL-2 receptor levels, and raised total serum IgE levels.[26,27] Radiographically, ABPA is characterized by pulmonary infiltrates during the acute phase; chest CT shows segmental and subsegmental varicose or cystic bronchiectasis and mucoid impaction, and small airways may demonstrate centrilobular nodules.[10,18]

Pathogenesis of Allergic Bronchopulmonary Aspergillosis

The earliest phases of ABPA are not understood. Inhaled Af spores may germinate in static mucus plugs or bind to bronchial epithelium. In either case, if normal clearance mechanisms fail, epithelial chemokine and cytokine responses are initiated.[28,29] Af antigens are processed and presented to the adaptive immune system, and this process leads to induction of a Th2-dominated immune response as a key feature leading to clinical ABPA.[30] Resident cell types such as epithelial cells, alveolar macrophages, vascular smooth muscle, and fibroblasts are potential sources of chemokines, which drive recruitment of $CD4^+$ T cells and eosinophils into the airway mucosa and submucosa.[31] Several chemokine signaling systems have been critical in inducing or modifying experimental murine ABPA.[32-34] Recent work in these models strongly suggests that Th2 skewing is due, at least in part, to production of chemokines preferentially evoking a Th2 response, with a prominent role for thymus-activated and thymus-regulated chemokine [TARC/CCL17] and macrophage-derived chemokine [MDC/CCL22] effects mediated through their receptor CCR4.[35] Th2 cytokines such as IL-4,

IL-5 and IL-13 play crucial roles in orchestrating the subsequent inflammatory pathology (Fig. 46-5).[30,36,37]

A role for other components of the innate immune response in susceptibility to ABPA has been shown by studies of collectins, innate opsonins important in fungal clearance that include the surfactant proteins A and D and mannose-binding lectin (MBL).[13,14,38] Studies of genetic polymorphisms of surfactant protein A and MBL genes revealed that patients with SP-A2 1649G or 1660G alleles, or the 1011A allele of MBL, are at markedly increased risk for ABPA.[38,39] Similarly, presence of the -1082 GG allele in the IL-10 promoter region is associated with susceptibility to ABPA.[40] This is important because a role for the anti-inflammatory cytokine IL-10 in protection against Af has been shown in experimental murine ABPA; this is in addition to the broader role of IL-10 as an anti-inflammatory cytokine in lung inflammation in both asthma and CF.[41-43] It is likely that further polymorphisms important in the immune response to Af will be found to contribute to ABPA susceptibility or protection.

Serologically ABPA is characterized by a marked local and systemic humoral immune response with highly elevated levels of *Aspergillus*-specific IgE antibodies, potent induction of a polyclonal (nonspecific) IgE response leading to very high serum IgE levels, and augmented IgG and IgA *Aspergillus*-specific antibodies. Predominantly local production of Af-specific IgE and IgA antibodies in the bronchoalveolar lavage fluids and bronchial lymphoid follicles has been demonstrated (Fig. 46-6).[44,45]

At the cellular level, adaptive immune responses have been characterized by in vitro studies of peripheral blood lymphocytes from ABPA patients and controls evaluating their phenotype and cytokine induction profile, which have shown a marked Af-specific $CD4^+$ Th2 response.[46] Af-reactive $CD4^+$ T cell lines from ABPA patients are activated ($CD25^+$, $HLA\text{-}DR^+$) and secrete interleukin-4 [IL-4] but not

interferon-γ, a pattern characteristic of the Th2 immune response phenotype, whereas cell lines reactive to other antigens such as tetanus toxoid include Th1 responses.[47] Increased sensitivity to IL-4 may represent an autocrine mechanism contributing to the Th2 skew in ABPA.[37] ABPA patients thereby have an increased frequency of circulating Af-reactive Th2 $CD4^+$ cells. Studies in murine ABPA using a variety of approaches including resistant and susceptible strains, targeted gene knockouts, and treatments with cytokine-specific monoclonal antibodies suggest that although IL-4 production is necessary for the elevated IgE levels, it is not necessary for other crucial features such as bronchial hyperreactivity, inflammation, and remodeling.[36,48] In contrast, $CD4^+$ T cells are necessary and sufficient to cause airway reactivity and inflammation in these models.[49,50]

An immunogenetic feature of ABPA is inheritance of major histocompatibility complex (MHC) alleles, which increase or decrease Th2 responses to Af. ABPA is much more likely in people with MHC alleles DRB1*1503 and 1501, whereas DQ2 is less frequent in ABPA patients than controls and modifies the risk if DR 2/5 alleles are present.[51,52] Thus, both susceptibility and protective alleles for ABPA risk appear to be associated with the MHC, implying pathogenetic roles for certain Af antigenic peptide—genetically restricted MHC interactions involving antigen-presenting cells in the lung. Af allergens associated with sensitization to Af and ABPA have been identified (discussed subsequently), suggesting that certain Af allergens are candidates for MHC-restricted disease induction.[53,54] Supporting this, in one murine model some Af allergens were shown to cause inflammation, airway hyperreactivity, high IgE, eosinophilia and a Th2 immune response, whereas others did not.[55] Af allergens are shown in Table 46-1.

Eosinophilia is a prominent feature of ABPA, although recently it has been shown that neutrophils are also involved.[56] Local eosinophilia and extracellular presence of presumptive proinflammatory eosinophil products such as major basic protein are pathologic features of ABPA lesions (Fig. 46-7).[57] Thus, local and systemic eosinophilia accompanies local and systemic augmented IgE secretion as a pathologic feature of ABPA. A role for mast cell and/or basophil activation by Af allergens cross-linking IgE antibodies fixed by high-affinity receptors on the cell surface is suspected from the universal presence of type I immediate hypersensitivity skin test reactions and in vitro basophil histamine release in ABPA patients, but because these phenomena are also seen in many asthmatics and atopics without ABPA, their pathogenic role is unclear. A schematic overview of ABPA pathogenesis is shown in Figure 46-8.

Susceptibility to ABPA appears to be increased by mutations in the cystic fibrosis transmembrane conductance regulator (CFTR) gene. This may explain, in part, the higher prevalence of ABPA in CF than in asthma, although many other phenotypic features may also be responsible. There is an increased frequency of CFTR mutations in non-CF asthmatics with ABPA, suggesting a gene-dose effect.[58,59] CF knockout mice have an altered response to Af challenge that strongly resembles human ABPA. CFTR appears to play a role in skewing immune responses to a Th2 phenotype in these CF mouse models.[60,61] It is also possible that *Aspergillus* may be preferentially selected for colonization of lungs in patients with asthma who are heterozygous for CFTR mutations, as well as for CF patients who are, by definition, homozygous for CFTR mutations on both alleles. This potential gene-dose effect may also help explain the higher prevalence of Af colonization and ABPA in CF patients than in asthmatics. Box 46-3 summarizes risk factors for ABPA that emphasize the critical interaction of environmental and host defense elements.

BOX 46-3 Environmental and Immunologic Risk Factors for Allergic Bronchopulmonary Aspergillosis

Environmental spore exposure (indoor, compost, ambient seasonal)[166,167]
Atopy[90]
CFTR homozygous or heterozygous mutation[58-61]
Surfactant protein polymorphisms (A2 A1660G, G1649C alelles)[38,39]
Mannose-binding lectin polymorphisms (G1011A allele)[39]
IL-10 promoter polymorphism (-1082GG allele)[40]
HLA-DR2 restriction (DRB1*1501 and *1503 alleles)[52]
(HLADQ2 [DQB1*0201 allele] protective)
T cell receptor Vβ chain restriction (Vβ 13)[172]
(Vβ 1 protective)
Increased B cell sensitivity to IL-4[37]
Colonization with *Stenotrophomonas maltophilia* (in CF)[173]

Allergic Bronchopulmonary Aspergillosis in Asthma

ABPA was first recognized in patients with asthma, and diagnostic criteria were developed in this setting.[26,27] Box 46-4 lists the criteria for ABPA in patients with asthma. Immediate cutaneous reactivity to *Aspergillus* species is detectable in 20% to 25% of patients with persistent asthma. In patients with asthma, most studies have reported occurrence of ABPA in 1% to 2% of patients, although recent studies routinely incorporating chest CT to detect central bronchiectasis in asthma patients screened by Af skin testing report prevalences of 5.7% to 8.1%, albeit in mainly adult populations.[62-65]

High-resolution chest CT is very useful in evaluating for ABPA, as bronchiectasis affecting three or more lobes (Fig. 46-9), centrilobular nodules, and mucoid impaction (Fig. 46-10) are findings highly suggestive of allergic bronchopulmonary aspergillosis in asthma.[66] High attenuation mucus plugs are specific for ABPA but insensitive, occurring in only ~25% of ABPA patients with asthma.[67]

Because it is possible to demonstrate serologic changes consistent with ABPA in patients who do not have central bronchiectasis, a partial or prodromal ABPA state termed *ABPA-serologic* [ABPA-S] has been suggested, along with the conventional ABPA with central bronchiectasis.[68] It is unclear how many of the former evolve into the latter if untreated, or over what period of time. Based on clinical, spirometric, serologic, and radiologic findings, ABPA-S patients have a milder type of ABPA.

ABPA onset in childhood was first observed in 1970, and may include acute life-threatening onset, but most cases occur in young adults.[69,70] ABPA can be recognized in five discrete stages, not necessarily phases, which are listed and

BOX 46-4 Diagnosis of Allergic Bronchopulmonary Aspergillosis in Asthma

Classic criteria
- Asthma
- Chest roentgenographic infiltrates—current or in past, may be detectable on CT examination when the chest film is normal
- Immediate cutaneous reactivity to *Aspergillus* species
- Elevated total serum IgE (>417 kU/L or 1000 ng/mL)
- Serum-precipitating antibodies to Af
- Central (proximal—inner 2/3) bronchiectasis on high resolution CT of chest
- Peripheral blood eosinophilia
- Elevated serum IgE-Af and or IgG-Af

Minimum essential criteria
- Asthma
- Immediate cutaneous reactivity to *Aspergillus* species
- Elevated total serum IgE concentration (>417 kU/L or 1000 ng/mL)
- Elevated serum IgE-Af and IgG-Af
- Central bronchiectasis

- Use of oral corticosteroids can reduce the total serum IgE concentration to <1000 ng/mL in some patients with allergic bronchopulmonary aspergillosis (ABPA).
- Confirmatory findings: *Aspergillus* in sputum or bronchoalveolar lavage fluid (BALF), expectoration of brown plugs, dual or late skin test reactivity to *Aspergillus.*

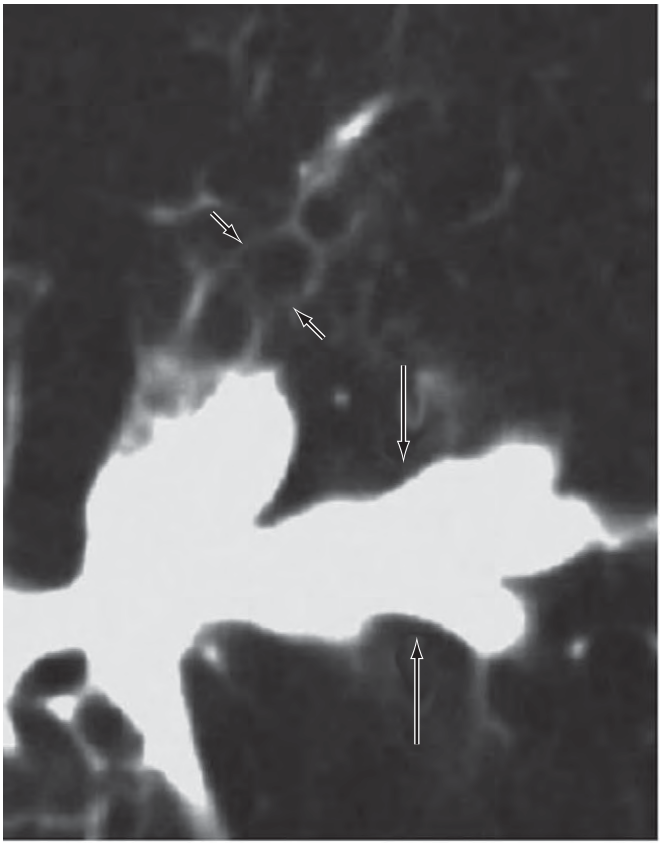

Figure 46-10 High resolution chest CT scan showns detail of patient with allergic bronchopulmonary aspergillosis (ABPA), illustrating varicose bronchiectasis (*short arrows*) and mucoid impaction (*long arrows*) producing "finger-in-glove" appearance. Figure 46-9 High resolution chest CT scan of patient with allergic bronchopulmonary aspergillosis (ABPA) illustrating proximal varicose bronchiectasis (*arrow*). (Reprinted from Buckingham SJ, Hansell DM: Aspergillus in the lung: Diverse and coincident forms. Eur Radiol 13:1786-1800, 2003.)

described in Table 46-2.[71] Treatment varies by stage, in that oral glucocorticosteroids are indicated in acute (stage 1) cases, may be tapered and withdrawn when the patient is in remission (stage 2), and addition of itraconazole is appropriate for patients with relapse (stage 3) or corticosteroid-dependent asthma (stage 4). The effectiveness of itraconazole as a steroid-sparing and anti-inflammatory agent, presumably via reduction in fungal burden, has been convincingly demonstrated. Similar data are not available for other antifungal agents, or for inhaled corticosteroids. It is not clear if any therapy is effective in patients who have end-stage pulmonary fibrosis (stage 5)—but this is rarely, if ever, seen in pediatric cases.[72] Patients with ABPA-S may be classified into stages 1 through 4 but do not have irreversible fibrosis or end-stage respiratory disease. These patients may have recurrent infiltrates and be categorized as stage 3. Fuller treatment recommendations are given in the section on treatment of ABPA in cystic fibrosis.

Allergic Bronchopulmonary Aspergillosis in Cystic Fibrosis

Colonization rates of the airways by Af in patients with CF have been reported to occur over a wide range, likely ascribable to variations in clinical sample acquisition and culturing methods. A large multicenter prospective evaluation in a defined CF patient population (age ≥ 6 years, *Pseudomonas*-positive, moderate lung disease) using a uniform sample acquisition protocol and methodology with centralized microbiology yielded an Af sputum colonization prevalence of about 25%.[73] Af strains differ between CF patients and can persist long term.[74] Both asthmatic and CF patients can develop ABPA with negative sputum cultures, so presence of

Table 46-2
Stages of Allergic Bronchopulmonary Aspergillosis

Stages	Clinical Characteristics	Biology	Radiology
I: Acute	Fever, cough, chest pain, hemoptysis sputum	Elevated total serum IgE levels (± blood eosinophilia)	Pulmonary infiltrate(s) (upper/middle lobes)
II: Remission	Asymptomatic/stable asthma	Normal or elevated total serum IgE levels	No infiltrates (in the absence of systemic corticosteroid therapy for >6 months)
III: Exacerbation	Symptoms mimicking the acute stage or symptomatic	Elevated total serum IgE levels (± blood eosinophilia)	Pulmonary infiltrate(s) (upper/middle lobes)
IV: Corticosteroid-dependent asthma	Persistent severe asthma	Normal or elevated total serum IgE levels	With or without pulmonary infiltrate(s)
V: Fibrosis (end-stage)	Cyanosis, severe dyspnea	Normal or elevated total serum IgE levels	Cavitary lesions, extensive bronchiectasis, fibrosis

Reprinted from Zander DS: Allergic bronchopulmonary aspergillosis: An overview. Arch Pathol Lab Med 129:924-928, 2005.

Af in sputum is not usually a criterion for diagnosis, although it may be supportive (see Box 46-4).[75,76]

In CF, reported ABPA prevalence rates are higher than in asthma, varying from 1% to 16%.[77-98] The USA Cystic Fibrosis Foundation Registry reported a prevalence of 2.2% for patients older than 5 years,[89] similar to the Epidemiologic Study of CF rate of 2% in 14,210 patients.[79] The European Registry of CF (ERCF), found an overall prevalence of 7.8% in 12,447 CF patients from 224 CF centers in nine European countries (range 2.1% in Sweden to 13.6% in Belgium).[97] A national study in 3089 Italian CF patients reported ABPA in 6.2%.[98]

A likely source of the wide range of reported ABPA in CF lies in the difficulty of case ascertainment. The CFF Registry relies on an ABPA diagnosis by the reporting center without stipulating diagnostic criteria. In the ESCF and ERCF Registries, diagnostic criteria were employed, but they varied, and it is not clear whether or how stringently they were applied by the reporting centers.[79,97] In single-center studies, a wide variety of diagnostic criteria have been used. A survey of ABPA diagnostic criteria in 45 U.K. centers found that *Aspergillus*-specific IgE was used only 54% and total serum IgE more than 1000 ng/mL only 45% of the time.[99] In a large single-center study in Italian patients, who were considered to have probable or possible ABPA depending on number of criteria present, 12.2% had probable ABPA and 11.2% had possible ABPA.[100] Notably, up to 10% of acute pulmonary exacerbations in CF may be due to ABPA.[90]

Diagnostic Considerations for Allergic Bronchopulmonary Aspergillosis in Cystic Fibrosis

In CF, diagnosis of ABPA is complicated by features of CF, listed in Box 46-5, that overlap classic diagnostic criteria of ABPA including bronchiectasis, infiltrates, and partially reversible obstructive pulmonary physiology and symptoms.[101] Critical criteria of asthmatic ABPA have been preserved—with the understanding that many CF patients exhibit a variable "asthmatic" component of their CF lung disease in the absence of ABPA (e.g., bronchial hyperreactivity, response to bronchodilators and steroids, wheezing, and response to steroids). Immunologic features of ABPA are also commonly seen in CF patients without ABPA, such as Af-specific immediate skin tests or IgE antibodies, Af-specific IgG or precipitins, and elevations in total IgE. Up to 60% of CF patients may have positive Af skin tests.[80,100-103] Precipitins may be found in up to 25% of CF patients.[92] Total IgE levels may be elevated in up to 25% of CF patients.[82,83,90,92] Most children with CF have serum IgG and IgE antibodies to Af by school age.[104,105] Half of CF patients followed up to 12 years showed loss of previously positive AF-specific IgG and/or IgE antibodies over time.[92] In CF, changes in total serum IgE may be an additional diagnostic variable. A four-fold rise from a stable baseline total IgE to more than 500 IU/mL, or similar large changes in patients with lower IgE, is suggestive of ABPA in CF.[106-108]

BOX 46-5 Similarities between Cystic Fibrosis and Allergic Bronchopulmonary Aspergillosis

Sensitization to *Aspergillus*
- Positive skin test/serum IgE antibody

Episodic obstructive airways disease
Pulmonary infiltrates
Bronchiectasis
Atopy
Humoral immune response to *Aspergillus*
- Serum IgG, IgE, IgA antibodies (ELISA)
- Serum precipitins

Elevated total serum IgE

Chest CT imaging cannot reliably distinguish ABPA from underlying CF. Thin section CT may show infiltrates and/or bronchiectasis not seen on plain radiography.[64,109-112] In general, although bronchiectasis is central in ABPA and more peripheral in CF, some degree of central bronchiectasis is also common in mild CF.[113,114] Although varicose and cystic bronchiectasis is more typical of ABPA than of CF (in which cylindrical bronchiectasis is more common), these forms of bronchiectasis are also seen in up to one third of CF patients.[115] High-attenuation mucus plugs are seen in only a minority of patients with ABPA, whereas mucoid impaction in CF usually lacks this distinctive feature.[67,116]

Because of these difficulties, diagnostic criteria for ABPA in CF patients have been modified as presented in Box 46-6. In addition, because of the high incidence of ABPA and dif-

BOX 46-6 Diagnosis of Allergic Bronchopulmonary Aspergillosis (ABPA) in Cystic Fibrosis

Full Diagnostic Criteria for ABPA in CF

- Acute or subacute clinical deterioration (cough, wheeze, exercise intolerance, exercise-induced asthma, decline in pulmonary function, increased sputum) not attributable to another etiology
- Serum total IgE concentration over 1000 IU/mL (2400 ng/mL), unless patient receiving systemic corticosteroids (if so, retest when off steroids)
- Immediate cutaneous reactivity to *Aspergillus* (prick skin test wheal >3 mm with surrounding erythema, off systemic antihistamines) or in vitro presence of serum IgE antibody to Af
- Precipitating antibodies to Af or serum IgG antibody to Af by an in vitro test
- New or recent abnormalities on chest radiography (infiltrates, mucus plugging) or chest CT (bronchiectasis) that have not cleared with antibiotics and standard physiotherapy

Minimal Diagnostic Criteria

- Acute or subacute clinical deterioration (cough, wheeze, exercise intolerance, exercise-induced asthma, change in pulmonary function, increased sputum) not attributable to another etiology
- Total serum IgE > 500 IU/mL (1200 ng/mL). Note: if ABPA is suspected and total IgE is 200-500 IU/mL, repeat testing in 1 to 3 months recommended. If on steroids, retest when off steroids.
- Immediate cutaneous reactivity to *Aspergillus* (prick skin test wheal >3 mm with surrounding erythema, off systemic antihistamines) or in vitro demonstration of IgE antibody to Af.
- One of the following:
  - Precipitins to Af or in vitro demonstration of IgG antibody against Af
  - New or recent abnormalities on the chest radiograph (infiltrates, mucus plugging) or chest CT (bronchiectasis) that have not cleared with antibiotics and standard physiotherapy

Adapted from Stevens DS, Moss R, Kurup VP, et al: Allergic bronchopulmonary aspergillosis in cystic fibrosis—state of the art. Cystic Fibrosis Foundation Consensus Conference. Clin Infect Dis 37:S225-S264, 2003.

BOX 46-7 Screening for Allergic Bronchopulmonary Aspergillosis in Cystic Fibrosis

- Maintain a high level of suspicion for ABPA after age 6 years.
- Obtain total serum IgE concentration annually. If the total serum IgE is >500 IU/mL, determine immediate cutaneous reactivity to Af or use an in vitro test for IgE antibody against Af. If positive, proceed to Minimal Criteria diagnosis consideration.
- If the total serum IgE concentration is 200-500 IU/mL, repeat if there is increased suspicion for ABPA, such as by a disease exacerbation, and perform further diagnostic tests (immediate skin test reactivity to Af or in vitro test for IgE antibody to Af, precipitins or serum IgG antibody to Af and chest radiography).

Adapted from Stevens DS, Moss R, Kurup VP, et al: Allergic bronchopulmonary aspergillosis in cystic fibrosis—state of the art. Cystic Fibrosis Foundation Consensus Conference. Clin Infect Dis 37:S225-S264, 2003.

ficulty in diagnosis, screening for ABPA in CF patients is recommended (Box 46-7).[75]

The development of methods to identify and produce purified, standardized allergens by recombinant DNA technology is important for both diagnosing and understanding the pathogenesis of ABPA. Af extracts used for skin tests and in vitro antibody assays are antigenically complex, containing dozens of allergens recognized by IgE antibodies in allergic sera.[117] They are not standardized and poorly reproducible. Recombinant DNA technology has allowed for identification and production of many Af allergens (shown in Table 46-1) which may play a role in pathogenesis and diagnostic testing.[118,119] Several show promise for diagnosis of ABPA in patients with CF as well as asthma.[120-127]

Treatment

Treatment of ABPA in CF, outlined in Box 46-8, is essentially the same as in asthma, except that it is complicated by several factors peculiar to CF.[27,75] First, recognition, and therefore prompt treatment, is more difficult because of the diagnostic difficulties and clinical similarities discussed earlier. Second, CF patients are more vulnerable to glucocorticoid toxicity including growth suppression, osteoporosis, and diabetes which are, unlike in asthma patients, common complications of the underlying disease.[128-130] Third, alterations in absorption, distribution and metabolism of drugs, and drug-drug interactions, are common in CF patients. Absorption of enteric-coated prednisolone may be compromised in CF patients, in whom the jejunal pH may be lower than desired.[131] Once absorbed, prednisolone is cleared more rapidly in CF patients, requiring increased dosing or shorter dose intervals.[132]

Itraconazole is an inhibitor of cytochrome P450 3A4. It increases exposure to methylprednisolone and dexamethasone but not prednisolone or endogenous cortisol.[133-139] Concomitant use of itraconazole and inhaled budesonide can result in adrenal suppression and even Cushing syndrome.[140-146]

Oral glucocorticoids are as effective for ABPA in CF as they are in asthma.[75,87,88,90,92,147-153] An attempt should be made to taper corticosteroids in 2 to 3 months. Despite this, in the European Registry of Cystic Fibrosis survey only 56% of CF patients with ABPA received oral corticosteroids (compared to 15% of CF patients without ABPA); inhaled corticosteroids were given to 75% of the CF patients with ABPA compared to 39% of CF patients without ABPA, despite a lack of published information on efficacy of inhaled cortico-

steroids for ABPA.[97] These data suggest that fear of glucocorticoid toxicity may play a significant role in clinician's approach to treatment of ABPA in CF.

Serum IgE levels are a useful way to follow response to therapy and guide dosing.[75,90,106,154] Consideration should be given to initiating oral corticosteroid therapy even in asymptomatic patients if the serum IgE level sharply rises (at least doubles) from a baseline value, even if the absolute level does not reach traditional diagnostic criteria levels of 500 to 1000 IU/mL.[106-108] However, IgE levels alone should not be used to make treatment decisions. Several scenarios to treatment approach are given in Table 46-3.

Reduction of fungal antigenic burden with antifungal agents is a logical addition to the treatment program.[155] This approach has been validated using itraconazole in asthmatic ABPA in several double-blind, placebo-controlled, randomized multicenter studies.[156-159] In CF, uncontrolled studies suggest similar benefits with good tolerance.[90,160] Itraconazole should be used if a patient has a slow or poor response to glucocorticoids, experiences a relapse, is steroid-dependent, or has steroid toxicity (see Box 46-8).[75]

Itraconazole can be given at an adult dose of 200 mg twice daily or a pediatric dose of 5 mg/kg once daily (up to 200 mg). Itraconazole blood levels (target, ≥1 μg/mL) to document adequate absorption (especially if concomitant acid-suppressive therapy), lack of response, or other possible drug interactions. Monitor use or levels of concomitant drugs with potential for drug-drug interaction, especially adrenal suppression with concomitant budesonide. Oral solution has 50% higher bioavailability than capsule.

BOX 46-8 Therapy for Exacerbations of Allergic Bronchopulmonary Aspergillosis

Oral Corticosteroids

Indications	All patients except those with steroid toxicity
Initial	0.5-2.0 mg/kg/day by mouth prednisone equivalent, maximum 60 mg/day, for 1-2 wk
Begin taper	Then 0.5-2 mg/kg/day every other day for 1-2 wk
Taper off	Attempt to taper off in 2-3 mo
Relapse	Increase corticosteroids, add itraconazole; taper corticosteroids when clinical parameters improve

Oral Itraconazole

Indications	Slow/poor response to corticosteroids, relapse, corticosteroid-dependent, or corticosteroid toxicity
Dosing	5 mg/kg/day, maximum dose 400 mg/day by mouth unless itraconazole levels obtained Twice daily dosing required when daily dose exceeds 200 mg.
Duration	3-6 mo
Monitor	LFTs: all cases. Serum itraconazole levels (steady state target ≥1 μg/mL) if concern for

Adjunctive Therapy

- Inhaled corticosteroids, bronchodilators, leukotriene receptor antagonists, omalizumab: no evidence for use in ABPA, may be used for the asthma component of ABPA. Budesonide metabolism (cytochrome P450) inhibition by itraconazole can lead to adrenal insufficiency.
- Uncontrolled reports of agents with possible efficacy: inhaled amphotericin, oral voriconazole, pulse intravenous methylprednisolone
- Environmental manipulation: attempt to search for and lessen mold spore exposure in refractory cases.

adequate absorption can be helpful in patients with a poor response. Administration of itraconazole with cola beverage 1 hour before meals or gastric acid suppression will improve absorption. Some patients need higher dosing or switching from capsules to the more bioavailable liquid cyclodestrin suspension (100 mg/5 mL).[161] It may be useful to check sensitivity of Af sputum isolates to azoles and amphotericin B. Itraconazole courses of 3 to 6 months are recommended, with baseline and periodic monitoring of liver function tests.[75]

Therapies for ABPA that have not been adequately evaluated and, therefore, should be considered unproven include use of inhaled corticosteroids, inhaled amphotericin, newer oral azoles (such as voriconazole), pulse methylprednisolone infusions, immunosuppressives (such as low-dose methotrexate and olamizulab).[162-164] Inhaled corticosteroids and other agents useful in asthma for the asthmatic component of ABPA as recommended by current asthma guidelines may be beneficial but should not be sole therapy.[165]

Cases of ABPA have been tied to environmental exposures.[166-168] The role of environmental controls in prophylaxis or treatment of ABPA has not been carefully studied. Measures that may contribute to remission and/or prevent exacerbation include avoidance of outdoor exposures such as turned compost heaps or moldy hay piles, examination and cleaning of humid moldy indoor areas, and use of high-efficiency particulate air (HEPA) filters. Measurement of indoor fungal spore counts may be helpful in identifying occult exposure.[169,170]

CHAPTER 47 Collagen Vascular Disorders

Jeffrey S. Wagener, Jennifer B. Soep, and Thomas C. Hay

TEACHING POINTS

- Collagen vascular or rheumatic diseases represent autoimmune conditions which can affect the lung.
- Therapy for collagen vascular disease–related lung disorders is focused on controlling the underlying collagen vascular disease.
- Interstitial lung disease and pulmonary vasculitis are the most frequent chronic pulmonary complications of the collagen vascular diseases.
- Inflammatory (non-infectious) pneumonias and pulmonary arterial hypertension can be the manifesting signs of collagen vascular diseases.

Collagen vascular diseases (CVDs) include many conditions that have in common active inflammation and an autoimmune basis (Box 47-1).[1] Within the category of CVDs are primarily vasculitic conditions (Box 47-2) and other systemic inflammatory conditions (including inflammatory bowel disease and Reiter syndrome). All of the CVDs have in common the ability to harm the lung, although the degree and pattern of harm varies greatly. Also, most severe pulmonary complications of CVDs occur primarily in adults, and children are only occasionally affected, suggesting that the CVD is either different in children (as with certain forms of rheumatoid arthritis), or the lung complications have an insidious onset and are not recognized in childhood. There is increasing evidence that pulmonary involvement in CVDs is more frequent in children than previously recognized, indicating the need for increased vigilance in monitoring the respiratory system.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Pulmonary abnormalities in patients with CVDs can be divided into three groups. First, patients with CVDs are at an increased risk for infection, both because of their primary disease and because of complications secondary to immunosuppressive therapy.[2-4] Opportunistic infections must always be considered first when a CVD patient has respiratory symptoms. Cough, sputum production, and fever are particularly important signs that suggest infection. Although all potential infecting organisms should be considered, particular attention should be paid to cytomegalovirus, *Escherichia coli*, *α-hemolytic streptococci*, *Klebsiella* and *Aerobacter* species, *Legionella pneumophila*, *Candida albicans*, *Aspergillus* species, *Mycobacterium*, and *Pneumocystic carinii*.[3,5,6]

Second, pulmonary complications from pharmacotherapy must be considered. In addition to general immunosuppression, some of the medications used to treat CVDs have selective harmful effects on the lung. Penicillamine can produce hypersensitivity pneumonitis and bronchiolitis obliterans and has been associated with acute pulmonary hemorrhage, alveolar and interstitial fibrosis, and a pulmonary and renal syndrome similar to Goodpasture syndrome.[7-9] Methotrexate can produce an acute pneumonitis as well as pulmonary fibrosis.[10-12] In sensitive individuals, salicylates and nonsteroidal anti-inflammatory drugs produce bronchoconstriction. Biotherapeutics (such as anti-B-lymphocytes and anti–TNF-α) can produce profound immunosuppression and can lead to reactivation of past infections, particularly with mycobacteria.[13,14]

Third, all CVDs have a degree of chronic systemic inflammation that can produce tissue damage either acutely or over time. Lung disease in patients with CVD can involve virtually every part of the respiratory system including the chest wall, diaphragm, pleura and pleural space, interstitium, pulmonary vasculature, alveoli, and airways (Table 47-1).[6]

Chest wall disease is usually related to muscle weakness, as occurs with dermatomyositis, or skeletal rigidity, as occurs with ankylosing spondylitis.[15,16] Muscle weakness may also represent a complication of steroid therapy.[17]

Diaphragm dysfunction and basilar lung atelectasis occur with systemic lupus erythematosus (SLE) in both adults and children.[18-20] This "shrinking lung" syndrome is rarely disabling or progressive if the primary disease is adequately treated.[21] Studies of lung mechanics demonstrate inspiratory and expiratory muscle weakness with decreased transdiaphragmatic pressures.

Pleurisy and pleural effusions are particular problems in patients with SLE but also occur with systemic juvenile rheumatoid arthritis (JRA).[20,22,23] Pleural effusions, although usually bilateral, can be unilateral resulting from a localized intrapleural immunologic reaction (Fig. 47-1). When effusions manifest acutely they should always be evaluated for a possible infectious etiology. Effusions caused by CVD will usually resolve with anti-inflammatory therapy without producing fibrosis or restrictive changes.

Interstitial lung disease (ILD) can begin early in the disease process and complicate any of the CVDs (Fig. 47-2). With disease progression, cytokines, particularly transforming growth factor-β, are released and activate gene expression, resulting in collagen deposition.[24] The result, seen almost exclusively in adults, is extensive fibrosis and honeycomb lung. A different pathologic picture seen in Sjögren syndrome is lymphocytic interstitial pneumonitis (LIP).[25] With LIP there is a dense infiltrate of lymphoplasmacytic cells that are within the alveolar walls and fill the alveolar spaces. The interstitial infiltrates in LIP do not show the heterogeneous cell types seen in the more common interstitial pneumonitis. LIP can have associated amyloid deposition, lymphoid follicles, and giant cells.

Vasculitis occurs in SLE and is the identifying pathologic finding of the various vasculitides. Patchy alveolar hemorrhage and adjacent lung necrosis (Fig. 47-3) develops from immune complex deposition and neutrophil adherence to the endothelium, leading to microangiitis and eventual vessel obstruction and vessel wall disruption.[26] Pulmonary capillaritis also can result in diffuse alveolar hemorrhage, and although this is usually related to a CVD, cases with no obvious systemic disease have been described.[27]

Pulmonary arterial hypertension (PAH) is now recognized to occur with surprising frequency in patients with CVDs. All patients with idiopathic PAH should be evaluated thoroughly because this can be the manifesting symptom of CVD. PAH is most commonly seen in variants of progressive systemic sclerosis (PSS or scleroderma), mixed connective tissue disease, and the CREST syndrome (calcinosis,

Raynaud phenomenon, esophageal dysfunction, sclerodactyly, and telangiectases).[28] Pulmonary hypertension related to CVD is a primary plexogenic arteriopathy and is characterized by "onion-skin" proliferation of the intima with medial thickening of the arterioles and small muscular arteries of the lung. Inflammation and vessel wall necrosis are not present as in vasculitis. Pulmonary arterial hypertension may also be related to increased pulmonary vasoreactivity and to pulmonary arteriolar thrombosis caused by circulating anticoagulants.[29]

Acute inflammatory (noninfectious) pneumonia is occasionally the presenting problem with CVDs and is most common in SLE (Fig. 47-4).[19,20] Pathologically there is diffuse alveolar damage with mixed interstitial inflammatory cellular deposits, interstitial edema, and fibrin deposition. Red blood cells and hyaline membranes are present in the alveoli.[30]

Diffuse alveolar hemorrhage is seen in SLE and is a possible complication of any of the vasculitic diseases.[31,32] Unlike acute immunologic pneumonia, diffuse alveolar hemorrhage is most likely a complication in an already diagnosed condition and does not usually occur with pleural or pericardial disease. Pathologic findings vary from diffuse microangiitis and capillaritis to hemorrhage without vasculitis. Diagnosis is based on the clinical presentation of an acute infiltrate and a dropping hematocrit. Bronchoscopy and lavage will demonstrate large numbers of red blood cells in the effluent.

Bronchiolitis obliterans (BO) usually occurs in adults with rheumatoid arthritis but may begin in childhood (Fig. 47-5).[33] BO represents progressive airway obstruction from persistent inflammation and fibrous proliferation of the terminal bronchiolar walls. Eventually there is total obliteration of the airway lumen. Bronchiolitis obliterans with organizing pneumonia (BOOP) is a distinctly different condition that has histologic findings of inflammatory polyps produced by proliferating collagen bundles with acute and chronic inflammatory cells in the terminal respiratory bronchioles. This organizing process extends into the alveolar spaces and produces a clinical picture of restrictive lung disease. The often acute onset of BOOP is distinctly different from that of BO, which is chronic and obstructive.

Airway disease similar to asthma occurs in patients with Churg-Strauss syndrome (allergic granulomatosis).[34] Also,

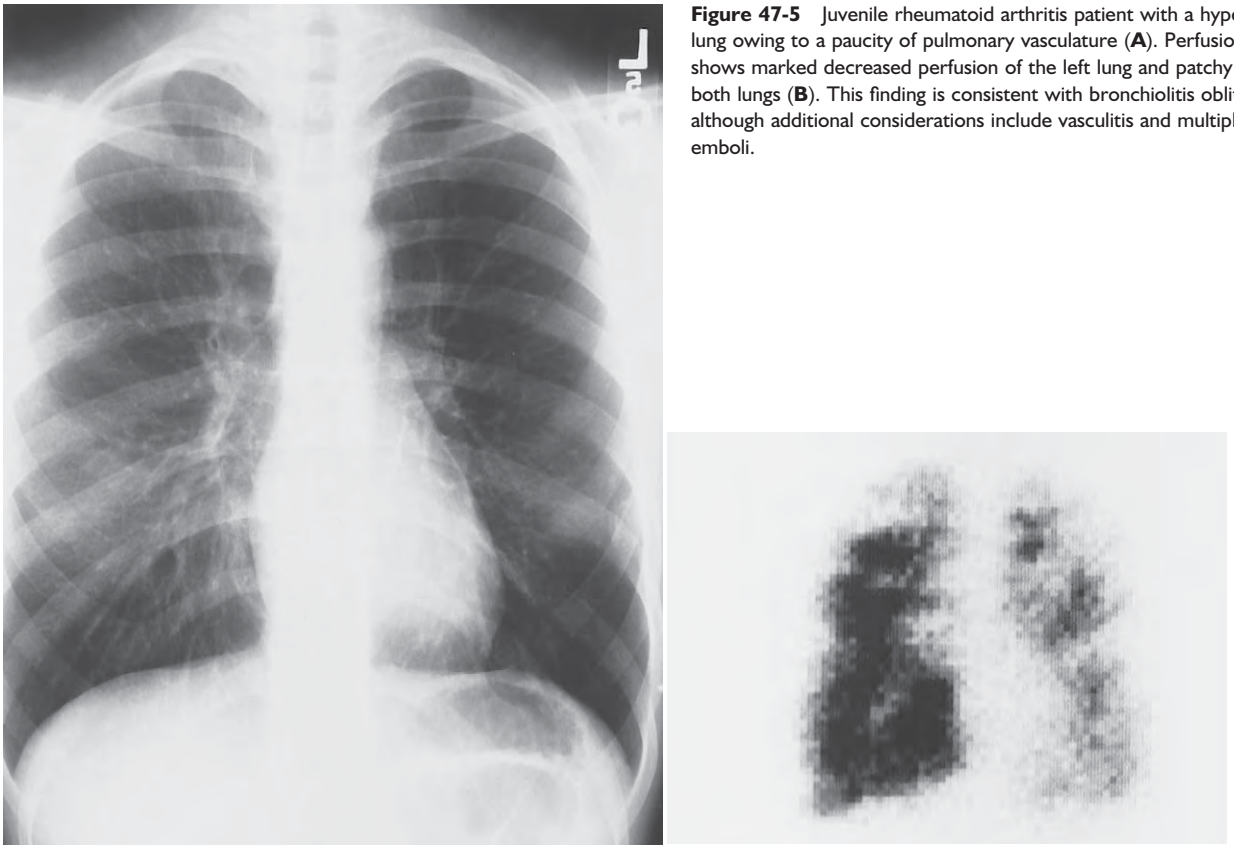
Figure 47-4 Systemic lupus erythematosus patient with a retrocardiac infiltrate caused by an immunologic pneumonia (**A**). A small pleural effusion is also present. Rapid resolution of pneumonia occurred with steroid therapy (**B**).



A B

Figure 47-5 Juvenile rheumatoid arthritis patient with a hyperlucent left lung owing to a paucity of pulmonary vasculature (**A**). Perfusion scintigraph shows marked decreased perfusion of the left lung and patchy perfusion of both lungs (**B**). This finding is consistent with bronchiolitis obliterans, although additional considerations include vasculitis and multiple pulmonary emboli.

endobronchial obstruction can occur from granulomas in some vasculitic diseases.[35]

CLINICAL FEATURES

Rheumatic Conditions

Juvenile rheumatoid arthritis is the most common CVD in children (see Box 47-1).[1] JRA can manifest with the following three different clinical patterns, all of which have different prognosis and sequelae:

1. Systemic-onset disease occurs most frequently in children younger than age 4 and includes fever, an evanescent macular rash, arthritis, hepatosplenomegaly, leukocytosis, and polyserositis. Pulmonary involvement at the time of presentation is common and includes pleural effusions and an acute inflammatory (noninfectious) pneumonia.[23]
2. Polyarticular JRA (five or more joints involved) resembles the adult disease, although only 10% of children have a positive rheumatoid factor. In contradistinction with the adult disease, symptomatic pulmonary complications are rare. Pulmonary function abnormalities, including a restrictive defect and abnormal diffusing capacity, are more common.[36] Potential complications include recurrent pleurisy with or without pleural effusion, pulmonary nodules, interstitial pneumonitis, and BO (see Fig. 47-5). Pulmonary hypertension is rarely seen in children.
3. Pauciarticular JRA is characterized by chronic arthritis of only a few (four or fewer), usually large joints. Systemic symptoms, except iridocyclitis, are uncommon. Although symptomatic pulmonary complications typically do not occur in children with this form of disease, abnormal carbon monoxide diffusion and small airway obstruction have been described.[36]

Juvenile ankylosing spondylitis (JAS) is an inflammatory joint disease involving the spine and sacroiliac joints. JAS occurs in late childhood and is most common in HLA-B27 positive males. The presentation is similar to that of pauciarticular JRA but the condition progresses to include the spine and sacroiliac joints. Because of limited chest wall motion, patients have restrictive pulmonary function changes with normal lung compliance.[16] Pneumonia may complicate the clinical course due to infections of upper lobe bullae. Clinical pulmonary symptoms are rare in the absence of infection.[6]

Systemic lupus erythematosus is less common than JRA, but is more likely to have pulmonary complications in children as well as adults.[19,37,38] This multisystem inflammatory disease is diagnosed by a constellation of diagnostic criteria. Life-threatening acute immunologic pneumonia can be the initial manifestation of SLE and is difficult to distinguish from an infectious pneumonia (see Fig. 47-4). Pleuritis with or without effusion is relatively common in children with SLE (see Fig. 47-1).[20] Effusions are typically small, but patients often have dyspnea, cough, and fever in addition to pleuritic pain.[22] Pleural fluid usually has a normal glucose and pH, separating this condition from bacterial empyema.[39] High concentrations of antinuclear antibody and double-stranded DNA in the pleural fluid are highly suggestive, but not diagnostic.[40] ILD has been reported in children with SLE from both clinical and autopsy studies.[3,19] Patients may have dyspnea, cough, and chest discomfort, or may have a normal examination and chest radiograph. Pulmonary function tests may show a restrictive pattern with reduced diffusing capacity.[41] Patients with active inflammation can be effectively treated with immunosuppressive therapy and fibrosis is rare in children. Alveolar hemorrhage can produce acute respiratory distress and usually occurs in previously diagnosed SLE patients.[31] Diffusing capacity is typically increased and patients have falling hemoglobin.[42] Diaphragm dysfunction and associated "shrinking lung" have been described in pediatric SLE patients.[19-21] Lower airway obstruction has been described, as has upper airway obstruction caused by laryngeal involvement.[43,44] Finally, the most insidious pulmonary complication of SLE is PAH. Mild PAH is common in adults and is associated with Raynaud phenomenon.[45] Early symptoms include dyspnea with exertion, and echocardiography should be obtained in all symptomatic patients.

Progressive systemic sclerosis, also known as scleroderma, is a rare disease in pediatrics; however, cardiopulmonary complications are common and have been associated with death in childhood.[1] Clinical diagnosis is based on a skin disease that progresses from an edematous phase to an atrophic, taut, immobile dermis in combination with a systemic disease including arthralgia, renal disease, Raynaud phenomenon, and pulmonary fibrosis. Some 50% to 90% of adults with PSS develop ILD, eventually leading to death.[46,47] Radiographic changes include a diffuse reticulonodular interstitial infiltrate (Fig. 47-6) with progression to cystic changes and honeycomb lung.[48] Vasculitis progressing to PAH has also been described in children.[28] Patients with CREST syndrome are at greater risk of developing primary pulmonary vascular disease and should be monitored closely for signs of PAH. Pulmonary function testing, including lung volumes, carbon monoxide diffusing capacity, and the degree of oxygen desaturation with exercise may be particularly helpful in detecting

Figure 47-6 Progressive systemic sclerosis patient with a diffuse reticular nodular infiltrate and a spontaneous pneumothorax.

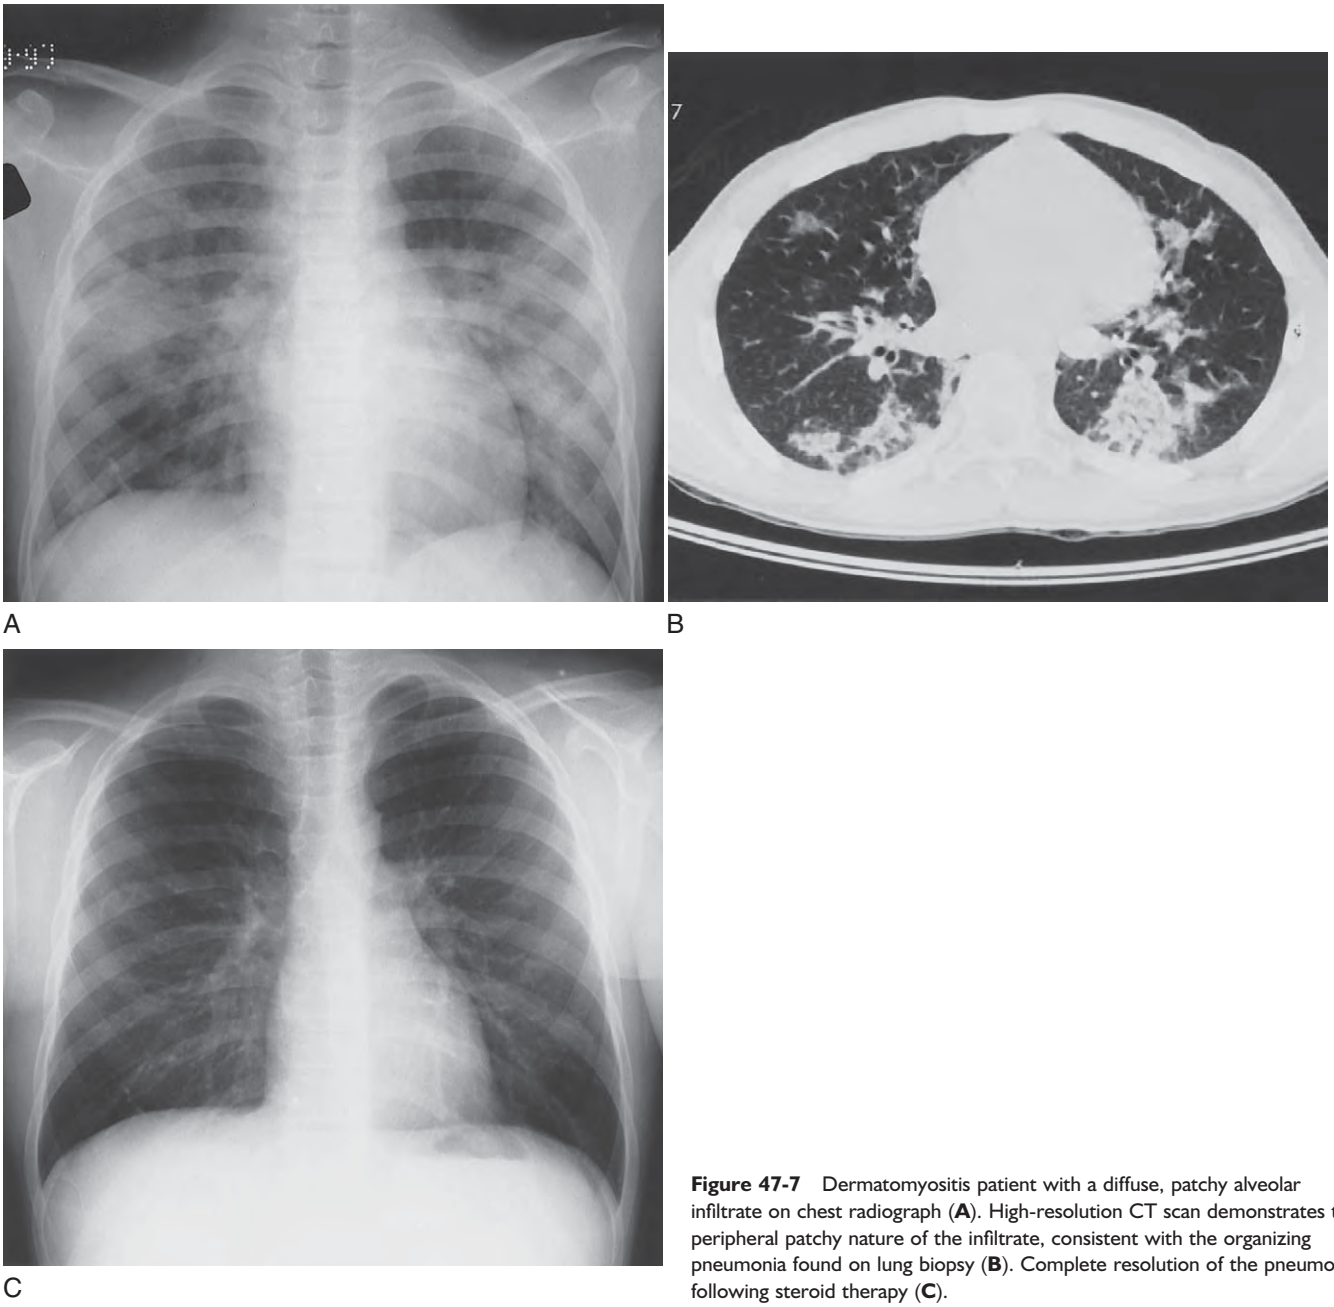


Figure 47-7 Dermatomyositis patient with a diffuse, patchy alveolar infiltrate on chest radiograph (**A**). High-resolution CT scan demonstrates the peripheral patchy nature of the infiltrate, consistent with the organizing pneumonia found on lung biopsy (**B**). Complete resolution of the pneumonia following steroid therapy (**C**).

the early effects of pulmonary restrictive and vascular complications.[49]

Dermatomyositis and polymyositis are characterized by chronic myopathy with vasculitis involving the skin and muscles. Diagnosis is based on the characteristic skin rash, symmetrical proximal muscle weakness, elevated serum levels of muscle enzymes, and if obtained, a myopathic electromyogram and a consistent muscle biopsy. The vasculitis seen in children is pathologically different from that seen in adults and is uniquely responsive to corticosteroid therapy. Respiratory problems can be related to difficulty swallowing due to the weakness of pharyngeal muscles and resulting aspiration.[50] Recurrent atelectasis may be seen on chest radiographs. Patients also may develop progressive respiratory muscle weakness, leading to decreased cough efficiency and eventually ventilatory insufficiency.[15] ILD associated with dermatomyositis, while common in adults, has rarely been reported in children.[51,52] Symptoms include dyspnea, dry cough, and rarely, fever. Longitudinal pulmonary function studies in children suggest that pulmonary disease can manifest in the absence of symptoms.[53] Chest radiographs may show diffuse infiltrates (Fig. 47-7), occasionally complicated with pneumothoraces. There is one reported pediatric case of pulmonary alveolar proteinosis complicating dermatomyositis.[54]

Mixed connective tissue disease is a clinical syndrome with features similar to those of SLE, dermatomyositis, and PSS associated with a circulating antibody specific for the ribonucleoprotein component of extractable nuclear antigen.[55] Pulmonary disease is common in children (Fig. 47-8) and includes pleural effusions, restrictive pulmonary function, and PAH.[56]

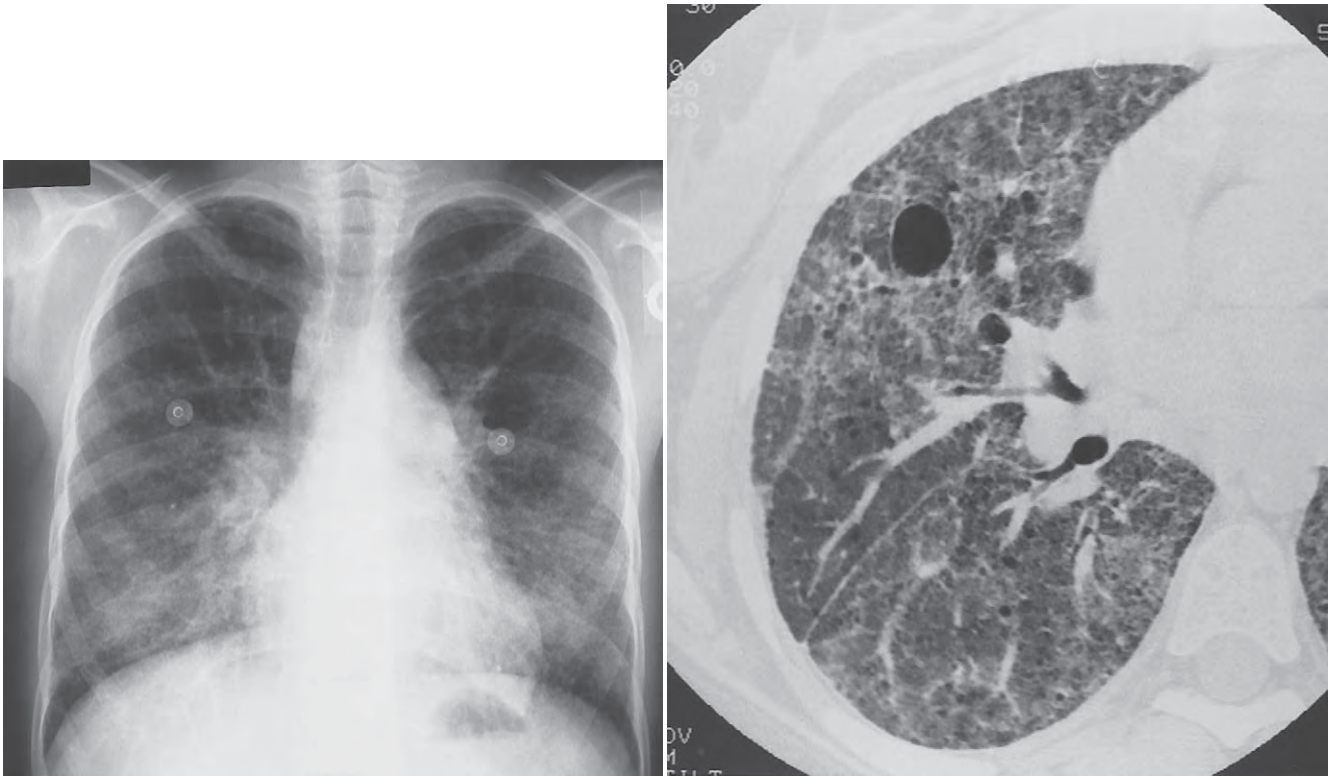

Figure 47-8 Mixed connective tissue disease with a diffuse reticular nodular infiltrate on chest radiograph (**A**). High-resolution CT scan demonstrates diffuse ground-glass opacity with cystic and fibrotic changes (**B**). Bronchiectasis is noted peripherally and is better defined than on plain chest radiography.

Sjögren syndrome is rare in children but can be associated with other CVDs including JRA, SLE, PSS, and dermatomyositis.[57] The classic symptoms of keratoconjunctivitis sicca (dry eyes) and xerostomia (dry mouth) are produced by a lymphocytic inflammation of the exocrine glandular tissue. Pulmonary manifestations occur in about 9% of adults and include pleurisy, atelectasis, pulmonary fibrosis, and LIP.[25,58] Diffuse airway dryness may be responsible for the dry cough and recurrent respiratory infections.[6] The pathologic finding of LIP in a patient with CVD is highly suggestive of Sjögren syndrome.

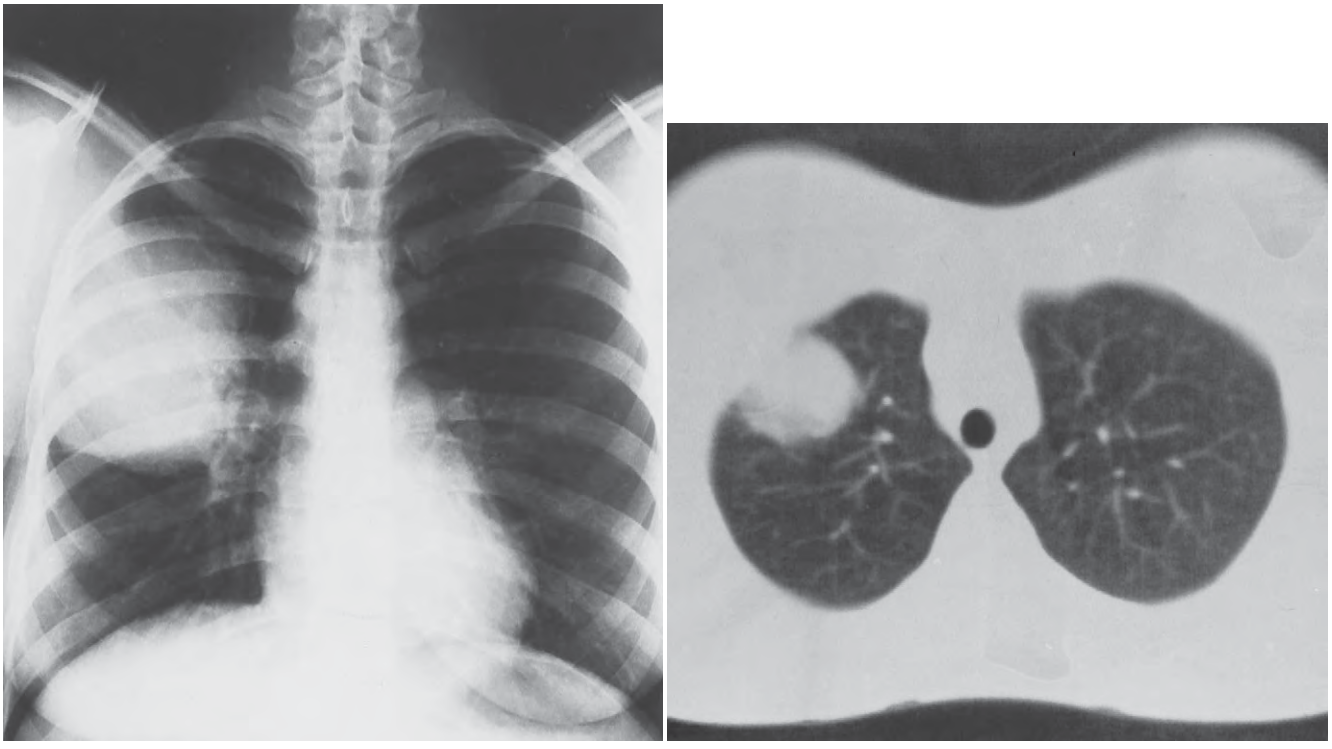
Antiphospholipid syndrome (APS) involves arterial and venous thrombosis and can complicate autoimmune disorders such as SLE and small vessel capillaritis.[59] APS is rare in children but should be considered in patients with complications including pulmonary embolism, primary thrombosis, pulmonary hypertension, and recurrent intra-alveolar hemorrhage. Diagnosis is based on the presence of anticardiolipin antibodies and/or lupus anticoagulant in the serum and is important because therapy includes anti-coagulation in addition to immunosuppression.

Sarcoid is a multisystem granulomatous disease typically developing in young adults and rarely in children.[60] Young children are also more likely to have multi-organ involvement and a poorer prognosis.[61] Respiratory involvement is usually mild and symptoms include cough and exertional dyspnea.[62] Chest radiographs may show hilar adenopathy and occasional parenchymal changes. Pulmonary fibrosis has not been reported in children. Lung function abnormalities are common, including restrictive changes and decreased carbon monoxide–diffusing capacity. Diagnosis requires histologic confirmation, although the serum angiotensin-converting enzyme level correlates well with disease activity.

Goodpasture syndrome is an immune complex disease affecting both the lungs and kidneys.[63] Pulmonary hemorrhage can be the manifesting sign, and diagnosis is based on finding serum antibodies directed to the glomerular basement membrane. Rarely, hemorrhage can be life threatening and require plasmapheresis in addition to immunosuppression.

Primarily Vasculitic Conditions

Wegener granulomatosis (WG) and microscopic polyangiitis are diffuse, small-vessel vasculitic diseases producing necrotizing granulomas, particularly in the respiratory and renal systems. Pediatric patients of all ages can be affected (see Box 47-2). Patients present with cough, fever, chronic rhinosinusitis (particularly in WG), arthralgias, vasculitic rash, hemoptysis, and hematuria or proteinuria.[64,65] Pulmonary disease may predate systemic symptoms and delay diagnosis, particularly in patients diagnosed with "idiopathic" pulmonary hemosiderosis (see Fig. 47-2). Radiographic changes typically include bilateral nodular infiltrates, often with cavitation (Fig. 47-9). Other findings include pleural effusions, pleural thickening, migratory infiltrates, pneumothorax, and endobronchial granulomas producing atelectasis.[35] Diagnosis



A B

Figure 47-9 Wegener granulomatosis patient with a large mass in the right upper lobe extending from the hilum to the pleural surface (**A**). Chest CT scan showing the homogeneous nature of the mass (**B**). Differential considerations include lobar pneumonia, inflammatory pseudotumor, or a chest wall mass. Wegener granulomatosis was diagnosed on biopsy.

is confirmed with the identification of positive antineutrophil cytoplasmic antibodies (cANCA in WG versus pANCA in polyangiitis).[66] Early initiation of vigorous immunosuppressive therapy is important to reduce the major complication of glomerulonephritis and chronic renal failure.[67]

Churg-Strauss syndrome, or allergic angiitis and granulomatosis, is characterized by eosinophilia, fever, vasculitis, and asthma. The most common pulmonary manifestation is asthma, which usually predates the vasculitis. Patchy, nodular lung infiltrates (see Fig. 47-4) can occur with rare cavitation (Fig. 47-10).[34] Histologic findings include eosinophilic pneumonia, necrotizing vasculitis, and granuloma formation.[68]

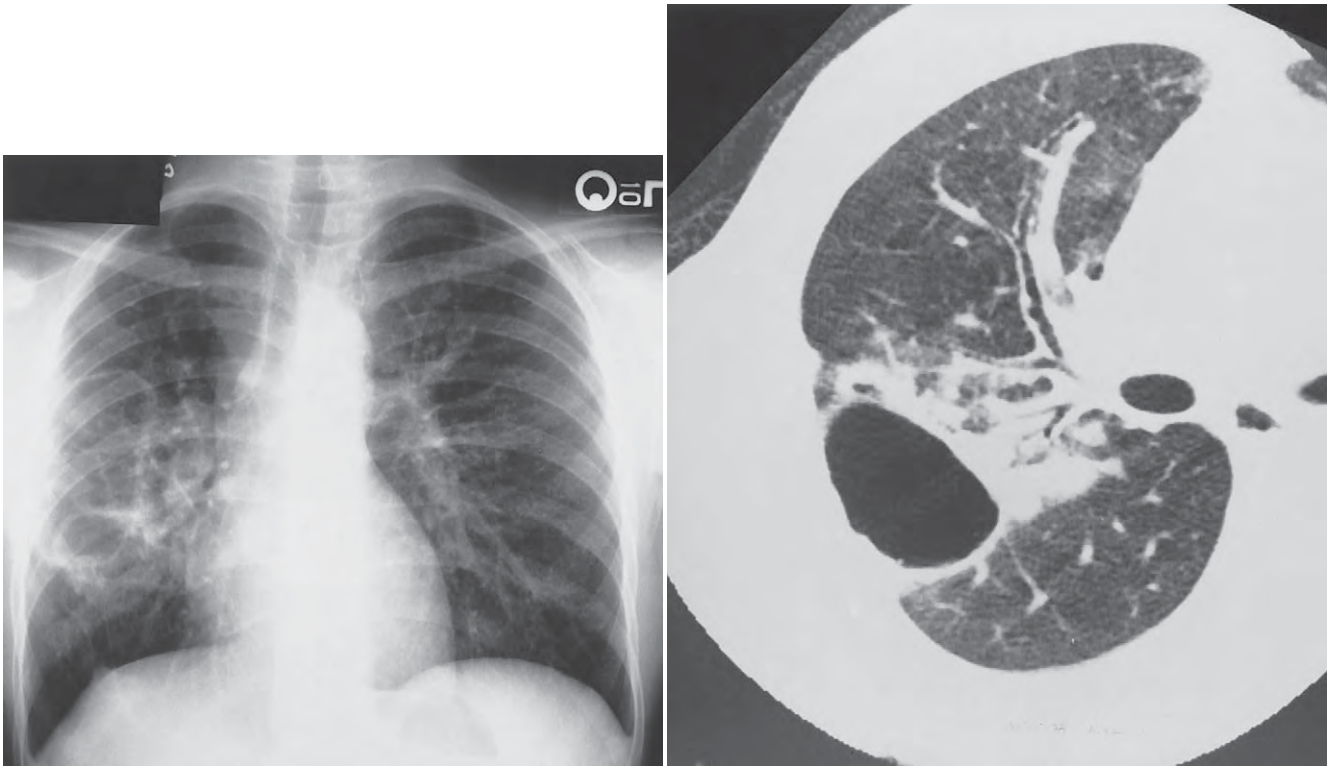
Henoch-Schönlein purpura (HSP), or anaphylactoid purpura, is one of the most common vasculitides in childhood. HSP is most common during the winter and is frequently preceded by an upper respiratory tract infection.[69] Characteristic signs and symptoms include arthritis, arthralgia, abdominal pain, nephritis, and nonthrombocytopenic purpura. Pulmonary complications are rare, but a few cases of fatal alveolar hemorrhage have been reported.[70,71]

Kawasaki disease is a necrotizing arteritis seen most commonly in young children. Patients present with fever, conjunctivitis, lymph node enlargement, rash, strawberry tongue, and erythema of the palms and soles. Cough and respiratory distress are occasionally present and chest radiographic abnormalities include reticulogranular infiltrates, peribronchial cuffing, pleural effusion, atelectasis, and air trapping.[72-74] In addition, cardiac involvement is frequent, with the most serious chronic complication being coronary artery aneurysm. Pulmonary edema secondary to heart failure can occur. Pathologic examination of the lungs often reveals interstitial pneumonia and pulmonary arteritis in fatal cases.

Polyarteritis nodosa is a multi-organ necrotizing vasculitis involving small to medium-sized muscular arteries.[75] Pulmonary complications are uncommon in children but include vasculitis, local thrombosis, and pulmonary edema secondary to cardiac and renal involvement.[76,77] The clinical onset of disease is usually insidious with unexplained fever and weight loss. Abdominal pain, central nervous system disease, arthritis, myalgia, and skin lesions eventually develop in most patients. Vascular thrombosis, necrosis, and aneurysms are seen in the kidneys, heart, and lungs.[75]

Behçet disease is characterized by oral aphthous and genital ulcers in addition to relapsing iritis. Disease onset can be insidious and prolonged. Pulmonary involvement has not been described in children; however, adults can have serious pulmonary complications including pleural effusion, hemorrhage, vasculitis, aneurysms, and emboli.[78]

Pulmonary capillaritis isolated to the lungs and without evidence of a systemic immunologic condition has been described in both children and adults.[27,79,80] Typically these patients present with crackles, cough, dyspnea, and occasionally hemoptysis. Further evaluation detects low oxygen, infil-



A B

Figure 47-10 Churg-Strauss syndrome patient with a large cavitary lesion in the peripheral lung with adjacent pleural thickening and volume loss of the right lung (**A**). Chest CT scan demonstrating bronchiectasis of the right middle lobe in addition to the cavitary lesion (**B**).

trates on chest radiographs, and low hemoglobin. Lung biopsy is needed to distinguish this vasculitis from idiopathic pulmonary hemorrhage. Early intervention with immunosuppression can be lifesaving.

Other Inflammatory Conditions

Reiter syndrome involves a triad of arthritis, conjunctivitis, and urethritis. This inflammatory syndrome occurs most frequently in HLA-B27-positive males, similar to ankylosing spondylitis. Pleuritic chest pain and pleural effusion have been described in acute Reiter syndrome.[81]

Inflammatory bowel disease (IBD) patients develop arthropathies similar to JRA. Other systemic inflammatory manifestations include erythema nodosum, pyoderma gangrenosum, and pulmonary disease.[82] The most common pulmonary complication is ILD, although vasculitis, bronchiectasis (Fig. 47-11), granulomas, pleuritis, and pleural effusion may occur in both adults and children.[83-87] These complications are seen in both ulcerative colitis and regional enteritis (Crohn disease). The ILD appears to improve with improved control of the underlying IBD.[88]

TREATMENT

The main challenge in managing pulmonary manifestations of CVDs is determining whether pulmonary symptoms represent a complication of the primary illness, an infectious complication, or a complication related to ongoing therapy. Because of the importance of this separation, invasive diagnostic techniques, such as bronchoscopy and bronchoalveolar lavage (BAL), are frequently necessary. Therapy includes treating infectious complications, reducing the exposure to toxic medications, or adjusting the pharmacologic management of the primary CVD.

BAL is both sensitive and specific for the diagnosis of infectious complications and may be helpful in diagnosing some pulmonary complications of CVDs, particularly alveolar hemorrhage.[89-91] The presence of neutrophils in the BAL fluid of patients with CVD indicates an active alveolitis and may be seen even in patients without clinical or radiographic evidence of pulmonary involvement. Lymphocytosis or eosinophilia may be seen prior to clinically detected ILD.[92]

High resolution computed tomography (HRCT) of the chest is extremely valuable for diagnosis, identifying diffuse or focal peripheral lung disease (Fig. 47-12), determining location for lung biopsy, and monitoring response to therapy in CVD patients with pulmonary complications (see Figs. 47-3, 47-7, and 47-8).[93-95] Combined inspiratory and expiratory HRCT scanning can be used to detect even early BO in CVD patients.[96]

Pulmonary function testing is valuable for explaining respiratory symptoms and can be used to monitor for early ILD.[97,98] Lung volumes and diffusing capacity should be mea-

Multiple poorly defined nodular densities are seen which were not appreciated on chest radiograph 4 days earlier (see Fig. 47-6).

sured in all patients with CVD and respiratory symptoms. Detecting airway disease and determining reversibility with bronchodilators can be helpful because respiratory symptoms may be related to mild asthma and unrelated to the CVD. Exercise testing, paying close attention to oxygenation, can be an easy and sensitive technique for detecting the earliest signs of ILD in CVD patients.

Echocardiography and estimation of pulmonary artery pressure is valuable in monitoring patients with known diffuse interstitial lung disease, as well as evaluating any patient with exercise limitation. Often echocardiography during exercise is needed to determine the degree of pulmonary vasoreactivity and to diagnose early PAH.[99,100]

PITFALLS AND CONTROVERSIES

Pulmonary complications from CVDs are infrequent in childhood but represent some of the most serious complications in adults. Acute infectious and medication-related complications need to be separated from complications related to the CVD. Chronic pulmonary complications can be insidious, and early detection may be able to reduce long-term disability. Some adult CVD complications may have their origin during childhood, and pulmonary function monitoring should be considered for all patients with CVD who are at risk for developing chronic pulmonary complications. Finally, any CVD patient with exercise limitation should be investigated for PAH as well as possible ILD.

CHAPTER 48 Pulmonary Alveolar Proteinosis

Jeffrey S. Wagener and Robin R. Deterding

TEACHING POINTS

- Alveolar proteinosis can be divided into three distinct patient groups.
- Alveolar lipoproteinaceous material is composed primarily of altered surfactant.
- Granulocyte-macrophage colony stimulating factor (GM-CSF) neutralizing antibody is present in acquired alveolar proteinosis.
- Whole-lung lavage and aerosolized GM-CSF are generally effective therapies in acquired alveolar proteinosis.
- Most patients eventually recover to a state of quiescent disease with minimal to no symptoms.

Pulmonary alveolar proteinosis (PAP) is a rare disease characterized by excess accumulation of proteinaceous and lipid-rich material in the alveolar spaces. Originally described in 26 patients by Rosen and colleagues in 1958,[1] PAP is now recognized to represent three distinct clinical forms with different pathogenic pathways (Box 48-1).[2] More that 90% of reported cases of PAP have historically had no identified etiology and are termed *acquired* or *idiopathic*. Recent descriptions of abnormal granulocyte-macrophage colony-stimulating factor (GM-CSF) activity are leading to a better understanding of the pathogenesis and potential therapy for these patients.[3]

Less common, and also occurring primarily in adults, is secondary PAP. Hematologic malignancies are the most common primary underlying condition leading to secondary PAP; however, other immunologic deficiency states and chronic dust exposure can be precursors to secondary PAP.[4,5] Congenital PAP occurs in patients most commonly with mutations in surfactant protein genes and rarely with an abnormal GM-CSF receptor gene.[6-8] Also very rare mutations of the SLC7A7 gene have recently been described associated with lysinuric protein intolerance and PAP.[9] These congenital forms of PAP are predominantly discussed in the chapter on childhood interstitial lung disease (see Chapter 44).

PATHOGENESIS AND EPIDEMIOLOGY

Surfactant production and clearance mechanisms are tightly controlled processes to maintain alveolar homeostasis. The alveolar macrophage is critical to the clearance of surfactant. GM-CSF is required to stimulate alveolar macrophages to process and reuse surfactant. Disruption of this clearance leads to excess surfactant and abnormal accumulation in the lung.

Understanding of the pathogenesis of acquired PAP has advanced rapidly since two groups of investigators described typical pulmonary pathology in gene knockout mice for GM-CSF.[10,11] GM-CSF replacement by gene overexpression or tracheal or aerosol administration prevented the development of lung disease.[12-15] Additionally, in humans with acquired PAP, reduced GM-CSF activity is associated with a neutralizing autoantibody against GM-CSF that is present in both serum and bronchoalveolar lavage (BAL) fluid.[16-19] Although this antibody does not appear to affect GM-CSF gene expression or the beta-c receptor, there is decreased protein secretion that leads to abnormal macrophage function, reduced surfactant clearance, and abnormal alveolar homeostasis.[20,21] These findings suggest that acquired PAP is a localized pulmonary condition resulting from decreased phospholipid clearance and accumulation of surfactant protein.[22]

Secondary PAP is significantly less common than the acquired disease. Rare cases have been reported in children, usually related to immunodeficiencies and hematologic malignancies, although one case was reported in a child with dermatomyositis.[7,23-26] Other causes of PAP in adults include high exposure to respirable-sized particles of silica, aluminum dust, cement dust, titanium dioxide, and cellulose fiber.[27-31] Immunosuppression related to organ transplantation has rarely been associated with PAP.[32] Although opportunistic infections occur in patients with PAP, they are unlikely to be causative. The most likely pathophysiology for secondary PAP is deficiency in number or function of alveolar macrophages and, thus, decreased clearance of surfactant. Of interest, myeloid leukemias and myelodysplastic syndromes may have alveolar macrophages derived from the malignant clone and following successful chemotherapy and normal hematopoiesis, the PAP may resolve.[5]

Most information on the epidemiology of PAP comes from the adult literature.[2] There is a male predominance and the median reported age of diagnosis is 39 years, although women with PAP tend to be younger than men. Diagnosis is often delayed, with the median time to diagnosis after first onset of symptoms being about 7 months. Most adult patients have a history of smoking tobacco. There is also a slight increased chance that the patient may have an autoimmune disorder such as rheumatoid arthritis, multiple sclerosis, and immunoglobulin-A nephropathy.[2]

BOX 48-1 Clinical Forms of Pulmonary Alveolar Proteinosis

- Acquired or "Idiopathic"
  - GM-CSF neutralizing antibody positive
  - Other
- Secondary
  - Hematologic malignancies
  - Immunodeficiency disorders
  - Dust exposure (silica, aluminum, etc.)
  - Other
- Congenital
  - Surfactant protein B gene mutation
  - Surfactant protein C gene mutation
  - GM-CSF receptor (beta-chain gene mutation)
  - Lysinuric protein intolerance (SLC7A7 gene mutation)
  - Other

CLINICAL FEATURES

Exercise intolerance is the most common initial symptom in older children and adults with PAP.[2,4,33,34] Patients with both acquired and secondary PAP usually have a gradual, progressive onset of dyspnea. This is in contradistinction with congenital PAP, which usually has a rapid onset. A minimally productive cough is occasionally present, as are signs of systemic illness including fatigue, weight loss, and low-grade fever when the diagnosis is delayed. In young children, respiratory symptoms are often insidious in onset and failure to thrive, gastrointestinal symptoms, and bacterial infections are more common. Persistent pneumonia and diffuse infiltrates on chest radiographs may be another sign that eventually leads to the diagnosis. Rarely, concomitant illnesses such as acquired immunodeficiency syndrome, malignancies, or opportunistic infections complicate the diagnosis because chills, weight loss, and hemoptysis can occur either primarily with PAP or with these underlying diseases.

Physical examination may be normal or may have mild findings of tachypnea, diffuse crackles, and occasionally, clubbing.[35] Late in the disease there may be cyanosis. High fevers are rare and should stimulate looking for secondary infectious complications.

Chest radiographic findings include bilateral alveolar filling defects in more than 50% of cases.[36,37] A symmetrical "batwing" appearance is due to the perihilar nature of the infiltrate and the sparing of disease in the costophrenic angles (Fig. 48-1). Heart size is typically normal and there is no pleural space disease. Additionally, the mediastinum is not involved and lymphadenopathy should not be seen. Computed tomography (CT) usually discloses a far more extensive pattern of diffuse involvement in the alveolar spaces (Fig. 48-2).[38,39] Localized disease should raise concern for another diagnosis.

In patients old enough to perform pulmonary function testing, there is a typical restrictive pattern with decreased total lung capacity and decreased forced vital capacity with proportionately decreased airflows.[34,35,38] Diffusing capacity is decreased—this is primarily related to the restrictive pattern, and diffusing capacity corrected for alveolar volume is commonly normal. Blood gases at rest are usually normal, but oxygenation can dramatically worsen with exercise. Exercise-related desaturation is one of the most sensitive measures of disease activity.[40] Longitudinal monitoring of the degree of exercise a patient can perform prior to desaturation is one of the simplest tests for monitoring disease progression. Infant and young child pulmonary functions have not been reported in PAP; however, one would expect similar findings of restrictive lung disease. Young children are more likely to have tachypnea at the time of diagnosis than are adults.

Figure 48-1 Chest radiograph of a 9-year-old child with pulmonary alveolar proteinosis.

DIAGNOSIS

Alveolar proteinosis is diagnosed histologically by the presence of periodic acid–Schiff (PAS)–positive, amorphous, granular material deposited diffusely in the alveolar spaces.[37] This material represents an accumulation of surfactant-derived proteins and lipids. Rarely, there is a mild lymphocytic interstitial infiltrate. Fibrosis is seen only as a late feature in some patients. Electron microscopy demonstrates large amounts of cellular debris without intact cells and numerous laminated phospholipid lamellar bodies.[41] Although open-lung biopsy has been the standard diagnostic technique, better understanding of this lipoproteinaceous alveolar material has led to most PAP cases being diagnosed by BAL.[40] Typically, the effluent is milky and on histology there are foamy-appearing macrophages with diastase-resistant, PAS-positive intracellular inclusions.[37]

Other valuable laboratory tests include looking for neutralizing anti-GM-CSF antibody in either the BAL fluid or serum.

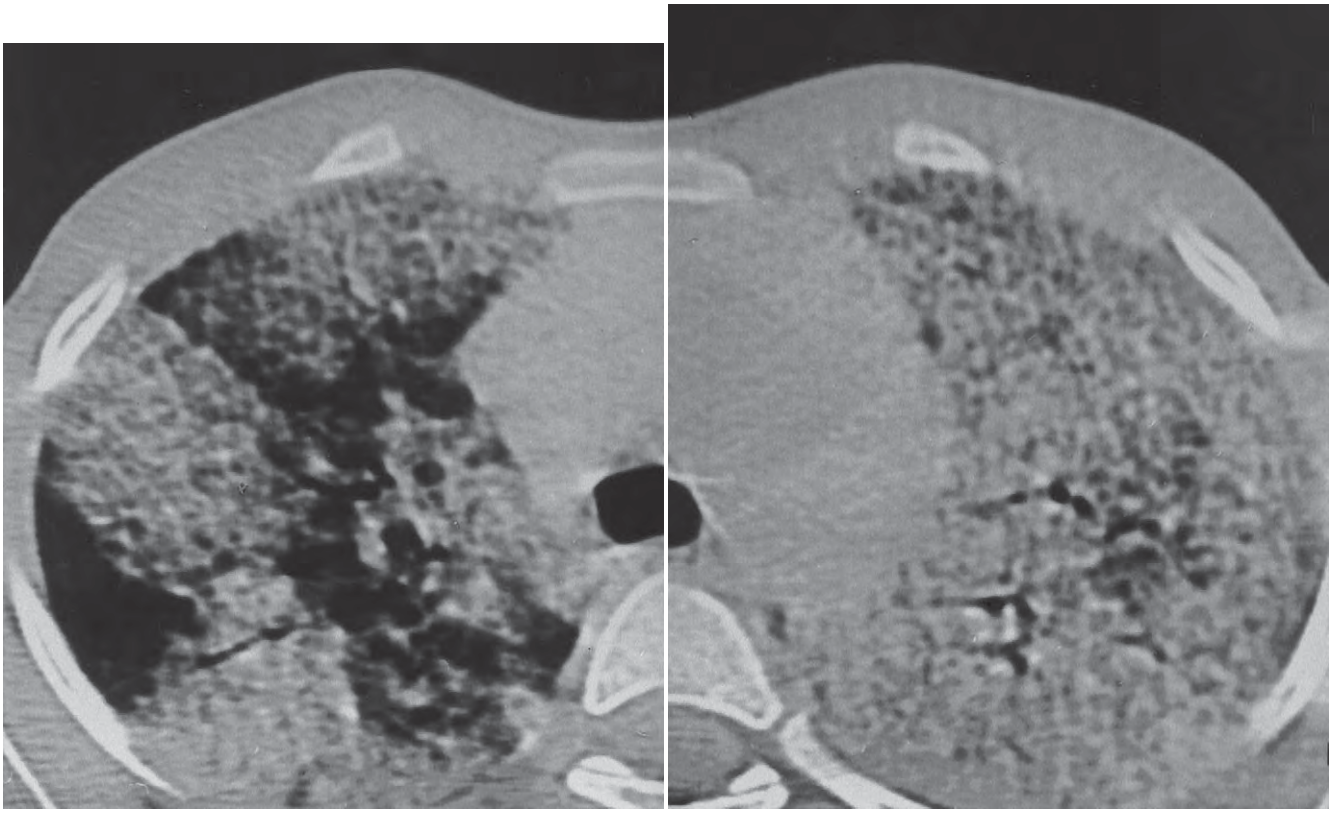

Figure 48-2 Chest computed tomography (CT) scan in the 9-year-old patient with pulmonary alveolar proteinosis whose chest radiograph is shown in Figure 48-1.

Serum anti-GM-CSF antibody is a highly sensitive measure for diagnosing PAP in adults, although it has limited value in monitoring therapy.[42-44] Although antibody has also been identified in children, perhaps due to the rarity of this disease, its value has not been well characterized in children with PAP. Serum LDH correlates well with disease severity and has been suggested as a means to monitor therapy.[45,46] However, LDH is not a sensitive test for diagnosis because most patients will have values in the normal range.

TREATMENT

Numerous therapeutic interventions have been tried unsuccessfully in the past, including systemic steroids and inhaled heparin, acetylcysteine, trypsin, streptokinase, potassium iodide, and surfactant.[2] No therapy was shown to be consistently effective until the introduction of whole lung lavage in 1963.[47,48] More recently the administration of GM-CSF, either systemically or by inhalation, has proved valuable in both adults and children.[22,49-52]

Whole lung lavage in children requires a team including nurses, respiratory therapists, anesthesiologists, and pulmonologists experienced in bronchoscopy and in managing infants and children.[53] The procedure is usually performed under general anesthesia with a double-lumen endotracheal tube inserted with bronchoscopic guidance, ensuring that the tip of the tube is in the main stem bronchus and the balloon, when inflated, is just below the carina and is occluding the main stem bronchus without occluding the upper lobe bronchus. Double lumen endotracheal tubes are generally not available for children who weigh less than 25 kg, and more limited lavage of individual lung segments must be performed. When the patient is appropriately intubated, the lung with the more severe disease, based on chest CT, is lavaged first. The side to be lavaged is deflated and placed dependent with the patient in the lateral recumbent position. Body temperature lavage fluid (normal saline with or without 0.1 U/mL heparin) is instilled, first using 3 to 5 mL/kg to ensure that no fluid leaks into the ventilated side, and then with 12 to 15 mL/kg. The tube through which the fluid is instilled is then clamped and allowed to sit for 1 to 2 minutes before the tube is unclamped and allowed to drain. Chest percussion while the fluid is in the lung may improve the yield of proteinaceous material. Initially, the fluid is milky and yellow to brown in color. The procedure is repeated numerous times until the effluent is clear. Usually only one side is lavaged at a single procedure in children and a repeat procedure is scheduled for the next day if the patient has no complications (Fig. 48-3). Bilateral lavages are routine in adults and can be performed in children if, after 10 minutes of recovery, the lavaged lung is able to maintain adequate ventilation and oxygenation when the remaining lung is degassed. Following the lavage, both lungs are ventilated for 15 to 30 minutes until improved compliance can be documented and oxygenation is adequate with spontaneous ventilation. Frequently, this procedure needs to be repeated several times over years before disease resolution occurs.[54,55] Complications are rare; however, serum electrolytes should be monitored after the

Figure 48-3 Chest radiograph following unilateral (left) lung lavage. Prelavage radiograph is shown in Figure 48-1.

procedure because large amounts of fluid can be absorbed from the lung, thereby producing hyperchloremia and hypokalemia.

GM-CSF has been administered both systemically and by inhalation to patients with PAP.[22,49-52] Although no comparison studies have been performed between whole lung lavage and GM-CSF, initial results suggest that inhaled GM-CSF is at least equally effective for patients with acquired PAP. Wylam and associates[22] report the use of GM-CSF in 12 patients with acquired PAP, two of whom underwent previous whole lung lavage. GM-CSF, 250 μg diluted with normal saline to 2 mL, was administered twice daily with a PARI LC Plus nebulizer (PARI, Starnberg, Germany) for 7 days, every other week. The dose was doubled if no response was documented after 12 weeks of treatment. Eleven patients had improved pulmonary function and only one patient had worsening oxygenation. Most patients reported symptomatic improvement within 4 weeks. Pulmonary function reached peak improvement by 34.5 ± 18.2 weeks. No adverse events were reported. Length of therapy was based on clinical improvement. Five patients relapsed after discontinuing GM-CSF therapy. Four of these patients restarted therapy and all parameters normalized. Several other authors have reported cases or smaller series of patients treated with GM-CSF including one 13-year-old who had not improved after whole lung lavage and was positive for anti-GM-CSF antibody.[49-52,56] Although limited safety data exist in patients with PAP, experience in using GM-CSF to treat malignancies has shown few problems.[57]

CLINICAL COURSE AND PROGNOSIS

Clinical course in acquired PAP can vary from progressive respiratory failure to complete resolution. Reported overall survival is 75% with most deaths due to respiratory failure.[2] The greatest complication risk is pulmonary infection, often from opportunistic organisms (most notably *Nocardia* and *Aspergillus*).[2,3] These infections appear to be related to abnormal macrophage function and often are systemic, suggesting that the effects of PAP are not simply local.[58,59] Infection complications are reduced in patients treated with whole lung lavage, possibly due to improved macrophage function following lavage.[60]

In general, three patterns of disease can be expected: progressive deterioration, stable but with persistent symptoms, and spontaneous improvement.[1] Spontaneous resolution is reported to occur in 8% to 50% of acquired PAP patients.[2] Many of these patients have been treated at least once with whole lung lavage and resolution refers to a lack of symptoms or need for further therapy. Whether the underlying pathophysiology has completely resolved, or is simply in a state of relative quiescence, is not clear because comprehensive evaluations of these patients are rarely reported.[2]

Patients with secondary PAP have a much better prognosis, particularly if the underlying cause (e.g., malignancy) can be effectively treated and macrophage number and function return to normal.[5] Congenital PAP has a generally poor prognosis, particularly if SP-B deficiency is the etiology. One patient with lysinuric protein intolerance had fatal recurrence of PAP following heart-lung transplantation.[9]

PITFALLS AND CONTROVERSIES

While there have been great advances in understanding the underlying pathophysiology of PAP, particularly for acquired disease, choice of therapy still remains challenging owing to lack of well-controlled comparative studies. Acquired disease may resolve spontaneously; however, most patients will require therapy. For patients with GM-CSF antibody, the use of inhaled GM-CSF is a logical choice.[61] However, this therapy may also be effective in patients without antibody and a clinical trial may be indicated in any patient with worsening disease. Whether or not GM-CSF therapy is as effective as whole lung lavage is not clear. Certainly for patients with respiratory distress or disease not improving with GM-CSF, the treatment of choice is whole lung lavage. Additionally, lavage should be considered for patients who have complicating infections. Finally, because of the limited number of patients previously treated, the risk of GM-CSF therapy is not known. Experience from GM-CSF use in malignancies suggests that the risk should be low.[57]

CHAPTER 49 Idiopathic Pulmonary Hemosiderosis

Shahid Ijaz Sheikh and Karen S. McCoy

TEACHING POINTS

- IPH is a rare syndrome. Its etiology may be autoimmune, allergic, or environmental.
- It may manifest acutely with hemoptysis, anemia, cough and dyspnea, and infiltrates on chest radiographs or chronically with pallor, failure to thrive, chronic lung disease—at times with normal physical examination.
- Diagnosis requires careful history and physical examination to confirm pulmonary hemorrhage. If there is clinical suspicion, bronchoscopy with lavage (hemosiderin-laden microphages) is helpful. Other causes of hemoptysis need to be ruled out.
- Pathology consists of thickened alveolar walls, intact erythrocytes in the distal airways, hemosiderin-laden macrophages, and absence of any other disease process or bleeding disorder.
- Treatment consists of systemic glucocorticoids. At times, other immunosuppressive agents including hydroxychloroquine, cyclophosphamide, azathioprine, and methotrexate may also be helpful.
- Prognosis improves with time; rarely it may be fatal.

Idiopathic pulmonary hemosiderosis (IPH) is a rare syndrome characterized by recurrent diffuse alveolar hemorrhage of unknown etiology. It can occur with or without hemoptysis and is associated with pulmonary infiltrates and iron deficiency anemia secondary to deposition of hemosiderin iron in the alveoli. It is more prevalent in children and may have a high mortality. Alveolar hemorrhage can be a life-threatening condition. Following a bleeding episode the hemoglobin's iron is converted into hemosiderin by the alveolar macrophages within 36 to 72 hours,[1,2] hence the term hemosiderosis. The term pulmonary hemosiderosis should be reserved for persistent or recurrent intra-alveolar bleeding because hemosiderin-laden macrophages reside for up to 4 to 8 weeks in the lungs.[1,2] There are numerous causes of alveolar hemorrhage and the diagnosis of IPH is reserved for those cases where other identifiable causes are excluded. Currently, in the presentation of a patient with hemoptysis, pulmonary infiltrates and anemia with no identifiable cause, the diagnosis of IPH is considered[3,4]—especially when vasculitis/capillaritis, granulomas, or immune depositions[5] are ruled out with appropriate studies.

EPIDEMIOLOGY

IPH is a rare disorder with less than 500 reported cases in the literature. Based on published data, an estimated incidence is between 0.24,[6] and 1.23,[7] per million of selected populations. In a biopsy study of interstitial lung diseases in children, lesions of IPH were found in 8% of cases.[8] About 80% of cases occur in children, the majority being diagnosed in the first decade of life.[4,5] Adult onset accounts for the remaining 20% of cases of IPH, but it is unclear how many are previously undiagnosed childhood-onset IPH; diagnosis is before 30 years of age in most patients. Gender distribution is balanced in childhood-onset IPH, but there is a slight male predominance in adult-onset IPH.[5,9] There have been reports of familial clustering in several reports,[10-12] suggesting a possible genetic or environmental contribution to the disease occurrence.

ETIOLOGY

The etiology of IPH remains unclear. Because a few clusters of cases have been identified, the possibility of environmental, familial, or genetic factors cannot be ruled out. Several familial cases have been reported, suggesting either a hereditary cause or a genetic predisposition to the influence of some unidentified environmental agents.[10,13,14] Some of the hypotheses mentioned in the literature are worth reviewing—although proof is lacking for any of them.

Autoimmune Theory

In the initial use of electron microscopy in investigating patients with IPH, many ultrastructural alveolar membrane lesions were noted. Among findings were vacuolization of the alveolar endothelial cells, focal thickening, and scattered ruptures of the alveolar capillary basement membranes,[15-17] although these lesions are not specific to IPH and were not confirmed by all authors.[18,19] An autoimmune etiology was hypothesized by some investigators based on the demonstration of circulating immune complexes,[20] even though the immunohistochemical examination of lung tissue generally has not supported an immunologic pathogenesis.[16,18-20] It is noted that among those with IPH who survive more then 10 years, almost one fourth of them subsequently develop some form of autoimmune disease.[21,22]

Allergic Theory

In 1962, a study published by Heiner and colleagues[23] suggested a possible causal relationship in a few children with IPH who had detectable plasma antibodies (precipitins and immunoglobulin E (IgE)) against cow's milk protein, which led to the hypothesis of a systemic allergic reaction to milk

components.[23-25] Later studies were mixed in respect to this hypothesis.[5,20]

In the original report by Heiner and colleagues[23] seven infants with this correlation were identified after screening more than 2000 patients with symptoms of chronic pulmonary and upper airway diseases. The children apparently improved on a milk-free diet, although a few of them were later able to tolerate reintroduction of milk in the diet. In 1975, Boat and coworkers[24] reported another group of infants ($n = 6$) presenting with a similar clinical picture and high titers of milk protein precipitins. These infants were identified after screening the sera of 160 children with idiopathic chronic lung disease. These six children presented with recurrent pulmonary infiltrates, associated with a mixture of findings including hemosiderin-laden pulmonary macrophages in five, intermittent wheezing in five, eosinophilia in four, anemia in four, and failure to thrive in four. Three out of these six children later went on to develop upper airway obstruction and cor pulmonale. Elimination of cow's milk from the diet, and adenoidectomy when indicated, resulted in improvement in all six patients. In a subsequent study, these investigators were not able to directly correlate milk precipitin levels as a differentiator between four children presenting with pulmonary hemosiderosis compared with other children with chronic lung diseases, gastrointestinal disease, and upper airway disease.[26] In the last 20 years, this hypothesis is questioned by others who were not able to reproduce the association.

Other researchers have identified more than 10 cases with both pulmonary hemosiderosis and celiac disease.[27-29] These patients had complete remission of their pulmonary manifestations after instituting a gluten-free diet.

Environmental Theory

Other authors[11,30] have proposed an association between the occurrence of IPH and exposure to insecticides, but this has never been confirmed. Recently, many studies linking environmental exposure to fungi (especially *Stachybotrys atra* or *S. chartarum*) in water-damaged houses in Cleveland, Ohio, with infantile pulmonary hemosiderosis suggested an infectious or mycotoxigenic pathogenesis.[31-36] Fungal toxin called *trichothecene* is postulated to be responsible by impeding the angiogenesis underneath the alveolar membranes, making the acinar region prone to bleeding. Review by the Center of Disease Control and Prevention questioned the causal relationship between the exposure to molds (e.g., *S. atra* or *S. chartarum*) and the diagnosis of hemosiderosis.[32] Some of the infants in this cohort had other features such as developmental delay, seizures, and hemoglobinuria, suggesting that these infants should be considered as a separate group due to possible confounding factors.

CLINICAL PRESENTATION

Most of the children with IPH presenting with respiratory symptoms are younger than 6 years of age. Although the absence of hemoptysis does not rule out pulmonary hemorrhage, especially in infants and young children, it is a common presentation of IPH. Infants and children usually present with varying severity of recurrent hemoptysis and anemia, which depends on the severity of the alveolar hemorrhage. In severe attacks, hypoxia and dyspnea may be noted. Between attacks the child may be well, apart from the effects of chronic lung disease and residual anemia, if any. Recovery from an episode of bleeding may be surprisingly rapid and complete. In children, failure to thrive and anemia can be the initial findings. In adults the respiratory symptoms can be more pronounced.[37]

The clinical course can be divided into two phases. Acute episodes correspond to intra-alveolar bleeding, with cough, dyspnea, hemoptysis and sometimes respiratory failure; anemia may be present. At times, there may be a normal examination. The chronic phase is characterized by a slow resolution of previous symptoms, with or without treatment; the patient may or may not return completely to baseline, depending on the degree of residual lung damage. The chronic phase manifests with varying respiratory compromise, pallor, emaciation, failure to thrive, hepatosplenomegaly and, sometimes, a normal examination. In those with fibrosis, bilateral crackles and clubbing may be present.

There are no pathognomonic radiologic findings for IPH. Certain radiologic patterns are closely correlated with the clinical phase. During the acute phase (IPH presentation or exacerbations) the chest radiographs show diffuse alveolar-type infiltrates, with the lower lung fields predominantly affected. On the high-resolution computed tomography (CT) scan,[38] this appears as ground-glass opacity mostly in the areas of infiltrate on plain radiograph. During remission, the alveolar infiltrates may resolve or may be replaced by interstitial opacities with a variable degree of fibrosis.[39]

Unless the bleeding is recent, hematologic investigation will usually show microcytic, hypochromic anemia. Reticulocytosis may be present, depending on available iron stores. In older children, sputum examination, although not very sensitive, can demonstrate intra-alveolar bleeding (erythrocytes and hemosiderin-laden macrophages), by hematoxylin-eosin and Prussian blue (Perl) stains. If the patient is not spontaneously producing sputum, inducing it can be dangerous. Bronchoalveolar lavage (BAL) from involved areas has a higher diagnostic yield than the sputum examination.[40-42] The predominant cellular types are the alveolar macrophages, filled with hemosiderin and intact erythrocytes.

In children old enough to perform tests of lung function, the typical picture is of restrictive lung disease with reduced forced vital capacity (FVC), reduced forced expiratory volume in 1 sec (FEV_1), and a normal FEV_1/FVC ratio.[43] Diffusion studies can reveal the single-breath carbon monoxide uptake to be low or normal during the chronic phase or elevated during the acute phase.[44] Varying respiratory insufficiency can be present and should be reflected in the severity of the pulmonary function abnormality, but the insufficiency may be appreciated only with activity. Investigations to exclude other causes of pulmonary hemorrhage, such as the pulmonary-renal syndromes or cardiac disease, will be negative in IPH.

DIAGNOSIS

To establish a diagnosis of IPH, one has to confirm diffuse alveolar hemorrhage and exclude other diseases that can be associated with diffuse alveolar hemorrhage. Pulmonary hem-

orrhage can be confirmed by the clinical picture, which may include cough, hemoptysis, dyspnea, and increased work of breathing. The presentation includes pallor, multiple opacities on chest radiographs and/or high resolution CT scan of the chest. A plain chest radiograph can be very helpful in determining the site of the bleeding, but a normal radiograph does not rule out diffuse pulmonary hemorrhage. A normal chest radiograph also does not prove that bleeding was of extrapulmonary origin. Presence of iron deficiency anemia in cases of recurrent hemorrhage and bronchoalveolar lavage with hemosiderin-laden macrophages on bronchoscopy can be of further help.

When pulmonary hemorrhage is confirmed, the next step is to rule out other diseases which can manifest with pulmonary hemorrhage, which should include a careful history, examination, and appropriate special investigations (Table 49-1). Computed tomography of the chest with contrast may be needed to define cavitary lesions or the very rare pulmonary arteriovenous malformations which can cause hemoptysis. Rare causes of pulmonary hemorrhage, such as hereditary hemorrhagic telangiectasia, may require pulmonary angiography. Bronchoscopy can be very helpful and should include careful inspection of the upper airway and bronchoalveolar lavage (BAL) where appropriate. During active bleeding, the approximate location of the bleeding can also be determined. It may be advisable to do rigid bronchoscopy in cases of severe acute hemorrhage, especially if any attempt to stop bleeding is desired because it can provide better control of the airway both for removal of blood and clots and for any corrective procedure. If there is no active bleeding and no obvious cause (e.g., foreign body) is suspected, BAL should be performed to look for hemosiderin-laden macrophages (HLMs) as an indication of previous pulmonary hemorrhage. Sherman and associates[2] reported that HLMs were not found during the first 2 days after an acute bleed, and were still present 5 days after the bleed, but not at autopsy in one infant 12 days after the bleed. Epstein and colleagues[1] in a mouse model reported that HLMs began to appear on day 3 (2.8% total cell count) after the acute introduction of blood into the lungs, peaked (60%) at day 6, remained high until day 10, and then fell to low levels (10%) by 1 to 2 months. Optimal timing of BAL for IPH diagnosis is from 3 days post bleed or, if complicated by respiratory failure, prior to extubation. Based on these studies, if the plain chest radiograph, bronchoscopy, and bronchoalveolar lavage (performed between 3 to 14 days after the suspected bleed) are all normal, then it is unlikely that there was a true pulmonary hemorrhage. In this instance, it would be advisable to wait to see if there are any further episodes of suspected bleeding, which can be investigated similarly.

Table 49-1
Common Causes and Related Diagnostic Studies of Hemoptysis

Possible Causes of Hemoptysis	Diagnostic Studies
Infection	
Bacterial	
Lung abscess	Chest radiograph
Tuberculosis	Purified protein derivative (PPD)
Bronchiectasis	Chest radiograph, high resolution chest computed tomography (CT) scan
Cystic fibrosis	Sweat chloride >60 mEq/L
Immune deficiency	Abnormal immunoglobulin levels
Fungal	
Histoplasmosis, Coccidioidomycosis, etc.	Positive immunodiffusion and/or complement fixation titers by serology
Vasculitis Syndromes	
Immune-Complex Mediated	C1q binding assay, C3b binding assay Raji cell assay, complement level (CH-50)
Henoch-Schönlein purpura	Purpura/arthritis/abdominal pains
Wegener granulomatosis	Anti-proteinase-3 antibody (cANCA)
Polyarteritis nodosa	Anti-proteinase-3 antibody (cANCA) Anti-myeloperoxidase antibody (pANCA)
Other Immune-Mediated Diseases	
Goodpasture syndrome	Circulating antiglomerular basement membrane antibodies, nephritis
Systemic lupus erythematosus (SLE)	Anti-double stranded DNA, high antinuclear antibodies (ANA), and erythrocyte sedimemtation rate
Allergic bronchopulmonary aspergillosis (ABPA)	*Aspergillus* skin reactivity, *Aspergillus fumigatus*–specific IgG and IgE antibodies in serum
Cardiovascular	
Congenital heart defects/ congestive heart failure	Electrocardiogram and echocardiogram
Congenital Pulmonary Malformations	
Pulmonary sequestrations	Infiltrate on chest radiograph and chest CT scan
Pulmonary Embolism	Abnormal ventilation/perfusion ($\dot{V}/\dot{Q}$) scan
Neoplasms	Abnormal chest radiographs, CT scan, and bronchoscopic examination
Retained Foreign Body	Foreign body seen on bronchoscopy
Hematologic	High prothrombin time (PT) and/or activated partial thromboplastin time (APTT)
Trauma	History of trauma
Idiopathic Pulmonary Hemosiderosis (IPH)	Hemosiderin-laden macrophages in bronchial lavage or sputum/anemia
Hereditary Hemorrhagic Telangiectasia	Pulmonary angiography
Factitious hemoptysis precipitated by patient or caretakers	Careful history and negative work-up

If bleeding into the lungs is confirmed and is not due to a localized lesion in the airway, and the child does not have CF or bronchiectasis from another cause, a cardiology evaluation including echocardiography should also be performed. In the absence of significant cardiac pathology, investigations for possible pulmonary-renal syndromes should begin. This should include ANA, anti-double-stranded DNA, ANCA (both perinuclear and cytoplasmic variants), anti-GBM antibodies, antiphospholipid antibodies, IgG and IgE cow's milk protein antibodies, and rheumatoid factor. Also, patients can be tested for celiac disease with plasma antigliadin and antireticulin antibodies, although a lack of gastrointestinal symptoms makes this diagnosis unlikely. These studies should be performed much earlier if the child is known to have a systemic disease or if there are suggestive findings such as a rash, blood, or cellular casts in the urine. In the absence of systemic disease, it is likely that the cause of the pulmonary hemorrhage is IPH, which is essentially a diagnosis of exclusion. Open lung biopsy is rarely needed.

PATHOLOGY

The diagnosis of IPH can usually be made by clinical presentation and by exclusion of other causes of pulmonary hemorrhage; lung biopsy is rarely, if ever, justified. Occasionally, when it is not possible to exclude all systemic causes, lung biopsy may be necessary. The lung histology in IPH shows many red blood cells in alveoli and the interstitium after recent active bleeding, without any evidence of vasculitis. After a few days, macrophages in both areas contain hemosiderin.

In IPH, the lungs demonstrate the macroscopic finding of the so-called brown induration[3] due to various degrees of fibrosis and infiltration with iron. The diagnosis is strongly supported by features on light microscopy[5,15,16,18,19] which include thickened alveolar walls, intact erythrocytes in the distal airways and alveoli (a reflection of recent/active diffuse pulmonary hemorrhage),[5] multiple hemosiderin-laden macrophages (subacute/chronic or recurrent intrapulmonary bleeding) and the absence of any focal or diffuse smooth muscle cell proliferation, malignancy, infections, vascular malformations, pulmonary infarcts, capillaritis/vasculitis, or granulomatous inflammation. Useful ancillary tests are immunohistochemistry and immunofluorescence to exclude any intrapulmonary immunoglobulin or immune complex deposition. Electron microscopy may be important in those cases where other studies do not specifically rule out an immune deposition, particularly in the alveolar basement membrane, but is not necessary in routine cases. Electron microscopy lacks any evidence of electron dense deposits in the alveolar basement membrane.[16,18,19,45]

TREATMENT

Because this disease is rare, prospective controlled studies and large longitudinal surveys are not possible and most of the concepts regarding management of IPH are developed from observational studies on small numbers of patients, and data collected over years of observation are often incomplete.

Among the available data, the most commonly used medications are systemic glucocorticoids, which have produced clinical improvement in many patients in the acute phase of IPH and have been shown to have an impact on mortality,[5,9,13] although the dose, efficacy, and duration of use in the post-acute phase is not clear. Recommended starting dose is around 1 mg/kg/day of prednisolone for weeks to months, until the new alveolar infiltrates improve, and then taper over the next few months if symptoms do not recur. The majority of the patients with IPH seem to respond favorably to chronic oral corticosteroids, with a decreased number of IPH exacerbations and, possibly, a decline in fibrogenesis.[13,18,46,47] In children and adolescents, long-term treatment with oral corticosteroids can have undesirable side-effects. There is also a risk of a higher rate of recurrence with decreasing dose of chronic corticosteroid therapy, and these patients should be monitored for ophthalmologic changes and effect on bone mineralization. Medic Alert identification for chronic steroids and education regarding stress-steroid prophylaxis are warranted. The role of *Pneumocystis carinii* prophylaxis is unclear. There are insufficient data on the use of inhaled corticosteroids[48,49] in this clinical setting.

Other immunosuppressive agents, including hydroxychloroquine, cyclophosphamide, azathioprine, and methotrexate, have been tried with variable results.[7,15,50-55] Only two cases of single-lung transplantation have been reported.[56,57] Unfortunately, both cases had a clinical course complicated by IPH recurrence in the transplanted lungs—raising questions regarding this therapeutic option in IPH.

PROGNOSIS

Because of the small number of patients and lack of follow-up studies with large patient numbers, it is difficult to assess short- and long-term prognosis. Mortality from IPH is usually from pulmonary causes, including acute respiratory failure secondary to massive alveolar hemorrhage or as a result of chronic respiratory failure and cor pulmonale owing to severe pulmonary fibrosis.[5]

Soergel and coworkers[5] in 1962 reported 68 patients with a mean follow-up of 4 years and in their series 20 patients died, 17 had recurrent exacerbations of pulmonary hemorrhage, 12 had chronic active disease with persisting dyspnea and anemia, and 19 remained asymptomatic.[5] Only 28 (41%) in the study were treated with steroids. In this case series, the average survival after the onset of symptoms was 2.5 years.

Chryssanthopoulos and associates[58] in 1983 reported the outcome of 30 children followed for an average of 5 years. The mean survival was 3 years (range, 3 months to 10.5 years) and the mean mortality rate was 60%. Nearly 87% of the patients received steroids at some point in time.[58] Their results suggested that the severity of the disease at its onset does not determine the survival; females have better survival; and younger age of the patients at the onset of IPH seems to carry a less favorable prognosis.

Kiper and colleagues[46] reported 23 children with IPH in 1999. In their study all patients were treated with prednisolone. On remission, patients were kept on low-dose prednisolone for 2 to 14 years. One patient died, seven were lost to follow-up. Fifteen (65%) were followed for an average of 8 years. Seven had no relapse after discontinuation of oral steroids. In the remaining eight patients, attempts to discon-

tinue prednisolone failed because of worsening symptoms. Two of these 8 patients were subsequently weaned to budesonide by inhalation.

Saeed and coworkers[47] in 1999 reported a 28-year experience at the Children's Hospital of Los Angeles. In their series were 17 children with IPH and the projected 5- year survival in the study was 86%. The mean duration of follow-up was 3.6 years (range 0.7 to 10.2 years). Initial treatment consisted of prednisone only in 14 (76%) patients and hydroxychloroquine in 2 (12%) patients. Thirteen patients (76%) required long-term corticosteroids. Eight patients (47%) required other immunosuppressants (hydroxychloroquine or azathioprine) in addition to prednisone to control hemoptysis. Prolonged immunosuppressive therapy might be responsible for better outcome in their study.

Le Clainche and colleagues[21] in 2000 reported data collected from pediatric and adult hospitals throughout France. Their series was limited to children known to have survived at least 10 years. They reported 15 children with mean follow-up of 17.2 years (range 10 to 36 years). In their series, three (20%) of patients, all females, developed systemic disease (rheumatoid polyarthritis or rheumatoid polyarthritis–like diseases). Five of 13 (38%) children were still on treatment at least 10 years after diagnosis. Twelve patients (80%) had mild or no respiratory symptoms (although many had abnormal pulmonary function testing and chest radiographs and were able to lead a normal life. Because an association has been reported between cow's milk allergy and IPH, many children with IPH are placed on milk-free diets. Unless there is unequivocal evidence of true milk allergy, this may not be necessary. In those who recover from IPH, lung function can recover to within the normal range, especially if no further bleeding occurs. In some studies, good prognosis often referred to survival, whereas functional status of survivors was not clearly described. By reviewing the prognosis and survival data over the last 50 years, it is clear that there is a positive pattern in the outcome of these patients that may be because of prolonged immunosuppression, or secondary to spontaneous remission during an era when general supportive medical care is improving.

CONCLUSION

Hemoptysis in children is rare but, if not managed appropriately, it can be fatal. When more common causes such as infection, cystic fibrosis, airway lesions, and cardiac diseases are excluded; focus should be on pulmonary-renal syndromes or idiopathic pulmonary hemosiderosis (see Table 49-1).

IPH is a rare disease of unknown etiology, manifesting with recurrent episodes of diffuse alveolar hemorrhage (with or without hemoptysis) and sideropenic anemia. It occurs most commonly in children. It manifests classically with cough, tachypnea, and hypoxemia. Most of the time, symptoms are accompanied by hemoptysis. Initial work-up includes a chest radiograph that may reveal alveolar infiltrates and hematologic evaluation that may reveal worsening anemia; both findings are suggestive of intrapulmonary bleeding. Confirmation requires numerous hemosiderin-laden macrophages in the alveoli that can be shown by bronchoscopy and examination of bronchoalveolar lavage. In older children, sputum examination may also yield hemosiderin-laden macrophages. Occasionally lung biopsy is needed to confirm absence of capillaritis/vasculitis, granulomatous inflammation, and deposition of immunoglobulins or immune complexes, but lung biopsy is usually not required.

The etiology of IPH is not clear and there are insufficient data to consider it an autoimmune disease, but glucocorticoids and other immunosuppressive drugs seem to be effective during exacerbations. In many patients, oral corticosteroids are also useful during the remission phase. Over the past few decades, there is a significant improvement in morbidity and mortality from IPH, which in part is due to aggressive management of acute alveolar hemorrhage and long-term use of immunosuppressant therapy.

CHAPTER 50 Sarcoidosis

Brigitte Fauroux and Annick Clément

TEACHING POINTS

- Sarcoidosis is a multisytem granulomatous disease of unknown etiology, most commonly affecting young adults; the diagnosis is relatively rare in children.
- Lesions can occur in almost any tissue or organ but the lungs, lymph nodes, eyes, skin, and liver are more commonly involved.
- Clinical symptoms are nonspecific, often minor, and sometimes absent.
- The diagnosis can be supported only by typical histopathologic findings with noncaseating epithelioid-cell granulomas.
- Corticosteroid therapy is the most common treatment and is often effective.
- The prognosis seems to be more severe in younger children and where there is multi-organ involvement.

Sarcoidosis is a multisytem granulomatous disease of unknown etiology, most commonly affecting young adults. The diagnosis is relatively rare in children.[1,2] Divergent prevalence rates and clinical appearances in different races support the existence of predisposing genes, with probably a predominant role of the major histocompatibility complex. Lesions can occur in almost any tissue or organ but the lungs, lymph nodes, eyes, skin, and liver are more commonly involved. Clinical symptoms vary according to the organ involved but they are generally nonspecific and minor. The diagnosis requires typical histopathologic findings with noncaseating epithelioid-cell granulomas. The prognosis seems to be more severe in younger children and with multi-organ involvement. Corticosteroids are the mainstay of therapy and are indicated in case of significant lung or eye lesions, cardiac, neurologic, or multi-organ involvement. Other anti-inflammatory agents occasionally have been used. Spontaneous resolution occurs less often in children than in adults, and despite treatment, a significant number of patients have residual organ system damage or progressive disease.

EPIDEMIOLOGY

The incidence and prevalence of sarcoidosis are influenced by age, race, and geographic localization, although part of this variation can be explained by regional differences in diagnostic awareness and efforts. The two sexes appear to be affected with equal frequency. The disease is encountered most frequently in young adults. The exact prevalence in children is unknown. Cases have been reported in infants as young as 2 and 3 months of age, but the disease is more common in preadolescents and adolescents.[1-3] A National Patient Registry collecting data on patients with sarcoidosis since 1979 in Denmark reported an incidence of 0.29 per 100,000 person-years ≤15 years of age during the period 1979-1994.[2] The incidence was 0.06 in children ≤4 years of age and increased gradually to 1.02 in children aged 14 to 15 years. Thereafter, the incidence continued to increase significantly with age.

Several reports of familial sarcoidosis, human leukocyte antigen (HLA) linkages, and divergent prevalence rates and clinical appearances in different races suggest the existence of genes predisposing for sarcoidosis. Indeed, in a large study on familial aggregation of sarcoidosis, a significant elevated risk of sarcoidosis was observed among first- and second-degree relatives of sarcoidosis patients compared with relatives of matched control subjects. White patients had a markedly higher familial relative risk than African Americans. Genome-wide searches for predisposing genes and a study performed on 225 microsatellite markers tested in 63 families with affected siblings have shown a predominant, although not exclusive, role of the major histocompatibility complex.[4]

ETIOLOGY

The cause of sarcoidosis is unknown (Table 50-1). A combination of environmental and host factors probably cause the characteristic granulomatous response. An infectious, in particular a viral cause, has been evoked in sarcoidosis because high titers of antibodies against lymphotropic viruses (Epstein-Barr virus, human herpesvirus, cytomegalovirus), parainfluenzae, and rubella have been found in some patients. However, a viral cause has not been substantiated by viral cultures or unequivocal tissue analysis. Similar hypotheses have been proposed for mycobacteria, fungi, protozoa, metazoa, spirochetes, and bacteria, but presently no conclusive evidence has been demonstrated. The presence of microorganism-specific antibodies in high titers might reflect generalized B-cell activation in sarcoidosis and does not necessarily indicate a causal relationship. Noncaseating epithelioid granulomas have also been observed in patients with immune disorders, vasculitis, and neoplasms. Exposure to respirable bioaerosols containing endotoxin and microbial contaminants has been shown to cause diseases that are clinically and histologically indistinguishable from sarcoidosis. Most interesting are the case

Table 50-1
Granuloma-Forming Disorders and Potential Etiologies for Sarcoidosis in Childhood

Category	Subcategory	Examples
Infections	Viruses	Epstein-Barr virus, herpes, rubella, measles, cytomegalovirus, coxsackie B, parainfluenza
	Fungi	*Histoplasma* spp, *Aspergillus* spp, *Coccidioides* spp
		Blastomycosis, cryptococcosis
	Protozoa	*Toxoplasma, Leishmania*
	Metazoa	*Schistosoma*
	Spirochetes	*Treponema pallidum*
	Mycobacteria	*Mycobacterium tuberculosis, M. leprae*, nontuberculous mycobacteria
	Bacteria	*Yersinia* spp, *Borrelia* spp, *Brucella* spp
Immune disorders	Idiopathic	Crohn disease, primary biliary cirrhosis, hypogammaglobulinemia, common variable immune deficiency, chronic granulomatous disease, histiocytosis X
Organic dust	Hypersensitivity pneumonitis	Farmer's lung
		Bird fancier's lung
Vasculitis	Idiopathic	Wegener granulomatosis
		Churg-Strauss allergic granulomatosis
		Bronchocentric granulomatosis
		Systemic lupus erythematosus
Neoplasms	Carcinoma, sarcoma	Malignancy-associated granulomas

reports of adult patients who suffered a relapse of sarcoidosis in a transplanted lung despite receiving immunosuppressive therapy. These observations suggest that the etiologic agent could hide within the lung and/or other compartments of the body.

PATHOLOGY AND PATHOGENESIS

The typical histologic findings are those of noncaseating granulomas diffusely scattered within the different tissues (Fig. 50-1). In contrast to granulomas seen in hypersensitivity pneumonitis they are well-formed, compact aggregates. They are usually of varying ages, ranging from highly cellular lesions to collections with diminishing cellularity, some fibrosis, and progressive hyalinization. Two characteristic zones can be seen in a typical, well-developed sarcoid granuloma: (1) a central zone or follicle that is tightly packed with cells, composed primarily of macrophages, multinucleated giant cells (Fig. 50-2), and epithelioid cells; and (2) a peripheral zone consisting of a collar of loosely arranged lymphocytes, monocytes, and fibroblasts. Although many microscopic features may suggest sarcoidosis, the epithelioid granulomas are indistinguishable from those of other idiopathic granulomatous disorders or granulomatous disorders of known origin such as tuberculosis, berylliosis, or hypersensitivity pneumonitis (see Table 50-1).

Studies of bronchoalveolar lavage (BAL) cells have improved the understanding of the immunopathogenesis of sarcoidosis.[5] Activated macrophages and T cells have been identified in different compartments of the sarcoid lung. Classically, the number of alveolar T cells is increased with an increase in CD4+ cells. The T cells of the granulomas exhibit a layer-like distribution, with CD4+ cells expressing an abundance of activation markers predominantly in the inner area and an accumulation of CD8+ cells with smaller numbers of those markers in the outer area. The major source of T cells seems to be a polyclonal nonspecific accumulation accompanied by a clonal expansion. This lymphocyte activation translates into the activation of a cytokine network, which can be summarized as follows.[5] An unknown agent activates resident T cells and macrophages, which subsequently release cytokines (interleukin [IL]-2, IL-12, IL-6, chemokines, and interferon-γ), which prime and activate neighboring cells and are chemotactic for mononuclear cells. The activated cells constitute an alveolitis and the cytokines released (IL-1 and tumor necrosis factor-α) induce and maintain the granulomas, which might contain the unknown "sarcoid agent." Once formed, the granulomas may resolve spontaneously, or if they persist, will become hyalinized and eventually fibrotic, with tissue scarring as the final outcome.

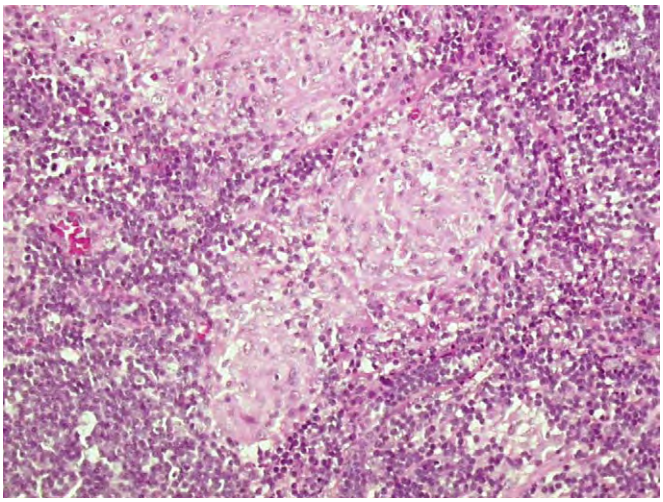

Figure 50-1 Noncaseating epithelioid-cell granulomas in the adenoids of an 11-year-old boy (coloration hematoxylin-eosin-safran [HES] stain, magnification ×25).

CLINICAL FEATURES

Lesions can occur in any tissue or organ. Because symptoms are primarily due to local tissue infiltration and injury by pressure and displacement from sarcoid lesions, the clinical manifestations depend on the organ or system involved (Table 50-2). A nation-wide study in childhood sarcoidosis performed in Denmark showed that common symptoms include

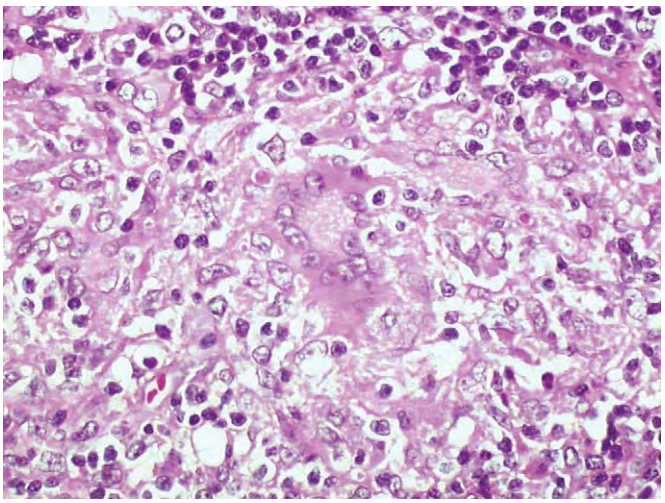

Figure 50-2 Multinucleated giant cell on the adenoid biopsy of an 11-year-old boy (coloration hematoxylin-eosin-safran [HES] stain, magnification ×40).

general malaise, weight loss, fever, lymphadenopathy, skin and ocular manifestations, and central nervous system (CNS) involvement. Clinical manifestations seem to vary according to age. In children younger than 5 years of age, the disease is mainly characterized by involvement of the skin, eyes, and joints; whereas in older children, involvement of the lungs, lymph nodes, and eyes predominate. More than one system is usually involved, and most often, children have at least five or more areas of involvement; this justifies a complete investigation when the diagnosis of sarcoidosis is made.

Whatever the organ involved, general symptoms are common and nonspecific and include weight loss, fatigue, lethargy, anorexia, headache, and, less commonly, prolonged fever. As such, a diagnosis of sarcoidosis must be considered in the case of unexplained, prolonged fever in a child.

Table 50-2
Clinical Manifestations of Sarcoidosis in Children

General symptoms	General malaise, fatigue
	Fever
	Weight loss
	Abdominal discomfort
Lung	Cough
	Chest pain
	Exertional dyspnea
Lymph nodes	Peripheral lymphadenopathy
	Mesenteric lymphadenopathy
	Hilar lymphadenopathy
Eyes	Granulomatous uveitis/iridocyclitis
	Conjunctival granulomas
	Edema of the optic papilla
	Keratitis
	Chorioretinitis
	Glaucoma
Skin	Erythema nodosum
	Papules, plaques, cutaneous and subcutaneous nodules
	Erythroderma, ulcerations, verrucous lesions
	Pustules, ichthyosis
	Calcifications and prurigo
Liver and spleen	Hepatomegaly
	Splenomegaly
Central nervous system	Headache
	Hydrocephalus
	Vertigo
	Seizures
	Nerve palsy
Bones and joint	Pain in extremities
	Arthritis
Heart	Heart block
	Dilated cardiomyopathy
	Ventricular arrhythmias
Other organs	Adenoids and tonsils
	Salivary glands and lacrimal glands
	Muscle granulomas
	Central diabetes insipidus
	Stomach, pancreas, kidney

Lung

The lung and the eyes are the most common organs involved in children. Symptoms referable to the chest are usually mild and often consist of a dry, hacking cough and exertional dyspnea, but most patients are asymptomatic.[6] Physical examination is often normal but findings may include crackles, rhonchi, wheezing, or decreased breath sounds. Bilateral hilar lymph node enlargement, with or without lung changes, is the most common radiographic finding in children. Chest radiograph findings are classified into four stages: stage 0 is a normal chest radiograph; bilateral hilar lymphadenopathy alone is stage I; bilateral hilar lymphadenopathy with pulmonary infiltrates is stage II; parenchymal infiltrates without hilar lymphadenopathy is stage III; and irreversible pulmonary fibrosis is stage IV (see later). In a Danish study including 48 children with sarcoidosis, chest radiographs were normal in 10% of the patients, 71% of the patients had hilar lymphadenopathy (stage I), 8.3% had associated parenchymal involvement (stage II), and only one patient had only parenchymal involvement (stage III).[3] None of the patients had evidence of irreversible pulmonary fibrosis (which some have called stage IV).

Involvement of the lungs is documented on BAL, which shows an increase in the proportion of lymphocytes with an increase in the CD4/CD8 ratio.[7] The presence of an increase in the number of polymorphonuclear neutrophils (PMNs) in BAL fluid has been shown to be associated with a less favorable outcome.[6] This BAL lymphocytosis is not correlated with the activity of the disease, the response to treatment, or the prognosis.[7] Systematic serial BAL is, therefore, not necessary.

Lung function abnormalities are common in children with lung sarcoidosis.[6] Significant decreases in vital capacity (VC), and/or dynamic lung compliance (CLdyn), and/or lung transfer for carbon monoxide (TLCO) are seen but are nonspecific.[6] Resting TLCO has been shown to be the best predictor of arterial desaturation during exercise. Significant lung function abnormalities are an indication for corticosteroid treatment. Improvements in VC and TLCO are generally observed within the first 6 months of treatment, often with no significant further benefit after this period. CLdyn does not seem to improve with treatment and the sole persistence of a decrease in this parameter warrants no specific treatment.[6]

More recently, the value of inflammatory markers in exhaled air has been studied in adult patients with sarcoidosis. Exhaled nitric oxide (NO) concentration is higher in patients with sarcoidosis compared to control subjects. Although this marker allows a nonspecific estimation of the

severity of airway inflammation in various respiratory tract diseases, in sarcoidosis, the concentration of exhaled NO did not relate to the radiographic stage, the activity, or the progression of the disease. Eight-isoprostane, which is thought to be an index of oxidative stress, seems to be interesting. Indeed, the concentration of 8-isoprostane was increased in patients with active sarcoidosis compared to those with nonactive disease and healthy controls, and correlated positively with serum angiotensin-converting enzyme (sACE). But these different inflammatory markers have not been evaluated in pediatric sarcoidosis.

Lymphatics

Similar to mediastinal lymphadenopathy, peripheral lymphadenopathy is common in children. Nineteen (40%) of the 48 children in the Danish study had peripheral lymphadenopathy and this localization contributed to the diagnosis in 15 of them, showing the typical epithelioid cell granulomas without necrosis.[3] The lymph nodes are generally discrete, painless, and freely movable. Involvement of the mesenteric lymph nodes is less common than peripheral and mediastinal lymph nodes.

Eyes

Ocular symptoms are common, with 29% of the children in the Danish study having them.[3] They are a frequent means of diagnosing sarcoidosis in children. Anterior segment disease is the most common, consisting of chronic granulomatous uveitis, acute iritis, and conjunctival granulomas. Posterior segment disease is less common. Sarcoidosis is not a unusual diagnosis in children with noninfected uveitis. Ophthalmologic slit-lamp examination must be performed in every child with documented or suspected sarcoidosis. Indeed, sequelae such as partial or total blindness may occur if treatment is inadequate.

Skin

Skin lesions are common and varied in sarcoidosis including papules, plaques, cutaneous and subcutaneous nodules, erythroderma, ulcerations, verrucous lesions, pustules, ichthyosis, erythema nodosum, calcifications, and prurigo. Nails can be involved but enlargement of lacrimal and salivary glands is more common. Changes in old scars have been observed. Lesions must be biopsied when the diagnosis of sarcoidosis is not firmly established and in situations where another diagnosis, such as connectivitis, must be ruled out. Skin lesions have the main advantage of offering an easy site for biopsy.

Liver and Spleen

Liver and spleen involvement has to be examined systematically with an abdominal ultrasound scan and liver enzyme tests. Indeed, clinical disease is rarely observed but histologic involvement is common, which may justify a liver biopsy when no other organ is easily available for a histologic confirmation.

Neurologic Symptoms

Neurosarcoid is rare and seldom recognized in children. Twenty-nine children have recently been reported in the world literature.[8] Ages were 3 months to 18 years and 48% presented before 13 years of age. Seizures were the most common manifesting symptom (11 of 29, 38%), and 73% of these children were younger than 13-years old at presentation. Twenty-one percent had hypothalamic dysfunction. Five children presented with headache, four with motor signs, and three with papilledema. Twenty-four percent (7 of 29) had mass lesions on imaging. This study shows that neurosarcoid manifests differently in children than in adults. Children are more likely to have seizures, probably because of space-occupying lesions, and less likely to have cranial nerve palsies. Their presentation evolves to an adult pattern as they progress through adolescence. Neurosarcoidosis has an unfavorable prognosis and is an indication for corticosteroid therapy.

Bones and Joint Involvement

Lytic bone lesions are rare in children and are often associated with skin lesions. Acute polyarthritis or chronic arthropathy is seen in 5% to 10% of children.[3] Granulomas are rarely found in joint tissue in transient arthralgia. Differentiation from juvenile rheumatoid arthritis may be difficult in some patients because uveitis can occur in both diseases.

Heart

Involvement of the heart is often underdiagnosed, justifying a systematic electrocardiogram and echocardiography. Cardiac disease, although uncommon, especially in children, has a wide spectrum of clinical manifestations such as heart block, dilated cardiomyopathy, and ventricular arrhythmias. An increased risk of sudden death has been reported in adult patients with sarcoidosis. Lesions of the myocardium have been described and may cause conduction abnormalities. Because the yield of endomyocardial biopsy for definitive diagnosis is low, the diagnosis is often made with a combination of electrocardiography, Holter monitoring, echocardiography, myocardial perfusion imaging and, most recently, magnetic resonance imaging. For symptomatic patients, medical therapy may include a trial of steroids and immunosuppressive therapy. Monoclonal antibodies against tumor necrosis factor may be employed in refractory cases. Heart block warrants a permanent pacemaker, whereas ventricular tachyarrhythmias are typically amiodarone-unresponsive, requiring implantation of a cardioverter-defibrillator.

Involvement of Other Organs

Peripheral neuropathy has been reported.[3] Sarcoidosis may affect the pituitary gland and diabetes has been reported in children. The tonsils are lymph nodes. Systematic histologic examination of enlarged tonsils, especially in older children, is recommended because some enlarged tonsils may be caused by sarcoidosis (see Fig. 50-1).[6] Involvement of the stomach, the pancreas, and the kidney has also been reported.[6]

LABORATORY INVESTIGATIONS

Laboratory changes are not specific and constitute a guide for the diagnosis that should be confirmed by the characteristic histologic features.

Elevation of the erythrocyte sedimentation rate is a common, nonspecific finding during the acute phase of the disease. Hemoglobin values are generally normal; moderate leukopenia, leukocytosis, or eosinophilia can be observed.[3] Hyperproteinemia is due to an absolute, nonspecific increase in serum globulin.

Anergy to tuberculin is classic in sarcoidosis and constitutes a strong element to the diagnosis of the disease, especially in cases of previous positivity. Tuberculin anergy is not influenced by the rate of the tuberculin test positivity in the general population.

Hypercalcemia is observed in approximately 30% of patients but is rarely symptomatic, although some cases of nephrocalcinosis have been reported.[3]

Serum alkaline phosphatase, glutamic-oxaloacetic transaminase, and glutamic-pyruvic transaminase are often elevated, even in the absence of clinical hepatomegaly. Levels are generally moderately elevated and decrease with treatment. Abnormalities of liver function tests can guide the biopsy for histologic diagnosis because in the absence of another organ easily accessible for biopsy, liver biopsy often shows typical sarcoid granulomas when liver function test abnormalities are present.

Serum angiotensin-converting enzyme (sACE) should be measured when a diagnosis of sarcoidosis is being considered. Indeed, although not pathognomonic, an elevation of this enzyme constitutes a strong diagnostic factor. The activity of the sarcoid lesions is associated with an elevation of sACE but also with other enzymes or proteins such as calcitriol and β_2-microglobulin. The source of the increased level of sACE is unknown but it seems to originate from the sarcoid granulomas. The use of sACE in the follow-up of pediatric patients with sarcoidosis has not been clearly established.

The Kveim test is currently abandoned. In this test, sarcoid tissue homogenate was injected intracutaneously, and, if a reaction developed, a biopsy was performed at 24 to 42 days to identify sarcoid granuloma. The lack of sensitivity and specificity, associated with the hazard of the injection of a tissue homogenate of unknown nature, contributed to the abandonment of this test.

HISTOLOGIC DIAGNOSIS

Biopsy of an easily accessible organ, such as a lymph node, a skin lesion, salivary glands, or the liver, should demonstrate the presence of a characteristic epithelioid cell tubercle without necrosis (see Figs. 50-1 and 50-2). These lesions are not pathognomonic and can also be observed in a number of other diseases (see Table 50-1).

TREATMENT

When the diagnosis is confirmed on a histologic examination, the type and number of organs involved should be assessed, together with the severity of the different lesions (Table 50-3). The involvement of some organs, or a severe involvement of a specific organ, requires immediate treatment. The presence of neurosarcoidosis, involvement of the heart, or severe eye or lung function abnormalities are criteria associated with a more severe outcome and justify immediate corticosteroid treatment (Table 50-4). Multiorgan involvement is also associated with a worse prognosis as in adult patients.[9] Young children seem to have a more severe disease than older children. They are less often asymptomatic and multiorgan involvement is frequent (see Table 50-4).[3] The involvement of the CNS and the heart are also pejorative and justify systematic corticosteroid treatment. The presence of PMNs on BAL has also been shown to be associated with a less favorable response to treatment.[6]

Because the cause of sarcoidosis is unknown, no specific therapy is available. Corticosteroids are widely used and are often effective.[9] Methylprednisolone pulses have been able to improve lung function in patients with very severe interstitial lung disease. Inhaled corticosteroids have been used for maintenance treatment in children but in a noncontrolled design and without being able to prevent relapses.

When the decision to initiate corticosteroid therapy has been made, treatment efficacy should be evaluated based on the clinical manifestations and the specific abnormalities of the organs involved. In case of lung disease, chest radiograph and lung function should be monitored regularly, but the systematic use of BAL is not justified in the absence of spe-

cific reasons (see Table 50-3).[6] Currently, biologic markers of the disease such as sACE cannot be used to guide treatment. A pediatric study has shown that 18 months of corticosteroid treatment may be a reasonable mean duration of treatment for pulmonary sarcoidosis, but the optimal duration for the other organs has not been established.[6] Close monitoring of the potential side effects of corticoid treatment is mandatory. Relapses are common, justifying the prolonged continuation of monitoring after treatment discontinuation. The respiratory disease is usually cured by corticosteroid treatment, but sequelae with fibrotic changes of the lungs may be observed (Fig. 50-3).

For adult patients for whom corticosteroid treatment fails, immunosuppressant drugs such as azathioprine or cyclosporine A have been prescribed, but side effects were severe.[10] Hydroxychloroquine therapy has been used with success in two Australian male children with diffuse sarcoidosis and low-dose methotrexate in seven others. More recently, successful steroid-sparing treatment of severe renal failure secondary to limited renal sarcoidosis was reported in a child treated with mycophenolate mofetil.

As observed in the incidence and presentation of the disease, clinical and genetic factors also influence the prognosis of the disease. A recent large study performed in 215 adults with documented sarcoidosis indicated that the majority of the patients improved or remained stable more than 2 years.[9] African Americans had less improvement in lung function parameters and a more common development of new organ involvement than did whites. Such large follow-up studies are not available in children, but sarcoidosis seems to be more severe in the younger age group. The HLA complex plays a major role in sarcoidosis and some genotypes seem to influence the outcome of the disease. HLA-B*07 independently increased the risk for persistent, as well as for resolving, disease in adults, suggesting an influence on factors common to both forms of sarcoidosis.[11] The allele combination A*03, B*07, DRB1*15 was most strongly associated with persistent disease. Further studies are warranted to evaluate the usefulness of these genetic markers in clinical management.

Some new inflammatory markers have been evaluated recently in sarcoidosis. As such, the soluble IL-2 receptor (sIL2R) appeared to be useful for monitoring respiratory disease severity in adult patients, but its sensitivity and specificity were broad and partially overlapped by sACE. Further studies are warranted, both in adult and pediatric populations.

CONCLUSION

Sarcoidosis is an uncommon disease in children. Diagnosis may be difficult and can be made only by histologic examination of the involved organs. The course of the disease seems to be more severe in younger children; improvement or cure is most often obtained with corticosteroid treatment.

CHAPTER 51 Congenital Immunodeficiency Syndromes

Andrew S. Kemp

TEACHING POINTS

- The clinical presentation of an immunodeficiency disorder depends on the nature of the immune defect.
- Defects in antibody function predispose to lower respiratory tract infection with encapsulated organisms.
- Defects in T cells predispose to viral or *Pneumocystis* infection.
- Defects in phagocytes predispose to infections with bacteria and fungi.
- Unusual associated features may suggest a rare immunodeficiency syndrome.

There are more than 100 primary immunodeficiency disorders. The respiratory system forms a major interface with the external environment and is frequently involved by infection resulting from immunodeficiency. Primary immunodeficiencies are usually congenital and hereditary, although the presentation may be delayed to later childhood or adult life. Table 51-1 shows the relative distribution. This chapter will focus primarily on the impact of these disorders on the respiratory tract.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

The prevalence of some immune deficiencies is shown in Table 51-2. Inherited disorders of antibody function uncommonly manifest in the first 6 months of life owing to transplacental transfer of maternal IgG. In contrast, disorders with T cell defects commonly manifest by 6 months with diarrhea, *Pneumocystis* pneumonia, and failure to thrive. Infants with functional disorders of phagocytes develop infections with *Staphylococcus aureus*, gram-negative enteric bacteria, and fungi—frequently commencing in the first 2 years of life.

Disorders of Antibody Function

Selective IgA deficiency is considered to result from impaired switching from IgM to IgA production.[1] Selective IgA deficiency is defined as a serum IgA level less than 0.05 g/L with normal IgG and IgM levels. The finding of asymptomatic subjects with IgA deficiency indicates that IgA deficiency does not necessarily predispose to significant disease. Because serum IgA levels are low in normal infants, age-related normal ranges are essential for interpretation. Subjects who lack IgA in their serum will also lack it in their secretions. Rarely, absent secretory IgA but normal serum IgA has been found. IgA deficiency may be transient, and children with absent serum IgA have developed IgA in later life. The finding of salivary IgA can indicate subjects with a transient IgA deficiency because salivary IgA levels reach normal adult levels by 6 months of age.[2] The significance of an IgA level below the normal limit but above 0.05 g/L is uncertain. These children should not be classified as having selective IgA deficiency because in at least one half of them, IgA levels will increase into the normal range.[3] Their incidence of respiratory infections may be the same as in normal children.[3] Some cases of IgA deficiency occur in conjunction with abnormalities of the MHC region.[1,4] IgA deficiency has been found in subjects with abnormalities in chromosome 18.[4] Phenytoin, penicillamine, sulfasalazine, and captopril can cause an acquired IgA deficiency.

Approximately one third of subjects with selective IgA deficiency have symptoms of recurrent bronchitis and otitis media.[5,6] More severe lower respiratory tract infections are uncommon and symptoms frequently improve with time. Suppurative disease of the upper or lower respiratory tract may be due to associated IgG2 subclass deficiency.[7] One study of 40 children reported an incidence of pneumonia of 30%,[3] but the presence of an associated IgG subclass deficiency was not determined. Common variable immunodeficiency (CVID) can manifest initially as selective IgA deficiency, with the IgG and IgM levels subsequently declining over a number of years, and should be considered in any patient with IgA deficiency who develops serious bacterial infections such as recurrent pneumonias or meningitis.[1] Immunoglobulin therapy is not indicated for patients with selective IgA deficiency. Anaphylactoid reactions to immunoglobulin can occur due to IgG anti-IgA antibodies that are found in about 25% of subjects.[8] Preparations of intravenous IgG that are low in IgA have been used when immunoglobulin therapy is required in an IgA-deficient subject[9]; however, the risk of anaphylaxis is not completely eliminated.[8,10]

IgG subclass deficiency consists of four subclasses (IgG1 65%, IgG2 25%, IgG3 7%, IgG4 < 5%). Antibody responses against peptides are predominantly IgG1 and IgG3 and against polysaccharides IgG2. The role of IgG4 is unclear, but

is increased in atopic dermatitis and asthma. Only IgG1 and IgG3 cross the placenta. Deficiency may occur in one or more subclasses. IgG subclass deficiency may be multiple or single. Normal individuals may have low or undetectable antibody subclasses.[11] Symptomatic cases have recurrent otitis media, recurrent sinusitis, and suppurative lower respiratory tract disease.[12,13] A history of recurrent bronchitis, particularly if associated with purulent sputum production, recurrent pneumonia, and persisting chest radiographic abnormalities, suggests the possibility of a subclass deficiency. Low IgG subclasses have been found in children with endoscopically proven chronic bronchitis.[14] The most commonly detected deficiencies are IgG2, IgG3, and IgG4; IgG1 deficiency is uncommon. Low levels of IgG1 may predispose infants to acute bronchiolitis.[15] Pre–school-age children are commonly found to have subclass deficiency, which may relate to the difficulties in establishing normal levels and a transient immaturity of the immune system.[16] IgG subclass levels increase with age.[17] In one study of children with sinusitis, one half of the patients were shown to have either low subclasses or poor response to polysaccharide antigens. IgG3 subclass deficiency was the most common abnormality.[18] Deletion of IgG heavy chain genes has occasionally been found in cases of combined IgG2 and IgG4 subclass deficiency.[19]

The significance of isolated IgG4 subclass deficiency is unclear. Confusion has arisen because of the varying sensitivity of the assays. With a sensitive radioimmunoassay, IgG4 deficiency has been detected in individuals with so-called *idiopathic bronchiectasis*, or chronic sinusitis and recurrent otitis media.[12] Individuals with isolated IgG4 deficiency have a normal response to polysaccharide antigens.[20]

The establishment of normal ranges for IgG subclasses throughout childhood has proved difficult and criteria for diagnosis of subclass deficiency are uncertain. Levels are age dependent. Lower levels have been observed in healthy black as compared with white children.[21] The assays have technical difficulties and the reliability of commercial kits has been questioned.[22] Healthy children may have low levels[23] and low levels do not necessarily correlate with defective antibody production.[24] Of more importance than the level is the functional activity, as healthy children with low IgG2 may have normal polysaccharide antibody responses whereas symptomatic children with normal levels can have a defective response.[23] It is important to examine specific antibody responses to polysaccharide antigens; however, the criteria for an adequate response have been difficult to define.[25] Immunization with unconjugated polysaccharides is required.[26] Subjects who fail to respond to unconjugated vaccines may respond to the conjugates.[26,27] Most normal children younger than 2 years have a defective antibody response to unconjugated polysaccharide antigens. The incidence of IgG2 deficiency in more than 500 healthy children was found to be 2% and all were found to have normal responses to polysaccharide antigens and normal in vitro production of IgG2.[23] IgG2 deficiency may also be transient in healthy individuals with resolution over 3 to 4 years. About 20% of the population may appear to be deficient in IgG4 because of the insensitivity of the assay—and to establish a deficiency, radioimmunoassay is required.[28]

Table 51-2
Approximate Prevalence of Immunodeficiency Disorders

Selective IgA deficiency	1 : 500
Common variable immunodeficiency	1 : 10,000
Severe combined immunodeficiency	1 : 12,000
Transient hypogammaglobulinemia of infancy	1 : 16,000
X-linked agammaglobulinemia	1 : 24,000
Chronic granulomatous disease	1 : 125,000

Selective antibody deficiency is a defective response to polysaccharide antigens with normal IgG and subclass levels.[29] This condition manifests with chronic otitis media with discharge, bronchitis, or sinusitis.[25,27] The clinical features are similar to those of children with symptomatic IgG subclass deficiency. The usual age of presentation is in the first 7 years of life. Selective antibody deficiency is diagnosed by demonstrating an impaired response to polysaccharide antigens by immunization with pneumococcal polysaccharide vaccine with normal total IgG and subclass levels.[30] It is important to immunize with unconjugated polysaccharide vaccines.[26]

Regimens for management of **IgG subclass and selective antibody deficiencies** are not well established. Trials comparing regular use of prophylactic broad-spectrum antibiotics and gamma globulin have not been carried out. Some patients will improve with regular broad-spectrum antibiotic use. Immunoglobulin therapy should be instituted only on the basis of a proven defect in antibody responses and significant respiratory tract disease. The dosage of IgG is uncertain but in general the dosages used for hypogammaglobulinemia (400 to 600 mg/kg) monthly have been used. A trial of monthly intravenous immunoglobulin in children with IgG3 subclass deficiency reduced hospitalizations and antibiotic use.[31] If immunoglobulin therapy is instituted, it is important to have a measurable end point such as diminution in episodes of otitis media with drainage, reduction in cough and purulent sputum, or reduction in episodes of documented lower respiratory tract infection. The appropriate duration of immunoglobulin therapy is not clear and the need for immunoglobulin therapy can diminish with age.

In **X-linked agammaglobulinemia (XLA)** pre-B cells in the marrow fail to develop into mature circulating B cells. This is caused by a defect in BTK (Bruton tyrosine kinase) gene on the X chromosome.[32] Tyrosine-kinase is required for normal B cell development. Mutations in immunoglobulin heavy chain genes lead to an autosomal recessive form of early onset hypogammaglobulinemia with clinical features similar to XLA[33]. Most subjects remain healthy for the first 6 to 9 months of life. Nearly all subjects will develop symptoms by 18 months of age, and the diagnosis is usually made within the first 3 years of life.[34,35] As maternally transferred IgG declines, the infant develops recurrent otitis media[35] and

upper and lower respiratory tract infections with common respiratory tract organisms, in particular, *Pneumococcus* and *Haemophilus influenzae* b.[34] *Staphylococcus aureus* may also be isolated from the sputum. Some subjects are susceptible to *Mycoplasma pneumoniae* infection, which can manifest as pneumonitis, sinusitis, or arthritis.[36] Most patients suffer infections at more than one anatomic site (Table 51-3). Absent or very small tonsils are a clinical clue. Recurrent pneumonia involving dependent lobes is a common presentation. In contrast to pneumonia in immunocompetent subjects, resolution is often slow and incomplete. There may be persistent collapse of affected lobes. Repeated infection may result in bronchiectasis, pulmonary fibrosis, cor pulmonale, and eventually respiratory failure. Early treatment will minimize complications, and high-dose intravenous gamma globulin reduces chronic lung disease. Death can also occur from severe and widely disseminated enterovirus infections.[34] In contrast to combined defects of antibody and cell-mediated immunity, *Pneumocystis* pneumonia and viral pneumonitis rarely occur in XLA.[34] Mono- or oligoarticular arthritis, which can mimic juvenile rheumatoid arthritis, is a presenting feature in approximately 20% of patients. Septic arthritis caused by *Haemophilus influenzae* b or pneumococcus occurs. Chronic or recurrent conjunctivitis is commonly related to deficiency of secretory antibodies. Transient neutropenia is often associated with acute infections.[34] Pulmonary function tests demonstrate an obstructive pattern with progressive disease. The incidence of pulmonary complications in XLA is less than that in patients with CVID.[37] This may partly relate to the associated T cell defects found in the latter condition. The diagnosis of XLA can be suspected by demonstrating reduced concentrations of IgG, IgA, and IgM, absence of circulating B cells, and no specific antibody response to common antigens, such as tetanus and diphtheria, and confirmed by demonstrating deficient BTK expression on flow cytometry[38] or BTK mutations.[39] The diagnosis can be made in newborn males with a family history by demonstrating absent cord blood B cells. Early diagnosis allows institution of therapy before the development of infection. Approximately 5% of subjects with early onset hypogammaglobulinemia and absent B cells are girls. This autosomal recessive disorder is due to mutation in the immunoglobulin heavy chain gene.[33,39]

Common variable immunodeficiency (CVID) is a heterogeneous group of disorders. Some cases may be caused by a defect in the major histocompatibility complex region on chromosome 6, resulting in arrested B-cell differentiation.[40] Some cases thought to be CVID with low B cells have been found to have BTK mutations, indicating a variant of XLA.[41] In contrast to XLA, there is usually a later onset and the symptoms may be more insidious. More than 95% of patients present after the age of 6 years[42] and presentation is most often in the second or third decades. The spectrum of respiratory infections is similar to that observed in XLA. Episodes of pneumococcal or *Haemophilus influenzae* pneumonia are common.[43] Uncommonly, pneumonia has been associated with *Pseudomonas aeruginosa* or *Pneumocystis carinii*. Another respiratory manifestation is lymphoid interstitial pneumonitis, which presents with cough, dyspnea, weight loss and an interstitial infiltrate—particularly at the lung bases.[44,45] Pulmonary function tests often show a restrictive pattern and lung biopsy may be necessary to make a definitive diagnosis. Some improvement may occur with gamma globulin therapy; however, pneumonitis may progress to pulmonary fibrosis.

Other clinical features are noncaseating granulomas of the lungs, spleen, skin, and liver[46] with hepatosplenomegaly. Diarrhea caused by *Campylobacter jejuni* and *Giardia lamblia* is common.[46] In adults, the incidence of lymphoma is increased. Atypical lymphoid hyperplasia may be confused with malignant lymphoma. CVID is associated with autoimmune hemolytic anemia, and neutropenia[46]; thrombocytopenia may be the initial manifestation.[47] The diagnosis of CVID is made by finding abnormal levels of immunoglobulin with normal or reduced B cells and defective antibody responses to common antigens. There is a variable T cell defect and the T helper (CD4) to T suppressor (CD8) ratio is often decreased.[48] CVID may be complicated by autoimmune hemolytic anemia, thrombocytopenia, or neutropenia, which often requires corticosteroid therapy. The associated T cell defects may worsen with age[42] and predispose to more severe pulmonary disease than is seen in XLA.[37] Despite apparently adequate immunoglobulin replacement, chronic respiratory symptoms are common and progression of lung disease with fibrosis and bronchiectasis has been demonstrated on high resolution computed tomography[49].

Hyper-IgM is the result of a defective ability of B cells to switch from IgM to IgG and IgA due to a defect in CD40 ligand. A T cell surface structure is required for antibody switching.[50,51] The defect leads to abnormalities in T cell function.[52] The disease is usually X-linked, however there are four autosomal recessive forms with a similar phenotype. One recessive form does not have T cell deficiency.[53] Children with hyper-IgM develop suppurative infections of the upper and lower respiratory tract. About one half of them present in the first year of life.[54] In contrast to XLA, *Pneumocystis* pneumonia is a common presentation[55] (Fig. 51-1), except in an autosomal recessive form with normal T cell function.[53] There is often cyclic or persistent neutropenia resulting in oral and upper gastrointestinal tract ulceration. Hemolytic anemia, thrombocytopenia, nephritis, and arthritis are also observed.[55] Bowel infection with *Cryptosporidium*

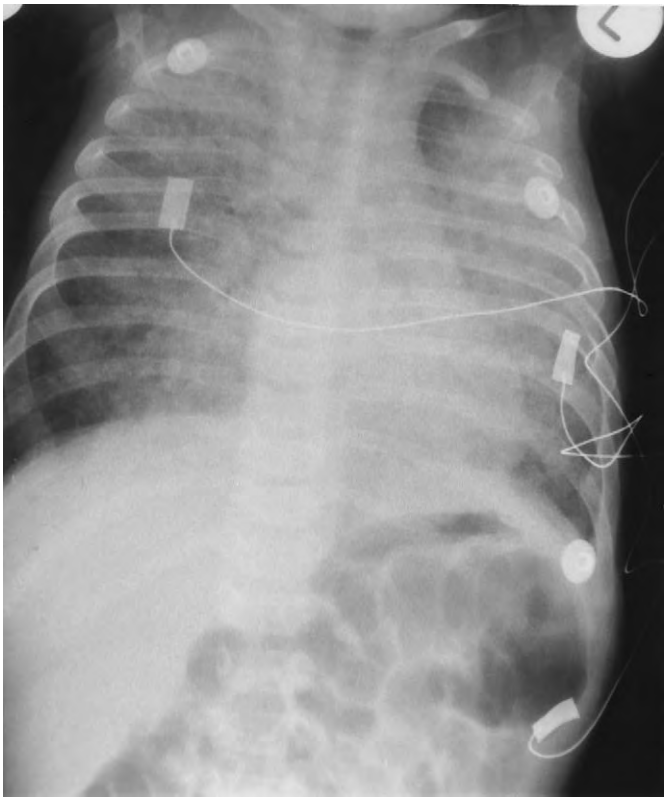

Figure 51-1 *Pneumocystis* pneumonitis in a 6-month-old male infant with immunodeficiency and elevated IgM.

is common and frequently leads to sclerosing cholangitis which may be fatal.[54] The diagnosis of hyper IgM is suggested by low IgA and IgG levels with a normal or elevated IgM. However, only one half of patients have an elevated IgM.[54] B and T cell numbers are usually normal. Primary and secondary antibody responses are diminished and limited to IgM; isoagglutinin titers are low or absent. Definitive diagnosis can be made by demonstration of absent CD40 ligand expression on activated T cells or by identification of mutations in the CD40 ligand gene[53]. Treatment of Hyper-IgM is similar to other forms of agammaglobulinemia with regular intravenous immunoglobulin therapy. Prophylaxis for *Pneumocystis* infection with trimethoprim-sulfamethoxazole should be given. The neutropenia may resolve after immunoglobulin therapy. In severe cases of neutropenia, stimulation with granulocyte macrophage colony-stimulating factor is indicated.

Transient hypogammaglobulinemia of infancy (THI) usually manifests in the second 6 months of life.[56,57] THI may be asymptomatic. Most children do not have serious infections,[56-60] and it is not clear whether children with THI have an increased incidence of infections compared with normal children. The IgG is low but rises into the normal range usually within the first 2 years of life. This disorder is often associated with IgA deficiency, which may persist. The incidence of atopic disease (food hypersensitivity, atopic dermatitis, and asthma) is increased.[57,60] Subjects with THI have a normal antibody response to antigens such as tetanus and diphtheria toxoids.[56] The diagnosis is established in retrospect by demonstrating that the low immunoglobulin levels come up into the normal range.

Immunoglobulin Therapy

For subjects with significant antibody deficiencies (e.g., XLA or CVID) immunoglobulin is usually administered intravenously. The usual dose is 400 to 600 mg/kg every 3 to 4 weeks.[61] This is based on a half-life of IgG in normal individuals of 21 to 28 days. The half-life of infused IgG is variable and dosages may need to be individualized. The aim is to keep the IgG level within the normal range for age or above an arbitrary trough level of around 5 to 6 g/L.[62] Home administration by the subcutaneous route has also been utilized.[63] Meticulous attention should be paid to the episodes of lower respiratory tract suppuration. Prophylactic antibiotics are not generally required but any occurrence of infection, as indicated by purulent sputum, should be treated vigorously with a broad-spectrum antibiotic. High resolution CT may show bronchiectasis or fibrosis not apparent on a chest radiograph.[49] If symptoms do not resolve, a chest radiograph is indicated to determine the extent of infection. Hospital admission for intravenous antibiotic therapy and physiotherapy may be required. The respiratory disease should be monitored by yearly pulmonary function tests. Following the change from intramuscular to high-dose intravenous immunoglobulin therapy, long-term results of high-dose therapy are not fully defined. Acute infections and complications such as pulmonary fibrosis and bronchiectasis appear to be reduced.[46]

With minimization of aggregate formation, serious reactions to intravenous infusions are uncommon. A rare complication of intravenous gamma globulin is non-A, non-B hepatitis which is thought to result from a breakdown in manufacturing process.[64] Subjects on regular immunoglobulin therapy should have liver function tests performed 3 to 4 times a year. Another uncommon complication is aseptic meningitis.[65] In older children, home administration of gamma globulin can be accomplished by the subcutaneous route. The duration of therapy is generally lifelong. With appropriate therapy, subjects may have minimal upper and lower respiratory tract symptoms. Other symptoms such as recurrent conjunctivitis and recurrent diarrhea are not eliminated by intravenous therapy because secretory IgA function is not restored.

Disorders of T Cells

Severe combined immunodeficiency (SCID) results in a deficiency of both B and T cell function. There are at least 10 different molecular defects.[66-68] The most common variant caused by mutations in the gene for the interleukin-2 receptor is X-linked; the others are autosomal recessive.[69] The differing forms are grouped according to the cell surface markers on peripheral blood into T–B+, T–B–, and other forms. The variant due to adenosine deaminase deficiency[70] has profound lymphopenia. SCID is associated with a profound deficiency of both T cell and antibody function. It generally manifests within the first 6 months of life with diarrhea, lower respiratory tract infections, and failure to thrive.[71] More than one half the children present with *Pneumocystis* pneumonia.[68] Early presentation within the first 2 months of life with pneumonitis is particularly likely in patients with ADA deficiency who have the most profound lymphopenia.[70,71] *Pneumocystis* infection may often be insidious with cough and pulmonary infiltrates that progress over

several weeks. In addition to *Pneumocystis* these children often have cytomegalovirus pneumonitis. Oral candidiasis and rashes, in particular a seborrheic dermatitis-like rash, are common. The finding of erythroderma and eosinophilia suggests either the occurrence of the Omenn syndrome variant[71,72] or graft-versus-host disease from maternal lymphocytes.[68] The presence of hepatomegaly and ascites suggests veno-occlusive disease of the liver.[68,73] Recurrent pneumonias can occur with cytomegalovirus, respiratory syncytial virus, *Pneumocystis*, *Candida*, and gram-positive and gram-negative bacteria.[68] Chest radiographs often show a diffuse bilateral disease that is alveolar and/or interstitial in nature (Fig. 51-2) and lung biopsy may show a nonspecific chronic inflammatory infiltrate with lymphoid or histiocytic cells. The lower respiratory tract disease may progress despite antimicrobial therapy and immunoglobulin. B cell proliferative disorders caused by Epstein-Barr virus (EBV) infection with paraproteins, lung infiltrates, and pleural effusions can occur as a complication of the immunodeficiency or following marrow transplantation.[74,75] Histology shows infiltration of immunoblasts in multiple organs. Without marrow transplantation, death in the pre-school years is usual, often from an overwhelming viral infection. SCID should be suspected in any infant who presents with *Pneumocystis* pneumonia. Other clues to the diagnosis are lymphopenia and low levels of immunoglobulins G, A, and M. The number of T cells is markedly reduced, the proliferative response of T cells to mitogens is low or absent, and specific antibody responses are lacking. More definitive diagnosis of the molecular defect should be undertaken where available. Treatment of SCID involves specific antimicrobial therapy and administration of intravenous immunoglobulin. The definitive therapy is bone marrow transplantation. Transplantation from a human leukocyte antigen (HLA)-identical sibling has a more than 90% success rate if performed early in life before the onset of significant infections.[76] In the absence of an HLA-identical donor, a T cell depleted bone marrow transplant from a parent, family relative, or unrelated donor is used. The overall success rate with a non HLA-identical T cell depleted marrow graft is less, with a 35% to 60% long-term survival.[77] Restoration of T cell function without B cell function may occur. Conditioning with intense immunosuppression before transplantation is more likely to result in restoration of B cell function but has a higher risk in the immediate post-transplant period of death from either sepsis or hemorrhage. Lung infection before transplantation is associated with a worse outcome.[77] Prophylactic therapy against *Pneumocystis* should be given. Live virus vaccines should be avoided and, before transplantation, patients should be isolated to prevent life-threatening infections with viruses such as measles, chickenpox, and influenza.

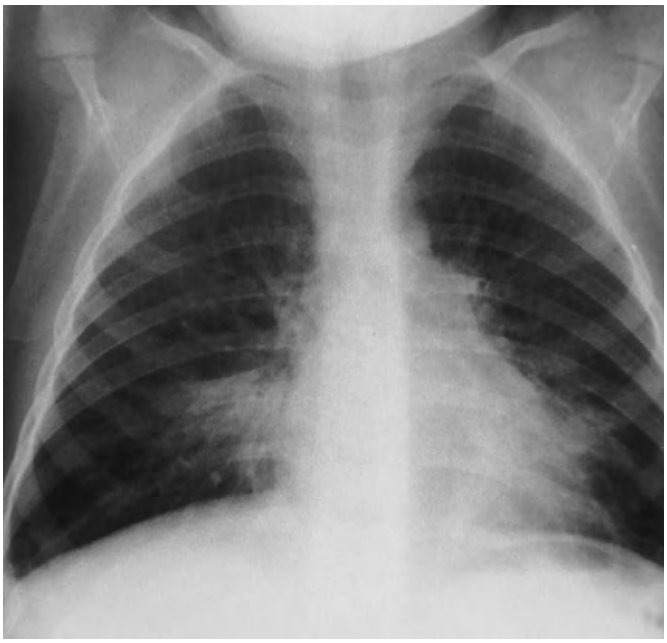

Figure 51-2 Chronic bilateral changes in a 4-year-old male with an X-linked combined immunodeficiency. Lung biopsy showed a nonspecific infiltrate with mononuclear and polymorphonuclear cells.

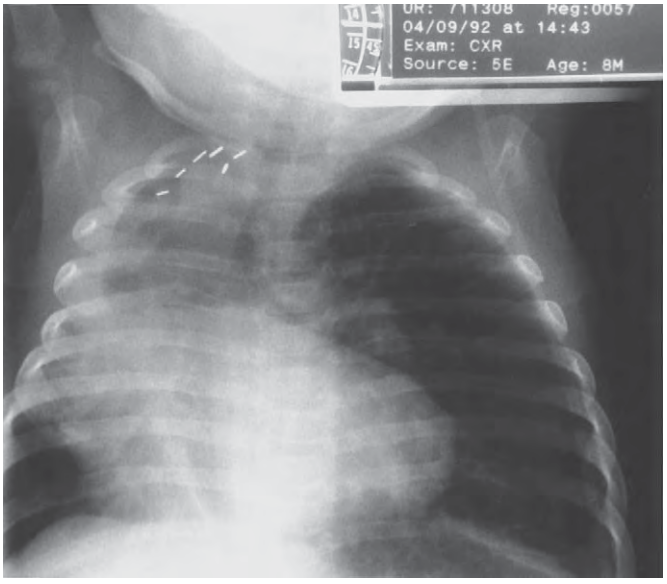
The **Di George syndrome** consists of a variable degree of thymic and parathyroid hypoplasia and cardiac outflow anomalies, especially truncus arteriosus and interrupted aortic arch.[78,79] The majority of cases result from deletions within chromosome 22q11.[80] Any of the structures derived from the first to the sixth pharyngeal arches and pouches can be affected. Infants usually present because of the cardiac problem. Hypocalcemia may be found and an absent thymus noted at operation. The immunologic defect is variable.[81-83] A 10^9 T helper cell count of less than 500×10^9/L has been associated with a greater incidence of subsequent immunologic problems.[83] Only a minority of cases develop serious infections—in particular viral and *Pneumocystis* pneumonia. Respiratory syncytial virus infections can be severe and there may be prolonged virus excretion. A complicating factor is the occurrence of tracheo- or bronchomalacia (Fig. 51-3) owing to vascular compression and abnormal embryogenesis with defective tracheal ring formation.[84] The natural history of the Di George syndrome is variable and immune function can improve with time. Subjects with T 10^9 cell counts less than 500×10^9/L and abnormal lymphocyte mitogenic responses should be given prophylactic trimethoprim-sulfamethoxazole. If a defective antibody response to common antigens such as tetanus and diphtheria is present, immunoglobulin therapy is indicated. Definitive cure of the immune defect has been difficult. Thymic transplantation has had some success[85] but because of the variability in the natural history, the efficacy is uncertain. Restoration of immunity has been achieved by bone marrow transplantation.[86]

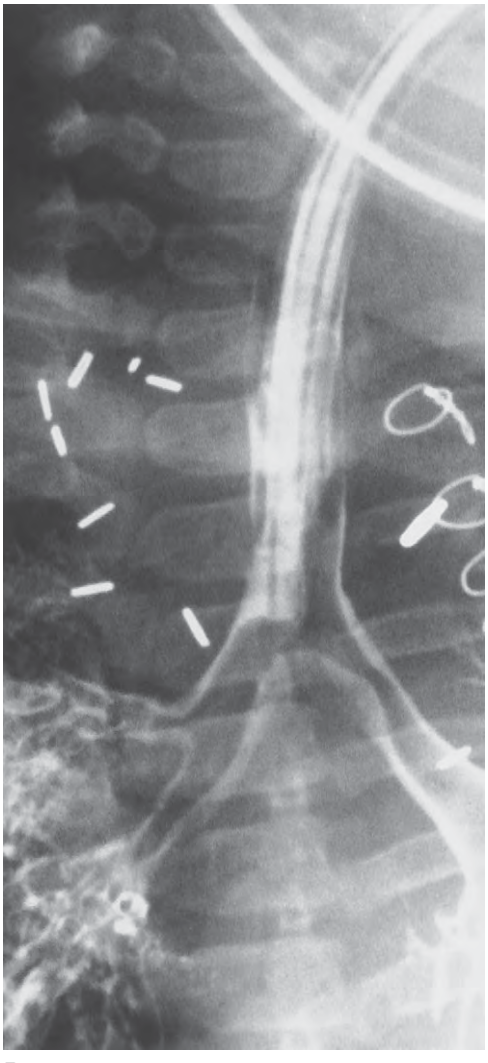
Idiopathic CD4+ T-lymphocytopenia is characterized by a decreased number of CD4+ T-lymphocytes ($<300 \times 10^9$ CD4+ cells/L or <20% of total T cells) on at least two occasions associated with opportunistic infections. The lower respiratory tract is frequently involved with pneumococcal pneumonia, varicella pneumonia, chronic bronchitis, and bronchiectasis.[87]

Disorders of Phagocytes

Chronic granulomatous disease (CGD) is a disorder of oxidative metabolism of phagocytes caused by defects in cytochrome B or cytosolic proteins required for oxidative activity. The phagocytes ingest microorganisms normally—but killing is defective. There are four different genetic causes of CGD.[88]



A



B

Figure 51-3 **A,** Right upper lobe collapse in an 8-month-old male infant with Di George anomaly. **B,** Bronchogram showing malacia in the left main stem bronchus and narrowing at the origin of the right upper lobe bronchus.

Two thirds are X-linked and one third are autosomal recessive. Patients with CGD develop recurrent infections with *Staphylococcus aureus*, *Serratia marcescens*, *Aspergillus*,[89,90] and unusual pathogens such as *Burkholderia cepacia*[91] and *Nocardia*.[92] The lung is the most common site of infection.[93] Infections often begin early in life. Lymphadenitis, cutaneous infections, and obstructive lesions of the genitourinary and gastrointestinal tracts (Fig. 51-4) occur.[94] Pulmonary lesions vary from a patchy bronchopneumonia to consolidation of an entire lobe or lung. Consolidation may be unilateral or bilateral, persist for months, and progress despite antibiotic treatment. An unusual "encapsulated" pneumonia with hilar lymphadenopathy occurs. Lung biopsy shows granulomas but not necessarily pathogenic organisms. Often lobectomy or segmentectomy is required for resolution.[95,96] Osteomyelitis of ribs and vertebral bodies with chest wall invasion is caused by *Aspergillus*.[97] Lung abscesses, empyema, and pleural effusion are uncommon. In a prospective study approximately one third of patients required admission to a hospital for treatment of pulmonary infection over a period of 9 months.[98] Another pulmonary manifestation of CGD is a widespread nodular infiltrate. Histology shows multiple small granulomata. This may be due to disseminated *Aspergillus*. The lesions are often asymptomatic but can progress to pulmonary insufficiency and death. The autosomal recessive disorders may have less severe clinical manifestations than the X-linked form.[99] The diagnosis of CGD is made by demonstrating defects in superoxide production.[100] The NBT slide test is widely available. Measurement by dihydrorhodamine flow cytometry is more quantitative and allows distinction of the autosomal recessive from the X-linked forms.[100]

For treatment of established infection in CGD standard antimicrobial therapies are often required in high dosage for long periods of time. Additional measures include white blood cell transfusions and use of interferon-gamma (INF-γ). Although INF-γ has been shown to be effective when given prophylactically, its role in established infections is less certain. In a controlled trial there was no significant benefit for established lymphadenitis and subcutaneous abscesses.[98] There are reports of resolution or improvement in infection following a combination of INF-γ with antimicrobial therapy.[101,102]

Long-term prophylaxis with trimethoprim/sulfamethoxazole reduced dermatitis and lymphadenitis[103] and may reduce the incidence of pneumonia.[104] Itraconazole is indicated as prophylaxis for *Aspergillus* infection in all cases.[90] Prophylaxis with subcutaneous INF-γ on 3 days per week significantly reduced serious infections.[98] Therapy was given for a mean period of 9 months. Lymphadenitis and episodes of lower respiratory tract infection, including fungal disease, were reduced. Although INF-γ increased the oxidative metabolic activity of phagocytes from some patients with CGD in vivo and in vitro, the mode of action when used prophylactically is uncertain. It is possible that the beneficial effects result from nonspecific activation of the immune system rather than restoration of a phagocyte metabolic defect. The beneficial effects of interferon were more marked in patients younger than 10 years of age and in the X-linked form of the disease.[98] Long-term interferon (years) may reduce serious infections.[105] If there are suitably matched donors, bone

marrow transplantation should be considered. The mortality of CGD is about 5% per year for the X-linked and 2% for the autosomal recessive forms.

Cell adhesion molecule deficiency is due to a deficiency of the beta chain subunit of the cell surface adhesion molecules, resulting in defective cellular motility. Moderate and severe phenotypes relate to the degree of expression of the cell adhesion molecules.[106,107] Children with cell adhesion molecule deficiency have delayed separation of the umbilical cord, profound gingivitis, otitis media, and extremely high levels of circulating neutrophils (20 to 60×10^9/L); however, they fail to form pus because of defective neutrophil migration. Viral respiratory tract infections may result in secondary bacterial infections of the trachea and bronchial tree[107]; however, pneumonia is seen in only a minority of subjects. Pyoderma gangrenosum–like skin lesions and delayed wound healing are common. The diagnosis of cell adhesion molecule deficiency is established by functional assays and demonstrating deficiency of cell adhesion molecules on neutrophils with monoclonal antibodies, anti-Mac-1, OKM1, or Leu15.[107] For the severe forms of cell adhesion molecule deficiency, the definitive treatment is bone marrow transplantation because these severe forms are usually fatal within the first 5 years of life.

Table 51-4
Clinical Clues to an Immune Deficiency Disorder in Patients with Severe Respiratory Infections

Disorder	Clinical Clues
Hyper IgE syndrome	Dermatitis, pneumatoceles
Mucocutaneous candidiasis	Persistent oral candidiasis
Wiskott-Aldrich syndrome	Eczema, purpura, thrombocytopenia
Ataxia telangiectasia	Conjunctival telangiectases Depigmented and hyperpigmented cutaneous lesions
Nijmegen breakage syndrome	Microcephaly
TAP deficiency syndrome	Cutaneous necrotizing granulomas
WHIM syndrome	Multiple warts, neutropenia
ICF (immunodeficiency, centromeric instability, and facial anomalies) syndrome	Abnormal facies
Interferon-γ receptor 1 deficiency	Disseminated BCG, disseminated infection with atypical mycobacteria

TAP, transporter associated with antigen presentation; WHIM, warts, hypogammaglobulinemia, infections, and myelokathexis.

Miscellaneous Disorders with Respiratory Tract Involvement

Many of these disorders are rare; however, it is important to be aware of the possibility of immunodeficiency in a child with chronic lower respiratory tract infection. The associated features of the syndromes frequently suggest the diagnosis (Table 51-4).

NATURAL KILLER CELL DEFICIENCY

Children present with severe overwhelming varicella infection, extensive varicella lesions on the skin and mucous membranes,[108,109] and lung involvement (Fig. 51-5). Some patients have a deficiency of circulating B cells although specific antibody function is present.[110] Because only a few cases have been described, the long-term outlook for this disorder is unknown. It is uncertain whether patients have a defective

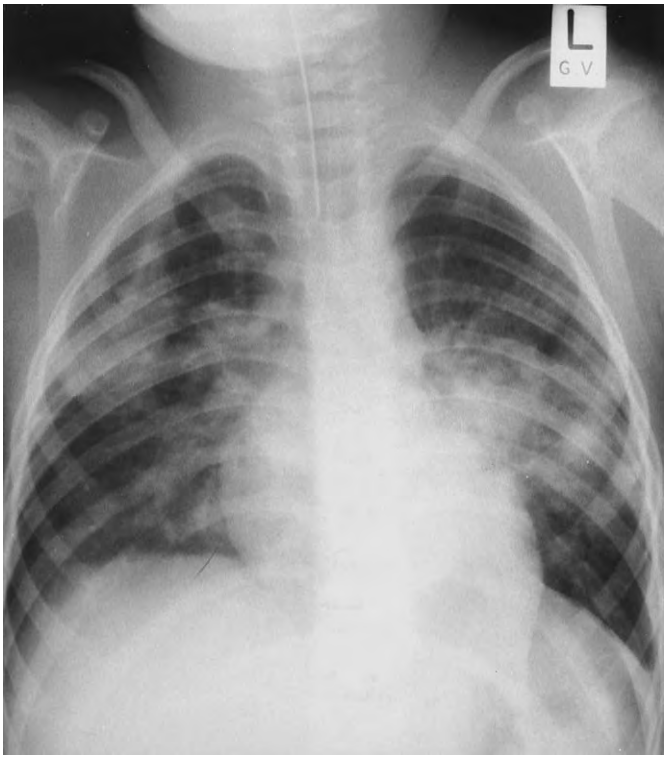

Figure 51-5 Varicella pneumonitis in a 5-year-old male with natural killer cell deficiency and defective α-interferon release. This condition was associated with extensive cutaneous lesions.

immune response to other herpesvirus infections. One patient developed a CMV interstitial pneumonia 4 years after the initial presentation with varicella. Varicella should be treated with intravenous acyclovir.

HYPER IgE SYNDROME

Hyper IgE syndrome was described in 1972.[111] There are autosomal dominant, recessive, and sporadic cases.[112] Hyper IgE manifests in infancy with coarse facies, eczematous dermatitis[113] or a vesicular eruption,[114] peripheral blood eosinophilia, and cutaneous *Candida* infection. The cutaneous changes in infancy are followed by lower respiratory tract infections and marked elevation in serum IgE. Subcutaneous cold abscesses and lower respiratory tract suppurative disease caused by organisms such as *Staphylococcus*, *Haemophilus influenzae*, and *Pseudomonas pyocyanea* often occur. Pneumonia and empyema develop in the first years of life. Pneumatoceles, pulmonary abscesses, bronchopleural fistula, and pneumothorax are common. Pneumatoceles are best demonstrated by CT scan (Fig. 51-6)[115]; they rarely resolve spontaneously, and lobectomy or pneumonectomy may be required.[116] The autosomal recessive form does not develop pneumatoceles.[112]

The immunologic defect is unknown. IgE levels are extremely high (often >10,000 IU/mL).Secretion of the Th1 cytokine INF-γ is reduced.[117] There are variable defects in neutrophil chemotaxis.[118,119] Specific IgE antibodies against *Staphylococcus aureus* and *Candida albicans* are found in the majority of patients. How these contribute to the pathogenesis is unclear.[120] Some subjects have a defective functional antibody response to polysaccharide antigens.[121]

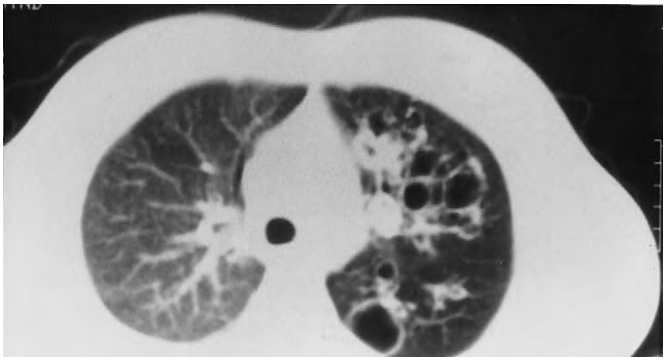

Figure 51-6 Pneumatoceles in a 12-year-old male with hyper IgE syndrome.

Management consists of long-term anti-staphylococcal antibiotic prophylaxis which may act to limit the severity of both the cutaneous involvement and the lung disease.[112] Sputum should be cultured regularly as the detection of *Pseudomonas* may require changes in therapy. The role of immunoglobulin and INF-γ is unclear. Despite regular medical attention, deterioration often occurs and respiratory failure eventually results.

MUCOCUTANEOUS CANDIDIASIS

Mucocutaneous candidiasis is characterized by *Candida* infections of the skin, mucous membrane, and nails. Many, but not all, cases have defects in cell-mediated immunity to *Candida* antigens when measured by delayed hypersensitivity skin tests or in vitro techniques. Some patients have an increased susceptibility to bacterial infections, and develop pneumonia caused by *S. aureus*, *Streptococcus pneumoniae*, or *H. influenzae* b. Fungal or viral pneumonias occur less commonly. A long-term multicenter follow-up study of patients with chronic mucocutaneous candidiasis showed that 14% of these subjects had bronchiectasis and another 40% had either obstructive or restrictive lung disease.[122] Lung disease has been associated with IgG2 and IgG4 subclass deficiency.[123] Patients with chronic mucocutaneous candidiasis and lower respiratory tract disease should have immunoglobulins, immunoglobulin subclasses, and antibody responses to polysaccharides measured. Management is particularly difficult because the use of broad-spectrum antibiotics exacerbates the candidiasis, despite concurrent use of antifungal agents. It is possible that subjects with an ineffective response to polysaccharide antigen would benefit from intravenous gamma globulin.

WISKOTT-ALDRICH SYNDROME

This is an X-linked disorder. Infants usually present with refractory atopic dermatitis and thrombocytopenic purpura. A defective antibody response to polysaccharide antigens is universal.[124,125] After the first year of life, otitis media and pneumonia are common. There is a variable T cell defect and infections with *Pneumocystis*[126] and herpesviruses can occur in later life. The syndrome is associated with a high serum

IgA and low or normal IgG and IgM. There is a variable reduction in T cell number and function. The diagnosis can be established by sizing the platelets, which are small.[127] More definitive diagnosis can be made by demonstrating reduced lymphocyte Wiskott-Aldrich syndrome protein.

Treatment consists of intravenous gammaglobulin when significant antibody defects have been demonstrated. Hemorrhage is a major threat and splenectomy can reduce the risk,[128] but this increases the risk of serious infection with encapsulated organisms. Definitive treatment is by bone marrow or cord blood stem cell transplantation. In the absence of a matched sibling donor, the success of bone marrow transplantation is considerably reduced and rejection of the graft is common.[128]

ATAXIA TELANGIECTASIA

Ataxia telangiectasia is an autosomal recessive disorder with neurologic, endocrinologic, immunologic, and cutaneous abnormalities. The gene for the disorder has been localized to chromosome 11. Most patients present with ataxia in infancy or early childhood. Subsequently, telangiectasia of the skin and conjunctivae and hyperpigmented and depigmented cutaneous patches develop. Approximately one half of the patients develop significant sinopulmonary infections—in particular recurrent sinusitis and lower respiratory tract suppurative disease,[129,130] which may progress to bronchiectasis. IgA deficiency is found in approximately 50% of cases and is usually associated with an IgG2 subclass deficiency.[131] IgE is often absent. Defects in T cell function and number are variable. The most common serologic abnormality is a raised α-fetoprotein, which is present in virtually all cases.[132] The defects in DNA repair lead to an increased incidence of chromosome breaks in cytogenetic studies. More severe respiratory tract disease appears to be associated with more severe neurologic abnormalities and aspiration may worsen the lung disease. Pneumonia is a major cause of death. Intravenous immunoglobulin and antibiotics are indicated if a significant antibody defect is demonstrated. There is a high incidence of malignancy of the lymphoreticular system.

NIJMEGEN BREAKAGE SYNDROME

The Nijmegen breakage syndrome is an autosomal recessive disorder with defects in DNA repair and similar immunologic, cytogenetic, and cellular abnormalities to ataxia telangiectasia; however, α-fetoprotein levels are normal. The affected children have microcephaly, abnormal facies, and suffer from recurrent lower respiratory tract infections.[133]

ICF (IMMUNODEFICIENCY, CENTROMERIC INSTABILITY, AND FACIAL ANOMALIES) SYNDROME

This is a rare autosomal recessive disease caused by abnormality in methylation of DNA. The facial anomalies include epicanthic folds, telecanthus, a flat nasal bridge, macroglossia and mild micrognathia. Subjects have recurrent and prolonged lower respiratory infections, which are a frequent cause of death.[134] Reduced IgA and IgG levels and poor antibody responses are common. There is instability of the chromosome centromeres in chromosomes 1, 9, and 16 resulting in abnormal multibranched configurations.

TAP DEFICIENCY SYNDROME

This syndrome results from deficiency of the transporter associated with antigen presentation (TAP), which is involved in a failure of the assembly of HLA class I molecules on the cell surface.[135] There is normal expression of class II molecules. Sinusitis and otitis media commence within the first 6 years of life and bronchitis and bacterial pneumonia leading to bronchiectasis typically occur in the second decade. Severe viral infections are absent. Lung infection with *Escherichia coli* and *Pseudomonas aeruginosa* occur in the chronic stage of the disease. Progressive lung damage leads to respiratory failure and death. Most patients also develop necrotizing granulomatous skin lesions, typically located on the extremities and on the midface. The cutaneous lesions usually develop after 15 years of age. Diagnosis can be made by demonstrating absence of class I and presence of class II HLA molecules on blood lymphocytes.

WHIM SYNDROME

The acronym WHIM refers to warts, hypogammaglobulinemia, infections, and myelokathexis (kathexis = retention). This syndrome is caused by mutations in chemokine receptor gene CXCR4.[136] Neutropenia in combination with reduced antibody and T cell function leads to recurrent bacterial infections. Respiratory tract involvement includes pneumonia, sinusitis, recurrent suppurative bronchitis, and abscesses. Multiple warts involve the skin and genital mucosa.[137]

HYPOHIDROTIC ECTODERMAL DYSPLASIA WITH IMMUNE DEFICIENCY

This X-linked recessive disorder is caused by mutations in the NEMO gene. Ectodermal abnormalities include sparse hair, delayed tooth eruption, conical teeth, and abnormal sweat glands. Immune deficiency results in failure to thrive, recurrent gastrointestinal tract infection with intractable diarrhea, and lower respiratory tract infections leading to bronchiectasis. Antibody levels may be reduced and there is a poor response to polysaccharide antigens.[138] Death has occurred from disseminated mycobacteria infections.

INF-γ RECEPTOR 1 DEFICIENCY

INF-γ–mediated immunity is a genetically controlled trait that determines the outcome of mycobacterial infection. INF-γ receptor 1 deficiency is caused by mutations in the receptor gene and is characterized by severe infections with environmental mycobacteria and bacille Calmette-Guérin (BCG) disease.[139] There are two forms: a recessive complete disease and a dominant partial deficiency. Subjects with the complete deficiency develop disseminated mycobacterial disease with hepatosplenomegaly, lymphadenopathy, and involvement of bones and lungs with onset in the first decade of life and disseminated BCG disease following BCG vaccination. Disseminated salmonellosis has also been observed. Multifocal mycobacterial osteomyelitis without other organ involvement is seen only in the dominant partial deficiency and manifestation is often delayed until the second decade. The diagnosis can be suspected by demonstrating a reduction of in vitro TNF-α production by peripheral blood mononuclear cells in response to interferon-γ.[139] Defects in IL-12 production have a similar phenotype.

CHAPTER 52

Cor Pulmonale and Pulmonary Complications of Cardiac Disease

Steven H. Abman

TEACHING POINTS

- Recent advances in vascular biology have demonstrated the important roles of nitric oxide (NO), prostacyclin (PGI_2), and endothelin (ET) in the pathogenesis of pulmonary hypertension in children.
- Manipulation of these three pathways has led to novel therapies including inhaled NO, sildenafil, prostacyclin analogs, and endothilin receptor antagonists, which have improved the outcomes of children with pulmonary hypertension.

Abnormalities of the pulmonary circulation contribute significantly to morbidity and mortality in many cardiac and pulmonary diseases of childhood. Structure and function of the pulmonary circulation can be altered by *primary* aberrations of lung growth or development (such as lung hypoplasia, pulmonary hemangiomatosis, arteriovenous fistula, anomalous pulmonary venous return, pulmonary veno-occlusive disease, and others), or *secondary* to injury associated with acute respiratory failure, chronic lung disease after premature birth, chronic hypoventilation, and congenital heart disease. Although the impact of pulmonary hypertension on the clinical course of children with congenital heart disease, persistent pulmonary hypertension of the newborn (PPHN), and idiopathic (or "primary") pulmonary arterial hypertension (iPAH) is most clearly appreciated, the contribution of pulmonary hypertension to the course and ultimate outcome of children with lung disease is often overlooked or underestimated. Pulmonary hypertension is too often a "silent" contributor to morbidity and mortality of many chronic lung disorders in pediatrics, including bronchopulmonary dysplasia (BPD), cystic fibrosis (CF), sickle cell disease (SCD), and various interstitial lung diseases.[1-10] For example, 42% of pediatric patients with interstitial lung disease have evidence of pulmonary hypertension early in their clinical course.[8] Progressive pulmonary hypertension and cor pulmonale, beginning in the pediatric age range, is a common cause and highly predictive of premature death in chronic diseases, such as sickle cell anemia.[7,10,11] In general, clinical strategies that anticipate the development of pulmonary hypertension may allow earlier recognition, more aggressive therapy, and slow the development of pulmonary hypertension in many chronic lung diseases.

Although disease mechanisms and the clinical management of pulmonary hypertension in pediatric patients are often similar to adults with pulmonary hypertension, many aspects of pulmonary vascular disease in children are unique. In contrast to pulmonary vascular disease in adults, pediatric pulmonary hypertension is intrinsically linked to issues of lung growth and development, including many prenatal, perinatal, and later postnatal events. First, the development of pulmonary hypertension in the neonate and young infant reflects the interplay between the normal transition of the pulmonary circulation from fetal to postnatal life. Second, the timing of pulmonary vascular injury is an important determinant of the subsequent response of the developing lung to such adverse stimuli as hypoxia, hypertension, high flow, inflammation, and others. Third, just as the proliferative response of the pulmonary vasculature may be more pronounced in the young lung, the developing lung may also have more potential for recovery over time after removal of an adverse stimulus.[12]

However, the impact of pulmonary hypertension on long-term outcome differs between various pediatric cardiac and respiratory disorders. For example, pulmonary hypertension in infants with BPD is often present early but frequently resolves with therapy over time[1,13,14]; in contrast, pulmonary hypertension develops late in patients with CF and accompanies the steady decline in lung function.[5,6] Thus, in young children and infants with chronic lung disease, changes in the pulmonary circulation and the right side of the heart represent an interplay between normal developmental changes and superimposed cardiovascular and pulmonary stresses (Fig. 52-1).

The purpose of this chapter is to provide a brief overview of the structure and function of the normal pulmonary circulation, and to characterize the clinical pathophysiology, evaluation, and treatment of pulmonary hypertension and cor pulmonale associated with lung diseases in children. Pulmonary hypertension caused by congenital heart disease, vascular rings and slings, vascular anomalies (such as those associated with pulmonary sequestration or lung agenesis), and IPAH are discussed in other chapters.

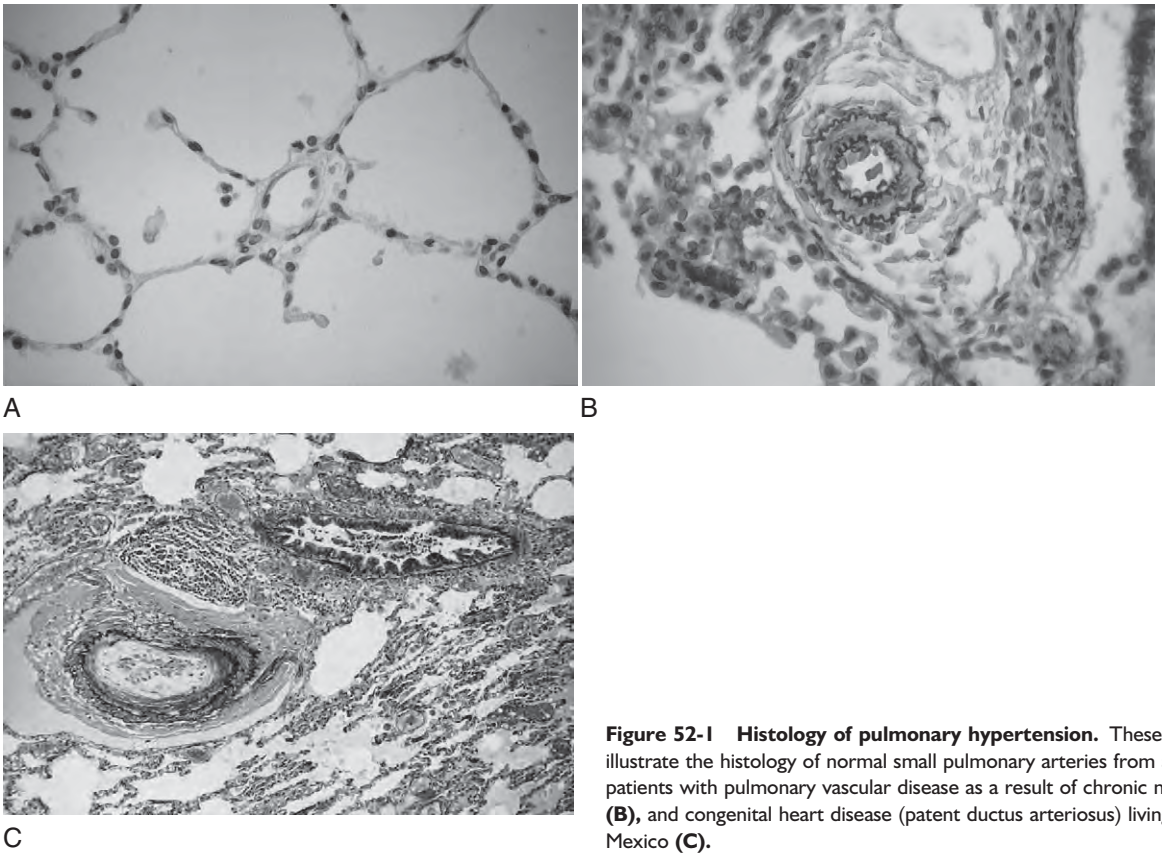

Figure 52-1 Histology of pulmonary hypertension. These photomicrographs illustrate the histology of normal small pulmonary arteries from a control patient **(A),** patients with pulmonary vascular disease as a result of chronic neonatal lung disease **(B),** and congenital heart disease (patent ductus arteriosus) living at high altitude in Mexico **(C).**

DEFINITIONS OF COR PULMONALE AND PULMONARY HYPERTENSION

Cor pulmonale is synonymous with *pulmonary heart disease*, and represents the adaptive response of the right ventricle to increased afterload caused by pulmonary hypertension.[15] Historically, cor pulmonale has been defined as "*hypertrophy* of the right ventricle resulting from diseases affecting the function and/or structure of the lung except where the pulmonary alterations are the result of diseases that primarily affect the left side of the heart or of congenital heart disease."[16] Right ventricular (RV) hypertrophy occurs in response to chronic increases in RV afterload. Although the term *cor pulmonale* has often been reserved for patients with overt signs of RV failure, such signs are generally present very late in the clinical course of pulmonary heart disease. Furthermore, clinical signs of overt right-sided heart failure can easily be masked by signs of severe chronic respiratory disease. A more clinically useful definition of cor pulmonale is the involvement of the right ventricle (either hypertrophy, dilation, or failure), as detected by clinical signs, chest radiograph, electrocardiogram (ECG), echocardiogram, cardiac catheterization, or autopsy, which is caused by altered pulmonary structure and function, provided that the changes are not the result of diseases primarily involving the left or right side of the heart. This is a more expansive definition because signs of advanced right-sided heart failure need not be present. The definition of pulmonary hypertension depends on age and altitude of residence. When directly measured by pulmonary artery catheterization, a mean pulmonary artery pressure (PAP) greater than 25 mm Hg is considered abnormal beyond early childhood. During the early neonatal period, mean PAP gradually falls from systemic levels immediately at birth to adult values by 3 to 6 months. Functionally, PAP is often considered to be clinically significant at a ratio or proportion of mean systemic arterial pressure greater than 50% systemic arterial pressure. ECG and echocardiogram criteria for pulmonary hypertension are discussed in the following section.

CLINICAL SETTINGS ASSOCIATED WITH PULMONARY HYPERTENSION

Pulmonary hypertension can occur as part of an acute or chronic cardiorespiratory process (Box 52-1). For example, high-altitude pulmonary edema (HAPE) or acute hypoxemic respiratory failure in a previously healthy child can cause moderate elevations of PAP as well as increased vascular permeability and altered vasoreactivity. The severity of pulmonary hypertension in response to acute respiratory disease depends in part on age, the presence of underlying cardiac or respiratory disease, genetic makeup, and other factors. For example, neonates with acute respiratory failure often have striking elevations in PAP, which may cause right-to-left shunting across the patent ductus arteriosus or foramen ovale, causing more marked hypoxemia. More commonly, pulmonary hypertension and cor pulmonale are recognized in association with chronic lung, neuromuscular, or cardiac diseases. Disorders commonly associated with chronic hypoxia can be divided into those associated with intrinsic lung disease or those with hypoventilation caused by neurologic or muscular impairment. Although chronic hypoxia contributes to the

BOX 52-1 Diseases Associated with Pulmonary Hypertension in Pediatrics: From the Revised World Health Organization Classification of Pulmonary Hypertension

Group I. Pulmonary Arterial Hypertension

Idiopathic (formerly known as "primary")
Familial
Persistent pulmonary hypertension of the newborn (PPHN)
Related conditions:
- Congenital heart disease (with systemic to pulmonary shunts)
- Portal hypertension
- Collagen vascular disease (esp. scleroderma)
- Drugs and toxins
- HIV infections
- Hemoglobinopathies (esp. sickle cell disease)
- Miscellaneous conditions: thyroid disease, Gaucher disease, glycogen storage disease, hereditary hemorrhagic telangiectasia, myeloproliferative disorders, splenectomy, others

Associated with significant venous or capillary involvement
- Pulmonary veno-occlusive disease
- Pulmonary hemangiomatosis, lymphangiectasia

Group II. Pulmonary Venous Hypertension

Left-sided atrial or ventricular heart disease
Left-sided valvular heart disease

Group III. Pulmonary Hypertension Associated with Chronic Lung Disease or Hypoxemia

Developmental abnormalities: alveolar capillary dysplasia, lung hypoplasia, congenital diaphragmatic hernia
Chronic lung diseases: Bronchopulmonary dysplasia, cystic fibrosis, interstitial lung disease
Sleep disordered breathing, obstructive sleep apnea, chronic upper airway obstruction
Chronic hypoventilation
- Neuromuscular disease, abnormal chest wall, or diaphragm function
- Central hypoventilation syndromes

Chronic high altitude exposure

Group IV. Pulmonary Hypertension due to Chronic Thrombotic and Embolic Disease

Pulmonary embolism (tumor, parasites, foreign material)
Thromboembolic obstruction of proximal, distal pulmonary arteries

Group V. Miscellaneous

Sarcoidosis, pulmonary Langerhans' cell histiocytosis, lymphangiomatosis, compression of vessels (adenopathy, tumor, fibrosing mediastinitis)

development and progression of pulmonary hypertension, pulmonary hypertension often occurs in settings where chronic inflammation and other stimuli are important etiologic factors as well (discussed later). The severity of pulmonary hypertension and degree of RV hypertrophy are likely related to the timing of injury (e.g., interruption of the normal decline in right ventricular predominance during early infancy), duration of pulmonary hypertension, and the presence or absence of left-sided congenital heart disease. Pulmonary venous obstruction, due to veno-occlusive disease or abnormal pulmonary venous return, can masquerade as interstitial lung disease.[8] Pulmonary hypertension is associated with high mortality in many chronic lung diseases, including BPD, CF, and interstitial lung disease—but in some settings, it is unclear whether RV hypertrophy serves as an important marker of advanced disease or an actual cause of death with advanced lung disease. Similarly, cor pulmonale is present in more than 70% of patients dying with CF,[5] but whether aggressive treatment of pulmonary hypertension will alter outcome is unknown.

DEVELOPMENTAL PHYSIOLOGY OF THE PULMONARY CIRCULATION

Insight into pulmonary hypertension in infants and young children begins with an understanding of normal growth and development of the perinatal lung, mechanisms that contribute to the normal postnatal adaptation of the pulmonary circulation after birth and during infancy, and unique responses of the developing lung circulation to injury.

Fetal Pulmonary Circulation

Development of the pulmonary circulation in utero is characterized by early growth of large central arteries with the subsequent development of the microcirculation later in gestation.[17] By the 16th week of gestation, all bronchial airway generations have formed along with their accompanying conducting pulmonary arteries. During the third trimester, pulmonary vascular surface area increases about 10-fold with the concomitant development of the distal airway, alveolar ducts, and saccules. Multiple mechanisms coordinate precise temporal and spatial signaling between vascular and alveolar growth, including critical roles for vascular endothelial growth factor (VEGF), nitric oxide (NO), and others.[18] Both angiogenic and vasculogenic mechanisms have been implicated in lung vascular growth during development, but the relative contributions of each during each phase of lung development are controversial. Importantly, disruption of vascular growth during fetal and early postnatal life can markedly impair lung structure and cause lung hypoplasia.[19]

In addition to increases in pulmonary artery number, changes in pulmonary vascular structure also occur with development. In the normal fetus, small pulmonary arteries associated with the respiratory bronchioles, alveolar ducts, and saccules have minimal smooth muscle (Fig. 52-2).[20] As the pulmonary circulation develops, pulmonary arteries acquire a muscle coat, which has a thickness roughly proportionate to vessel size. At birth, few intra-acinar arteries are muscularized, and vascular smooth muscle cells differentiate in distal arteries with normal postnatal growth. Larger arter-

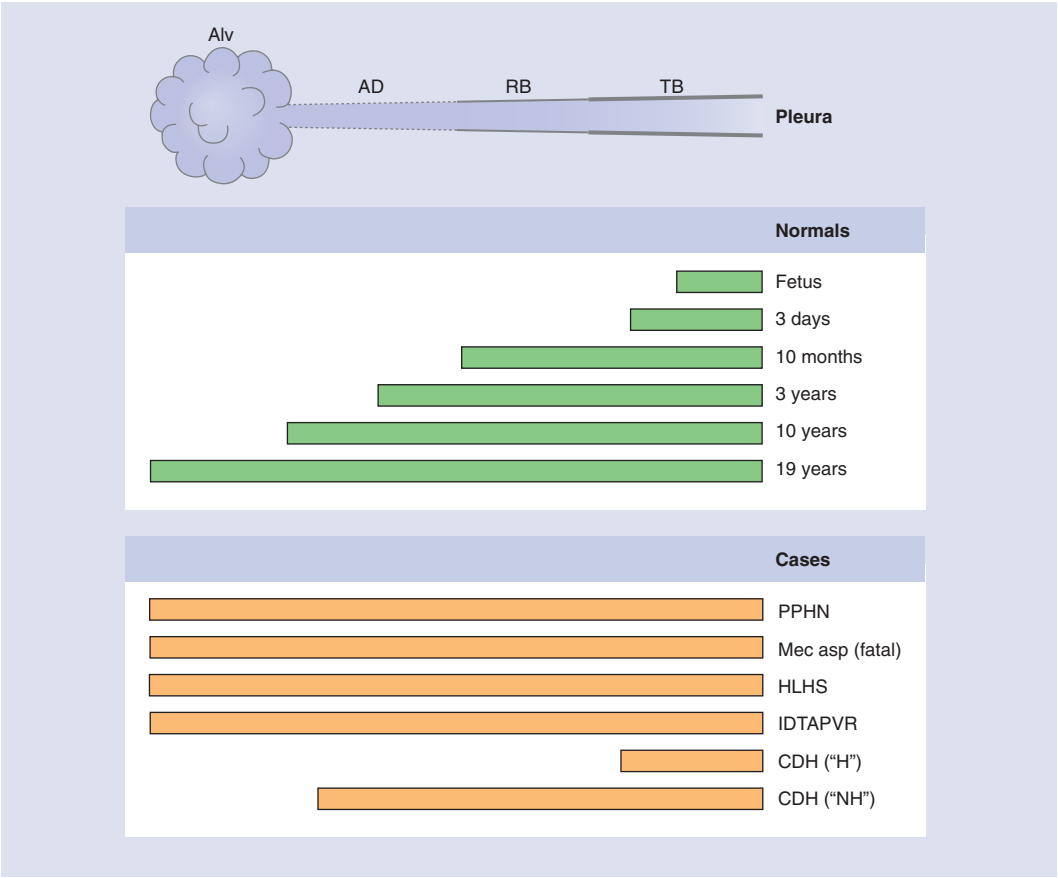

Figure 52-2 Maturational changes in the distribution of smooth muscle in the fetal and postnatal pulmonary circulation. Small pulmonary arteries that accompany the respiratory bronchioles (RB), alveolar ducts (AD), and alveoli (Alv) lack muscularization during fetal life, and extension of smooth muscle occurs throughout childhood. Neonates dying with persistent pulmonary hypertension (PPHN), meconium aspiration (Mec asp), hypoplastic left heart syndrome (HLHS), infradiaphragmatic total anomalous pulmonary venous return (IDTAPVR), and congenital diaphragmatic hernia (CDH) with and without a honeymoon period ("NH") demonstrate increased muscularization of small preacinar and acinar vessels, suggesting altered intrauterine growth. (From Reid L, Fried R, Geggel R, Langleben D: Anatomy of pulmonary hypertensive states. In Bergofsky EF [ed]: Abnormal Pulmonary Circulation. New York, Churchill Livingstone, 1986, p 227.)

ies (>200 μm) are muscularized early, and intermediate pulmonary arteries have variable medial coats, appearing either fully, partially, or nonmuscularized.[20] The apparent lack of extension of smooth muscle in small pulmonary arteries has been misinterpreted to suggest that the pulmonary circulation after premature delivery lacks the ability to vasoconstrict and that pulmonary vasospasm plays a small role in premature infants with respiratory failure. More recent studies have clearly demonstrated that high pulmonary vascular resistance (PVR) in premature neonates can be the result of active vasoconstriction, suggesting a role for vasodilator therapy in some newborns with severe hyaline membrane disease.[21]

The fetal pulmonary circulation receives less than 8% of combined ventricular output as a result of its high basal PVR, causing most of the RV output to cross the ductus arteriosus to the aorta, bypassing the lung.[22] Despite the apparent low level of pulmonary blood flow, blood flow remains essential for providing adequate substrate to allow lung growth; it has been shown that pulmonary artery ligation in the late-gestation fetal lamb causes lung hypoplasia.[23] Similarly, hypertension itself can impair lung vascular growth and decrease alveolarization in the late fetus,[24] suggesting additional mechanisms through which mesenchymal-epithelial "cross-talk" is required to achieve normal lung structure at birth.

During late gestation, pulmonary blood flow increases in proportion to lung weight and increased vascular cross-sectional area, as the number of blood vessels increases more than 10-fold. Although flow increases with advancing gestation, mean PAP increases as well, and when corrected for lung weight, PVR increases with gestational age. Mechanisms maintaining high fetal PVR include physical stimuli, such as the lack of a gas-liquid interface and rhythmic distention of the lung. In addition, low oxygen tension (normal fetal Pa_{O_2} is 20 to 25 mm Hg), low basal production of endogenous dilator products (such as prostacyclin [PGI_2] and nitric oxide [NO][25]), and increased production of vasoconstrictor substances (including endothelin-1[26-28] and leukotrienes[29]) also contribute to high PVR in utero.

In addition to the structural changes previously described, marked changes in pulmonary vascular tone and reactivity also occur with development.[30] For example, experimental

studies of maturational changes of pulmonary vasoregulation suggest that endogenous NO production modulates basal fetal PVR and that the fetal smooth muscle is responsive to vasodilators, such as NO or NO-donors, quite early in gestation.[31-33] Maturational changes in endothelial and smooth muscle function contribute to the regulation of vascular tone in fetal life (Fig. 52-3).

The distal lung develops extensively during the third trimester, including a dramatic increase in small pulmonary arteries, which continues during the first few years after birth.[34] With premature birth, the normal sequence of lung growth and development is disrupted, and at least in children requiring mechanical ventilation because of respiratory distress syndrome, lung growth may be severely impaired by hyperoxia, barotrauma, and inflammation, causing BPD.[35] In older patients dying with BPD, lung septation and capillary surface area are markedly decreased.[36-38] Impaired vascular growth may not only cause a dysmorphic pulmonary circulation in BPD, but it may also disrupt alveolarization.[19,39,40] As a result, premature birth, respiratory distress, and vascular injury during its treatment are a major cause of pulmonary hypertension in BPD (as discussed subsequently).

During late gestation, intrauterine stimuli, such as inflammation, infection, or systemic or pulmonary hypertension, can alter vascular growth, leading to striking hypertensive remodeling and decreased vessel number. Although exact mechanisms causing vascular remodeling are incompletely understood, experimental studies suggest that intrauterine hypertension may be more critical than chronic hypoxia in the pathogenesis of structural and functional impairment during the transition at birth.[41-44] Partial compression or early closure of the ductus arteriosus in fetal lambs alters vascular reactivity and lung structure, leading to the failure of postnatal adaptation at delivery, providing an experimental model of persistent pulmonary hypertension of the newborn (PPHN).[41,42]

Transitional Pulmonary Circulation

At birth, the pulmonary circulation undergoes a dramatic transition because pulmonary blood flow rapidly increases 8- to 10-fold and PAP decreases to levels approximately 50% of systemic arterial pressure.[22] Mechanisms causing this fall in PVR include establishment of an air-liquid interface, rhythmic lung distention with respiration, increased oxygen tension, and altered production of vasoactive substances.[30] Marked stimulation of endogenous NO, primarily the result of increased oxygen and shear stress, contributes substantially to the fall in PVR.[25,45] Similarly, PGI_2, largely released from increased lung ventilation and shear stress, but not increased oxygen, also contributes to postnatal adaptation.[46] Decreased production or responsiveness to local vasoconstrictors, such as leukotrienes or endothelin-1, may also contribute to the normal fall in PVR.[27] A concomitant structural reorganization of small pulmonary arteries occurs, as the vascular endothelium is flattened with high flow, and vascular dimensions change rapidly with birth.[47] Progressive pulmonary vascular dilation, recruitment, and structural adaptations are reflected by further decreases in resistance during late infancy, when adult values of PVR are achieved.

The pulmonary circulation during this transitional period (at birth and during early infancy) may be particularly sensitive to injury. Not only is this a time of rapid vessel growth, but functional changes in vascular tone and reactivity occur with age as well. Such developmental aspects of the pulmonary circulation not only are important in regard to PPHN, congenital heart disease, and BPD, but also have clinical ramifications in other settings of pediatric pulmonary hypertension. As suggested in two experimental models of chronic pulmonary hypertension, the immature or infant lung circulation may not only be more susceptible to injury, but it may also be uniquely capable of recovering more readily than adult circulation. Insight into responses of the developing lung to

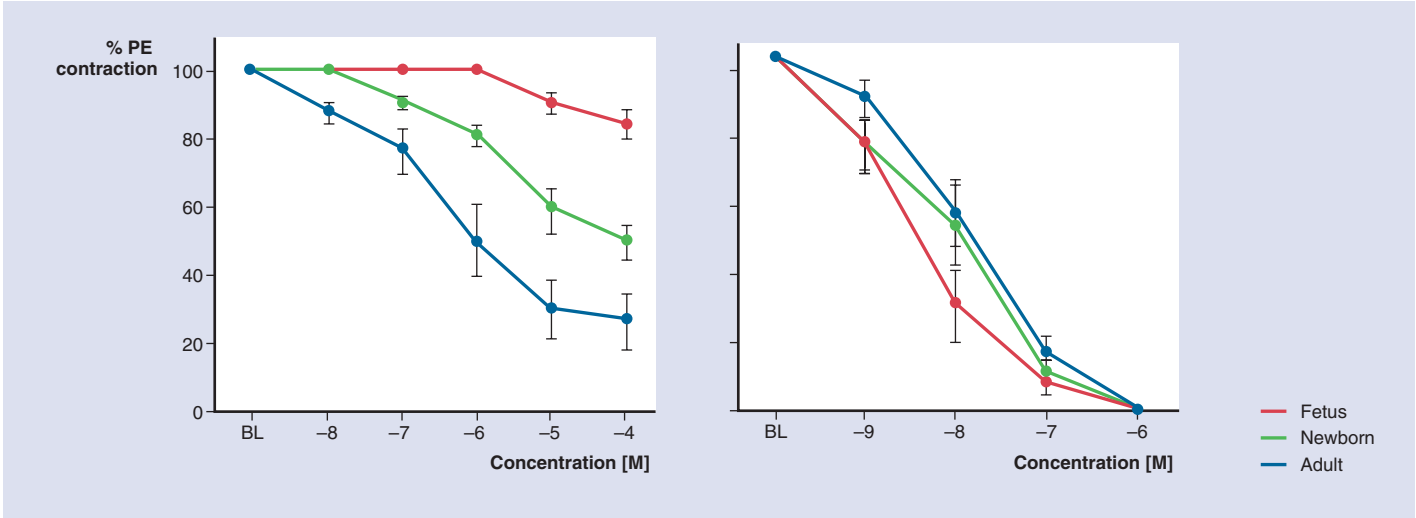

Figure 52-3 Maturation-related changes in pulmonary vasodilation to endothelium-dependent and independent stimuli. In comparison with neonatal and adult pulmonary arteries, pulmonary arteries isolated from late-gestation fetal lambs have diminished relaxation to acetylcholine (ACH), an endothelium-dependent agonist (*left*). In contrast, the relaxation to sodium nitroprusside (SNP), an agent that directly stimulates smooth muscle cell relaxation, causes marked relaxation at each age (*right*). These findings suggest that maturational changes occur in endothelial function but that vascular smooth muscle is able to respond to vasodilator stimuli early in development. (From Abman SH, Chatfield BA, Rodman DM, et al: Maturational changes in endothelium-derived relaxing factor activity of ovine pulmonary arteries in vitro. Am J Physiol 260:L280-L285, 1991.)

growth factors, vasoactive mediators, and related stimuli are likely to provide novel approaches toward the management of pediatric pulmonary hypertension.

Normal Postnatal Anatomy

Blood flow in the lung has two sources, including the pulmonary and bronchial circulations, which behave differently in health and disease states.[48] The pulmonary circulation includes the RV outflow tract, main pulmonary artery and its major branches to left and right lung, lobar branches, intrapulmonary arteries, arterioles, capillaries, venules, and large pulmonary veins. Normally, the right pulmonary artery divides into a lower branch, which supplies the right middle and lower lobes, and a smaller upper branch to the right upper lobe. The left pulmonary artery lies above the left mainstem bronchus up to the first branch, then travels behind the bronchus. Some variability exists with the distribution of smaller arterial branches.

There are striking differences in vascular growth and function of vessels throughout the pulmonary circulation, at least partly dependent on their size and location, which may be related to chronic exposure to different hemodynamic forces (discussed later). There are three types of arteries. First, elastic pulmonary arteries (>1000 μm external diameter) consist of distinctive layers of elastic fibers in a coat of smooth muscle cells in central pulmonary arteries and extralobular pulmonary arteries. Second, muscular pulmonary arteries (100 to 1000 μm external diameter) have a thin medial layer of muscle between internal and external elastic laminae, which is usually less than 5% of the external diameter of the vessel. Muscular arteries accompany bronchioles within lobules. Third, pulmonary arterioles (<100 μm external diameter) are the terminal branches of the pulmonary arterial tree and, at their origin from muscular arteries, contain a partial layer of muscle that gradually disappears. Pulmonary arterioles supply alveolar ducts and alveoli.

Two types of small pulmonary artery branches have been described, including "conventional" branches, which accompany airways, and "supernumerary" branches, which travel alone and are usually smaller. Conventional arteries branch from main arterial channels and extend to the periphery, at the end of the respiratory bronchioles. Supernumerary vessels outnumber the conventional branches, constituting 25% of the total cross-sectional area of the pulmonary arterial bed near the hilum and about 40% at the periphery. Supernumerary arteries are present at birth and can participate in gas exchange. Extensive growth of conventional and supernumerary branches accompanies the development of new alveolar ducts and alveoli and contributes to the progressive increase in surface area during the first few years of life.[34] After 18 months, the number of conventional arteries is fixed, but supernumerary arteries continue to increase with septation and formation of new alveoli (up to 3 years of age).

The microcirculation consists of small capillaries that form an extensive network in interalveolar septa. Capillaries are mostly composed of cytoplasmic extensions of endothelial cells, which, by their contiguous arrangement, form a thin vascular tube. More recently, lung vascular growth has been shown to result from angiogenesis and vasculogenesis, but the relative importance of lung vasculogenesis during postnatal life is unclear.[49] Both the endothelium and the neighboring alveolar epithelium lie on separate basement membranes. Fusion of endothelial and epithelial basement membranes cover half of the capillary border, forming the thin portion of the alveolar-capillary membrane, which provides the site for gas exchange. For the other half of the capillary perimeter, these basement membranes remain separated by an interstitial space and are sites for liquid and solute exchange.

Arterial and venous blood supplies of pulmonary lobules differ anatomically. A lobule consists of a cluster of three to five terminal bronchioles, and neighboring lobules are partly contained by connective tissue septa. Branches of pulmonary arteries and small bronchi travel together, supplying terminal respiratory units within a single lobule. In contrast, pulmonary veins drain blood from several different lobules. Normal veins have less muscularity and much thinner walls than arteries, but like arteries, veins are either conventional or supernumerary. Small intrapulmonary venules successively fuse to form increasingly larger veins until a lobar vein emerges from each lobe. The right upper and middle lobe veins usually combine; thus, there are superior and inferior pulmonary veins from each lung. Although the branching pattern of the airways increases the cross-sectional area of the bronchial tree longitudinally, the cross-sectional area of the vascular bed gets smaller from the central vessels to the arterioles or venules. Most of the blood in the pulmonary circulation is contained in large, not small, vessels. Velocity of blood flow in arteries decreases as vessels get smaller, but the decrease is not as marked as with airways.

Although the bronchial circulation normally receives only 1% to 2% of the total cardiac output, it provides flow, which is essential for maintaining normal lung growth and function.[48] The bronchial circulation is the principal source of nutrient blood and oxygen to airways (large and small), pulmonary nerves and ganglia, walls of elastic and some muscular pulmonary arteries and veins, lymph nodes and connective tissue septa, and the pleura. Bronchial blood flow may increase substantially with pathologic conditions, such as in diseases associated with chronic inflammation and injury (such as CF, BPD, and bronchiectasis).[1,50] Acute increases in bronchial flow may also contribute to lung edema with acute lung injury.[51] There is marked variability of bronchial branching patterns; 40% of children have one bronchial artery to each lung. Bronchial blood returns to the heart via bronchial veins, from branches perfusing the lobar and segmental bronchi and from branches from the pleura near the hilus. Bronchial venous blood empties into the azygos, hemiazygos, or intercostal veins and then flows into the right atrium. Veins that originate from bronchial capillaries within the lung unite to form tributaries that join pulmonary veins (bronchopulmonary veins). Blood leaving the capillary bed near terminal bronchioles flows through anastomoses with the alveolar capillaries, and the mixture of blood returns to the left atrium through pulmonary veins. About one fourth to one third of blood goes to the right atrium via bronchial veins; the remainder flows to the left atrium via pulmonary veins.

Normal Postnatal Physiology

Although the lungs normally receive the entire cardiac output, PAP remains low because of the low basal vascular resistance.

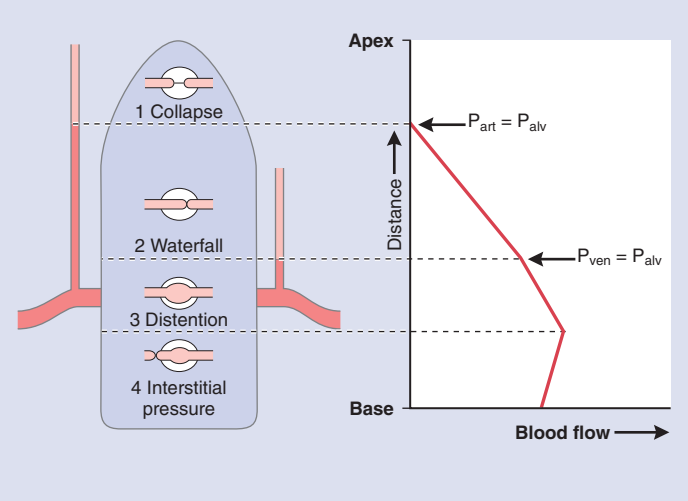

Figure 52-4 Effects of alveolar, arterial, and venous pressures on regional distribution of blood flow in the pulmonary circulation. (From Murray JF: The Normal Lung. Philadelphia, WB Saunders, 1986, pp 139-150.)

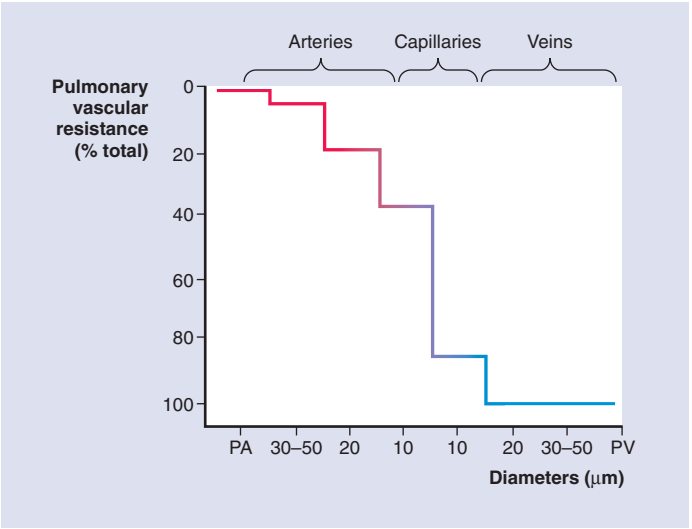

Figure 52-5 Distribution of resistance in pulmonary circulation from isolated perfused dog lung. PA, pulmonary artery; PV, pulmonary vein. (From West JB, Dollery CT, Naimark A: Distribution of blood flow in isolated lung; relation to vascular and alveolar pressures. J Appl Physiol 19:713-724, 1964.)

The distribution of pulmonary flow within the lung is nonuniform and depends partly on relationships among gravity, alveolar pressure, PAP, and pulmonary venous or left-atrial pressure.[52] Three zones have been proposed to explain regional variations in flow (Fig. 52-4). In zone 1, normal PAP is insufficient to perfuse the uppermost regions of the lung, and pulmonary capillaries are collapsed because alveolar pressure exceeds pulmonary arterial and venous pressures. Pulmonary blood flow begins at the top of zone 2, as PAP exceeds alveolar pressure, and continues to increase with increased PAP. As alveolar pressure is greater than pulmonary venous pressure, flow is determined by the difference between pulmonary artery and alveolar pressures. In zone 3, both pulmonary artery and venous pressures exceed alveolar pressure; therefore, driving pressure is determined by the difference between inflow and outflow vascular pressures. In the normal upright adult, most of the lung is in zone 3 conditions. Passive changes in PVR are affected by differences between pressures within and surrounding pulmonary blood vessels, shifts of blood into and out of the lungs, and changes in whole blood viscosity. Changing hydrostatic pressures relative to the height of the lung affect distribution of pulmonary blood flow (for example, distribution of flow is more even while supine than in the upright position). Increased pulmonary artery or left atrial pressure acutely increases flow, causing a drop in PVR. The longitudinal distribution of PVR in the normal lung using micropipette techniques demonstrated that under zone 3 conditions, the largest contribution to resistance lies in the capillaries of the alveolar septum, with most of the remaining resistance in arterioles, and little contribution from venules to veins (Fig. 52-5).[53]

Multiple mechanisms regulate vascular tone and the distribution of blood flow within the lung. Active and passive changes in PVR during exercise and the regional effects of hypoxia illustrate how the lung can alter distribution of blood flow to sustain gas exchange. Because of its low basal PVR and high compliance, the normal pulmonary circulation tolerates marked increases in flow during exercise, with only small increases in pressure and decreases in PVR. Pulmonary artery and capillary wedge pressures rise, increasing flow to the upper lobes and making overall perfusion more uniform. With high flow during exercise, low PVR is maintained by passive vascular distention, recruitment of small pulmonary arteries, and vasodilation. Patients with chronic lung disease can have marked increases in PAP because of the increase in pulmonary blood flow during exercise—even apparently during normal resting pulmonary hemodynamics.

As first described by von Euler,[54] the unique ability of pulmonary arteries to constrict with exposure to low oxygen tension plays a central role in controlling the distribution of blood flow through the lung. Although many vasoactive substances modulate the degree of hypoxic vasoconstriction, hypoxia causes contraction by direct effects on vascular smooth muscle.[55] Regional vasoconstriction redirects blood flow to lung regions with better aeration, enhancing ventilation-perfusion ($\dot{V}/\dot{Q}$) matching and preserving gas exchange.

In addition to its gas exchange function, the pulmonary circulation also provides nutritional and metabolic support for the lung and is the site for synthesis, storage, and metabolism of various circulating and local vasoactive substances. Although past studies primarily emphasized its barrier function, the endothelial cell releases multiple vasoactive products that regulate vascular tone, smooth muscle growth, angiogenesis, liquid and solute transport, thrombosis, synthesis or clearance of circulating hormones, and others. Clinical and experimental studies suggest that vascular metabolic functions are altered with pulmonary vascular injury, contributing to hemodynamic and structural abnormalities in chronic pulmonary hypertension.

DISEASE MECHANISMS

As with pulmonary hypertension in adults, numerous factors contribute to disease severity in pediatric patients, including

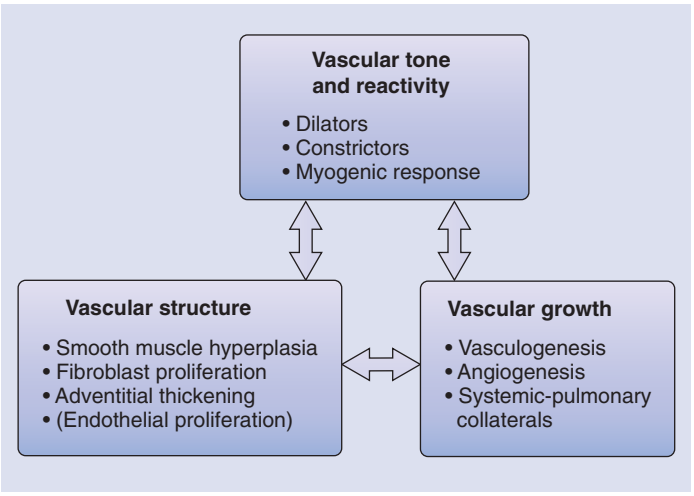

Figure 52-6 Components of pulmonary hypertension.

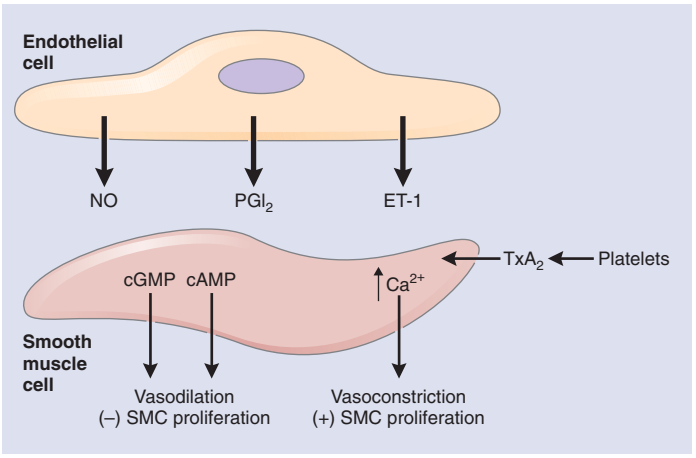

Figure 52-7 Endothelial–smooth muscle cell interactions in pulmonary hypertension. NO, nitric oxide; PGI_2, prostacyclin; SMC, smooth muscle cell; TxA_2, thromboxane.

high basal tone, abnormal vasoreactivity, thrombosis, inflammation, and altered vascular growth and remodeling (Fig. 52-6). Although pulmonary hypertension occurs in diverse clinical settings, several features are common regardless of the specific disease associated with pulmonary hypertension. First, pulmonary vascular disease is generally associated with changes in both structure and function, and the relative contribution of remodeling with changes in vascular tone is variable—even within diseases. Second, pulmonary vascular disorders are commonly associated with altered vascular reactivity, not only high basal pulmonary vascular tone, and exaggerated vasoconstriction to certain stimuli (especially acute hypoxia) is often central to pathophysiologic features. For example, altered pulmonary vasoreactivity leads to the vasolability or "flip-flopping" in patients with PPHN,[56] recurrent cyanotic episodes in apparently normal children,[57] recurrent high altitude pulmonary edema (HAPE),[58] sudden death or "dying spells" in BPD, and other disorders. Mechanisms contributing to heightened pulmonary vasoreactivity are poorly understood, but may include alterations in endothelial-smooth muscle cell interactions. Third, reduced arterial density, as typically observed in lung hypoplasia, congenital diaphragmatic hernia, BPD, Down syndrome and other settings, markedly increase the risk for advanced pulmonary hypertension. This may, in part, be due to increased hemodynamic stress of even normal cardiac output through a "hypoplastic" vasculature, and likely accounts for the accelerated pulmonary vascular disease observed in patients with BPD, Down syndrome, and other disorders, in the presence of relatively modest increases in pulmonary blood flow due to cardiac shunts.

Recent developments in vascular biology have demonstrated that the endothelial cell produces a wide variety of vasoactive compounds, including dilators such as PGI_2 and NO (Fig. 52-7). In addition, vascular endothelium can produce potent vasoconstrictors, including endothelin (ET-1), thromboxane, and other endothelium-derived contracting factors. Vascular injury from hemodynamic stresses (high flow, high pressure, shear stress, or stretch), hypoxia, or inflammation alters endothelial production of these products, creating an imbalance between vasodilators and vasoconstrictors, which favors increased basal tone or heightened vasoreactivity. Increased superoxide production may further worsen vascular tone owing to impaired NO production or endothelial injury.[59] However, in vitro studies of human pulmonary arteries suggest that impaired endogenous NO activity is likely to contribute to heightened pulmonary vasoconstriction in patients with pulmonary hypertension associated with several chronic lung diseases, including CF and chronic obstructive pulmonary disease (COPD).[60] In addition, increased immunoreactivity and gene expression of ET-1 is present in children with BPD and adults with severe pulmonary hypertension, suggesting that enhanced ET-1 production may also contribute to heightened vasoreactivity and hypertensive vascular remodeling in chronic pulmonary hypertension.[61]

Unlike the pulmonary vascular response to acute hypoxia, prolonged exposure to hypoxia causes sustained elevations of PAP that do not totally improve with the acute return to normal oxygenation. In addition to hypoxia, other mechanisms that contribute to the development of chronic pulmonary hypertension include hemodynamic stresses (increased pressure, flow, shear, stretch, and wall tension), sustained release of vasoactive products and growth factors (inflammatory, autocoids, paracrine mediators, or neurohumoral stimuli), and combinations of these stimuli. Pulmonary vascular responses to these stimuli are also dependent on the strength and duration of the stimulus, the patient's age, genetic factors, infection, inflammation, and others. Whereas the short-term responses to these agonists generally alter vascular tone and reactivity, long-term exposure to the same stimuli is likely to contribute to altered vascular growth and remodeling. Persistent elevation of PAP can be due to at least four general causes, including vasoconstriction, vessel wall proliferation and remodeling, thrombosis in situ, and decreased vessel number or surface area.

Pulmonary hypertension is commonly defined as mean PAP above 25 mm Hg, with normal values reported between 10 and 16 mm Hg. As discussed previously, mean PAP is roughly 50% of systemic arterial pressure at the end of the first day of life and gradually decreases during early infancy.[62] Determinants of PAP include cardiac output (CO), PVR, and

pulmonary capillary wedge or venous pressure. Because CO varies with body size, PVR is often indexed according to surface area (PVRI). PVR is often expressed as resistance units (mm Hg/L/min) or as dynes/sec/cm^{-5} (multiply PVRI by 80).

Diverse mechanisms may contribute to high PAP, including high PVR caused by vascular remodeling, vasoconstriction, vascular occlusion (from thromboemboli), or compression of small pulmonary arteries (for example, at high or low lung volumes during mechanical ventilation). In addition, elevated pulmonary capillary wedge pressure (PCWP) resulting from left-ventricular failure, pulmonary venous obstruction or constriction, mitral valve disease, and others can also increase PAP without marked changes in PVR. For example, assessments of transpulmonary artery pressure gradient are important in the setting of high PCWP to directly assess pulmonary vascular disease in potential candidates for cardiac transplantation because of severe cardiomyopathy. PAP may be elevated in the absence of high PVR with anatomic cardiac lesions with large left-to-right shunting. Long-standing pulmonary venous obstruction or high-flow lesions are associated with high PVR resulting from upstream pulmonary vascular disease from remodeling or vasoconstriction. Hyperviscosity and intrathoracic pressure can also influence PVR in the presence of marked polycythemia associated with chronic hypoxia and during mechanical ventilation, respectively. Positive end-expiratory pressure (PEEP) influences lung volume, depending on its effects on lung volume and intrathoracic pressure.[63] Whereas low lung volumes may elevate PVR because of the loss of the "tethering" effect of normal distention of neighboring parenchyma, hyperinflation may cause mechanical compression of intra-acinar vessels.

The earliest clinical signs of pulmonary hypertension first become apparent during exercise, even in the presence of normal or minimal increases in baseline PAP.[64,65] The normal physiologic response to exercise includes a marked increase in CO with small increases in PAP and PCWP, decreasing PVR by 60% to 70% from baseline. Increased pulmonary blood flow would markedly increase PAP if there was not a concomitant decrease in pulmonary vascular tone and an increase in vascular distention and recruitment.

With early pulmonary vascular disease, increased CO during exercise markedly increases PAP as a result of high blood flow through a restricted vascular bed and its inability to distend or dilate because of altered vascular structure and reactivity. With severe pulmonary hypertension, exercise is extremely limited because CO is unable to increase, predisposing patients to fatigue, dyspnea on exertion, and with advanced disease, syncope or sudden death. In the absence of shunt lesions, right- and left-ventricular outputs are the same.

Because PVR is normally about 20% of systemic vascular resistance, the right ventricle has a thinner wall and a greater volume and surface area than the left ventricle. This configuration is better suited to ejecting large volumes of blood with minimal myocardial shortening, providing a highly compliant chamber that better accommodates increases in filling pressure, as with normal exercise. Unfortunately, the right ventricle is poorly designed to handle rapid increases in wall tension and high systolic ejection pressure, such that an abrupt rise in RV afterload markedly increases RV end-diastolic pressure, decreasing ejection fraction, and RV output. A sudden rise in PVR rapidly dilates the right ventricle, as it attempts to improve function according to the Frank-Starling curve. Mean PAP near 50 mm Hg is poorly tolerated, leading to acute right-sided heart failure.[66] For example, although cardiac transplant patients may have tolerated moderate pulmonary vascular disease before surgery, rapid deterioration of function in the right side of the heart can occur after surgery because of the lack of adaptation of the "new" right ventricle. Interestingly, the failing right ventricle may not be able to generate enough CO to sustain elevated PAP despite high PVR, causing overt clinical signs of right-sided heart failure in some patients with only mild or moderate elevations of PAP. Reduced right coronary artery perfusion pressure, especially during systole, decreases oxygen delivery and causes subendocardial ischemia, further contributing to right ventricular dysfunction.

Experimental studies suggest that even small increases in PAP result in rapid reduction of RV stroke volume. With the gradual development of pulmonary hypertension that occurs with chronic lung disease, the right ventricle is able to adapt to increased afterload by muscle hypertrophy. Acute pulmonary hypertension does not develop until there is a 60% reduction in functional surface area.[67,68] With chronic pulmonary hypertension, smaller degrees of obstruction or loss of vascular bed increases PAP and causes RV hypertrophy. Hypertrophy represents an adaptive response that reduces ventricular compliance and increases RV end-diastolic and right-atrial pressure. High right-atrial pressure is an important marker of advanced RV failure because CO falls with right-atrial pressure above 8 to 10 mm Hg in adults.[68] Systemic venous distention, hepatomegaly, peripheral edema, and other clinical signs of right-sided heart failure can develop with acute elevations of PAP in patients with chronic mild-to-moderate pulmonary hypertension, as with respiratory syncytial virus infections in patients with BPD and congenital heart disease.

Left-ventricular function is generally well preserved in most patients with chronic lung disease despite pulmonary hypertension and suboptimal RV function.[69] However, high PVR can impair CO, especially with exercise, and in some patients, poor left-ventricular function is present, further aggravating lung mechanics and gas exchange.[70,71] High PVR causes left-ventricular dysfunction by decreasing preload and causing paradoxical interventricular septal motion (ventricular interdependence).[72] Increased RV dilation mechanically distorts the left ventricle, impedes left-ventricular filling, and decreases CO in proportion to the severity of RV failure. Histologic studies suggest remodeling of left ventricular myocytes and interstitium, suggesting that along with functional changes in left- and right-ventricular interactions, structural remodeling may also account for changes in myocardial compliance or function. Left-ventricular hypertrophy may represent an adaptive response to increased septal wall tension and is not uncommon in infants with BPD and pulmonary hypertension.[1] Mechanisms leading to the development of left-ventricular hypertrophy in BPD or other chronic lung diseases are unclear, but they may be related to systemic hypertension, β-agonist therapy, or other stimuli. Low CO is an important marker of severe pulmonary hypertension and poor long-term outcome. Decreased CO increases fluid and salt

retention as a result of increased antidiuretic hormone and aldosterone release, which may account for worsening peripheral edema and other signs of congestive heart failure.[73]

Pulmonary hypertension can alter lung mechanics and gas exchange, causing mild decreases in lung compliance and volume.[74] The direct effects of pulmonary hypertension on gas exchange are difficult to distinguish from signs and symptoms of chronic lung disease. However, patients with primary pulmonary hypertension have only mild abnormalities in ventilation-perfusion ($\dot{V}/\dot{Q}$) matching.[75] Pulmonary hypertension with chronic lung disease may further impair lung function and gas exchange by increasing pulmonary edema formation in addition to altering reactivity.

ASSESSMENT AND DIAGNOSIS

The diagnosis, evaluation, and management of pulmonary hypertension requires a methodical approach, but can vary according to the associated disease. Increased awareness of at-risk patient populations with chronic lung disease and other disorders associated with pulmonary hypertension may allow for earlier diagnosis and a greater likelihood for successful intervention. Too often, pulmonary hypertension is not recognized until overt RV dysfunction is already present. Clinically, RV dysfunction may occur at lower PAP in chronic lung disease than with patients with IPAH, making diagnosis and assessments of its contribution to the clinical picture in those with chronic lung disease difficult. Whereas patients with IPAH may tolerate mean PAP above 60 mm Hg, those with chronic obstructive lung disease often have RV dysfunction at 40 mm Hg.[76] Importantly, pulmonary vascular disease in patients with chronic lung disease can limit activity and cause exercise intolerance even in the absence of striking pulmonary hypertension by echocardiogram at rest because PAP can markedly increase with even modest activity in some cases.

Once recognized, assessment and treatment of factors that contribute to progressive pulmonary vascular disease becomes critical. For example, causes of intermittent or chronic hypoxemia, such as obstructive sleep apnea, chronic aspiration, unrecognized airway lesions, and unsuspected anatomic cardiac disease, can potentiate pulmonary vascular injury associated with any primary etiology. As with adult pulmonary hypertension, clinical symptoms and signs commonly associated with pediatric pulmonary hypertension include dyspnea, fatigue, exercise intolerance, syncope, cyanosis, chest pain, palpitations, intermittent dry cough, or vomiting. Unexplained seizures, especially in children living at or visiting high altitudes, can be a manifesting sign of reactive pulmonary hypertension. IPAH may appear to be unexplained "portal hypertension" caused by hepatomegaly,[77] recurrent cyanotic episodes, or seizures. Young infants often have feeding difficulties, including cyanosis, choking, sweating, decreased intake as a result of fatigue, and failure to thrive. Evaluations should seek a history of snoring and obstructive sleep apnea (even in the presence of underlying chronic lung disease), including inquiries regarding daytime somnolence, enuresis, and systemic hypertension.

Signs and symptoms of pulmonary hypertension in children with cor pulmonale can be nonspecific and are often difficult to distinguish from progression of the underlying respiratory problem. Such signs include dyspnea, fatigue, exercise intolerance, recurrent cyanotic or breath-holding spells, poor growth, diaphoresis, chest pain, syncope, and palpitations. Infants and young children often have poor feeding associated with choking, sweating, and cyanosis. In selected cases, unexplained seizures can be a presenting sign, especially in children with primary pulmonary hypertension. As pulmonary hypertension worsens and contributes to the underlying lung disease, progressive dyspnea, fatigue, and other signs are often attributed to exacerbations of the primary lung disease. Similarly, physical findings of pulmonary hypertension are often subtle early; neck vein distention, peripheral edema, hepatomegaly, syncope, and other problems manifest late in the course. Signs of worsening exercise intolerance or fatigue in the absence of proportionate declines in airflow limitation or lung mechanics by formal pulmonary function testing raises the possibility that pulmonary hypertension and cardiac dysfunction may be contributing factors. Physical examination may disclose signs of associated multisystem diseases that can cause pulmonary hypertension, such as cirrhosis, collagen vascular disorders, and hematologic abnormalities.

Common findings on physical examination in patients with moderate pulmonary hypertension include tachypnea, tachycardia, an increased second heart sound with narrow or fixed splitting, and a systolic ejection murmur at the left upper sternal border. Signs of advanced RV failure include RV heave, increased jugular venous distention (prominent a wave), hepatomegaly and hepatic tenderness, and peripheral edema. In patients with chronic lung disease, signs and symptoms of pulmonary hypertension are often difficult to distinguish from progressive respiratory deterioration. Fluid retention, increasing hepatomegaly, hepatic tenderness, and peripheral edema should heighten suspicion of RV failure in this setting. Although differentiating signs and symptoms from the primary lung disease versus pulmonary hypertension is difficult, awareness of the risk for pulmonary hypertension and early evaluation may lead to the diagnosis. For example, CF patients with progressive dyspnea or exercise intolerance that seems discordant with the degree of decline in pulmonary function or that persists despite aggressive antimicrobial and anti-inflammatory therapy may suggest a significant clinical contribution of pulmonary hypertension and cor pulmonale. Similarly, infants with BPD and unexplained poor growth, persistent or increased oxygen requirements, recurrent cyanotic episodes, or the lack of resolution of RV hypertrophy by ECG warrant more extensive investigation.[78]

The clinical evaluation depends on whether the evolution of pulmonary hypertension is for patients with recognized lung disease or in patients with an unknown etiology. The role of laboratory studies is to identify the presence and severity of pulmonary hypertension, to identify pathogenetic mechanisms that may contribute to its severity, and to assess response to therapeutic intervention. Although ECG, echocardiogram, and cardiac catheterization are direct assessments of pulmonary hypertension, studies such as chest radiographic examinations, chest computed tomography (CT), $\dot{V}/\dot{Q}$ scans, and pulmonary angiography provide important clinical information in many settings. Initial evaluation includes arterial blood gases (to assess chronic hypoventilation), chest radiograph, ECG, echocardiogram, $\dot{V}/\dot{Q}$ scan,

BOX 52-2 Diagnostic Evaluation of Pulmonary Hypertension

The following tests may be useful depending on the clinical features:

- Arterial blood gas
- Prolonged pulse oximetry studies (awake, asleep, exercise)
- Electrocardiogram (ECG)
- Echocardiogram
- Cardiac catheterization (including acute vasodilator testing, angiography)
- Exercise testing
- Complete blood count with platelet count, urinalysis
- Liver function tests (liver enzymes, albumin, clotting studies) plus imaging studies (ultrasound)
- Coagulation studies: DIC screen, factor V Leiden, antithrombin III, protein C, protein S, anticardiolipin IgG or IgM, antiphospholipid antibody, Russell viper venom test
- Collagen vascular disease evaluation: ESR, ANCA, ANA with profile (DNA, Smith, RNP, SSA, SSB, centromere, SCL-70), rheumatoid factor
- Complement
- Thyroid function tests
- Toxicology screen
- Chest radiographs
- Pulmonary function testing with DLCO
- Barium swallow
- Esophageal pH study
- Sleep study
- $\dot{V}/\dot{Q}$ scan
- Chest CT scan

BOX 52-3 ECG Criteria for Right-Ventricular Hypertrophy

- Right-axis deviation (RAD)
- Right-atrial hypertrophy: (p-pulmonale: P waves >3 mm)
- Increased rightward and anterior QRS vector
  - R in V_1, V_2, or aV_R > upper limit of normal (ULN) for age
  - S in I and V_6 > ULN for age
- Abnormal R : S ratio in favor of right ventricle (in absence of bundle branch block)
  - R : S ratio in V_1 and V_2 > ULN for age
  - R : S ratio in V_6 < 1 after 1 month of age

sleep study, exercise testing, and others (Box 52-2). In addition to excluding the presence of parenchymal disease in patients with unexplained pulmonary hypertension, a basic laboratory work-up may include hematologic, liver function tests, clotting studies, screening for collagen vascular disease, and others.

Chest radiograph findings suggestive of pulmonary hypertension in chronic lung disease include RV enlargement with prominent appearance of dilated central pulmonary arteries. In older patients, a descending right pulmonary artery diameter greater than 20 mm and an increased hilar thoracic index are highly suggestive of pulmonary hypertension.[79] Vascular markings may appear reduced in the lung periphery, coinciding with the appearance of "pruning" detectable by angiography. Pulmonary veno-occlusive disease can appear as reticular or reticulonodular infiltrates, masquerading as interstitial lung disease. Obstruction and infiltrates may be unilateral. Irregular or marginated densities may be suggestive of pulmonary vasculitis. One of the major problems in the evaluation of pulmonary hypertension with underlying chronic lung disease is that hyperinflation masks cardiomegaly. Also, interstitial infiltrates of patchy large densities can obscure vessels. Absence of changes by chest radiograph should not limit further evaluation. Chest CT scans may help evaluate lung parenchyma for signs of early interstitial lung disease and help image pulmonary arteries. Magnetic resonance imaging (MRI) may provide an additional noninvasive method for evaluating pulmonary hypertension by assessing right-ventricular wall thickness (RVWT) and the ratio of RVWT to left-ventricular posterior wall thickness, and RV end-systolic and diastolic volume indexes.[80]

Perfusion studies using radiolabeled albumin are helpful for identifying pulmonary vascular abnormalities, such as arteriovenous malformations and intrapulmonary shunting in patients with cirrhosis. $\dot{V}/\dot{Q}$ scans aid in differentiating thromboembolic disease from other causes of pulmonary hypertension because thrombosis produces large perfusion defects in contrast with the small "moth-eaten" peripheral defects found with advanced pulmonary hypertension from other mechanisms. Pulmonary arterial angiography provides a more precise approach to the identification of vascular obstruction, the presence of structural lesions such as hemangiomatosis and arteriovenous malformations, as well as assessments of vascular pruning. Unfortunately, the degree of pruning, or distal vascular narrowing and small vessel filling, is not a sensitive method for distinguishing severe pulmonary hypertension caused by vascular remodeling versus vasoconstriction.

Detection and assessment of pulmonary hypertension and its severity primarily requires serial ECG and echocardiogram studies. Although ECG findings of RV hypertrophy or strain are diagnostically useful for patients with pulmonary hypertension, signs are usually less pronounced with chronic lung disease. This may be due to the effects of hyperinflation or the presence of milder levels of pulmonary hypertension commonly associated with lung disease. ECG findings of RV hypertrophy are present in 28% to 75% of patients with cor pulmonale.[81] Because the developmental shift from RV predominance normally occurs during infancy, diagnostic evaluations with ECG and echocardiography must take into account normal age-related changes in right-axis deviation, indices of RV hypertrophy, and other physiologic changes (Box 52-3).

Advances in Doppler and two-dimensional echocardiography have markedly improved noninvasive assessments of pulmonary hypertension. A major problem, however, is the technical difficulty of obtaining interpretable information in severe obstructive lung diseases, because marked hyperinflation and marked swings in intrathoracic pressures with respiratory efforts reduce the windows through which the right ventricle and valves can be imaged. Echocardiographic signs of pulmonary hypertension include increased RVWT, chamber size, flattening or paradoxical motion of the interventricular septum, early closure of the pulmonic valve, and incomplete tricuspid valve closure. Increased RV anterior wall thickness and interventricular septal wall thickness reflect RV hypertrophy. Paradoxical septal wall motion is a sign of impending RV failure. Quantitative assessments of pulmonary hypertension include measurements of right ventricular systolic time interval (RVSTI), tricuspid regurgitation, and the myocardial performance index (MPI, or Tei index). RVSTI is the ratio of measurements of RV pre-ejection period (PEP) to ejection time (ET). The PEP is the duration of time after electrical activation of the ventricle to the onset of ejection during systole. Right ventricular ET is measured from the time of opening to closure of the pulmonary valve during systole. Pulmonary hypertension delays pulmonary valve opening (because the valve does not open until RV systolic pressure exceeds PAP), causing prolongation of PEP and shortening ET. RVSTI increases the sensitivity of the echocardiogram and provides a noninvasive quantitative assessment for serial comparisons with subsequent clinic visits. Although several past publications used measurements of RVSTI to reflect acute changes in PAP during exposure to oxygen or vasodilators,[82] variability and lack of sensitivity makes this measurement unreliable for routine assessments of reactivity.

Perhaps a more sensitive assessment of pulmonary hypertension is the measurement of peak pulmonary artery systolic pressure obtained from continuous-wave Doppler measurements of the tricuspid jet.[83] The tricuspid insufficiency jet, as measured by pulsed Doppler echocardiography, reflects the pressure difference between the right ventricle and the right atrium. By using the Bernoulli principle (pressure = $4V^2$, where V is the peak systolic velocity in msec), the sum of this measurement with estimated or measured right-atrial pressure provides a fairly accurate assessment of RV systolic pressure. As with other echocardiographic assessments of pulmonary hypertension, imaging the tricuspid regurgitant jet can be difficult with chronic lung disease, leading to a low success rate (24%) in adults with COPD.[84] The absence of a measurable TR jet does not preclude the presence of pulmonary hypertension. The myocardial performance (or Tei) index has recently been shown as accurate in assessments of right ventricular performance in children with iPAH.[85]

Although serial studies with ECG or echocardiogram are useful during long-term follow-up, cardiac catheterization may be necessary to better define the role of pulmonary vascular disease in the clinical course. Cardiac catheterization quantifies the severity of pulmonary hypertension; to rule out anatomic cardiac lesions, structural pulmonary vascular lesions, thromboemboli, or significant hypertrophy of bronchial collaterals; to define optimal treatment levels for supplemental oxygen; to assess pulmonary vasoreactivity; and to test or select potential pharmacologic agents for long-term therapy. It is especially important to rule out LV diastolic dysfunction, which can contribute to pulmonary hypertension in some children with chronic lung disease, especially BPD.

Delays in performing cardiac catheterization in patients with chronic lung disease are common—potentially contributing to delays in diagnosis or therapy. Probe-patent foramen ovale may be present in many young children, suggesting that intracardiac shunt may contribute to the severity of hypoxemia in patients with pulmonary hypertension more often than expected. Cardiac catheterization should include angiography to avoid missing structural lesions, such as pulmonary arterial stenosis, pulmonary veno-occlusive disease, enlarged bronchial collateral vessels with chronic lung disease, diffuse pulmonary hemangiomatosis or arteriovenous shunts, and other diagnoses. Although concerns persist regarding the potential risks of angiography in precipitating pulmonary hypertensive crises or dysrhythmias in severe pulmonary hypertension, the use of newer contrast material seems to have decreased these risks. Undersedation and subsequent agitation may also increase the risk for precipitating a pulmonary hypertensive crisis.

Assessment of pulmonary vasoreactivity is an essential part of the evaluation, but it is too often not included with basal hemodynamic measurements. For example, exaggerated vasoconstrictor responses to acute hypoxia in patients with only mild baseline pulmonary hypertension may help explain episodic cyanosis or progressive pulmonary hypertension in children with recurrent cyanosis, HAPE, BPD, or other diseases (see Fig. 52-7).[86] The use of anesthesia and inadvertent oversedation, hypoventilation or hyperventilation, and hypoxia can alter basal PAP and reactivity during cardiac catheterization, potentially limiting the usefulness of clinical information. On the other hand, controlled hypoxic challenges during catheterization may provide critical insight into pulmonary vascular hyper-reactivity. For example, some patients require higher target oxygen saturations to maintain maximal decreases in PVR and to lower the risk of intermittent spikes in PAP. Whereas the vasodilator response while breathing 100% oxygen is commonly used to assess potential reversibility of pulmonary hypertension, correlation between the dilator response to oxygen and outcome is unclear. Measurement of acute hemodynamic responses while breathing high concentrations of supplemental oxygen is useful to assess vasoreactivity because of its selective pulmonary vasodilation and also because it allows adjustment of oxygen therapy. However, hyperoxia alone is not a potent vasodilator beyond its ability to reverse hypoxic vasoconstriction, and this response is often used to prognosticate on reversibility of pulmonary hypertension and outcome.

Long-term therapy with supplemental oxygen to correct hypoxia-induced pulmonary vasoconstriction will decrease the adverse effects of chronic or intermittent hypoxia and often improve clinical course. However, the response to high oxygen concentration may not be sufficient for determining the relative contributions of vasoconstriction versus structural remodeling to basal pulmonary hypertension. For example, pharmacologic vasodilators (such as inhaled NO) can often cause further vasodilation than high concentrations of inspired oxygen alone, as recently observed in infants with chronic neonatal lung disease (CNLD). Although several

agents can be used to acutely assess pulmonary vascular tone, inhaled NO may be a good choice because of its short half-life, selectivity for the pulmonary circulation (less risk for systemic hypotension, fatal dysrhythmia), and its ability to improve gas exchange, rather than worsen oxygenation, with lung disease.

Links between acute pulmonary vasoreactivity and long-term outcome require further study. Clinical decision making is often based on data from small numbers of patients with congenital heart disease because of the lack of data from patients with chronic lung disease. Conclusions regarding the relative contribution of vasoconstriction versus vascular remodeling to the severity of pulmonary hypertension presume that the degree of pulmonary hypertension remaining after administration of a vasodilator must be due to structural remodeling. This is not always true and may partially depend on the selection and relative potency of the vasodilator. Similarly, the acute response may not predict the potential for reversal of pulmonary hypertension with time. Chronic treatment with intravenous epoprostenol, a PGI_2 analog, has been shown to improve pulmonary hemodynamics and cardiac output in patients with iPAH, despite the absence of an acute vasodilator response to brief treatment.

Lung biopsies are used to assess the severity of structural changes in some cases and for further diagnostic evaluation (to rule out interstitial lung disease, veno-occlusive disease, and others). The biopsy allows grading of vascular lesions, but tissue should be obtained from multiple sites to allow for heterogeneity. In general, the histology of patients with secondary pulmonary hypertension lacks the severe intimal changes present in patients with primary pulmonary hypertension or congenital heart disease. Uncertainty exists regarding the potential reversibility of pulmonary vascular structural lesions, and further studies are needed to examine the relation between vascular reactivity, remodeling, and outcome.

MANAGEMENT

Acute management of severe right-sided heart failure requires rapid lowering of PAP to reduce RV afterload to maintain CO, systemic blood pressure, and tissue oxygen delivery. Dramatic elevations of PAP are more common in patients with iPAH, PPHN, and PAH owing to congenital heart disease than with pulmonary hypertension associated with acute respiratory failure or chronic lung disease. Patients with life-threatening acute episodes of pulmonary hypertension are managed by sedation, paralysis, hyperventilation, alkalosis, and high inspired concentrations of oxygen. Acute treatment with inhaled NO (20 ppm) may provide initial pharmacologic vasodilator therapy, especially in patients in whom RV failure is unresponsive to oxygen and general measures, or in the setting of marked pulmonary "vasolability." Extra caution is necessary to avoid the sudden discontinuation of inhaled NO in this setting because the rebound effects of inhaled NO withdrawal can cause a dramatic rise in pulmonary artery pressure, leading to a marked decrease in cardiac output, hypotension, and perhaps sudden death.

Pulmonary artery catheters provide close monitoring of PAP and PCWP, CO, systemic vascular resistance, and related hemodynamic measurements during acute therapeutic interventions. Whereas pharmacologic therapy may rapidly decrease PAP, intravenous vasodilators (such as sodium nitroprusside) can impair $\dot{V}/\dot{Q}$ mismatch in the setting of severe lung disease, causing worsening hypoxemia, or may lower systemic arterial pressure and worsen oxygen delivery. Inhaled NO may provide selective pulmonary vasodilation without adverse effects on gas exchange in children with severe pulmonary hypertension and lung disease.

The primary goal of long-term treatment of pulmonary hypertension in patients with chronic lung disease is to improve cardiac (especially RV) performance at rest and during exercise, thereby improving exercise tolerance and quality of life. In addition to managing right-sided heart failure, the long-term goal is to avoid the adverse effects of sustained pulmonary hypertension on progressive pulmonary vascular remodeling. Mechanisms leading to reversibility of pulmonary hypertension and vascular structure are poorly understood but partly depend on the severity of vascular remodeling at diagnosis and recognition of complicating factors that contribute to its progression. Thus, early anticipation and recognition of pulmonary hypertension in at-risk patients may improve outcome in many cases.

Therapy generally targets three areas: (1) optimal management of underlying lung disease (for example, lung inflammation and infection in CF, mechanical ventilation with hypoventilation and neuromuscular weakness, and others); (2) diagnosis and treatment of complicating or unsuspected cardiopulmonary abnormalities (such as aspiration, upper airway obstruction, or anatomic cardiac defects in BPD, and others); and (3) treatment of the pulmonary hypertension with oxygen and pharmacologic agents.

Because hypoxia is the most common cause of progressive pulmonary hypertension in chronic lung disease, supplemental oxygen is the mainstay of therapy. Oxygen therapy is the only treatment that has been shown to improve the clinical course of patients with pulmonary hypertension and chronic lung disease.[87,88] The British Medical Research Council study[87a] and the NIH Nocturnal Oxygen Therapy Trial (NOTT)[87b] demonstrated that adults with COPD who use supplemental oxygen for the greatest period of time each day (19 versus 12 hr/day) derive the greatest advantage in survival, and that oxygen therapy prevents further increases in PAP. Whether patients who decrease PAP during acute administration of supplemental oxygen have a better survival than nonresponders is unproven, but it has been suggested in a small clinical trial.[88] Mortality was significantly decreased by oxygen therapy in adults with COPD and slowed progression of pulmonary hypertension; these responses were directly related to the duration of daily use.

Long-term oxygen therapy may enhance oxygen delivery in addition to its effects on pulmonary vasodilation and may partially explain improved clinical outcome. In addition, long-term oxygen therapy counters the adverse effects of episodic hypoxia on intermittent elevations of PAP with sleep or activity and may influence smooth muscle cell growth or production of extracellular matrix independent of its effects on lowering pressure. Hence, an aggressive approach toward maintaining adequate oxygenation is recommended (avoidance of hypoxemia while targeting oxygen saturations above 92% to 94% while awake or asleep, and with activity) (Fig. 52-8). Recent studies have raised new questions regarding the safety of excessive levels of supplemental oxygen in former

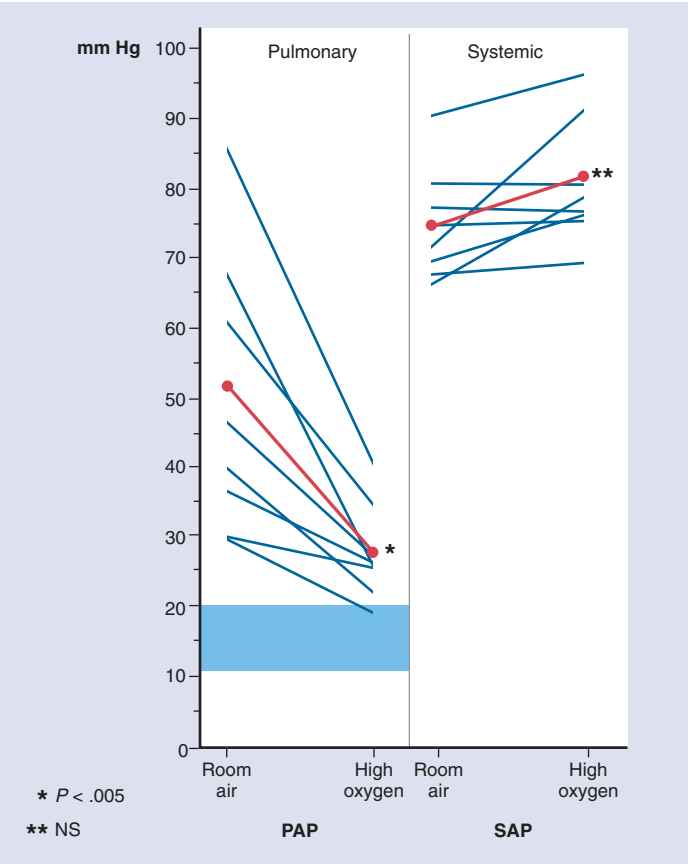

Figure 52-8 Exaggerated hypoxic pulmonary vasoconstrictor response during brief exposure to hypoxia in children with BPD. Responses of mean pulmonary artery pressures and systemic arterial pressures to high levels of inspired oxygen ($F_{IO_2} > 0.80$). premature infants regarding adverse effects on retinopathy and worsening lung disease.

Infants with chronic lung disease require frequent noninvasive assessments of oxygenation and serial ECGs or echocardiograms while receiving supplemental oxygen, especially if signs of RV hypertrophy persist despite therapy. Monitoring of oxygenation to avoid even intermittent hypoxemia will enhance recovery or slow progression of pulmonary hypertension in children with pulmonary hypertension of many etiologies. Perhaps the clearest illustration of this strategy is in infants with BPD.[1] Chronic intermittent or persistent hypoxia blocks recovery and accelerates progression of pulmonary vascular disease. Infants with BPD are often undertreated because of fear of oxygen toxicity during the chronic stages of disease despite the presence of pulmonary hypertension. Once persistent signs of pulmonary hypertension have been identified in older BPD infants, even mild levels of hypoxia should not be tolerated. Reversal of hypoxia with supplemental oxygen in patients with chronic lung disease will acutely lower PVR in many patients and avoid intermittent episodes of hypoxic pulmonary vasoconstriction.

Progression of pulmonary hypertension in association with any disease should lead to investigation of potential contributing factors, including obstructive sleep apnea, chronic aspiration, structural airway lesions, and other problems. For example, children with Down syndrome with or without anatomic heart disease often have more severe pulmonary hypertension than other children, which is often partly due to chronic pharyngeal collapse with sleep, tracheomalacia, or other structural airway lesions. Evaluations should include sleep studies, imaging of the upper airway by flexible laryngoscopy and bronchoscopy, radiologic studies (such as barium swallow and Isovue bronchograms), pulmonary function testing, and lung biopsy in selected cases. In addition to correction of hypoxemia, acidosis and hypercarbia may contribute to progressive pulmonary hypertension. Although hypercarbia is commonly tolerated with chronic lung disease, a more aggressive ventilator therapy is recommended in patients with chronic lung disease and concomitant pulmonary hypertension.

Diuretics and digoxin are commonly prescribed in patients with chronic lung disease and cor pulmonale. Although diuretics may acutely improve gas exchange in chronic lung diseases such as BPD,[89] mechanisms underlying this response are more likely related to relief of pulmonary edema than direct improvement of pulmonary hypertension. When administered for treatment of right-sided heart failure, diuresis can acutely decrease fluid retention, especially in patients with hepatomegaly, peripheral edema, and signs of systemic venous congestion. Frequent use of diuretics in the presence of high PVR may markedly decrease RV preload, thereby decreasing pulmonary blood flow and CO. In addition, electrolyte imbalance with chloride depletion and elevated serum bicarbonate may cause metabolic alkalosis and hypoventilation. Digoxin use in cor pulmonale remains controversial. Although it may improve myocardial performance and CO in patients with impaired left-ventricular function, most patients have little clinical benefit.

DRUG THERAPY FOR CHRONIC PULMONARY HYPERTENSION

Pharmacologic agents can acutely lower PAP, but pulmonary vasodilation in the setting of parenchymal lung disease can cause hypoxemia by worsening $\dot{V}/\dot{Q}$ mismatch, limiting their usefulness in the presence of lung disease.[90] Insights into basic vascular biology, especially with regard to the NO-cGMP, PGI_2 and ET-1 systems, have led to dramatic improvements in the pharmacology of pulmonary hypertension. Multicenter randomized trials have shown striking benefits of several strategies in the treatment of IPAH and chronic pulmonary arterial hypertension associated with congenital heart disease, but in contrast, benefits of pharmacologic vasodilator therapy in the long-term management of pulmonary hypertension secondary to chronic lung disease remain unproven. Recent evidence-based guidelines from the American College of Chest Physicians (ACCP) provide clear recommendations for the treatment of severe pulmonary hypertension.[91] Overall, a step-wise approach has been outlined, based on severity of symptoms, pulmonary vascular reactivity during acute testing during cardiac catheterization, and clinical response to treatment. Whether similar approaches should be applied to patients with chronic lung disease, especially in younger children, remains uncertain, but currently provides a useful perspective.

Calcium Channel Blockers (CCBs)

Historically, CCBs have been used in patients with pulmonary hypertension who demonstrate marked acute vasoreactivity to supplemental oxygen, inhaled NO, or other agents, during cardiac catheterization—especially in patients with chronic lung disease. In the past, CCBs (such as nifedipine and diltiazem) were used primarily because of the absence of other choices. A relatively small proportion of patients with IPAH, who demonstrate a favorable response to acute vasodilator testing at the time of cardiac catheterization, initially do well with CCB therapy.[92] Sitbon and colleagues reported results of a retrospective analysis of adult iPAH patients tested acutely with intravenous epoprostenol (a PGI_2 analog) or inhaled NO.[93] Using the criteria of a >20% decrease in both mean pulmonary artery pressure (mPAP) and PVR, only 13% of patients were reactive. Of these patients, about one half demonstrated favorable long-term clinical responses to chronic CCB therapy. Thus, although true responders to vasodilators are uncommon among patients with severe iPAH, long-acting nifedipine or diltiazem, or amlodipine can be tried in this subset of patients, but caution is urged in light of negative inotropic effects in some patients, and failure to sustain clinical response should lead to the rapid transition to another agent. Because a greater proportion of patients with chronic lung disease may have acute responsiveness to vasodilator testing in the catheterization laboratory, CCBs may be a good initial choice for therapy in this population. However, there are no data comparing other oral agents (including type V phosphodiesterase [PDE-5] or ET receptor antagonists [ETRAs]) antagonists as an initial choice in patients with pulmonary hypertension.

Type V Phosphodiesterase (PDE-5) Inhibitors

Augmentation of NO-cGMP signaling with inhaled NO has been a successful strategy for the treatment of term newborns with severe pulmonary hypertension, as well as in other diseases, especially with acute pulmonary hypertension in the intensive care setting. Although noninvasive delivery of inhaled NO has been shown to be potentially effective in some cases, inhaled NO as a chronic therapy is experimental and limited by the need for multiple gas tanks and bulky delivery systems. In contrast, augmentation of cGMP through inhibition of PDE-5 provides a useful and practical approach for chronic pulmonary hypertension therapy. Sildenafil, a potent and highly specific PDE-5 inhibitor, is approved for erectile dysfunction, and has recently been approved for chronic pulmonary hypertension therapy. A double-blind, placebo-controlled study (the SUPER-1 study), randomly assigned 278 patients with symptomatic PAH (idiopathic, associated with collagen vascular disease or after repaired congenital systemic-to-pulmonary shunts) to placebo or sildenafil for 12 weeks.[94] Distance walked in 6 minutes increased from baseline in the sildenafil groups. In addition, sildenafil reduced mean PAP, and improved functional class. Side effects included flushing, dyspepsia, and diarrhea. The incidence of clinical worsening did not differ significantly between the patients treated with sildenafil and those treated with placebo. A smaller study suggested that children with pulmonary hypertension also improve during sildenafil therapy,[95] which is currently approved by the FDA for the treatment of PAH. Case reports suggest that sildenafil is well tolerated by older patients with chronic lung disease, such as idiopathic pulmonary fibrosis and CF, without worsening of gas exchange, and may be a good initial choice for treating moderate pulmonary hypertension in chronic lung disease.[96]

Endothelin Receptor Antagonists (ETRAs)

ETRAs, including bosentan, a nonselective ET A and B receptor antagonist, provide an effective oral strategy for the treatment of chronic pulmonary hypertension, but most studies have been performed in adult patients with PAH not associated with chronic lung disease.[97] Treatment with bosentan improved 6 minutes walk test, hemodynamics, and functional class. Due to the potential for abnormal liver function tests, monthly tests are needed to monitor patient safety. Bosentan has also recently been studied in children with iPAH and congenital heart disease,[98] demonstrating improvement or lack of worsening of WHO functional class in 46% and 44% of patients, respectively. Bosentan is currently approved by the FDA for the treatment of patients with WHO functional class III-IV PAH. Because the ET B receptor may also have beneficial effects in pulmonary hypertension, two newer agents that are selective inhibitors of the ET A receptor have been studied.[99,100] Sitaxsentan and ambrisentan, an oral ET A receptor-selective antagonist, have been shown to improve clinical courses in patients with pulmonary hypertension, but studies in children are lacking.

Prostacyclin (PGI_2) Analogs

EPOPROSTENOL

For patients with more advanced or poorly responsive disease, the use of intravenous PGI_2 analogs has been shown to improve survival and clinical course.[101] A 12-week, prospective trial demonstrated that when added to conventional therapy, intravenous epoprostenol improved 6-minute walk test, quality of life, hemodynamics, and survival in adult patients.[102] A multicenter, open-label study of intravenous epoprostenol in patients with scleroderma-associated pulmonary hypertension also showed improvement in exercise capacity and hemodynamics; however, improved survival was not observed.[103] Other observational studies have also shown improvement in adult patients with severe disease, and similar observations have been suggested in pediatric patients as well. Long-term PGI_2 therapy in young children and infants with IPAH or Eisenmenger syndrome is promising, but experience has been limited in patients with concomitant lung disease owing to concerns of worsening hypoxemia.

TREPROSTINIL

Numerous advances have led to the development of newer PGI_2 analogs, which have been studied as alternative approaches to intravenous epoprostenol therapy. Treprostinil (or Remodulin) has been shown to be effective for at least short-term therapy when infused subcutaneously in patients with functional class II, III, or IV PAH.[104] This effect was limited by infusion site pain and skin reactions, which led to discontinuation of therapy in several cases. Recent work suggests that intravenous treprostinil may be effective in treating severe disease, and the FDA has approved the use of intra-

venous treprostinil in patients in whom subcutaneous infusion is not tolerated.

ILOPROST

A more novel approach to the use of PGI_2 analogs is in the use of iloprost as an inhalational agent. Although several studies suggest efficacy in adults with idiopathic pulmonary hypertension,[105] the need for six to nine inhalations per day to sustain its effects may severely limit its utility. Alternate strategies include the use of inhaled iloprost with a second, oral agent, such as PDE-5 or ETRAs). Development of more potent and sustained PGI_2 analogs may decrease the need for frequent treatments, and would represent a significant advance in the field. Early experience with iloprost suggests that some children may experience acute bronchospasm during inhalation, which may limit tolerance to long-term therapy.

SPECIFIC DISEASES ASSOCIATED WITH PULMONARY HYPERTENSION

Persistent Pulmonary Hypertension of the Newborn

PPHN represents the failure of the pulmonary circulation to achieve or sustain the normal decrease in PVR at birth. High PVR in the neonate causes marked hypoxemia as a result of right-to-left shunting of blood across the patent ductus arteriosus or foramen ovale. The diagnosis of PPHN has replaced the older term *persistent fetal circulation,* and refers to a clinical *syndrome* of a wide variety of cardiovascular and pulmonary disorders, such as meconium aspiration syndrome, sepsis, pneumonia, congenital diaphragmatic hernia, or respiratory distress syndrome, or can be idiopathic. Idiopathic PPHN is characterized by severe cyanosis with tachypnea and respiratory distress in term or postdate newborns with chest radiograph findings of clear lung fields and a normal cardiothymic silhouette. Although often associated with perinatal stress (for example, maternal bleeding or asphyxia), specific etiologies are rarely identified in idiopathic PPHN. When associated with asphyxia or marked stress, meconium aspiration may be present, further complicating the clinical course. Most patients with asphyxia, intrauterine growth retardation, or meconium aspiration, however, do not develop PPHN. Etiologic mechanisms leading to the failure of postnatal adaptation are incompletely understood, but intrauterine stimuli, such as chronic hypertension or closure of the ductus arteriosus, may contribute to the characteristic alterations of pulmonary vasoreactivity and structure that are present at birth. Mechanisms underlying PPHN may include failure to release sufficient vasodilators (such as endogenous NO or PGI_2); increased vasoconstrictor production (ET-1, leukotrienes, and thromboxane); altered smooth muscle cell responsiveness to vasoactive stimuli; or altered vascular growth (smooth muscle hypertrophy and increased extracellular matrix production). Evidence supporting the hypothesis that chronic prenatal events may lead to PPHN include data from experimental animal models as well as autopsy data demonstrating extensive vascular remodeling in neonates dying with PPHN within the first days of life.[106]

Although the diagnosis of PPHN requires echocardiographic confirmation of right-to-left shunting at the ductus arteriosus or foramen ovale in the absence of anatomic heart disease, several clinical features are highly suggestive: (1) marked or "labile" hypoxemia; (2) differences in preductal and postductal Pa_{O_2} of at least 5 to 10 mm Hg (not present if shunting is predominantly at the foramen ovale); and (3) clinical improvement with hyperventilation. Treatment includes high F_{IO_2}, hyperventilation, and infusions of sodium bicarbonate (for alkalosis) and cardiotonic agents (dopamine, dobutamine) for cardiovascular support. Optimal lung inflation is essential for aggressive treatment of parenchymal lung disease that contributes to high PVR as a result of mechanical vascular compression and marked intrapulmonary shunting at low lung volumes. Pharmacologic vasodilators, such as tolazoline, prostaglandins (PGI_2 or PGE_1), and sodium nitroprusside, have been used with success in some cases. Intravenous vasodilator therapy has been limited, however, by adverse side effects, including systemic hypotension because of the lack of selectivity for the pulmonary circulation and aggravation of right-to-left shunting, and by worsening of $\dot{V}/\dot{Q}$ mismatch in patients with parenchymal lung disease. Patients failing conventional therapy often require extracorporeal membrane oxygenation (ECMO) therapy. Although lifesaving in many cases, ECMO is costly and associated with significant complications, such as intracranial hemorrhage or systemic bleeding from heparinization. It also requires carotid artery ligation, which may contribute to adverse neurologic sequelae. ECMO centers are now using venovenous ECMO in patients with stable cardiac function to avoid carotid artery cannulation. However, unrecognized or late development of myocardial dysfunction may lead to failure of venovenous ECMO, requiring conversion to a veno-arterial approach.

Recent studies have clearly demonstrated that inhaled NO can improve oxygenation and reduce the need for ECMO therapy in term newborns with acute hypoxemic respiratory failure and PPHN (Fig. 52-9).[107-111] Successful therapy is generally associated with striking increases in oxygenation with clinical and echocardiographic evidence for reversal of right-to-left shunting. Combined modalities, such as inhaled NO with high frequency oscillatory ventilation, may provide more effective therapy in some patients with parenchymal lung disease and pulmonary hypertension because responsiveness to inhaled NO appears to partly depend on achieving adequate lung inflation for delivery of NO to high resistance vessels in the distal lung. Poor responders or patients who have a prolonged need for inhaled NO may have underlying lung hypoplasia, such as alveolar capillary dysplasia, surfactant protein deficiency, or other lung disorders. PPHN survivors are at modest risk for chronic lung disease, including airways hyperreactivity and neurodevelopmental sequelae, but late pulmonary hypertension is rare.

Bronchopulmonary Dysplasia

BPD is the chronic lung disease of infancy that follows ventilator and oxygen therapy for neonatal respiratory distress. Since the earliest descriptions of BPD, pulmonary hypertension and cor pulmonale have been recognized as being associated with high mortality.[1] Mortality in BPD patients with persistent echocardiographic findings of pulmonary hypertension beyond 4 months of age has been reported as 50%.[112,113] Recent studies have reported similar mortality in selected

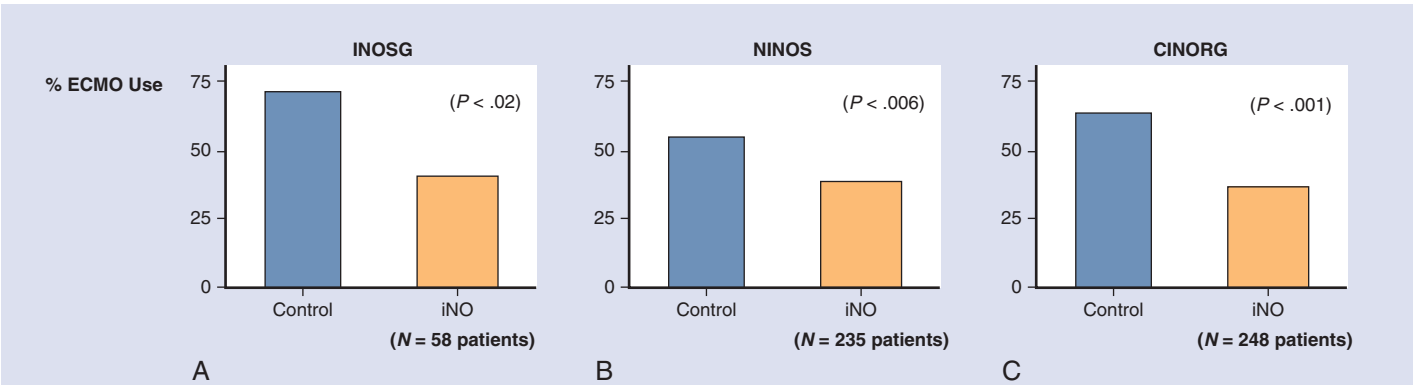

Figure 52-9 Inhaled NO decreases the need for ECMO therapy in PPHN as shown from the results of three multicenter randomized trials. populations of older BPD infants with persistent pulmonary hypertension.[3] Clinically, BPD infants with severe pulmonary hypertension are prone to recurrent pulmonary edema, frequent respiratory exacerbations, congestive heart failure, and late morbidity from viral infections or sudden death.[1,113] Related cardiovascular sequelae include left-ventricular hypertrophy, systemic hypertension, and hypertrophied systemic-to-pulmonary collaterals.[1] Pulmonary vascular disease in BPD reflects the direct effects of ventilator- and hyperoxia-induced lung injury, but chronic inflammation, hypoxia, neurohumoral stimuli, and altered production of vasoactive substances contribute to the severity or persistence of pulmonary hypertension.

Physiologically, the pulmonary circulation in BPD is characterized by heightened pulmonary vasoreactivity, hypertensive vascular remodeling (increased muscularization with adventitial thickening), and decreased arterial number as a result of altered surface area caused by lung injury and decreased septation ("alveolar simplification").[36] Altered metabolic lung function, as assessed by decreased uptake of circulating norepinephrine, has been described in BPD infants with pulmonary hypertension.

As described previously, clinical management of pulmonary hypertension in BPD revolves around vigilant monitoring and aggressive use of supplemental oxygen therapy.[13] Although oxygen saturations below 90% may be well tolerated in normal children recovering from viral respiratory infections, BPD infants require better oxygenation to minimize the adverse effects of chronic hypoxic pulmonary vasoconstriction (see Fig. 52-8).[86] Based on clinical studies, oxygen saturations above 94% while awake, while asleep, and during feeding are often recommended for infants with CNLD and pulmonary hypertension.[1]

Resolution of pulmonary hypertension by ECG or echocardiographic criteria is often found with appropriate therapy over time.[112] Children with persistent RV hypertrophy require more aggressive measures to evaluate potential mechanisms complicating their recovery. These include reassessment of oxygenation levels during prolonged pulse oximetry studies; formal sleep studies; and assessment for unsuspected cardiac or lung problems contributing to the severity of the clinical course (such as aspiration, upper airway obstruction, anatomic heart disease, large bronchial collaterals causing pulmonary edema, and others). Early identification and treatment of left-to-right shunt cardiovascular lesions may enhance long-term outcome in selected BPD patients, decreasing progressive pulmonary vascular injury in a lung circulation that is already limited by decreased surface area, vascular remodeling, and vasoconstriction.

Hemodynamic improvement in BPD infants with pulmonary hypertension has been reported after brief vasodilator therapy with PGI_2[4] and nifedipine[114] during cardiac catheterization. However, PGI_2 increased CO but did not lower PAP, and although PVR fell by 23%, systemic vascular resistance decreased by 39%.[4] Similarly, the drop in mean PAP achieved during acute nifedipine treatment was similar to the response to supplemental oxygen alone.[114] Because nifedipine increased CO, however, PVR was lower after nifedipine administration than after oxygen therapy. Whether the combination of supplemental oxygen with chronic calcium channel blockers will enhance long-term outcome in selected BPD patients with pulmonary hypertension has not been studied. More recently, acute pulmonary vasodilation to inhaled NO has been demonstrated in children with BPD during cardiac catheterization, suggesting that vascular tone contributes to high PAP even late in the clinical course and that inhaled NO is effective in lowering PVR in BPD (Fig. 52-10).[115] Whether chronic treatment with PDE-5 inhibitors, including sildenafil, or ETRAs can improve long-term course in BPD patients with pulmonary hypertension without adverse effects is unknown. Thus, management of pulmonary hypertension in BPD remains largely supportive, with careful attention to the avoidance of the adverse effects of episodic hypoxia and hypercarbia on lung vascular remodeling and reactivity. In selected cases, long-term therapy with CCBs or other agents with oxygen therapy may be indicated, but patient selection would require careful initial assessment with cardiac catheterization and close follow-up.

Cystic Fibrosis

Pulmonary hypertension was first recognized as a significant clinical problem in CF more than 60 years ago,[116] but the detection and management of pulmonary hypertension in CF

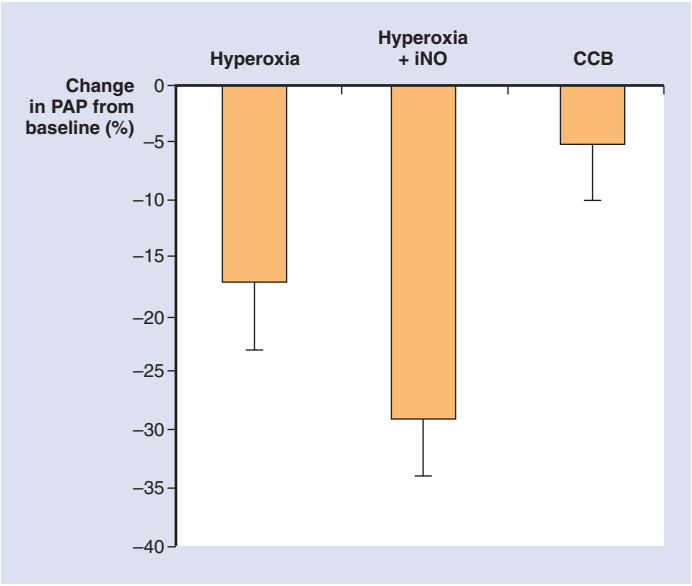

Figure 52-10 Pulmonary vasoreactivity testing in children with BPD. Brief exposure to hyperoxia lowered pulmonary artery pressure and PVR from baseline values measured during normoxia. The addition of inhaled nitric oxide (iNO; up to 20 ppm) caused further pulmonary vasodilation. Both responses were greater than the acute response to calcium channel blockade (CCB). (Adapted from Mourani PM, Ivy DD, Gao D, Abman SH: Pulmonary vascular effects of inhaled NO and oxygen tension in BPD. Am J Respir Crit Care Med 170:1005-1013, 2004.)

remains an ongoing challenge. Despite dramatic advances in our understanding of the genetics and pathophysiology of CF, little progress has been made regarding the contribution of pulmonary hypertension to mortality and morbidity in CF or its treatment.[5,6,117-119] In 1951, Royce[117] reported that 70% of patients dying with CF had marked RV hypertrophy at autopsy. In 1980, Stern and coworkers[5] found that 46% of CF patients who died after 15 years of age had clinical signs of right-sided heart failure for at least 2 weeks before death and that mean survival was only 8 months after the onset of RV failure. Whether pulmonary hypertension and RV dysfunction are markers of disease severity or directly contribute to mortality is unclear. Similarly, whether aggressive management of pulmonary hypertension could improve morbidity and long-term outcome is unknown.

Mechanisms leading to the development of pulmonary hypertension in CF include chronic hypoxia caused by severe $\dot{V}/\dot{Q}$ mismatch from severe lung disease with airways obstruction and chronic infection and inflammation. Although chronic hypoxia contributes significantly to the progression of pulmonary hypertension in CF, it is unlikely that hypoxia is the sole factor in its pathogenesis. Chronic hypercarbia with acidosis may cause intermittent spikes in PAP, leading to vascular remodeling. Exaggerated respiratory efforts can increase intrathoracic pressure, which may increase RV afterload. In addition, severe bronchiectasis with progressive interstitial disease decreases alveolar-capillary surface area, further promoting the development of pulmonary hypertension. Chronic infection and inflammation caused by increased release of vasoactive bacterial products and mediators from inflammatory cells (cytokines, lipid mediators, others) can also directly alter pulmonary vascular reactivity and structure. In its early stages, active vasoconstriction contributes to high PAP resistance in CF, which appears to predate subsequent development of hypertensive vascular remodeling found in older patients with CF. The role of vasoconstriction was first clinically demonstrated with studies of the acute pulmonary vasodilator response to supplemental oxygen and tolazoline treatment.[116-119,120] Although structural pulmonary vascular lesions contribute to cor pulmonale over time, recent in vitro studies of conduit pulmonary arteries from CF patients undergoing lung transplantation have suggested that impaired release of NO contributes to increased vasoconstriction and high PVR with advanced lung disease.[121] These findings suggest that altered pulmonary vasoreactivity persists late in the clinical course of CF and that this is, in part, due to endothelial dysfunction.

Recognition of clinical signs of cor pulmonale generally occurs late. Clinical predictors of cor pulmonale in CF include Pa_{O_2} less than 50 mm Hg, Pa_{O_2} greater than 45 mm Hg, forced vital capacity less than 60% of predicted, and right-axis deviation by ECG.[119] The degree of hypoxia while breathing room air is inversely correlated with severity of PAP. The diagnosis of cor pulmonale in CF by clinical evaluation can be masked by severe CF lung disease. Signs that are usually ascribed to right-sided heart failure, such as tachypnea, hepatomegaly, hepatic tenderness, and cyanosis, may be results of underlying lung or liver disease. Increased second heart sounds, murmurs, and gallop rhythms may not be heard during auscultation because of loud adventitious breath sounds. Peripheral edema is rarely detected, even with cor pulmonale, and is usually caused by poor nutrition with low oncotic pressure from hypoalbuminemia. Chest radiograph findings may include dilated central pulmonary arteries; heart size may appear normal as a result of hyperinflation or infiltrates. ECGs are not sensitive because RV hypertrophy may be absent by ECG even when moderate pulmonary hypertension is found with cardiac catheterization.[122]

Echocardiographic estimates of pulmonary hypertension, such as RV systolic time intervals, appear to correlate well with PAP directly measured at cardiac catheterization and RVWT at autopsy. Although echocardiograms increase the diagnostic yield of pulmonary hypertension, cardiac imaging can be difficult because of severe hyperinflation. For example, complete assessments of RV function were obtained in less than 50% of CF patients. However, longitudinal studies have reported RV wall thickening and dilation, even in some cases of mild CF lung disease. Exercise stress testing with echocardiography may further increase the diagnostic yield and may be present in patients with relatively mild CF lung disease. Radionuclide measurements of RV ejection fraction are more sensitive than echocardiogram or ECG studies of RV function.

Left-ventricular dysfunction has been identified in some patients with CF, but its role in clinical disease is unclear. Left-ventricular free wall weight can be increased at autopsy and areas of myocardial fibrosis have been reported. Echocardiography can demonstrate flattening or compression of the left ventricle along its minor dimension by a massively dilated right ventricle. RV enlargement could produce left-ventricular dysfunction in severe CF.[123] Left-ventricular compression and abnormal interventricular septal motion can cause dyskinetic contraction and relaxation, which could contribute to diminished stroke volume.

Therapy includes liberal use of supplemental oxygen while continuing aggressive management of the underlying lung disease. In theory, improved lung function will enhance gas exchange, decrease regional hypoxia, and slow the progression of pulmonary hypertension. Similarly, relief of airways obstruction and reduction of lung infection and inflammation should decrease lung injury and alter production of vasoactive mediators or growth factors that contribute to pulmonary vasoconstriction, structural remodeling, and loss of vascular surface area. Supplemental oxygen therapy should be administered to avoid episodic or persistent hypoxemia; target Pa_{O_2} is generally recommended to be maintained above 60 to 65 mm Hg, or oxygen saturations by pulse oximetry greater than 94% during sleep and while awake. Oxygen therapy may further attenuate increases in PAP during acute or subacute respiratory deteriorations. Serial evaluations of CF patients with ECG and echocardiogram should be performed regularly to monitor for signs of RV hypertrophy, especially with moderate lung disease, even in the absence of overt signs of cor pulmonale. Echocardiograms before and immediately after cardiopulmonary exercise testing (CPET) may provide a more clinically-useful assessment of underlying pulmonary vascular disease, even in the absence of high baseline PAP by echocardiogram.

Sleep-associated hypoxemia should be sought and treated in CF patients with early morning headaches, signs of obstructive sleep apnea, or in the presence of RV hypertrophy. Recent changes in ECG or echocardiogram, excessive fatigue, poor exercise tolerance, cardiac signs on examination, hepatomegaly, right upper quadrant tenderness, and declines in pulmonary function or CPET may warrant further evaluations, such as cardiac catheterization.

Most recommendations for the use of supplemental oxygen therapy in CF are based on clinical observations or data from studies of other chronic lung diseases. No published data have demonstrated benefits from early and long-term oxygen therapy in CF. One study that examined the effects of nocturnal oxygen therapy on the short-term (6-month) course of CF patients with advanced lung disease reported no improvement.[124] In this study, however, patients were treated only with nocturnal oxygen despite having hypoxia (room air Pa_{O_2} less than 65 mm Hg) while awake. In addition, no documentation of sleep-associated hypoxemia or its resolution with therapy was present, and ECG and echocardiographic assessments of pulmonary hypertension were not included. Whether early and aggressive use of supplemental oxygen improves clinical outcome, reduces pulmonary hypertension, and enhances the quality of life in CF patients remains speculative.

Data on the role of drug therapy are also limited. Acute diuretic therapy improves signs of systemic venous congestion in CF patients with severe cor pulmonale, decreasing mean PAP without changing CO.[125] Whether long-term diuretic therapy sustains clinical improvement is unclear. Aggressive diuresis could potentially worsen hemodynamic status by dropping RV preload, further decreasing pulmonary blood flow and systemic CO. If diuretics are used, careful monitoring of fluid and electrolyte status are important to avoid the dangers of marked hypokalemic, hypochloremic metabolic alkalosis, and aggravation of chronic CO_2 retention. Digoxin has been used in some patients with severe right-sided heart failure and may be of benefit in selected patients with signs of left-ventricular dysfunction.

Several studies have examined acute hemodynamic responses to vasodilators, including CCBs. Davidson and colleagues[126] compared the acute effects of supplemental oxygen and CCBs in eight CF patients with mild clinical disease. Increased F_{IO_2} lowered mean PAP by 23%, and PVR by 21%; nifedipine did not alter PAP but lowered PVR by increasing cardiac index by 30%. Diltiazem lowered mean PAP by 24% without changing cardiac index. The degree of oxygen-induced pulmonary vasodilation was not predictive of responses to CCBs. In some cases, supplemental oxygen lowered mean PAP to normal values, reflecting the relative lack of structural remodeling in early disease. Geggel and coworkers[127] also reported a favorable acute hemodynamic response to oxygen but no improvement with calcium-channel blockers. Sustained improvement in exercise tolerance has been reported in some CF patients. A recent report describes a favorable response to sildenafil therapy in a patient awaiting lung transplantation.[96] Whether chronic therapy will improve long-term outcome, exercise tolerance, or the quality of life in CF patients with cor pulmonale is not known.

Pulmonary Hypertension and High Altitude

Studies of physiologic adaptations to acute and chronic exposure to high altitude provide unique insights into mechanisms of human diseases associated with hypoxia.[128] In most clinical settings, chronic hypoxia accompanies severe lung disease, making it difficult to differentiate the effects of hypoxia itself on lung function. To determine the direct cardiopulmonary effects of severe hypoxia, extensive studies of adult volunteers were performed before and during exposure to hypobaric hypoxia by simulating altitude of 8848 meters.[129] These investigators demonstrated that high altitude increased PAP (from 15 to 33 mm Hg); decreased forced vital capacity, which was interpreted as reflecting a restrictive defect caused by increased central blood volume and edema; altered $\dot{V}/\dot{Q}$ mismatch caused by continued perfusion of poorly ventilated regions; and normal cardiac function at rest and with exercise. These findings demonstrate that chronic hypoxia, in the absence of underlying lung disease, markedly impairs respiratory function.

In children living at altitude, the normal postnatal decline in PAP is delayed.[130] For example, infants living above 4200 meters in Peru have higher mean PAP (45 mm Hg at 1 to 5 years; 28 mm Hg at 6 to 14 years) than do children at lower altitudes. Children living at high altitude have persistence of RV predominance by ECG; increased RV weight; increased muscularization of small pulmonary arteries; and increased incidence of patent ductus arteriosus. However, there is marked individual variability in basal PAP in long-term residents of high altitude.[131-134]

Although acute hypoxia generally increases mean PAP from 13 to 17 mm Hg in normal adults, the pulmonary vasoconstrictor response is markedly heightened in some individuals, even in the absence of underlying cardiopulmonary disease. For example, some children develop severe symptomatic pulmonary hypertension while living at high altitude. Khoury and Hawes[130] described 11 infants (younger than 2

years of age) residing above 3000 meters in Leadville, Colorado. Symptoms included cyanosis, dyspnea, poor growth, cough, sleeplessness, oliguria, seizure, syncope, and cyanotic spells. Cardiac catheterization revealed suprasystemic or near systemic levels of pulmonary hypertension. At autopsy, advanced hypertensive pulmonary vascular lesions (Heath-Edwards grade 3 to 6) were common. To determine mechanisms that may contribute to severe pulmonary hypertension, a subsequent study examined pulmonary vascular responses to acute hypoxia in a similar study group from Leadville.[58] Although mean PAP was only mildly elevated while breathing room air (mean, 24 mm Hg), PAP increased dramatically (to 81 mm Hg) while the group was exposed to an hypoxic gas mixture (16% F_{IO_2}). Marked pulmonary vascular hyperreactivity has been observed in children with chronic lung disease and early in the course of primary pulmonary hypertension. This exaggerated responsiveness is likely to contribute to progressive pulmonary vascular injury associated with these diseases and may be present in occasional cases of children with unexplained cyanotic spells. High altitude can have dramatic effects on pulmonary vascular disease in chronic heart and lung disease. For example, more advanced pulmonary vascular disease was experienced in patients with anatomic shunt lesions such as ventricular septal defect or patent ductus arteriosus at high altitude—suggesting that the combined effects of hypoxia with high flow may accelerate vascular injury.

Mechanisms causing altered pulmonary vasoreactivity to hypoxia in patients without underlying cardiopulmonary disease are unknown. Pulmonary vascular responses to high altitude depend on multiple factors, including age, genetics, severity of elevation, duration of exposure to high altitude, presence of triggering factors (for example, viral infection), and the presence of underlying chronic cardiovascular or lung disease. Although acute hypoxic pulmonary vasoconstriction is primarily due to direct effects of low oxygen tension on the vascular smooth muscle, various mechanisms play a vital role in modulating vascular tone and reactivity (discussed previously). Local mediators (such as NO, PGI_2, endothelin, endothelium-derived contracting factors, and lipid mediators) and various neurohumoral stimuli modulate the degree of pulmonary vasoconstriction. For example, an inability to produce increased NO to attenuate the severity of pulmonary vasoconstriction may lead to more sustained, severe pulmonary hypertension during acute hypoxia. The contribution of genetics to exaggerated pulmonary vasoreactivity and increased susceptibility to hypoxic pulmonary hypertension has been suggested by animal and clinical studies. Grover and colleagues[133] identified increased severity of hypoxic pulmonary hypertension ("brisket disease") in some cattle strains. Similarly, human infants who are born at sea level but later moved to high altitude (3600 meters) in Lhasa, Tibet, develop severe pulmonary hypertension and right-sided heart failure within weeks to months. Massive RV hypertrophy and hypertensive pulmonary vascular remodeling is present at autopsy. This disease (called subacute infantile mountain sickness) represents the failure of lowlanders of Han origin to adapt to hypobaric hypoxia.[134] Other Hans have lived in Lhasa for generations, but are apparently well adapted to high altitude, demonstrating biologic variability. Polymorphisms of the endothelial NO synthase gene that contribute to impaired NO production may increase susceptibility to poor tolerance of high altitude.

HAPE primarily occurs in previously healthy individuals ascending to altitudes, usually above 2400 meters. Typically, patients have made a rapid ascent from sea level. Additional risk factors include poor conditioning, increased activity at altitude, underlying viral illness, lack of progressive adaptation to altitude by gradually increasing altitude, sleep apnea, and alcohol intake. HAPE often occurs in patients who have previously tolerated altitude and with re-ascent of some long-term altitude residents after travel for a few days at a lower altitude. The incidence of HAPE is unclear, but severe disease occurs in less than 0.1% of visitors to Summit County, Colorado; however, mild disease is unlikely to require medical attention. Clinical signs include severe dyspnea, fatigue, weakness, dry cough, and anxiety or restlessness. Some patients develop hemoptysis. A viral illness is often initially suspected in young children with HAPE because of such nonspecific signs as anorexia, vomiting, and low-grade fever. The differential diagnosis also includes congestive heart failure, pneumonia, pulmonary embolus, alcohol consumption, viral syndrome, severe exhaustion, or carbon monoxide poisoning. On examination, patients have tachypnea, tachycardia, cyanosis, and diffuse crackles. Chest radiographs generally show fluffy densities, which may appear unilateral early, along with pulmonary artery enlargement, normal heart size, and progressive alveolar infiltrates. ECG studies often show tachycardia, peaked p waves, right-axis deviation, ST-T changes, and perhaps RV hypertrophy. Arterial blood gas tensions show severe hypoxia with low CO_2 (early). If cardiac catheterization is performed, marked pulmonary hypertension with normal PCWP and normal left-sided heart function is often found. Follow-up studies generally report normal or mildly elevated baseline PVR, which increases dramatically with acute hypoxia.[58]

Detection of high concentrations of albumin in bronchoalveolar lavage fluid confirms that HAPE is characterized by permeability edema[135,136] and is associated with increased inflammation, as reflected by increased inflammatory cells and products, including leukotrienes.[143] Mechanisms that disrupt the alveolar-capillary barrier leading to increased permeability are unclear but may be related to the direct effects of hypoxia on endothelium through altered cyclic adenosine monophosphate (cAMP) activity. Although pulmonary edema in HAPE may not be primarily caused by pulmonary hypertension per se, elevation of microvascular pressure contributes to the severity of edema formation in the presence of increased permeability. Patients with a history of HAPE have marked hypoxic pulmonary vasoconstriction, which is likely to accelerate edema formation. Thus, the sequence of events contributing to the pathophysiology of HAPE may be as follows: at high altitude, alveolar hypoxia disrupts the alveolocapillary barrier, promotes lung inflammation, causes intense vasoconstriction, and worsens $\dot{V}/\dot{Q}$ mismatch. Overperfusion of some nonconstricted capillaries may cause stress failure, worsening vascular injury and increasing interstitial and alveolar edema formation. Etiologic factors contributing to HAPE include exposure to high altitude, nonspecific triggers (such as viral illness), and genetics. Because a marked individual variability in susceptibility and recurrence risks for HAPE exists, the role of genetic factors has been suggested. Hypoxic

ventilatory drive is often diminished in individuals with recurrent HAPE, perhaps because of altered nocturnal respiratory patterns. Nocturnal hypoxia caused by hypoventilation may contribute to the development of acute mountain sickness and HAPE.

Treatment of HAPE includes early recognition of its signs and symptoms, rapid descent to lower altitude, administration of supplemental oxygen, cautious use of diuretics, and bed rest. There is no role for digoxin or antibiotics. Although treatment is simple, mortality is high if untreated; early treatment should lead to full recovery. With severe symptoms, nifedipine and inhaled NO can lower PAP and hasten recovery.[137] In anticipation of ascent to high altitude, gradual increases in altitude with limited activity is recommended. Dexamethasone, sildenafil, and CCBs often provide effective prophylaxis in HAPE-susceptible individuals.

Chronic Upper Airway Obstruction

Pulmonary hypertension develops in children with upper airway obstruction or obstructive sleep apnea caused by repeated episodes of marked hypoxia. Diverse etiologies of upper airway obstruction share common pathophysiologic features of episodic hypoxia, causing intermittent elevations of PAP, which can eventually lead to sustained pulmonary hypertension and RV hypertrophy. Although airway obstruction can lead to striking cor pulmonale in otherwise healthy children, it can accelerate pulmonary hypertension associated with chronic lung and heart disease. Every child with significant pulmonary hypertension should be evaluated for upper airway obstruction and obstructive sleep apnea. Clinical signs include noisy breathing, snoring, restless sleep with frequent arousal, appearance of air hunger, and retractions with sleep. Other signs include excessive daytime somnolence, deteriorating school performance, behavioral changes, enuresis, systemic hypertension, and morning headache. Failure to thrive is not uncommon, with growth improving with therapy. Similarly, correction of hypoxia can improve neurodevelopmental delays in children with chronic obstruction, as in infants with Pierre-Robin syndrome. Diagnostic evaluations include pulse oximetry and arterial or capillary blood gas tension (to evaluate $PaCO_2$), sleep studies, flexible bronchoscopy, barium swallow, and other studies as indicated. Management depends on the cause and severity of obstruction, whether hypoxia is easily corrected with supplemental oxygen, and the severity of pulmonary hypertension. The roles of tonsillectomy with adenoidectomy, oxygen therapy, repeat sleep studies, nasal continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP) ventilation, tracheostomy, and other strategies are discussed elsewhere. Although pulmonary hypertension from upper airway obstruction can be severe at presentation, diagnosis and therapy usually lead to complete resolution with time.

Pulmonary Circulation in Liver Disease

Pulmonary vascular disease associated with chronic liver disease includes two strikingly different clinical abnormalities, including (1) low-resistance vascular lesions with marked hypoxemia and (2) high PVR, often with extensive structural remodeling (often with "onion-skinning").[138] Hypoxemia with chronic liver disease may be due to lung disease, including decreased lung volumes, pleural effusions, atelectasis, or pulmonary edema. However, up to one third of patients with chronic liver disease have hypoxemia without underlying cardiac or lung disease. Patients with hepatopulmonary syndrome have severe dyspnea on exertion, shortness of breath, clubbing, cyanosis, and cutaneous spider nevi. Hypoxemia is often severe and is aggravated in the upright position (orthodeoxia) and with exercise. Hypoxemia may precede the onset of severe liver disease, and there is little correlation between the degree of hypoxemia and severity of hepatic function. Chest radiographs may be normal or show increased interstitial markings with more prominence in the bases. Pulmonary function tests may demonstrate restrictive or mixed abnormalities. Diffusing capacity for carbon monoxide (DLCO) is abnormal. Chest CT shows increased central and peripheral vascularity without interstitial abnormalities. Diagnosis is confirmed by perfusion lung scans using technetium Tc 99m-labeled macroaggregated albumin, in which radiolabeled albumin particles, 20 to 60 microns, are injected intravenously. With normal pulmonary capillaries, which are 8 to 15 microns in diameter, the particles are trapped in the pulmonary microcirculation and do not pass to the systemic circulation. Increased activity in extrapulmonary sites as detected by scanning over the kidneys or brain implies the presence of marked right-to-left cardiac or intrapulmonary shunting. Echocardiography rules out intracardiac shunting. Pulmonary angiography is usually not necessary for diagnosis but would show a diffuse (spongy) arterial phase or discrete focal arteriovenous communications.

Hypoxemia and exercise intolerance in the hepatopulmonary syndrome is partly due to low $\dot{V}/\dot{Q}$ zones at the lung bases from airway closure during tidal volume breathing. Impaired hypoxic pulmonary vasoconstriction has been demonstrated in patients with cirrhosis, suggesting that an inability to redistribute blood flow to match ventilation further contributes to $\dot{V}/\dot{Q}$ inequality.[139] Lack of marked improvement while breathing 100% oxygen in these patients, however, implies that $\dot{V}/\dot{Q}$ alone does not account for severe hypoxemia. Intrapulmonary shunting through dramatically enlarged or dilated vessels in the microcirculation causes refractory hypoxemia The marked increase in vessel diameter increases diffusion distance for oxygen from the alveolus to capillary blood; equilibrium may not be achieved, especially with exercise. Alternatively, the low resistance in these vessels may decrease perfusion of distal microcirculation within the lung periphery. Pulmonary vascular lesions are associated with spider angiomas on the skin and pleura, suggesting that an unknown systemic factor contributes to altered vascular function or growth. Past unsuccessful medical therapies have included drug treatment with estrogens, β blockers, cyclooxygenase inhibitors, and somatostatin. Almitrine, a drug that augments hypoxic pulmonary vasoconstriction, has little effect in these patients. Although in the past hypoxemia was considered a contraindication for liver transplantation, recent evidence has suggested that hypoxemia, clubbing, and related signs of hepatopulmonary syndrome improve after transplantation.

In contrast with the low-resistance shunt vessels in the lung microcirculation, some patients have severe unexplained pulmonary hypertension. The presence of portal hyperten-

sion may be a critical factor among cirrhotic patients who develop pulmonary hypertension because pulmonary hypertension has complicated portal hypertension in the absence of underlying liver disease. Pulmonary hypertension is not restricted to specific types of liver disease and can be present in the absence of portal hypertension. The pathogenesis is unknown, but it has been speculated to be related to an autoimmune process or related to circulating mediators with potent vasoconstrictor or growth-stimulating effects that may be produced in excess or not cleared by the diseased liver. Clinically, patient evaluation should include a work-up for portal vein thrombosis and hypercoagulability. Moderate pulmonary hypertension may serve as a contraindication for liver transplantation because of the risks of graft dysfunction from severe postoperative right-sided heart failure as well as the difficult hemodynamic management of these patients in the immediate perioperative period. Preoperative evaluation may be aided by assessing pulmonary vasoreactivity in these patients; however, whether the acute hemodynamic response to vasodilators predicts a favorable outcome is unproven.

Acute Respiratory Distress Syndrome

Current treatment of acute hypoxemic respiratory failure, including acute respiratory distress syndrome (ARDS), is often unsuccessful, with mortality at 50% to 75%. Although death is commonly associated with multiple organ failure, progressive respiratory failure contributes to poor outcome. Injury to the pulmonary circulation during acute respiratory failure leads to increased permeability, leading to pulmonary edema with surfactant inactivation, low lung compliance, and decreased gas exchange. In addition, the pathophysiology of ARDS is characterized by pulmonary hypertension and altered pulmonary vasoreactivity, which worsens $\dot{V}/\dot{Q}$ mismatch, accelerates pulmonary edema formation, and may cause RV dysfunction. Despite the presence of pulmonary hypertension, vasodilator therapy has been limited by the inability to selectively lower PAP without causing systemic hypotension or worsening gas exchange by increasing perfusion of underventilated lung regions. The contribution of pulmonary vasoconstriction to the pathophysiology of ARDS has been recently demonstrated in studies examining the response to inhaled NO.[140-142] Inhaled NO selectively lowers PAP and improves gas exchange in many patients with severe ARDS, and can improve cardiac output in the setting of moderate to high PVR. Despite improvement in oxygenation, inhaled NO has not been shown to improve long-term outcomes such as mortality or ventilator-free days.

RESPIRATORY COMPLICATIONS OF CARDIAC DISEASE

Because chronic lung disease contributes to pulmonary hypertension, altered cardiac function can also adversely affect lung function. Many respiratory complications accompany cardiac disorders, complicating acute management following surgical repair of anatomic heart disease as well as long-term outcome. Three general categories of cardiovascular lesions cause concomitant abnormalities in lung function: first, vascular anomalies that obstruct large airways; second, high pulmonary blood flow caused by large volume left-to-right shunts; and third, inflow or outflow obstruction to the left (systemic) ventricle. Central airways obstruction resulting from vascular compression can be caused by structural lesions such as double aortic arch, right-sided aortic arch, aberrant right subclavian artery, anomalous innominate artery, and pulmonary artery sling. These can accompany congenital cardiac lesions and should be sought in clinical settings of stridor, recurrent or persistent wheezing, cough, apnea, and feeding difficulties. In addition, structural abnormalities of the central airways can also be associated with cardiac lesions, such as complete tracheal rings and narrowing (with agenesis of right lung or pulmonary sling). Structural abnormalities of small airways may also accompany some cardiac lesions. Small airway obstruction with heart disease is commonly caused by mechanical compression by small pulmonary arteries, pulmonary edema, bronchial edema, or bronchoconstriction (discussed later).

Increased pulmonary blood flow occurs with large left-to-right anatomic shunts, such as with ventricular septal defects, patent ductus arteriosus, atrioventricular canals, single ventricle, aortopulmonary window, or truncus arteriosus. High pulmonary blood flow distends small pulmonary arteries and increases PAP. High flow also increases left-ventricular end-diastolic volume and pressure, which raises left-atrial and pulmonary venous pressures. Increased blood flow with elevated pulmonary arterial and venous pressures contribute to peribronchial and interstitial edema, causing small airway obstruction and "cardiac asthma," which is characterized by clinical signs of high airway resistance as a result of small airway obstruction. Airway edema causes mechanical obstruction of small airways as a result of peribronchial and mucosal swelling. Distended pulmonary arteries cause extrinsic compression of small airways, which can occur with high flow even in the absence of overt heart failure. Bronchoconstriction and altered bronchial reactivity may further contribute to small airways narrowing.[143] Chronic elevation of pulmonary blood flow may also be associated with increased peribronchial wall thickening caused by smooth muscle hypertrophy and increased extracellular matrix production.

Along with increased airways resistance, high pulmonary blood flow decreases lung compliance and increases work of breathing, especially when associated with mean PAP above 25 mm Hg.[144,145] Marked left-atrial enlargement can compress the left or right mainstem bronchi, causing airflow obstruction and hyperinflation. Clinical findings include tachypnea with shallow breathing, which may increase physiologic dead space. Other signs are retractions, rhonchi, and wheezing. Chest radiograph findings include hyperinflation or, in some cases, lobar emphysema or atelectasis. Therapy includes medical management of pulmonary edema and failure (diuresis, digoxin), and acute assessment for clinical improvement after an inhaled bronchodilator. These patients are at marked risk for severe respiratory failure with superimposed lower respiratory infections, including respiratory syncytial virus bronchiolitis. Surgical correction of the underlying lesion should improve respiratory signs, but in some cases, airways obstruction persists.

Inflow or outflow obstruction to the left (or systemic) ventricle, from pulmonary veno-occlusive disease, total anomalous pulmonary venous return, mitral stenosis, cor triatriatum, and left-ventricular obstruction caused by coarcta-

tion of the aorta, interrupted arch, aortic stenosis, or atresia and cardiomyopathy, can also impair lung function. Pulmonary venous obstruction or hypertension initially increases pulmonary blood volume and interstitial edema, causing many of the effects on lung mechanics discussed previously. Clinically, children can present with clinical signs of airways obstruction, but more commonly, they present with "interstitial lung disease," with marked tachypnea, cyanosis, and rales. Chest radiograph usually shows a normal cardiac silhouette with increased venous or interstitial markings. Asymmetry may suggest unilateral venous obstruction. Prolonged pulmonary venous hypertension over time can subsequently lead to striking structural venous and arterial changes, contributing to severe pulmonary hypertension.

PLASTIC BRONCHITIS

Plastic bronchitis (PB) is a relatively rare but frustrating cause of airways obstruction and respiratory distress in children with diverse cardiac and respiratory conditions, including congenital heart disease, lymphangiectasis, sickle cell anemia, asthma, and others.[146-148] PB is characterized by respiratory signs caused by the formation of large mucinous or gelatinous airway casts that can plug and obstruct medium-sized or small airways. These casts can be discovered at the time of bronchoscopy for persistent atelectasis or unexplained deterioration in respiratory course, or can be expectorated spontaneously. In many patients with PB, symptoms may persist and lead to recurrent episodes of respiratory distress and, in some cases, have been attributed as the cause of death.

The prevalence of PB is unknown, but multiple reports and small case series have been published. PB is associated with a wide range of diverse diseases, and its pathogenesis is unclear. Most often, it is observed in postoperative cardiac patients who have undergone palliative repair for cyanotic heart disease, including Fontan, Glenn and Blalock-Taussig procedures. PB has also been observed in the setting of lymphatic obstruction associated with chylous effusions, lymphangiectasia, lymphangiomatosis, or lymphatic obstruction associated with total anomalous pulmonary venous return. PB has also been found in diseases not associated with cardiovascular disease, such as asthma, allergic bronchopulmonary aspergillosis, sickle cell anemia during acute chest syndrome, collagen-vascular disease (such as systemic lupus erythematosus) and others.

Clinically, patients with PB present with dyspnea, wheezing, or pleuritic chest pain, and may have fever. Auscultation may yield focal wheezing or asymmetric breath sounds. Chest radiograph often reveals focal collapse of the involved lobe or segment with compensatory hyperinflation, or consolidations with volume loss. PB should be considered in patients with pleural effusions in the setting of cyanotic heart disease after palliative surgery or with chylothorax. Although patients can spontaneously expectorate casts, the diagnosis of PB is generally made during bronchoscopy, in which casts of the airway can be pulled from the airway. These casts often have a rubbery texture, and have often been characterized as either "inflammatory" or "noninflammatory." This classification may not be helpful, and even in the absence of inflammatory cells, it is believed that airway inflammation may be a significant initiating trigger. Currently, there are no unifying theories that link lymphatic obstruction, cyanotic congenital heart disease, or other diseases with PB. Treatment is empirical, with bronchodilators, inhaled or systemic steroids, and airway clearance methods typically used. With marked obstruction, bronchoscopy is warranted for removal of casts, which act as "foreign bodies." Some advocate the use of inhaled heparin, urokinase, tissue plasminogen activator (TPA), or dornase alfa, but experience is limited to case reports, and treatment failures with each approach have been noted. Oral macrolide antibiotics have also been proposed to modulate mucus production, but efficacy is uncertain. The natural history and clinical course is closely linked with the associated disease, as the highest mortality is noted in patients with severe complex cyanotic heart disease.

CHAPTER 53

Pulmonary Arterial Hypertension

Eli Gabbay, Robert G. Weintraub, and Lewis J. Rubin

TEACHING POINTS

- A new classification for pulmonary hypertension based on mechanisms and etiology allows more useful description of natural history and response to treatment.
- *Idiopathic pulmonary arterial hypertension* has replaced the term *primary pulmonary hypertension.*
- Idiopathic pulmonary arterial hypertension arises from an interplay of genetic and environmental factors.
- A greater understanding of the pathogenesis of pulmonary arterial hypertension has led to the development of various classes of treatments that have improved quality of life, exercise capacity, and survival.
- Future therapeutic options include newer classes of drugs, combinations of existing therapies, and gene and stem cell therapy with the potential to improve prognosis.

Pulmonary arterial hypertension (PAH) refers to a group of diseases that have in common narrowing of the small pulmonary arteries and arterioles resulting in progressive elevation of pulmonary vascular resistance (PVR) and potential development of right ventricular failure and death.[1-3] The last few years have seen major changes in the classification of pulmonary hypertension, a greater appreciation of its prevalence, and improved understanding of the pathogenesis that underlies the clinical syndrome. As a result, newer therapies have been developed and, although still a life-threatening disease, the prognosis for patients with PAH has improved considerably.

DEFINITION AND CLASSIFICATION

PAH is defined by a sustained elevation of mean pulmonary arterial pressure to a level greater than 25 mm Hg at rest or greater than 30 mm Hg during exercise, with a normal pulmonary artery wedge pressure less than 15 mm Hg.[1-3] Previously, pulmonary hypertension was further described as primary pulmonary hypertension (PPH) or secondary pulmonary hypertension.[4] However, the term *secondary* was confusing because it referred to heterogeneous diseases including diseases that resemble PPH but had known associations such as pulmonary hypertension in association with anorexigen use as well as diseases that are very different from PPH, such as cardiac diseases (e.g., pulmonary hypertension secondary to left ventricular dysfunction) and parenchymal lung disease (e.g., cor pulmonale).

As a result, the World Health Organization–sponsored Expert Working Group suggested replacing the terms *secondary* and *primary* pulmonary hypertension with a new classification (Table 53-1).[5] This classification distinguishes pulmonary hypertension by a combination of mechanisms and etiology and is more useful when considering the natural history, prognosis, and potential therapies of the different causes of pulmonary hypertension.

In this classification, the term PPH has been replaced by the terms *idiopathic pulmonary arterial hypertension* (iPAH) and *familial pulmonary arterial hypertension* (fPAH). This chapter focuses on that group of diseases in group 1; iPAH, fPAH, and conditions known to be associated with PAH (APAH).

Although similarities exist in the diagnosis, prognosis, and therapeutic options for patients with pulmonary hypertension secondary to congenital systemic to pulmonary shunts (Eisenmenger syndrome), these syndromes are significantly different from iPAH in terms of their pathogenesis and natural history and are dealt with elsewhere in the text. However, in some children, the differentiation between iPAH and Eisenmenger syndrome is less clear. For example, children with small atrial septal defects may develop PAH without ever manifesting large left-to-right shunts and it may be more appropriate that such patients are considered to have iPAH.[6]

Within the group of conditions classified under the heading PAH, there are two rare conditions in which pulmonary arterial changes are associated with significant venous or capillary involvement. In both pulmonary veno-occlusive disease (PVOD) and pulmonary capillary hemangiomatosis (PCH), similar changes to iPAH are found in the pulmonary arterioles and the clinical presentation is similar.[7,8] The major difference and the importance of differentiating them from iPAH is that life-threatening pulmonary edema may result from epoprostenol and other therapies that are often used in the treatment of iPAH.

Persistent pulmonary hypertension of the newborn (PPHN) is a separate entity arising from failure of the PVR to decrease after birth.[9] In the fetus, PVR is very high and little blood flows through the fetal lung. At birth, with the onset of ventilation, the increased oxygen tension in the alveoli results in pulmonary vasodilatation, reduced pulmonary pressure, and increased pulmonary blood flow. PPHN or *persistent fetal circulation*, as it is also known, may arise as a result of abnormally strong pulmonary vasoconstrictive response to hypoxemia and is often seen in association with conditions that result in neonatal hypoxemia, such as con-

Table 53-1
Revised Clinical Classification of Pulmonary Hypertension

Pulmonary arterial hypertension (PAH)
Idiopathic (iPAH)
Familial (fPAH)
Associated with (APAH)
Collagen vascular disease
Congenital systemic-to-pulmonary shunts
Portal hypertension
HIV infection
Drugs and toxins
Other (thyroid disorders, glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy)
Associated with significant venous or capillary involvement
Pulmonary veno-occlusive disease (PVOD)
Pulmonary capillary hemangiomatosis (PCH)
Persistent pulmonary hypertension of the newborn
Pulmonary hypertension with left heart disease
Left-sided atrial or ventricular heart disease
Left-sided valvular heart disease
Pulmonary hypertension associated with lung diseases and/or hypoxemia
Chronic obstructive pulmonary disease
Interstitial lung disease
Sleep-disordered breathing
Alveolar hypoventilation disorders
Chronic exposure to high altitude
Developmental abnormalities
Pulmonary hypertension caused by chronic thrombotic and/or embolic disease
Thromboembolic obstruction of proximal pulmonary arteries
Thromboembolic obstruction of distal pulmonary arteries
Nonthrombotic pulmonary embolism (tumor, parasites, foreign material)
Miscellaneous
Sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

From Simonneau G, Galiè N, Rubin LJ, et al: Clinical classification of pulmonary hypertension. J Am Coll Cardiol 43:5-12, 2004.

genital diaphragmatic hernia, meconium aspiration, pneumonia, and acute respiratory distress syndrome.[10]

Pulmonary hypertension may also arise as a result of chronic thromboembolic disease.[11] Although an important differential in the assessment of pulmonary hypertension, chronic thromboembolic pulmonary hypertension (CTEPH) represents a different mechanism of disease when compared to PAH. The natural history and prognosis is different and most importantly treatment is predominantly surgical,[12] although medical therapy may be effective in selected cases.[13-16] It is discussed in greater depth in the chapter on pulmonary embolism.

Pulmonary hypertension can complicate left heart disease and can occur in association with lung disease and/or hypoxemia. The mechanisms differ from those of PAH and treatment is directed to the underlying cause and correction of hypoxemia. However, it may yet transpire that in lung conditions associated with pulmonary hypertension, medical treatment with specific PAH therapies (see later) may have a role in selected patients[17-19]

EPIDEMIOLOGY

Idiopathic Pulmonary Arterial Hypertension

The incidence and prevalence of iPAH is uncertain. The reported incidence of iPAH is 1 to 2 per million per year but this may represent an underestimate of the true incidence. It is likely that some patients die without a diagnosis and many others are managed without referral to a hospital clinic. A recent study examining prevalence in Scotland found that in adults between 16 and 65 years of age there was a prevalence of 2.5/million/yr in males and 4/million/yr in females.[20] Autopsy studies in unselected patients have suggested that in 0.13% of cases changes compatible with PAH are found.[21] Idiopathic PAH is more common in women[22] (female to male ratio of between 1.7 and 3.5) and although it has a peak incidence in the third decade of life in women and fourth decade in men, it can manifest at all ages.[23] No ethnic predisposition is apparent, but the disease may have a worse prognosis in African Americans and Asians compared to whites.[24]

Familial PAH

The incidence of PAH is higher in certain families. Familial PAH accounts for between 6% and 10%[23,25,26] of all patients, and close family members of patients with PAH have a significantly increased risk of developing PAH (see later).

Associated PAH

CONNECTIVE TISSUE DISEASE

Pulmonary arterial hypertension has been found in association with almost every type of connective tissue disease.[27] The presence of a connective tissue disease may also be associated with other potential causes of pulmonary hypertension such as interstitial lung disease, direct proliferative lung vascular involvement, or left ventricular dysfunction. However, isolated PAH can occur in 10% to 33% of patients with scleroderma depending on the diagnostic criteria used,[28,29] and is most significantly associated with the limited cutaneous form, often referred to as CREST syndrome.[30] PAH complicates the clinical course 5% to 10% of patients with systemic lupus erythematosus (SLE)[31,32] and 10% to 15% of patients with mixed connective tissue disease.[33] It can rarely complicate rheumatoid arthritis, dermatomyositis, and polymyositis.

PORTOPULMONARY HYPERTENSION

The prevalence of PAH in patients with chronic liver disease varies from 1 in 140 in an autopsy study[21] to as high as 1 in 15 referred for liver transplantation.[34] The development of PAH appears to be related to the duration of portal hypertension rather than the development of cirrhosis per se.[34-37]

DRUGS AND TOXINS

The use of the anorexigens aminorex fumarate, fenfluramine, and dexfenfluramine has been associated with the development of PAH.[35,38,39] The risk is greatest with prolonged use but has been described after only 3 to 4 weeks' exposure.[40] In one review, if fenfluramine was taken for greater than 3 months, there was a 23-fold risk of developing PAH.[35] Other agents likely to be associated with PAH include contaminated rapeseed oil,[41,42] L-tryptophan,[43] cocaine,[35,43] amphetamines, and meta-amphetamines.[44] Certain chemotherapeutic agents, especially mitomycin-C, carmustine, etoposide, and cyclophosphamide, have been linked with PVOD.[45]

HIV INFECTION

PAH complicates HIV infection in approximately 1 in 200 cases.[46] The longer the duration of HIV infection, the greater appears the risk. Many patients with HIV infection may have coexistent portopulmonary hypertension from hepatitis B and C infection or thromboembolic pulmonary hypertension from intravenous drug use. In the absence of these factors, co-infection with human herpes virus 8 (the causative agent of Kaposi sarcoma) may be central to the development of PAH.

HEMATOLOGIC DISORDERS AND SPLENECTOMY

Pulmonary hypertension is seen with a greater prevalence than in the general community in myeloproliferative disorders,[47] myelodysplasia, POEMS syndrome,[48] and thrombocytosis.[49] This relationship is, in part, due to the development of platelet emboli, previous splenectomy[50] (a risk factor in its own right), chemotherapy-induced PVOD, and infiltration of the pulmonary parenchyma by hematopoietic cells—but isolated PAH appears to be more frequent even in the absence of these confounders. PAH complicates sickle cell disease in 8% to 30%[51] of patients and is an important predictor of mortality in these patients. In β-thalassemia, PAH was found to be present in as many as 75% of patients, but because this study relied entirely on echocardiographic indices, it probably represents an overestimate.[52]

GENETIC AND METABOLIC DISEASES

PAH appears to be more prevalent in poorly controlled thyrotoxicosis[53] and may occur in up to 15% of patients with hereditary hemorrhagic telangiectasia.[54] It also complicates the rare storage diseases, Gaucher's[55] and von Gierke disease.[56]

In children, PAH associated with congenital heart disease is more prevalent than in adults, but PAH associated with connective tissue disease, portal hypertension, HIV infection, and drugs and toxins is less prevalent.[2] Chronic thromboembolic pulmonary hypertension is rare in children.[2,57]

PATHOLOGY AND PATHOGENESIS

The normal pulmonary circulation is a low-pressure system attributable to the large combined surface area of the small pulmonary arteries. The thin muscle layer of these arteries and arterioles ensures that they are compliant and can usually accommodate large changes in blood volume.[58] The resistance across the total pulmonary circulation is usually between one tenth and one fifteenth of the systemic circulation. In PAH, the arterial luminal area is reduced by a combination of vasoconstriction, vascular remodeling, and thrombosis.[59] The vascular remodeling includes smooth muscle proliferation, intimal and adventitial thickening, and formation of plexiform lesions (Fig. 53-1).[4,7] There is distal extension of

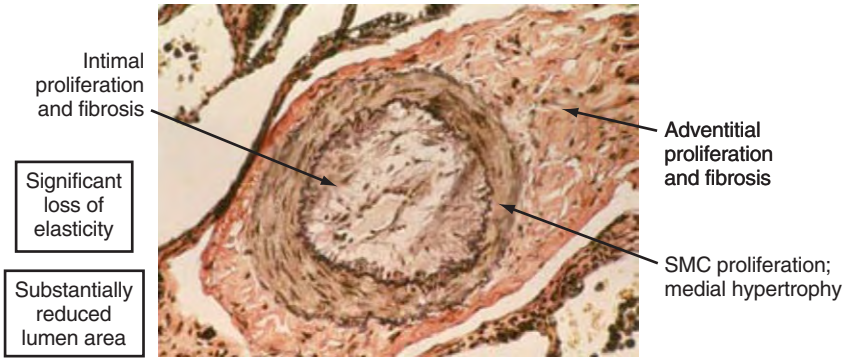

Figure 53-1 Microscopic features seen in pulmonary arterial hypertension. smooth muscle into the smallest normally nonmuscular pulmonary arterioles. This progressive luminal obstruction leads to elevation of pulmonary vascular resistance. In response to increased afterload, there is hypertrophy of the right ventricle that may result in bowing of the intraventricular septum and compression of the left ventricular wall (Fig. 53-2). Eventually the right ventricle will begin to fail.

CELLULAR CHANGES AND MOLECULAR ABNORMALITIES

Although there remains much that is unknown about the pathogenesis of PAH, what is clear is that PAH arises from a complex interplay of several cellular changes and associated molecular and genetic abnormalities.[60] The main cellular changes involve the endothelium, platelets, smooth muscle cells, and adventitial fibroblasts. These abnormalities lead to vasoconstriction, remodeling, and thrombosis via an imbalance between vasodilators and vasoconstrictors, between growth inhibitors and mitogenic factors, and between antithrombotic and prothrombotic mediators (Table 53-2).[61] It remains unclear if the abnormalities in these cellular groups represent changes in local cells or reflect bone marrow–derived progenitor endothelial and smooth muscle cells and fibroblasts that migrate to the pulmonary arteries in response to abnormal stimuli.[62]

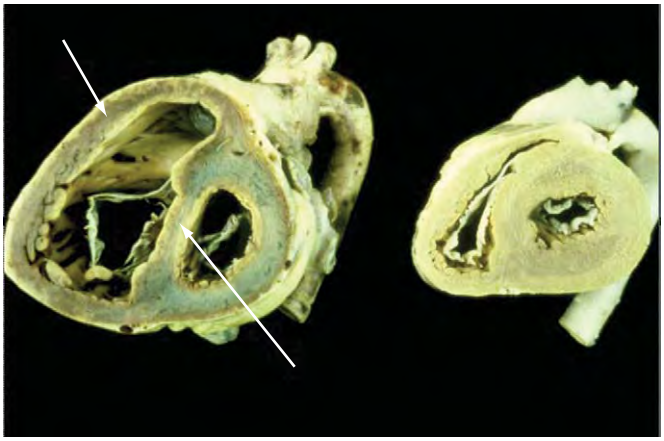

Figure 53-2 Macroscopic view of a heart removed at autopsy from a patient with pulmonary arterial hypertension. When compared to the smaller normal heart, there is evident right ventricular hypertrophy (*short arrow*) and bowing of the intraventricular septum resulting in a D-shaped left ventricle (*long arrow*).

ENDOTHELIAL CELL DYSFUNCTION, PROSTACYCLIN, NITRIC OXIDE, VASOACTIVE INTESTINAL PEPTIDE, AND ENDOTHELIN

The initiating factor, at least in the majority of cases of PAH, appears to be endothelial cell injury—although other cellular components are important and interrelated. In iPAH, the cause of endothelial dysfunction is unknown.

Endothelial cell dysfunction leads to monoclonal expansion of endothelial cells in plexiform lesions.[59,63] Further, there is an imbalance in concentration of mediators normally produced by the endothelium, with reduced production of prostacyclin (PGI_2), nitric oxide (NO) and vasoactive intestinal peptide (VIP) and upregulation of endothelin-1 (ET-1). This imbalance in mediators results in the abnormal proliferation and contraction of pulmonary smooth muscle cells via three pathways that are potential targets for therapy (Fig. 53-3).[64]

ET-1 acts via the two receptors endothelin receptor A and B and, as well as its effects on pulmonary smooth muscles, it also contributes to fibroblastic proliferation and inflammation.[65] ET-1 levels in the serum and expression of ET receptors within the plexiform lesions are increased in PAH and correlate with the severity of hemodynamic changes and prognosis.[66,67]

As well as its antiproliferative and vasodilatory effects on pulmonary vascular smooth muscle cells, PGI_2 normally acts to reduce platelet aggregation. Reduced production of PGI_2 coupled with increased platelet release of the prothrombotic mediator thromboxane (TXA_2),[68] as well as abnormalities in the clotting cascade and impaired fibrinolysis, potentiates the development of in situ thrombosis. Nitric oxide is a potent vasodilator and platelet inhibitor, and reduced levels of endo-

Table 53-2
Cellular, Genetic, and Molecular Mechanisms Involved in Pulmonary Arterial Hypertension*

Cell	Molecular/Genetic Abnormality	Pathobiology
Endothelial cell	↓ NO, PGI_2, VIP	Procoagulant
	↑ ET-1 and TXA_2	Platelet aggregation
	↓Growth suppressor genes	Endothelial proliferation
	↑ VEGF	Smooth muscle proliferation
Smooth muscle	Dysfunctional K^+ channels	Vasoconstriction
	↑ Angiopoietin-1	Smooth muscle proliferation
Platelets	↑ Release of serotonin	Platelet aggregation
	↑ Release of PDGF and VEGF	Vasoconstriction
		Smooth muscle proliferation
Adventitial fibroblast	↑ Elastase	Migration of myofibroblasts and formation of neointima
	↑ MMPs	Smooth muscle proliferation
	↑ L-Allele of 5HTT	
Inflammatory cells	↑ Expression of fractalkine	Cell recruitment and inflammation

*Although described separately, there is significant interaction between the cellular, molecular, and genetic abnormalities.
ET-1, endothelin; 5HTT, serotonin transporter; MMPs, matrix metalloproteinases; NO, nitric oxide; PDGF, platelet-derived growth factor; PGI_2, prostacyclin; TXA_2, thromboxane; VEGF, vascular endothelial growth factor; VIP, vasoactive intestinal peptide.

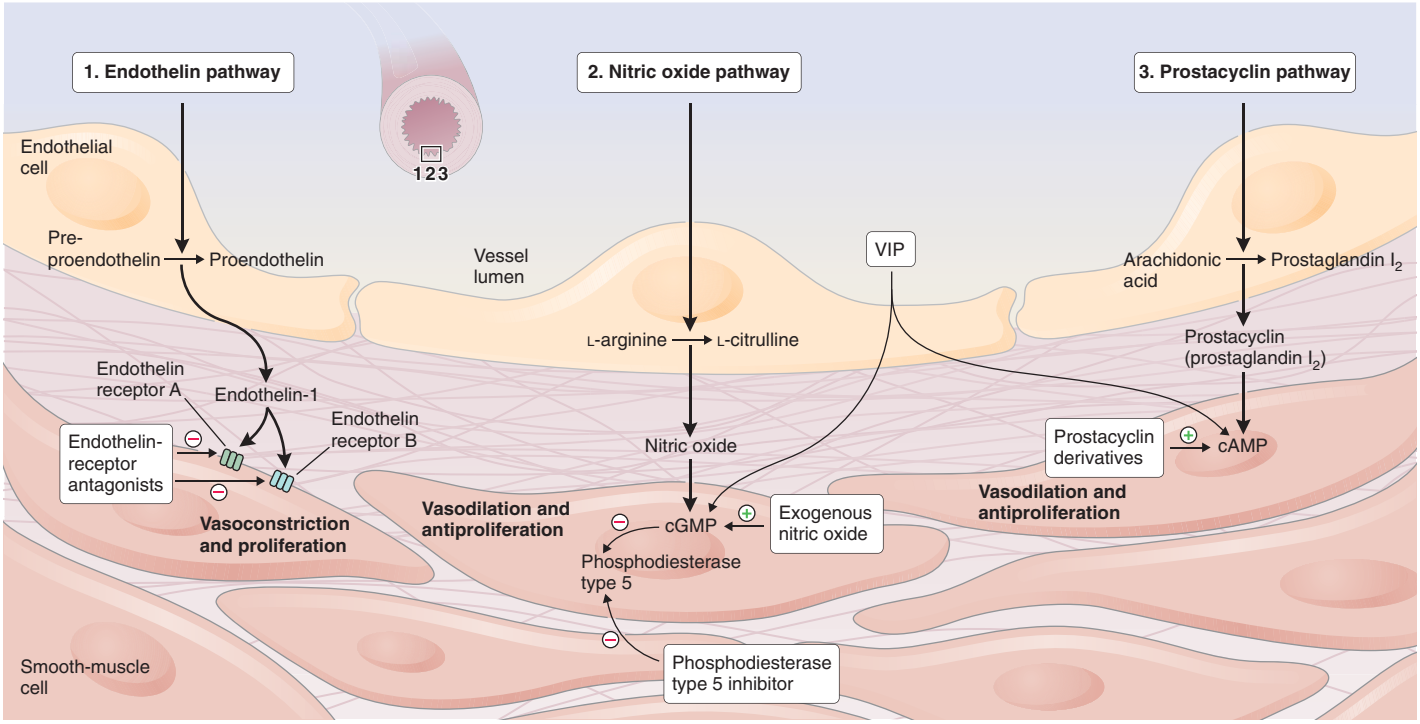

Figure 53-3 Consequences of endothelial dysfunction on pulmonary vascular smooth muscle showing potential targets for therapy. Three major pathways and associated therapeutic targets in abnormal proliferation and contraction of smooth muscle cells are shown. Dysfunctional endothelial cells have decreased production of prostacyclin and endogenous nitric oxide and increased production of endothelin-1. This imbalance of mediators along with decreased production of vasoactive intestinal peptide (VIP) results in a condition favoring vasoconstriction and proliferation of pulmonary artery smooth muscle cells. In addition to their actions on smooth muscle, these mediators have other properties including antiplatelet effects of nitric oxide and prostacyclin and profibrotic and proinflammatory effects of endothelin. + denotes an increase in intracellular concentration; – reflects blockage of a receptor, inhibition of an enzyme, or a decrease in the intracellular concentration; cAMP, cyclic adenosine monophosphate; cGMP, cyclic guanosine monophosphate. (Modified from Humbert M, Sitbon O, Simonneau G: Drug therapy: Treatment of pulmonary arterial hypertension. N Engl J Med 351:1425-1436, 2004.)

thelial NO synthetase are seen in the lungs of patients with PAH, resulting in decreased NO production.[69,70]

PLATELETS, SEROTONIN, VASCULAR ENDOTHELIAL GROWTH FACTOR, AND PLATELET-DERIVED GROWTH FACTOR

In addition to their role in coagulation, platelets release serotonin and vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF). PAH is characterized by an increased platelet release of serotonin.[71] Precisely how serotonin affects the pulmonary vessels is uncertain, but it appears likely to contribute to smooth muscle vasoconstriction and proliferation.[72,73] Selective serotonin reuptake inhibitors (SSRIs) block serotonin transport and activity and have a potential role in therapy of PAH.[74]

VEGF is important in the normal homeostasis of the pulmonary vasculature, helping to maintain normal endothelial cell function. Whereas the VEGF A isoform is protective and appears a likely candidate for gene transfer therapy,[75] the VEGF B isoform may exacerbate endothelial cell dysfunction.[76] In the plexiform lesions, VEGF expression is increased along with its receptors, whereas signaling molecules that are important to the normal response to VEGF are downregulated.[63,77,78] It appears likely that dysregulation of this pathway is part of an abnormal response allowing clonal expansion of endothelial cells.[78] PDGF and other growth factors such as epidermal growth factor (EGF) and insulin-like growth factor-1 are upregulated in PAH[78] and also may contribute to endothelial cell dysfunction and proliferation, as well as abnormal smooth muscle and adventitial proliferation.

SMOOTH MUSCLE CELLS, POTASSIUM CHANNELS, AND ANGIOPOIETIN-1

The vascular smooth muscle is a target for growth factors and mediators that promote abnormal contraction and proliferation, but changes within the smooth muscles themselves appear to be central to the pathogenesis of vasoconstriction and vascular wall remodeling and endothelial dysfunction.

Within the smooth muscle cells, loss of some of the normal voltage-gated potassium (K^+) channels leads to increased intracellular calcium and resultant vasoconstriction and smooth muscle proliferation.[79] It remains unclear if these K^+ channel abnormalities are genetically determined or acquired. Further, abnormal K^+ channels in platelets may contribute to the increased serotonin release seen in PAH.[80]

Angiopoietin-1 is a vascular growth factor that is essential for lung vascular development.[81] Produced by smooth muscle cells, its receptor is present only on endothelium and after development is completed is present in only very small quantities in the lung. One study has suggested that it is

upregulated in PAH[82] and another study has suggested that it directly contributes to vascular remodeling in experimental forms of PAH.[81] Alternatively, another study has suggested that it has a protective role.[83]

ADVENTITIA, NEOINTIMA, MATRIX METALLOPROTEINASES, AND PROTEOLYSIS OF EXTRACELLULAR MATRIX

In PAH, fibroblast proliferation leads to adventitial thickening, and a layer of myofibroblasts and extracellular matrix develops in the neointima between the endothelium and internal elastic lamina. The matrix metalloproteinases (MMPs) are matrix-degrading enzymes involved in extracellular matrix (ECM) turnover. Changes in the balance of these and related enzymes and their inhibitors contributes to migration of myofibroblasts, deposition of excess ECM, and may interact with growth factors, leading to enhanced smooth muscle proliferation.[84-86]

MMP2 and MMP9 are gelatinases that break down basement membrane and allow the migration of myofibroblasts from the adventitia through the media and into the neointima. Upregulation of MMP2 and MMP9 occurs in PAH, and increased release of smooth muscle–derived serine elastase contributes to the increased activity of MMP2 and MMP9. Further, the upregulation of MMPs and serine elastase may lead to the formation of breakdown products that interact with EGF leading to smooth muscle cell proliferation. The increased deposition of ECM may arise from an imbalance between collagenase MMP1 and its inhibitor (tissue inhibitor of metalloproteinase 1 [TIMP-1]).[85]

The importance of the role of dysfunctional proteolysis in PAH is highlighted by the observation that serine elastase inhibitors reverse vascular changes in experimentally induced severe PAH.[87]

INFLAMMATORY MECHANISMS

Inflammatory mechanisms are likely to be important, at least in certain forms of PAH. Inflammatory infiltrates are commonly seen within plexiform lesions, and increased expression of the chemokines RANTES and fractalkine, as well as their receptors, have been observed in PAH.[88] Patients with PAH have higher serum concentrations of IL-1 and IL-6, which upregulate endothelin and PDGF and may have procoagulant activity.[89] Immunosuppressive medications have been shown to be effective in some forms of PAH.[89]

ANGIOTENSIN-CONVERTING ENZYME

Within both the intima and plexiform lesions seen in patients with PAH, angiotensin-converting enzyme (ACE) expression is upregulated.[90,91] ACE leads to the production of angiotensin II, a potent vasoconstrictor and activator of smooth muscle proliferation. However, the role of ACE in the pathogenesis of PAH is unclear[92] and clinical studies with ACE inhibitors have failed to find a benefit.

Genetic Abnormalities

Familial PAH shows an autosomal-dominant inheritance but with only 10% to 20% penetrance.[22] At least 80% of those who receive the abnormal gene do not develop disease. Inheritance shows genetic anticipation, with the disease developing at a younger age and often with greater severity in successive generations.[3,22,93]

Underlying the development of both fPAH and iPAH are genetic mutations in the TGF-β receptor family. Proteins encoded by these genes are central to vascular remodeling. The first candidate gene identified in PAH encodes bone morphogenetic protein receptor type 2 (BMPR-II).[94,95] Binding of ligand to this receptor activates intracellular pathways acting via the SMAD group of proteins and mitogen-activated protein kinases (MAP kinase), which suppress the growth of vascular smooth muscle cells. In 50% to 60% of patients with fPAH, mutations in BMPR-II have been identified.[94,95] However if postsomatic mutations are included, then BMPR-II gene abnormalities are found in at least 90% of patients with fPAH.

In contrast to fPAH, only 10% to 26% of patients with iPAH have mutations in the BMPR-II gene.[94-96] The absence of BMPR-II mutations in the majority of sporadic cases suggests that other genes probably also contribute to the development of PAH. Genetic mutations linked to PAH have been discovered in other genes in the BMPR-II/TGF-β superfamily. These include ALK-1 and endolgin in hereditary hemorrhagic telangiectasia[54,97] and mutations that directly affect SMADs, MAP kinase, and nuclear transcription factors.[98,99] In the plexiform lesions, the monoclonal endothelial cells show defects in the growth suppressor genes TGF-β receptor and Bax, suggesting that such mutations allow clonal expansion of endothelial cells.[100]

The precise interactions at different levels in this pathway are complex. However defective BMP signaling and loss of its antiproliferative effects appears to be central to the development of both iPAH and fPAH. The role of BMPR-II mutations in conditions associated with PAH is less clear, with such mutations not identified in studies of scleroderma-associated PAH and HIV-associated PAH—but probably of some significance in PAH seen with anorexigen use.[101-103]

Other than genetic mutations arising directly within the TGF-β superfamily, there are likely to be other modifier genes in other pathways that interact with the primary mutation and influence whether or not PAH develops. One study has suggested that upregulation of angiopoietin-1 occurs in PAH and that acting via its receptor TIE2 on endothelium may contribute to defective BMPR-II signaling.[80] This raises the possibility that a gene in this pathway is a suitable candidate to be such a modifier gene.[81]

Another gene pathway likely to be important in PAH is the serotonin (5-HT) pathway. Plasma levels of serotonin released from platelets are increased in PAH and may contribute to pulmonary vasoconstriction and increased proliferation of pulmonary vascular smooth muscle cells. A polymorphism in the 5-HT transporter (5-HTT) has been found. The L-allele (long form) induces a greater rate of synthesis of the transporter and has been found in 65% of patients with iPAH but only 26% of controls.[104]

Another potential modifier gene encodes plasminogen activator inhibitor type 1 (PAI-1), dysfunction of which leads to impaired fibrinolysis and a procoagulant state of the pulmonary vessels. Other candidate genes include those that encode prostacyclin synthase, NO synthetase, serine elastase, MMP2 and MMP9, voltage gated K^+ channels, angiotensin-converting enzyme, and VEGF and VIP.[105]

Environmental Factors

PAH develops in only a small percentage of the carriers of the BMPR-II, ALK-1, and 5HTT mutations, suggesting that environmental triggers are probably required for the development of disease. Clues as to the nature of these stimuli are evident from the known associations of PAH and act via cellular and molecular mechanisms important in PAH.

Acute hypoxia causes pulmonary vasoconstriction, in part via upregulation of endothelin and serotonin and by K^+ channel dysfunction.[106,107] Although changes are initially reversible, chronic hypoxia results in proliferation of vascular smooth muscle and matrix, resulting in irreversible changes. Therefore, chronic hypoxia may contribute to the PAH seen in people living at high altitude but also may be relevant to the ongoing remodeling of the pulmonary vasculature with disease progression.

In connective tissue diseases, especially SLE, the presence of antinuclear antibodies and deposition of complement fraction in the vascular smooth muscle wall suggest an immunologic mechanism.[108] Further, antiendothelial cell antibodies specific to certain receptors on the pulmonary vasculature are present in patients with the limited cutaneous form of scleroderma.[109] In connective tissue diseases, PAH often occurs in association with Raynaud phenomenon—suggesting a similar pathogenesis.[110]

Anorexigens increase plasma serotonin levels by inducing platelet serotonin release or inhibiting its metabolism.[111] Additionally, they block K^+ channels.[112] This combination may contribute to vasoconstriction and vascular smooth muscle proliferation. It is likely that in the presence of portal hypertension, the presence of portosystemic shunts might allow vasoactive substances such as serotonin to bypass the liver, where they are normally metabolized, and reach the pulmonary circulation in greater concentration.[113] In HIV, co-infection with HHV-8 may allow clonal expansion of endothelial cells by dysregulatory cell growth.[114]

In sickle cell disease, destruction of nitric oxide by increased concentrations of free hemoglobin may be important to the development of PAH,[115] and it is plausible that in the myeloproliferative diseases, increased release of platelet-derived serotonin and growth factors contributes directly to pulmonary vascular smooth muscle proliferation.

The environmental stimulus/stimuli that underplay iPAH remain elusive, although two interesting observations may give some insight. The presence of antiendothelial cell antibodies in patients with iPAH raises the prospect of immune mechanisms at play, and the finding of HHV-8 infection in plexiform lesions of 10 out of 16 patients with iPAH suggests that vasculotropic viruses may be important triggers in some individuals.[116]

It is evident that one genetic mutation and/or one environmental stimulus cannot explain all forms of PAH, and it is likely that development of disease requires interplay between multiple genetic and environmental factors. This has led to the development of a multi-hit hypothesis,[61] requiring primary gene abnormalities which are influenced by modifier genes and environmental stimuli, to develop into clinically evident PAH.

Clinical Features

SYMPTOMS

Common symptoms of pulmonary hypertension include lethargy and reduced exercise capacity. Anorexia, chest pain, syncope, and congestive heart failure may also be present. Syncopal episodes are usually related to exertion or emotional upset and may culminate in a brief generalized seizure.

Although intended primarily for adults with pulmonary hypertension, the WHO classification of functional status of patients with pulmonary hypertension provides a useful framework for describing symptom severity in children as well[117]:

Class I: Patients with pulmonary hypertension in whom there is no limitation of usual physical activity; ordinary activity does not cause increased dyspnea, fatigue, chest pain, or presyncope.

Class II: Patients with pulmonary hypertension who have mild limitation of physical activity. There is no discomfort at rest, but normal physical activity causes increased dyspnea, fatigue, chest pain, or presyncope.

Class III: Patients with pulmonary hypertension who have a marked limitation of physical activity. There is no discomfort at rest, but less than ordinary activity causes increased dyspnea, fatigue, chest pain, or presyncope.

Class IV: Patients with pulmonary hypertension who are unable to perform any physical activity at rest and who may have signs of right ventricular failure. Dyspnea and/or fatigue may be present at rest and symptoms are increased by almost any physical activity.

PHYSICAL EXAMINATION

Cyanosis is usually absent unless there is intrapulmonary shunting, or reversed shunting through a congenital septal defect or arterial communication. The jugular venous pressure may be elevated with visible a waves present. The peripheral pulses may be reduced in volume if cardiac output is low. The right ventricular impulse is usually forceful and pulmonary valve closure may be palpable at the upper left sternal edge. On auscultation the pulmonary component of the second heart sound is louder than normal and may narrowly split from the aortic component or, more commonly, may overlap with aortic closure so that the second heart sound is both loud and single. The murmurs of tricuspid and pulmonary valve regurgitation may be audible at the left lower and upper sternal edge, respectively. Signs of right ventricular failure include hepatomegaly, ascites, and occasionally peripheral edema. Because of ventricular interdependence and altered left heart filling, there may be signs of biventricular heart failure, with tachypnea also present, particularly in young infants.

DIAGNOSIS AND ASSESSMENT

The clinical features of PAH are nonspecific and, therefore, it is important to consider the possibility of pulmonary hypertension in any patient presenting with unexplained progressive breathlessness or fatigue, especially when more common causes such as anemia, obstructive lung diseases, and left heart failure are excluded.[3,4,118]

The diagnosis of iPAH is one of exclusion. The assessment involves establishing the precise diagnosis using the WHO classification (see Table 53-1), determination of potential contributing factors, and assessment of prognosis and response to therapy. A full medical history should be taken to elicit the presence and duration of symptoms, prior illnesses, exposure to drugs or medications, and the presence of other family members with similar symptoms. Clues to the possibility of pulmonary hypertension may be found in the physical examination, in an abnormal ECG and/or chest radiograph, although all three can be normal especially in the early stages. The following investigations are standard in the work-up of someone with known or suspected pulmonary hypertension.[117]

Electrocardiogram

This typically shows right atrial enlargement and right ventricular hypertrophy, manifest as tall R waves and upright T waves in the right chest leads and deep S waves in the lateral chest leads. If severe, ST and T wave changes may be present in the anterior and lateral leads and there may be intraventricular conduction delay. In isolation, the ECG is an inadequate screening tool for the detection of PAH.[117]

Chest Radiograph

The chest radiograph may be normal especially early in the presentation.[117] However, as the disease progresses, changes are usually seen. The main pulmonary artery is usually enlarged, as are the branch pulmonary arteries. The cardiac silhouette may appear abnormal in shape, with late right atrial and right ventricular enlargement. Decreased peripheral lung vasculature may be present but is often subtle.

Echocardiogram

The best screening tool for detection of pulmonary hypertension is a transthoracic echocardiogram (TTE). The patient should be relaxed and comfortable and with appropriate family members present, especially with younger children. Sedation may be required but should be used judiciously. A segmental approach is required to the visualization of all normal structures and exclusion of potential cardiac defects.

Right ventricular systolic pressure (RVSP) and pulmonary artery diastolic pressure can be estimated from the velocity of the tricuspid and pulmonary regurgitant jets if present. RVSP is calculated from the formula:

$$\text{RVSP} = 4V^2 + \text{right atrial pressure}$$

where V = velocity of the tricuspid regurgitant jet. The absence of adequate tricuspid regurgitation does not exclude the presence of pulmonary hypertension.

TTE can also detect other features of pulmonary hypertension including right ventricular wall thickness and dilatation, right atrial dilatation, flattening of the intraventricular septum and right ventricular function, although there is no fully validated measure of right ventricular systolic function on routine echocardiography.[119] A patent foramen ovale or a modest secundum atrial septal defect is commonly found in subjects with atrial dilatation, with any pattern of interatrial shunting possible, and may be secondary rather than representing the primary cause. Right ventricular free wall thickness does not vary much between early infancy and adult life, and right ventricular hypertrophy is usually present but the amount of right atrial and right ventricular dilatation can be variable.

In experienced hands, TTE should be able to reliably exclude congenital cardiac malformations associated with pulmonary hypertension, including anomalies of pulmonary venous return, left heart inflow obstruction (mitral stenosis, cor triatriatum, septal defects, patent ductus arteriosus and aortopulmonary window). Agitated saline may be used to detect evidence of intracardiac shunting. TTE is a valuable tool to detect features of left ventricular or other left-sided heart disease.[120] TTE is less reliable in detecting diastolic dysfunction of the left ventricle. Occasionally a transesophageal echocardiogram (TOE) is useful to highlight cardiac malformations.

Tests to Exclude Other Causes

Abdominal ultrasound and liver function tests should be undertaken to exclude liver disease and portal hypertension. Pulmonary function testing, arterial blood gas assessment, and a sleep study are undertaken to exclude lung disease and various forms of sleep apnea.[121]

Computed tomography of the chest or a nuclear ventilation perfusion test to exclude thromboembolic disease are standard among older subjects presenting with pulmonary hypertension, and at least one of these is usually undertaken in young children.

Hepatitis C, HIV, scleroderma, SLE and other connective tissue disorders, as well as hematologic abnormalities, should be excluded with appropriate blood studies. If there is evidence of thromboembolic disease, then testing for a hypercoagulable disorder should be performed.

Measurements of Exercise Capacity

A 6-minute walk test (and less commonly, a shuttle walk test) is usually undertaken in older subjects (adolescents and adults) but prior practice on the part of the patient is required in order to ensure a reproducible result. This test is not required for the diagnosis of pulmonary hypertension but does provide a useful baseline and measure of functional status.[122] More sophisticated cardiopulmonary exercise testing, with measurement of gas exchange, has also been used,[123] but is not essential for diagnosis or management. Both the 6-minute walk test and WHO functional class can be used to monitor response to therapy, and improvements in these parameters with therapy suggest a better prognosis.[124]

Cardiac Catheterization

Right heart catheterization should be undertaken in almost all subjects in whom PAH is suspected. In children, this investigation should be undertaken in an institution that has experience with both pediatric cardiac catheterization and the assessment of pulmonary hypertension. An experienced pediatric anesthetist should be available to manage sedation requirements, and general anesthesia is best avoided in subjects with advanced right ventricular dysfunction.

Cardiac catheterization is required to confirm the presence of pulmonary hypertension and to ensure that the pulmonary wedge pressure is normal. It is valuable in excluding

congenital heart disease and/or determining intracardiac shunt fraction. A complete assessment requires not only measurement of pulmonary pressure but also measurement of cardiac output indexed to body surface area, measurement of right atrial pressure, and mixed venous oxygen concentrations, all of which help determine the severity of disease and the prognosis in an individual patient.[125]

At the time of catheterization it is possible to assess the response to a selective pulmonary vasodilator (inhaled nitric oxide, infusion of prostacyclin or intravenous adenosine). A positive acute pulmonary vasodilator response is defined as a fall in mean pulmonary artery pressure >10 mm Hg to reach a mean pulmonary artery pressure <40 mm Hg, with an increase or unchanged cardiac output in response to an acute pulmonary vasodilator challenge.[117] A positive response is more common in the pediatric population and can help guide initial therapy.[126] Pulmonary angiography is required to determine if thromboendarterectomy should be performed in patients with chronic thromboembolic pulmonary hypertension.[127]

Other Investigations

There have been numerous reports using serum markers such as brain natriuretic peptide[128] and von Willebrand factor[129] in assessing prognosis and response to therapy. Cardiac MRI may be helpful in defining the cardiac anatomy and assessing prognosis.[130] Measurements of quality of life are used in clinical trials of new therapies but are rarely practical in routine clinical practice.[123]

A thoracoscopic lung biopsy is very rarely performed because of the significant risk of mortality associated with this procedure in this population.[131] It is occasionally used when other tests indicate the possibility of an unusual interstitial lung disease or pulmonary vasculitis and on occasions when PVOD or PCH is suspected.

THERAPY

In recent years the therapeutic options for various forms of PAH have proliferated (Fig. 53-4). The level of evidence differs for various therapies, with most evidence coming from studies of affected adults. It remains unclear if subjects with stable, mild PAH require treatment. However, the outcome for children with iPAH is poor, with data indicating a median survival of only 9 months.[126,132]

Conventional Therapy

General measures include management of underlying or contributing factors, avoidance of pregnancy, early treatment of intercurrent respiratory infections with antibiotics and oxygen as required, and the use of diuretics and digoxin if there are signs and symptoms of congestive heart failure. Nonsteroidal anti-inflammatory medications are usually avoided when possible because of their potential effects on renal function and fluid balance.

The evidence for efficacy of anticoagulants is based on single center, retrospective studies.[133,134] Several studies noted improved survival of treated subjects when compared with controls. Long-term systemic anticoagulation has become routine in subjects with all forms of PAH because of the predilection for pulmonary microthrombi in this condition, regardless of underlying etiology.

With the advent of specific PAH therapies, the role of the nonselective vasodilators, calcium channel blockers has been redefined. Improved clinical status and survival have been noted in subjects with iPAH who demonstrated acute reactivity in response to pulmonary vasodilator testing, and who received high-dose calcium channel blockers.[126,132,134] The observed difference in survival may have been due to the poorer prognosis of control subjects who did not demonstrate acute reactivity. Calcium channel blockers are reserved for subjects with class II and III symptoms who display acute reactivity and remain stable.[135] Recent data suggest that of both children and adults, who are initially suitable for treatment with calcium channel blockers, at least one half will require additional therapy within 5 to 10 years of presentation.[136]

Specific PAH Therapies

The current understanding of the mechanisms underlying PAH has led to the development of therapies that have favorably influenced survival, exercise capacity, hemodynamics, and quality of life. These agents have protean effects on the pulmonary vasculature. They are effective, in part, because they redress the imbalance of mediators in PAH which favors not only vasoconstriction but also vascular remodeling and thrombosis. There are four main classes acting upon three main intracellular pathways (see Fig. 53-3).[64]

1. *Synthetic prostacyclin (epoprostenol) and prostacyclin analogs:* Epoprostenol has been tested in two randomized controlled trials of subjects with iPAH.[137,138] Improvement in symptoms, exercise capacity, and hemodynamics was demonstrated in treated subjects. To date, epoprostenol remains the only agent that has been shown, in a randomized, controlled trial, to improve survival in subjects with iPAH.[138] The long-term use of epoprostenol has been shown to significantly improve survival when compared to historical controls.[124,139] Improved survival has also been reported in retrospective trials of children with iPAH and those with congenital heart disease.[140]

Use of intravenous epoprostenol is limited by the need for a continuous intravenous infusion pump and associated problems of line sepsis, as well as flushing, gastrointestinal disturbance, and headaches, which may occur as a direct effect of the medication.

Several randomized controlled trials have been performed with prostacyclin analogs. Both continuous subcutaneous infusion of treprostinil and inhaled iloprost, which has to be given at least eight times per day, have been shown to improve exercise capacity and hemodynamics in 3-month randomized trials.[141,142] Beraprost, an orally active analog, showed improvement in exercise capacity and clinical events in a randomized trial at 6 months but the benefit was not sustained at 12 months.[143]

2. *Endothelin-1 receptor antagonists:* Two randomized trials of bosentan, a dual endothelin receptor antagonist, have shown improvement in multiple parameters including exercise capacity, functional class, hemodynamics, and time to clinical worsening.[144,145] Preliminary data for both sitaxsentan and ambrisentan, orally active endothelin A receptor antago-

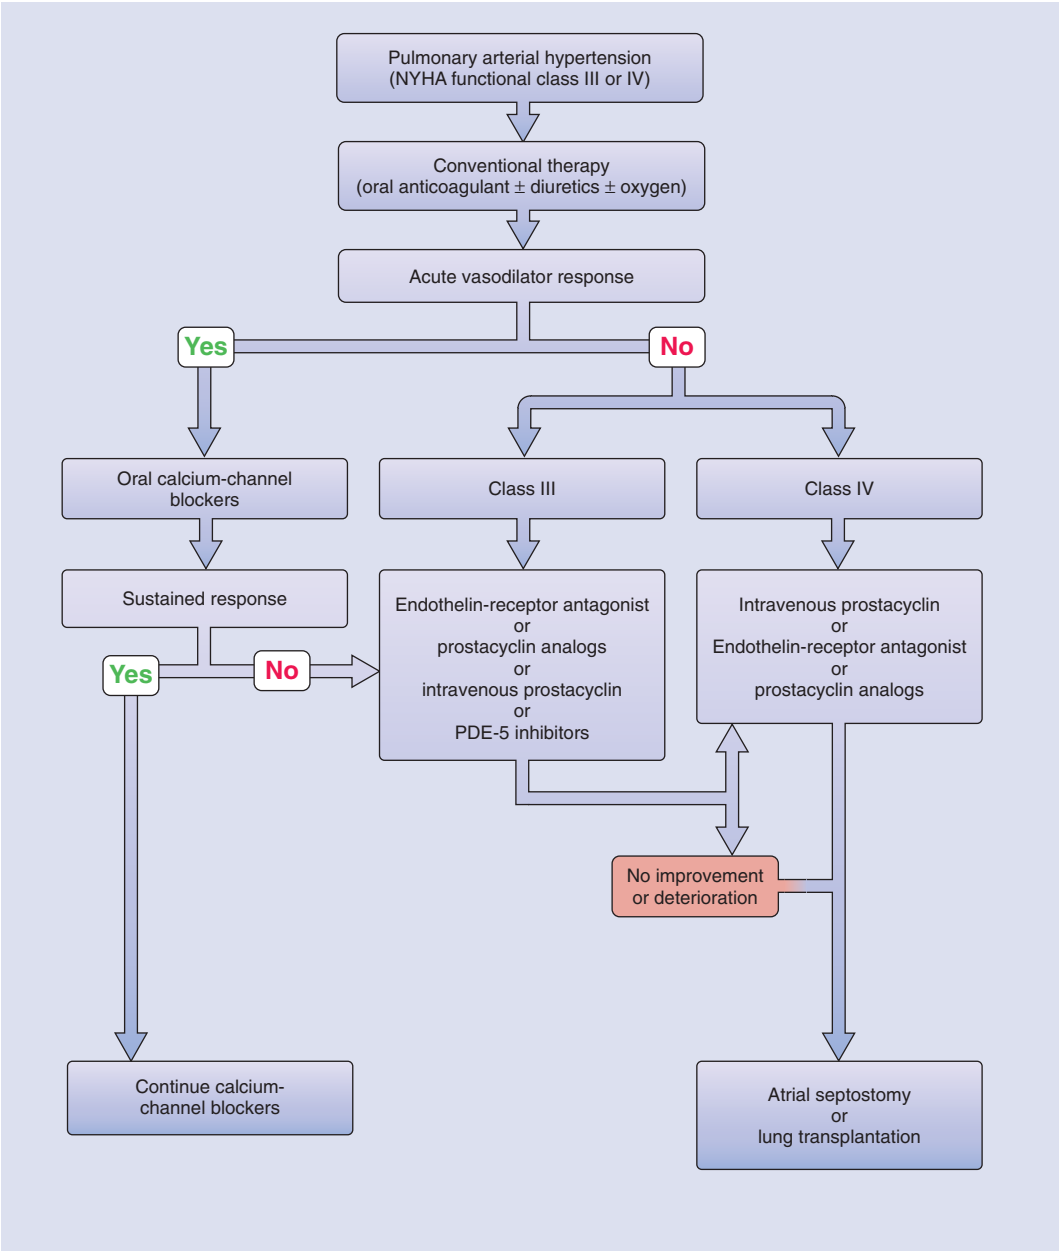

Figure 53-4 Algorithm for the treatment of pulmonary arterial hypertension. This algorithm applies only to patients in NYHA functional class III or IV, because very few data are available for patients in NYHA function class I or II. The treatments have been evaluated mainly in idiopathic (primary) pulmonary arterial hypertension and in cases associated with systemic sclerosis or with exposure to anorectic agents. The drugs of choice for testing of acute vasoreactivity are short-acting agents (e.g., intravenous prostacyclin, intravenous adenosine, or inhaled nitric oxide). Patients with a sustained benefit from calcium-channel blockers are defined as those in NYHA functional class I or II who have near-normal hemodynamic values after at least 1 year of follow-up. Most experts recommend that patients in NYHA functional class IV receive continuous intravenous epoprostenol. The experience with phosphodiesterase type 5 (PDE-5) inhibitors, including sildenafil, is preliminary, and controlled studies are ongoing to determine its efficacy and safety. The combined use of drugs with different mechanisms of action warrants further investigation. Lung transplantation is considered an option for all eligible patients who remain in NYHA functional class IV after 3 months of receiving epoprostenol. Atrial septostomy is proposed for selected patients with severe disease.

nists, suggest improved exercise capacity and hemodynamics comparable to bosentan.[135]

3. *Phosphodiesterase-V inhibitors:* Several preliminary reports and one randomized crossover study of sildenafil[146] have reported improvement in symptoms and exercise capacity in subjects with PAH. A placebo-controlled trial has reported improvements in 6-minute walk test, WHO functional class, and hemodynamics.[147] The role of sildenafil in the treatment algorithm for subjects with PAH is as yet unclear but it may be a reasonable alternative to bosentan or nebulized iloprost, especially in patients in WHO functional class II or III.

4. *Nitric Oxide (NO) and NO donors:* Inhaled NO is a potent selective pulmonary vasodilator and can lower pulmonary pressures, improve hemodynamics, and improve oxygenation in the ventilated patient.[148] Outside of this setting, its use is limited by the toxic product of its metabolism and practicalities inherent in delivering it by the continuous inhaled route.[149]

L-Arginine is the substrate from which NO is produced and trials of L-arginine suggest that although it may have limited effects on pulmonary pressures,[150] overall it probably provides no clear benefit.[149]

The number of available therapies for patients with iPAH has led to the development of suggested treatment algorithms as shown in Figure 53-4. Whatever therapies are employed it is important to carefully monitor the patient by use of symptoms, serial echocardiography, measurements of exercise tolerance and, occasionally, repeat cardiac catheterization. This will help guide escalation or gradual reduction in therapy, allow better assessment of prognosis, and consideration of timing for listing for transplantation.

TREATMENT OF ASSOCIATED PAH

It is important to diagnose or exclude conditions that are known to be associated with PAH, not only because these conditions warrant therapy in their own right, but also because treatment of the underlying condition may itself improve pulmonary pressures and associated hemodynamics.

There is increasing evidence for the use of the specific PAH therapies discussed above to control PAH when it is associated with the connective tissue diseases, especially scleroderma,[145,151,152] and when it is seen in association with HIV infection,[153] portopulmonary hypertension,[154,155] and hematologic abnormalities.[156] The role for anticoagulation in these conditions is less clear, and the risk-to-benefit ratio needs to be assessed in scleroderma because of associated reflux esophagitis and also in portopulmonary hypertension and some myeloproliferative disorders because of coagulopathy, thrombocytopenia, and other risks of bleeding.[2] In terms of specific therapies, in portopulmonary hypertension, although potentially effective, there is an increased risk when using bosentan or other drugs with hepatic toxicity.[2] Further, beta-blockers, which are normally used to treat portal hypertension and reduce risk of variceal bleeding, should be used with caution because of their negative inotropic effects on the right ventricle. The phosphodiesterase inhibitors such as sildenafil are contraindicated in patients who are receiving highly active antiretroviral therapy (HAART) for HIV disease because of reports of sudden death owing to markedly increased plasma levels.

In PAH associated with connective tissue diseases, there are reports of improvement in pulmonary pressures with immunosuppressive therapy.[157-159] This is more likely to be seen with SLE and mixed connective tissue disease, and there is little indication for corticosteroid and/or other immunosuppressive therapies in scleroderma-associated PAH—unless there is associated pulmonary fibrosis.[160,161] Treatment of thyrotoxicosis, where present, may help reduce pulmonary pressures.[53] Whole-lung radiotherapy has been shown to reduce pulmonary pressures where extramedullary hematopoiesis was found to be contributing to elevated pulmonary pressures seen in some patients with myeloproliferative disorders.[162] Corticosteroid therapy was shown to contribute to reduction in pulmonary pressures in a series of patients with POEMS syndrome.[48] The withdrawal of anorexigens has been associated with improvements in pulmonary pressure.[163] Chelation therapy may be helpful in β-thalassemia–associated PAH[164] and hydroxyurea helpful in the PAH associated with sickle cell disease.[51,156] There have been case reports suggesting improved pulmonary hemodynamics following HAART in HIV-associated PAH.[46,165]

In patients being assessed for liver transplantation, the presence of portopulmonary hypertension is associated with increased perioperative risk and is usually considered a contraindication to transplantation.[166] However, treatment with selective PAH therapies may reduce PVR sufficiently to allow transplantation to be performed successfully.[167,168] Further, if hepatic transplantation is feasible in these patients, then this may result in improvements in pulmonary pressures.[169]

Patients with PVOD and PCH may benefit from specific PAH therapies but these need to be used with great caution because of the high risk of developing pulmonary edema—especially with epoprostenol. The only curative therapy for these two conditions is lung transplantation.[2]

Atrial Septostomy

The observation that patients with iPAH and a patent foramen ovale (PFO) have a survival advantage over those without a PFO has led to the therapeutic intervention of balloon atrial septostomy, which results in the formation of an intra-atrial right-to-left shunt.[170] In patients with severe iPAH, this shunt allows decompression of the volume-overloaded right ventricle, thereby reducing signs and symptoms of right heart failure, and results in increased left ventricular preload, improving systemic cardiac output, and reducing symptoms such as syncope.[171] Further, despite a fall in systemic arterial oxygen tensions, the increased cardiac output allows greater systemic oxygen delivery.[172] Studies have shown improvements in cardiac index following atrial septostomy from between 15% and 58%,[172-175] which appear to correlate with improved functional class, exercise capacity, and possibly survival.[172,174] Occasionally the procedure needs to be repeated because of subsequent closure of the defect.[172]

However, atrial septostomy is associated with a mortality of between 5% and 50% depending on the center's experience and patient selection.[176] Therefore, its role is probably limited to highly experienced centers where septostomy is performed with low morbidity, and reserved for patients with severe iPAH suffering from recurrent syncope or right heart failure and in whom other therapies are unavailable or have failed or as a bridge to transplantation.[177]

Lung Transplantation and Combined Heart and Lung Transplantation

Either single (SLT) or bilateral lung transplantation (BLT) or heart-lung transplantation (HLT) have been employed for patients with severe iPAH and may improve survival and quality of life.[178] Benefits from transplantation are limited by a lack of suitable organs[179] (a problem compounded in children), by relatively high rates of early mortality when compared to transplantation for other indications, and by the development of chronic graft dysfunction or bronchiolitis obliterans syndrome.[178,180-182]

The international survival figures following transplantation for iPAH are 65%, 46%, and 25% at 1, 5, and 10 years, respectively.[178] Overall median survival is approximately 4 years with a slight trend to better survival for BLT that does not reach statistical significance. Survival figures are generally worse for pediatric recipients compared to adult recipients. Transplantation is best reserved for selected patients with functional class III or IV who deteriorate despite medical therapy. The timing of listing is complicated by the unpredictability of the period on the waiting list. A recent study found that for those being treated with epoprostenol for at least 3 months, persistence of functional class III or IV and failure of PVR to fall by more than 30% from baseline, as well as presence of right heart failure, were associated with a poor prognosis. The authors recommended that the presence of any of these factors should give rise to consideration of listing for transplantation.[124]

Combined liver and lung or heart-lung transplantation has occasionally been performed for portopulmonary hypertension.[183] Transplantation for PAH in association with scleroderma is not offered by many centers because of generally poor results, and the presence of HIV disease is usually considered an absolute contraindication to transplantation.[184]

PROGNOSIS

Prior to the advent of epoprostenol and the other specific PAH therapies, the prognosis for patients with iPAH had been well defined by several studies including the National Institute of Health (NIH) registry.[125] There was an estimated median survival from presentation of 2.8 years. Prognosis was worse the lower the cardiac index, and the higher the mean pulmonary artery pressure and mean right atrial pressure.

Treatment with epoprostenol has impacted favorably on survival.[124,139] Typical results from adults receiving a continuous epoprostenol infusion have suggested a median survival in excess of 5 years. Similar improvements have been seen in children.[140] Use of first-line bosentan has also been shown to improve survival in a group of patients in WHO functional classes III and IV.[185] In this study, the 2-year survival was 89% compared to a predicted 2-year survival of 57% for historical controls from the NIH registry.

The prognosis for patients with HIV-associated PAH and scleroderma-associated PAH appears to be worse than for iPAH. Survival for patients with Eisenmenger syndrome is superior than that for iPAH.[186]

FUTURE DIRECTIONS

Although the outlook for patients with PAH has improved considerably, PAH is incurable and many patients still die.[1-3,57] Even in those who obtain a good response to therapy, the hemodynamics often will not normalize. Better outcomes are likely to result from further improving the understanding of the disease process. It is still not fully understood which cells initiate the process and why. Further, it remains unclear if, once established, this process is inexorably progressive or if it requires ongoing stimuli with the potential for reversal.[105]

Screening for Disease

On most occasions, PAH is diagnosed late in the disease with most patients having significantly reduced exercise capacity and increased PVR by time of diagnosis. Diagnosing patients earlier in their disease course is an attractive proposition because earlier treatment may be more effective and prevent onset or progression of disease. This has led to the development of screening programs for those at risk, such as patients with scleroderma[187] or family members of affected individuals.[1] The role of exercise echocardiography and other noninvasive screening tests to help establish the disease in asymptomatic or minimally symptomatic individuals requires further evaluation.[188,189] Because of incomplete penetrance, genetic testing of family members, if offered, should include careful and detailed counselling.[1]

Combination Therapies

Current therapies act on three intracellular pathways, nitric oxide, prostacyclin, and endothelin, known to be abnormal in PAH (see Fig. 53-3). A logical extension is to use a combination of two or more of therapies—each acting on a different one of these pathways.[190,191] Such an approach is successful in systemic hypertension, and uncontrolled case series in PAH have suggested that this may be beneficial but further work is required.[192,193]

Emerging and Potential Therapies

There are data suggesting that tackling other pathways known to be involved in the pathogenesis of PAH may be promising. Tackling the serotonin pathway has led to the use of SSRIs, which inhibit serotonin transport. These have been shown to protect against hypoxia-induced pulmonary hypertension.[74]

Inhalation of vasoactive intestinal peptide may be efficacious.[194] Given the importance of platelet aggregation in the pathogenesis of PAH, there is potential benefit in the use of aspirin or other platelet inhibitors as well as other anticoagulants with less toxicity than those currently available.[195,196]

The hydroxy methyl glutaryl-coenzyme-A reductase inhibitors or statins have pleiotropic effects on the vascular wall, including preventing downregulation of endothelial NO synthetase and repressing the vascular smooth muscle proliferative effects in response to PDGF.[197,198] Statins are known to protect against experimental forms of PAH[199] and case reports of their use suggest promise.[200]

Tyrosine kinase is central to the actions of the growth factors PDGF, EGF, and VEGF. The tyrosine kinase inhibitor imatinib (Glivec) reverses two experimental forms of PAH[201] and has been shown to improve exercise capacity and hemodynamics in a patient who was deteriorating despite established therapies.[202] Elastase inhibitors ameliorate experimental forms of PAH[87,203] but clinical studies are required. Additionally, targeting the angiotensin pathway[204] and abnormalities in the K^+ channels may provide useful alternatives,[60] as might inhibitors of the chemokine fractalkine.[88] IL-1 inhibitors reverse PAH in animal models induced by inflammation and warrant further study.[205]

Further, the use of VEGF gene transfer has promise, as do other forms of gene therapy.[60] Increasing data show that bone marrow–derived progenitor cells such as progenitor endothe-

lial cells, fibroblasts, and smooth muscle cells migrate to the pulmonary vasculature and contribute, at least in part, to pulmonary vascular remodeling.[62] Therefore, a future therapeutic option may include stem cell and bone marrow transplantation.[105]

Pharmacogenomics

The relation between genetic and environmental factors in the pathogenesis of PAH is complex and likely not to be the same in all forms of PAH. Understanding which genetic factors are important in an individual may influence which therapies are likely to be more effective; therefore, there is potential application for pharmacogenomics in the future treatment of PAH.

CONCLUSIONS

Despite advances, pulmonary arterial hypertension remains an incurable disease, which is usually diagnosed late in its clinical course. Therefore, it is important to consider the possibility of pulmonary hypertension in any patient presenting with unexplained dyspnea and/or fatigue. There is a potential that screening programs in at-risk groups may allow earlier diagnosis at a time when treatment may be more effective.

When a patient is found to have pulmonary hypertension, it is necessary to establish whether the problem is pulmonary arterial hypertension or another cause (as per the WHO-sanctioned classification), consider possible contributing factors, and assess the prognosis. If pulmonary arterial hypertension is diagnosed, the clinician has several effective treatments available and once treatment is commenced, patients require ongoing careful assessment to determine if there is a need to increase therapy and consider listing for transplantation. With the advent of newer therapeutic strategies, it remains to be seen if pulmonary arterial hypertension can become a chronic manageable problem with prolonged survival and minimal impact on quality of life.

CHAPTER 54 Pulmonary Embolism

Brenda Wittman and Richard Donnerstein

TEACHING POINTS

- Although a pulmonary embolism is unusual in children, the diagnosis is frequently missed.
- Most pediatric patients with a pulmonary embolus will have one or more significant risk factors.
- Although most patients will be symptomatic, clinical findings are generally nonspecific and are frequently attributed to an underlying disease.
- The primary diagnostic imaging modalities are selective pulmonary angiography, ventilation/perfusion scanning, and computed tomography.
- In most cases, the object of therapy is to prevent clot extension and recurrence through the use of anticoagulants. Early treatment is with unfractionated or low molecular weight heparin followed by longer therapy with warfarin or low molecular weight heparin. The use of thrombolytics is controversial.
- If diagnosed and treated early and appropriately, mortality from a pulmonary embolus in children is significantly less than in older individuals.

Pulmonary thromboembolism is defined as pulmonary arterial obstruction by embolism or local thrombus. Although pulmonary emboli may be caused by air, fat, amniotic fluid, tumors, infected masses, or foreign bodies, as well as thrombus, this chapter refers primarily to thromboemboli.

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Although it has been more than 140 years since Löschner described a case of a pulmonary thromboembolism in a 9-year-old child,[1,2] pulmonary embolism is infrequently clinically diagnosed or treated in children.[2-4] The reported incidence of pulmonary embolism in childhood depends on the population investigated, diagnostic techniques, and clinical suspicion. Results from registries, hospital discharge data, and autopsy series differ.[3-9] Excluding autopsy data, studies have suggested an annual incidence of thromboembolic disease of about 0.5 to 0.8 per 100,000 children beyond the neonatal period, with about 10% to 20% of these having a pulmonary embolus.[5,7-9] Hospital discharge data from the United States estimated an incidence of about 0.9 per 100,000 children per year with the rate in African-American children 2.4 times higher than that in European-American children.[6] However, autopsy data suggest that the incidence of pulmonary embolism in infants and children is likely to be underestimated to a significant degree.[3] There is a bimodal age distribution of thromboembolic events with the highest incidence in neonates followed by a peak in adolescence.[5-8,10-14] When pulmonary embolism is specifically investigated, the incidence appears to be significantly higher in select populations such as children with nephrotic syndrome or with long-term central venous lines.[15,16] Although it is a common event in adults, fatal pulmonary embolism is a relatively unusual occurrence in infants and children.[3,17] Nonetheless, autopsy series have suggested that most clinically significant pulmonary emboli in children are not recognized before death.[3]

Virchow noted more than 150 years ago that the risk of thrombosis is increased with stasis of blood flow, injury to the vessel wall, and hypercoagulability of blood.[15,18] Specific processes in younger patients that result in stasis, vascular injury, or hypercoagulability differ from those in adults. High-risk factors in children and adolescents include infection, malignancy, trauma, immobility, pregnancy or use of oral contraceptives, nephrotic syndrome, ventriculoatrial shunts for hydrocephalus, central venous catheters, congenital coagulation disorders, and cardiac diseases—particularly cardiomyopathies or the presence of a right heart bypass procedure such as the Fontan.[2-6,11,15,16,19-25] Although many thromboses in neonates are associated with indwelling central catheters, these are frequently related to other risk factors such as maternal disease, peripartum asphyxia, dehydration, septicemia, trauma, congenital heart disease, or recent surgery.[5,12,26]

Whereas nearly 30% of adults may have no identifiable cause for a thrombosis, significant risk factors are found in almost all children with a thrombosis.[5,7,16,17,21,27] Children and infants in intensive care settings are at particular risk for thromboembolism because of the high incidence of immobility, central venous catheterization, and recent operations.[2,28] Advances in pediatric critical care and more frequent use of central venous lines have increased the incidence of pulmonary embolic disease.[17,29,30] Central venous catheters have become the most important acquired risk factor for thrombotic disease in children and neonates and are the leading cause of death from pulmonary emboli.[7,30] Possible mechanisms for catheter-induced thromboemboli include damage to the vessel wall, infused substances, blood flow obstruction, and thrombogenic catheter materials.[16]

Multiple defects in the hemostatic system have been associated with thromboembolism.[19,31,32] Inherited deficiencies

of the endogenous anticoagulants protein C, protein S, factor V Leiden, and antithrombin III have been observed in some patients with thromboembolism.[13,20,31,32] Numerous other congenital defects of the coagulation system such as activated protein C resistance, dysfibrinogenemia, or prothrombin 20210 mutations have also been identified.[11,13,16,20,32] Increased levels of lipoprotein(a) and homocysteine may also be risk factors.[13,20,32] Thrombophilia may also be acquired from conditions such as systemic lupus erythematosus, antiphospholipid syndrome, or nephrotic syndrome.[20,31,32] Screening is indicated for children with spontaneous thrombotic events where a significant proportion have been found to have prothrombotic disorders but remains controversial in the presence of other significant risk factors.[11,13,18,20,21,31,32] Patients with homozygote or multiple inherited disorders are at significantly higher risk.[13,20]

As in adults, pulmonary embolism in children is frequently associated with a deep vein thrombosis. The anatomic sites of venous thrombi associated with pulmonary emboli in children differ from those in adults. Similar to adults, the child described by Löschner had a symptomatic thrombus of a lower extremity.[1,2] However, when compared with thrombi in adults, venous thrombi in children are often asymptomatic and are less likely to involve the veins of the pelvis or lower extremities and more likely to involve the upper venous system.[1,7,12,27,30]

An acute increase in pulmonary vascular resistance associated with right-ventricular failure and shock is the principal cause of death after pulmonary embolism.[15] In the absence of preexisting pulmonary hypertension, mean pulmonary pressure increases approximately in proportion to the degree of obstruction of the pulmonary arteries.[33] Because of the limited ability of the normal right ventricle to respond to an acute increase in afterload, a right-ventricular systolic pressure greater than 60 mm Hg, or a mean pulmonary artery pressure of 30 to 40 mm Hg, represents severe pulmonary artery hypertension.[33-35] However, patients with underlying chronic pulmonary hypertension may generate right-ventricular pressures near or greater than systemic pressures.[33,35] Although vasoactive substances and baroreceptor reflexes may affect pulmonary vascular resistance after pulmonary embolism, vascular obstruction by the embolus is probably the major cause of the pulmonary hypertension.[33] Inflammatory mediators may alter capillary permeability and surfactant function, which can significantly compromise pulmonary function.[17,25]

Acute changes in ventilation and perfusion result in abnormalities of gas exchange.[22,33,36] Following a pulmonary embolus there is a redistribution of blood flow from obstructed to nonobstructed lung units. An increase in alveolar dead space, resulting from a ventilated but poorly perfused lung, can affect CO_2 elimination.[33,36] However, except for the most severe pulmonary embolism, hyperventilation compensates for this increased dead space, and many patients are hypocarbic.[22,33,36,37] This hyperventilation and resulting hypocapnia are rarely eliminated by the correction of hypoxemia with supplemental oxygen, suggesting that it is a reflex response of proprioceptors or chemoreceptors to stimuli other than oxygen or carbon dioxide.[33] Abnormalities of ventilation and perfusion, right-to-left shunting through a patent foramen ovale, right ventricular failure, and decreased mixed venous saturation caused by a low cardiac output may all contribute to an abnormally low PaO_2.[22,33,36,38] When resulting atelectasis and pulmonary edema contribute to hypoxemia caused by a pulmonary embolus, supplemental oxygen or positive airway pressure may help alleviate the hypoxemia.[33,36,38] Arterial blood gas abnormalities such as hypoxemia or hypocarbia may not be as prominent in adolescents and young adults as they are in older adults.[22] This is probably because of the more intact pulmonary bed and cardiopulmonary reserve in most younger patients.[15,22]

Pulmonary infarction is unusual following a pulmonary embolus[33]—probably because of multiple sources of oxygen supply to the lung tissue. When infarction does occur, it may be due to obstruction of distal pulmonary arteries and hemorrhage into the airways.[33]

CLINICAL FEATURES

Most small pulmonary emboli are asymptomatic.[15] The presentation of a symptomatic pulmonary embolus may often be subtle and nonspecific, and this is probably especially true for younger patients.[18,22,25,27] Because most children will have significant risk factors, the presence of a primary disease may further complicate the diagnosis.[17,18,27,30] For many reasons, a diagnosis of pulmonary embolism is frequently delayed in children.[18,23] Clinical diagnosis may be particularly difficult in infants because underlying respiratory disease is common.[21] The most common symptoms of pulmonary embolism, such as chest pain (pleuritic or nonpleuritic), shortness of breath, cough, tachycardia, hemoptysis, and diaphoresis, are nonspecific and may occur in a variety of disease states—including acute respiratory infections.[3,4,18,20,22,28] Moreover, the diagnosis of pulmonary embolism is often masked by the underlying disease, or concomitant sedation, muscle relaxation, or artificial ventilation. Although patients may present with acute right heart failure, hypotension or even sudden death,[27] signs of pulmonary or cardiac dysfunction are less common in younger patients than in adults.[22] Nonetheless, data from two large registries have shown that almost all children with a significant pulmonary embolus will be symptomatic.[5,17] Chest pain is the most common presenting complaint in teenagers.[4,18] The nonspecificity of the signs and symptoms makes diagnosing a pulmonary embolism solely on clinical grounds hazardous.[4] Nonetheless, this diagnosis should be considered in the evaluation of unexplained shock, pulmonary hypertension, respiratory insufficiency, or other pulmonary symptoms in children—particularly in the presence of risk factors.

DIAGNOSIS

Prompt diagnosis and therapy can significantly reduce mortality in patients with a pulmonary embolus. Unfortunately, because symptoms are frequently nonspecific, clinical diagnosis is not reliable and this diagnosis is often not considered in children. The relatively low incidence of pulmonary embolism and problems of long-term anticoagulation in the pediatric age group make accurate diagnosis essential.[17] Chest radiographs and electrocardiograms are often normal in young patients with a pulmonary embolus, and abnormalities, if present, are usually nonspecific.[15,17,22,25,27] Although most

patients will have some degree of hypoxemia, a significant proportion will have a normal $\mathbf{PaO_2}$ and the alveolar-arterial oxygen tension difference, $P(A\text{-}a)O_2$, is a more sensitive indicator of problems with gas exchange.[22,37,39]

D-Dimer quantification is a sensitive technique for detecting conditions in which thrombus is formed.[25,28,40] Although it is highly sensitive for excluding a pulmonary thromboembolic event in adults with a low pretest probability, a positive test lacks specificity and may not be helpful.[15,40] This is particularly true in children because D-dimer levels may be elevated owing to their underlying disease.[27] In children considered at high-risk, a negative result should not alter the decision to pursue further evaluation.[17,28]

Much of the information regarding imaging modalities available for the diagnosis of pulmonary emboli in children has been derived from adult experience. Currently available techniques include pulmonary angiography, ventilation/perfusion ($\dot{V}/\dot{Q}$) scans, computed tomography (CT), magnetic resonance imaging (MR) and echocardiography.[16,20]

Selective pulmonary angiography remains the standard and should be considered in children and adolescents with a suspected pulmonary embolus (Fig. 54-1).[15,17,18,20,21,25,27,40] Nonetheless, because of the relative invasive nature and risks of pulmonary angiography, other imaging modalities are now more frequently used.

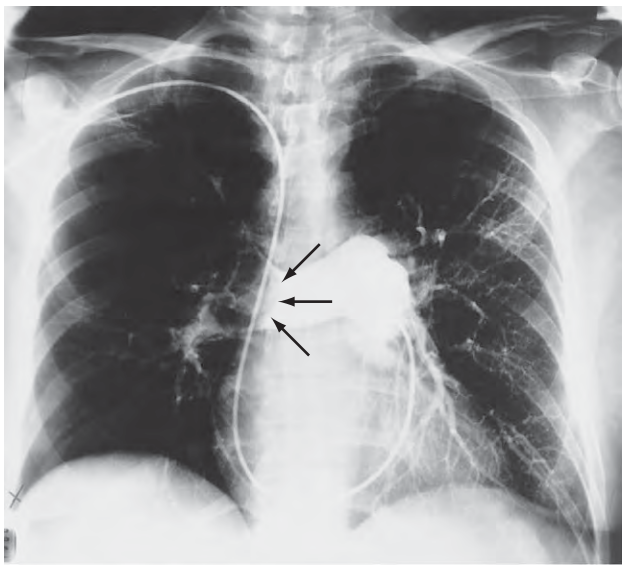

Figure 54-1 Pulmonary angiography in a patient with pulmonary embolism. A large filling defect is seen in the proximal right pulmonary artery (*arrows*). Smaller filling defects are seen in branches of the left pulmonary artery.

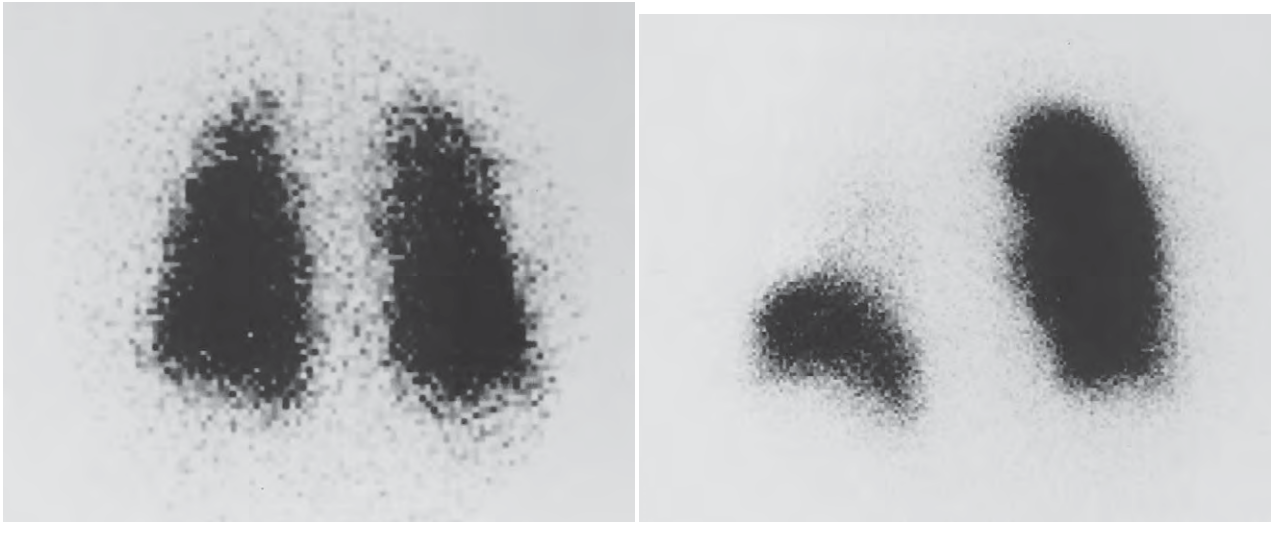
In the presence of obstructed pulmonary vessels caused by pulmonary embolism, **ventilation and perfusion radionuclide studies** would be expected to show mismatched defects with areas of absent or abnormal pulmonary perfusion associated with normal ventilation (Fig. 54-2). Whereas a high-probability scan strongly suggests pulmonary embolism, a significant portion of adult patients with proven pulmonary embolism will not have a high-probability scan.[15,40] Patients with normal scans rarely have a clinically significant pulmonary embolus.[15] However, the majority of scans are nondiagnostic.[17,27,40] Although a matched defect (abnormal ventilation and perfusion) suggests other pulmonary disease, a pulmonary embolus cannot be excluded.[2] These studies are frequently used in children[15,17,18,20,21,27] and may be highly suggestive of the diagnosis. However, scans are often not definitive for the diagnosis of pulmonary embolism,[17,27] and other imaging methods may be necessary.

Magnetic resonance imaging and **computed tomography** may detect significant emboli in the central pulmonary arteries.[15,17,21,27] Modern multidetector CT scanners have significantly improved diagnostic capability when compared to earlier generations, and spiral CT pulmonary angiography is now commonly used as the initial imaging modality to diagnose pulmonary thromboemboli (Fig. 54-3) in adults[15,40,41] as well as children.[17,18,27] In adults, they yield fewer nondiagnostic results when compared to $\dot{V}/\dot{Q}$ scans.[15,27]



A B

Figure 54-2 Ventilation and perfusion scans from a patient with pulmonary embolism. **A,** Posterior view of the ventilation scan shows normal xenon-133 distribution in both lungs. **B,** Posterior view of the perfusion scan demonstrates markedly decreased perfusion of the left upper lobe with smaller filling defects of the right lung.

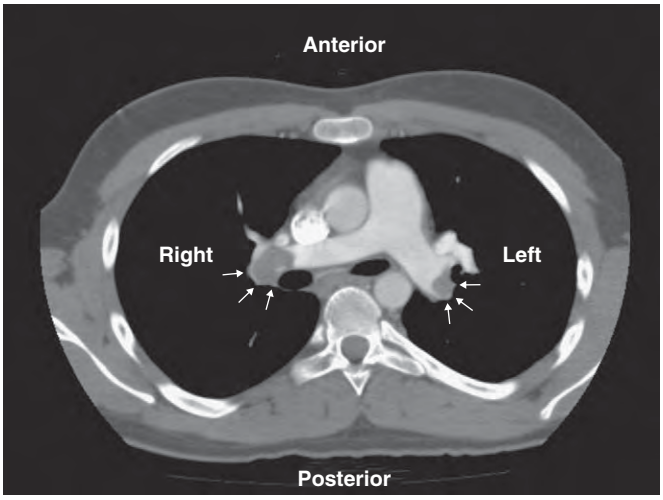


Figure 54-3 Computed tomographic angiography in a patient with pulmonary embolism. Large thrombi are seen in both the right and left pulmonary arteries.

Disadvantages include the need for contrast agents requiring satisfactory renal function, significant radiation exposure,[15,27] and insensitivity to small, subsegmental thrombi.[17,27,40] Although it is considered reasonable to withhold treatment in adults with a negative spiral CT scan, it is unclear whether this is also true for children, especially in a high-risk patient.[15,17]

Magnetic resonance angiography has also been shown to be an effective imaging modality with high specificity and reasonable sensitivity for the diagnosis of a pulmonary embolus.[15,27] Although it may be insensitive to small emboli, it has the advantages of being noninvasive and requiring no radiation.[27] Disadvantages include long imaging times and difficulties in obtaining the study in some acutely ill patients. It is likely that continued advances in computed tomography and magnetic resonance imaging will further improve their usefulness for diagnosing pulmonary emboli in the pediatric population.[25]

Transthoracic **echocardiography** has poor sensitivity for diagnosing pulmonary embolism.[42,43] However, this technique is useful for detecting signs of acute right-ventricular overload or failure, and many patients with a significant pulmonary embolus will have detectable echocardiographic abnormalities.[18,42,44,45] Even if pulmonary embolism is diagnosed by other means, echocardiography should be performed to assess right-sided hemodynamics.[44-46] In adults, significant hemodynamic changes suggest obliteration of more than one third the pulmonary arterial bed.[25,35,42,44] When acute right-ventricular afterload is excessive, right-ventricular failure will ensue with passive venous congestion and a decrease in forward cardiac output. Echocardiography may help identify those patients with significant hemodynamic compromise before the onset of clinically apparent cardiogenic shock and assist in stratifying risk and assessing response to therapy.[42,45-47] Two-dimensional echocardiographic findings that suggest a pulmonary embolus include dilation or hypokinesis of the right ventricle, abnormal ventricular septal motion, or decreased left ventricular diastolic size.[42] Thrombi within the right-sided cardiac structures such as the right atrium, right ventricle, or proximal pulmonary arteries, as well as the venae cavae, may also be detected.[18,34,35]

Doppler echocardiography can accurately estimate pulmonary pressures in the presence of tricuspid or pulmonary regurgitation.[34,35] Many normal individuals and most patients with acute pulmonary embolism and right-ventricular failure will have some degree of tricuspid regurgitation. In the absence of structural heart abnormalities, flow velocities of tricuspid regurgitation can be used to estimate systolic right-ventricular, and therefore, systolic pulmonary artery pressures, whereas pulmonary regurgitation flow velocities can be used to estimate diastolic pulmonary artery pressures.[34] Color-flow Doppler or contrast echocardiography can be used to assess for the presence of a patent foramen ovale as a source of right-to-left shunting.[42]

TREATMENT

Mortality from pulmonary emboli can be significantly reduced if promptly diagnosed and treated.[20] Unfortunately, there are no large randomized controlled pediatric trials for thrombolytic and anticoagulant agents, and most recommendations for children have been extrapolated from adult studies.[18,21,28,48-52] Because the coagulation and fibrinolytic systems are age-dependent, infants and children respond to anticoagulation and thrombolytic agents differently than adults and regimens should consider both weight and age.[7,11,17,52-54] However, definitive protocols for treatment of pulmonary emboli in children will almost certainly lag behind those of adults because of the scarcity of pediatric patients diagnosed and treated for pulmonary embolism.

Because a major objective of treatment for pulmonary embolism is to prevent clot extension and recurrent emboli, anticoagulation is used in most patients.[16,18,19,21,55] When possible, a pediatric hematologist with experience in treating thromboemboli should be involved in the care of these patients.[48,52,55] **Unfractionated heparin** (UFH) has the advantage of a short half life and is easily reversible if bleeding develops or if the patient needs an emergent invasive procedure.[52,55] UFH may be started with an initial bolus of 75 to 100 U/kg over 10 minutes followed by continuous infusion at a rate of 20 U/kg/hour for children over 1 month of age and 28 U/kg/hour if younger than 1 month of age.[14,19,21,52,55] Premature infants and neonates as well as patients with deficiency of antithrombin III may require even higher doses to achieve adequate anticoagulation.[55] The infusion rate should be adjusted to maintain an anti-Xa level of 0.35 to 0.70 or a PTT prolongation to two to three times the baseline value.[14,17,21,52,55] Heparin can be rapidly reversed by administering protamine sulfate.[55]

Pediatric hematologists are using **low molecular weight heparin** (LMWH) more frequently because it has the advantages of subcutaneous administration, fewer adverse effects than unfractionated heparin,[19] and less frequent monitoring of levels.[11,15,17,21,28,52] For enoxaparin, a suggested regimen for children greater than 1 year of age is 1 to 1.25 mg/kg/dose subcutaneously every 12 hours[14,17,19-21,25,52,55] and for infants 1 to 12 months of age 1.5 mg/kg/dose subcutaneously every 12 hours.[14,19-21,25,52,55] Neonates and infants younger than 1 month of age may require initial doses as high as 1.65 mg/kg/dose.[55] When using LMWH, a therapeutic goal for anti-

Xa is 0.5 to 1.0 U/mL in a sample taken 4 to 6 hours after injection.[14,17,19,25,28,52]

When a patient has achieved adequate anticoagulation with heparin, oral therapy with **warfarin** is subsequently started if not contraindicated.[17,19,52,55] The initial dose for children is 0.2 mg/kg/day and then adjusted according to published nomograms.[52] Warfarin therapy should be titrated to obtain an international normalized ratio (INR) of approximately 2.0 to 3.0.[11,19-21,25,28,52] However, warfarin dosages may vary widely between patients and may be difficult to manage in infants and young children. Because of dietary changes, changes in physiologic levels of vitamin K–dependent proteins, and frequent changes in other medications, INR must be monitored closely.[21,25,52,56] Warfarin therapy should overlap therapy with UFH or LMWH, which can then be discontinued when the INR is therapeutic.[14,52] Anticoagulation is generally continued for at least 3 to 6 months and possibly longer if the underlying cause is still present.[17,19,25,52,55] Shorter times may be appropriate for neonates.[52] Long-term LMWH may be used in lieu of warfarin and, for practical reasons, may be easier to manage in neonates and young children.[11,14,28,52]

Although still investigational for pediatric patients, three thrombolytic agents (urokinase, streptokinase, and recombinant tissue plasminogen activator) have been used to dissolve vascular clots and pulmonary emboli in children.[15,19,25,48,51,52,57] Although these agents have been shown to facilitate clot lysis, their use has been limited because of bleeding and other complications.[44,49,51,52,58,59] Short-term results using thrombolytics in children and adults have demonstrated rapid dissolution of the embolus and improvement of hemodynamics.[58,60,61] However, studies in adults have not found a significant long-term difference between the outcome of patients routinely treated with thrombolytic agents or heparin for pulmonary embolism.[44,59,62-65] Except for severe pulmonary embolism with hemodynamic compromise, these results have discouraged the use of these agents for routine therapy in patients with pulmonary emboli and decisions to use it should be individualized.[18,28,44,50-52,60-62,66] When it is thought that potential benefits of thrombolytics outweigh risks, human recombinant tissue plasminogen activator (rt-PA) has become the most common thrombolytic agent used in children.[21,25,28,50,52,54,58,60,67] Suggested infusion rates for rt-PA range from 0.1 to 0.6 mg/kg/hour over a period of 6 hours,[25,50-52,60] but recent studies have suggested that lower doses (0.03 to 0.1 mg/kg/hour for 24 to 96 hours) may be effective in children and have fewer complications than standard doses.[25,51,55,58,60,67] Directed thrombolytic therapy through a pulmonary artery catheter does not appear to be safer or more effective than delivery through a peripheral vein.[52] Concomitant anticoagulation with low-dose unfractionated heparin has been used in some studies, and the patients should be closely monitored and receive replacements of platelets, fibrinogen, or other clotting factors as needed.[51,55,58,60]

Embolectomy can be considered in the presence of a massive pulmonary embolism if thrombolytic therapy is contraindicated, if severe hemodynamic compromise limits the time for response to thrombolytic therapy, or if the patient shows hemodynamic deterioration despite thrombolytic therapy.[25,65,68] Both surgical[15,25,69-73] and transcatheter[15,25,72,74,75] techniques have been reported in infants and children.

Venous filters have been used in children at risk for a pulmonary embolus if their vessels are large enough to accommodate the device.[15,19,76,77] Depending on associated risk factors, these can be positioned in either the inferior or superior vena cava.[66]

CLINICAL COURSE AND PROGNOSIS

The clinical course in a child with a pulmonary embolus is frequently related to the underlying disease and treatment as well as to the embolus itself. Although some evidence is accumulating regarding overall mortality,[5,7,8,29] at this time the long-term risks of complications such as recurrence and pulmonary hypertension remain unknown.[5,8,15,25] The lung has an effective fibrinolytic system and most pulmonary emboli will spontaneously resolve.[46,78] Because of their better underlying cardiopulmonary fitness, when properly diagnosed and treated, mortality from pulmonary embolism in children and younger adults appears to be significantly lower than in older individuals.[7,17,22]

CHAPTER 55 The Global Burden of Asthma

Paulo Márcio Condessa Pitrez, Renato T. Stein, and Fernando D. Martinez

TEACHING POINTS

- Childhood asthma prevalence seems to have reached a plateau after 2 decades of persistent increases.
- Asthma affects children in both developed and developing countries, but the predominant etiology seems to be different in the two areas: atopic asthma is more prevalent in school children of better-off countries, whereas nonatopic asthma is more prevalent in poorer societies.

Asthma is a chronic airway disease occurring at all ages worldwide—frequently beginning in childhood. The prevalence has increased over the last 4 decades in some countries and there are very few places in the world untouched by this illness. It is currently the most common chronic disorder in children. However, it has been demonstrated that the distribution of childhood asthma varies significantly between countries (2% to 33%).[1] Given that asthma is a heterogeneous condition with different phenotypes, its complex genetic-environmental interactions explain the particular expression in different subjects and populations. Despite its uneven distribution, asthma still poses a major global health problem, resulting in extraordinarily high morbidity.[1,2]

It is estimated that around 300 million people currently suffer from asthma in the world. It has been demonstrated that the prevalence of asthma increases as populations become more urbanized and developed.[3,4] This illness brings a significant burden on patients, families, health systems, and society in general. In developing countries, regardless of different prevalence rates, the burden of asthma may be even more serious because of economic, social, and educational limitations associated with poverty and inadequate health care facilities.

The assessment of the impact or burden of a disease on society is essential to improve quality of life, decrease mortality, and reduce costs. This burden can be estimated using parameters such as prevalence, severity/mortality, medical visits, treatment regimens, quality of life, and costs. A new approach was recently developed using a standard unit, called the disability-adjusted life year (DALY). DALY assesses the years of healthy life lost because of a disease—combining information about morbidity and mortality in terms of healthy years lost. World asthma accounts for approximately 1% of all DALYs lost and it is estimated to be about 15 million/year. Moreover, the number of DALYs lost due to asthma is similar to that for diabetes, liver cirrhosis, or schizophrenia.[5]

PREVALENCE

The prevalence of asthma has increased steadily over the last decades. Considering that these changes in prevalence have occurred concomitantly with massive urbanization worldwide, it is estimated that there will be an additional 100 million people with this illness by 2025.[4] There is no clear or unique explanation for these marked increases in prevalence, occurring in a relatively brief period of time. English-speaking countries have the highest prevalence of asthma-related symptoms, ranging between 17% and 30% in the United Kingdom, New Zealand, and Australia. The general trend for asthma to be more prevalent in such affluent nations has suggested the so-called *hygiene hypothesis*, which postulates that the degree of exposure to microbial products, especially in early life, is a major determinant of the likelihood of developing allergies and asthma.[2] It is clear, however, that other factors must be at play, because the ISAAC study has also shown that some developing countries in Latin America have a high prevalence of asthma-related symptoms.[1] Of interest is the fact that, in these countries, the most prevalent form of asthma is one not associated with sensitization to aeroallergens, suggesting that the factors that have determined the observed increases in the prevalence of asthma are heterogeneous and have an impact beyond the presence of atopy.

Despite the fact that the frequency of asthma appears to have peaked in some developed countries,[6,7] asthma continues to be a major health problem in both the developed and developing nations,[8] and addressing its impact on the lives and well-being of children worldwide is a high public health priority.

MORTALITY AND SEVERITY

Data on asthma mortality is difficult to assess and is often unreliable, especially in areas where the health care system is less well organized. Even so, it is estimated that 250,000 people die from asthma every year worldwide. In Europe and the United States, asthma mortality seems to be slightly decreasing over the last 2 decades.[9,10] However, even considering the relative lower prevalence, mortality is higher in developing countries, where diagnosis is not properly carried out and therapy is not widely available.[4] In Brazil, for

example, mortality has been estimated to be 2200 deaths per year over a period of 5 years, which is a much higher frequency when compared with data from more affluent communities. The highest mortality rates in Latin America were found in Mexico and Uruguay.[11,12]

In children from developed countries, asthma often presents racial disparities and a disproportionate burden among the poor. In the United States, black children, and especially those living in inner cities, have a higher risk of developing asthma and visiting emergency departments because of this illness.[13] Moreover, Puerto Rican children have a higher prevalence of lifetime asthma (26%) and recent asthma attacks (12%) when compared with non-Hispanic blacks (16% and 7%, respectively), non-Hispanic whites (13% and 6%, respectively) and Mexican-American children (10% and 4%, respectively).[14] The factors that determine these differences in prevalence and severity between children with distinct ethnic backgrounds from the same population are not well understood. Nevertheless, recent interventional studies to decrease exposure to allergens and other indoor contaminants in inner cities in the United States have suggested that decreasing these exposures may be an effective therapeutic strategy to lessen the burden of disease in these communities.[15]

Hospitalizations are not uncommon in children with asthma. Admissions are a marker of the quality of a health care system. Admission rates for asthma are higher in infants and toddlers. On the other hand, the length of hospital stay increases with age. In developing countries, asthma hospitalization rates and length of stay are higher than in more affluent communities.[16] In Finland, the implementation of a national asthma treatment program has decreased the number of hospitalizations.[17]

Visits to an emergency department (ED) are common in children regardless of asthma severity. In a 2-year survey (2000 to 2001), 67% of acute asthma in EDs occurred in children younger than 15 years.[18] The highest rates of ED visits for asthma in children are among those aged between 1 and 4 years. The peak of visits to EDs occurs in winter. The number of visits to EDs is a good marker of failure of an asthma prevention strategy in a population.

IMPACT ON THE PATIENT AND THE FAMILY

Quality of life is a very important issue in any disease process. Asthma in childhood has a significant impact on the lifestyle of patients and their families. Several factors are directly associated with quality of life. Fear, stress, anxiety, and depression are common psychological features associated with asthma among children. Missed school days, interference with social activities, unscheduled visits to physicians and visits to EDs also have a strong impact on family life. Nearly 50% of the children with asthma report missing one half day or more of school in the last month and 30% reported one or more ED visits in the last year for asthma-like symptoms.[19] Sleeping difficulties are also common and occur in nearly 50% of children with asthma. Tobacco use and alcohol consumption can be higher among asthmatic adolescents.[20] Allergic rhinitis and passive smoking are preventable and treatable factors that are highly prevalent among asthmatics, thereby increasing morbidity.

Questionnaires may be useful to measure quality of life in chronic diseases. Based on clinical experience with the Asthma Quality of Life Questionnaire (AQLQ), Juniper and colleagues developed the Pediatric Asthma Quality of Life Questionnaire (PAQLQ).[21] This questionnaire was developed as a tool to evaluate quality of life in children with asthma and was validated in many countries.[22-25] Further studies comparing quality of life of asthma in childhood are required to pursue better strategies of treatment and prevention of disease.

The uncertainty and unfamiliarity of many characteristics of asthma in children brings significant anxiety and apprehension to the family. Therefore, asthma education must be a continuous process and should be emphasized in every medical consultation. The need for long-term prophylactic treatment, fear of severe attacks, and doubts about adverse effects of medications are some of the major issues that should be constantly stressed in family asthma education.

The cost of treatment is an important issue to be considered in asthma management, and this is especially true among nonaffluent populations for whom available resources are limited. Aggressive policies providing free access to prophylactic treatment for every child with moderate to severe asthma would have a significant impact on the patient's and family's quality of life.

COSTS TO SOCIETY

The economic costs of asthma to society are substantial. Between 1990 to 2000, costs for asthma care increased approximately 50% in the United States, with inpatient costs declining and outpatient costs, especially for asthma medications, increasing. In 1998, the costs of asthma were estimated to be 12.7 billion dollars.[3,26] The financial burden of asthma is both direct in health care costs and indirect in personal burden for the patient and family. Medical consultations, hospitalizations, and prescribed medications are some of the most important direct costs to the society. Time lost from school or work and premature death are very important indirect costs that play a role in the burden of disease. Low quality of life because of asthma is very difficult to measure, but the cost is certainly substantial for any population

HOW TO REDUCE THE BURDEN OF DISEASE

There are different strategies that can be implemented to reduce the impact of the disease in both an individual and on a community level. An approach taken by many health-related institutions is the organization of international or national-based guidelines on the management of asthma for both adults and children. These widely publicized guidelines, such as GINA, the NHLBI Asthma Guidelines, and the British Thoracic Society guidelines, are probably the ones with the greatest public impact.[27-29] Many other local initiatives have been taken in the same direction, but the positive impact of these publications on the burden of disease is not clearly established.

National or local programs have been shown to have some impact on asthma burden, but this impact has been surprisingly less than expected. Despite the fact that the guidelines have been widely publicized, outpatient management of

asthma remains inadequate in most locales.[30] This situation may be the consequence of limited access of the guidelines by physicians or because of their complex format. It seems that education plays a key role in reducing the impact of disease, so the greatest challenge is to produce simplified guidelines that are accessible in different locales, either by physicians or patients and their families. The best strategy seems to be the development of partnerships between health care providers and local communities, in which the need to prescribe and use pharmacologic and environmental preventive measures is not imposed but understood and encouraged. An example of such successful partnerships has been the dramatic decreases in the prevalence of smoking in communities where this collaborative approach has been adopted.

Some studies have shown that low-income urban minority neighborhoods present the highest rates of asthma hospitalizations.[31,32] Many factors may contribute to the correlation between proportion of low-income minority populations in a neighborhood and high rates of asthma hospitalizations. However, asthma hospitalization rates may not necessarily reflect asthma prevalence. It is possible that higher rates of hospitalizations in neighborhoods of low socioeconomic status with predominantly low-income minority residents can result from a high proportion of individuals with severe disease, poor levels of education, mistrust of the health care system, and/or lack of access to preventive medical care. It is not known which factors are the strongest contributors to the urban asthma epidemic. Race/ethnicity, income, and local environmental factors have been associated with these observed high asthma levels, especially in urban areas, for the past 3 decades.[33,34]

Other than possible environmental exposures, perhaps more frequently in low-income communities, differences in health insurance status, access to proper preventive care, and medication utilization/availability may contribute to increased asthma hospitalizations.[35] There are valid data showing that low-income minorities are more likely to obtain asthma care from EDs, a place where they are less likely to receive asthma education on prevention techniques.[36]

There is strong evidence indicating that community-based education for asthma management could have a strong impact in lowering asthma morbidity. Two major needs today are the development of locally adapted, simple management guidelines and access to free preventive medications for all children with asthma. Given the impact that such measures could have in reducing suffering among children worldwide, the very limited accessibility to these resources in most communities is morally unacceptable. Making these resources widely available is, therefore, a high priority for all those who care for children with asthma.

CHAPTER 56 Genes, Environment, and Their Interactions

Peter N. Le Souëf

TEACHING POINTS

- The environmental factors that caused the increase in asthma in the late 20th century are still largely unknown.
- Known or suspected gene by environment interactions have been reported and these can be short-, medium- or long-term.
- Host response to an acute respiratory virus infection is genetically determined and may be impaired in those with atopic genotypes.
- Host response to vaccines is genetically determined and impaired in those with pro-Th2 alleles.
- Exposure to farm animals, cats, and dogs and the associated reduction in susceptibility to asthma is genetically determined.
- Adverse effects of environmental tobacco smoke exposure are influenced by genetic factors, particularly in the genes for glutathione-S-transferase.
- Long-term interactions may act through natural selection—tropical parasitic infections may be critical in these interactions.
- With regard to finding new approaches to the treatment or prevention of asthma, the most promising areas of gene by environment research are exposure to acute viral respiratory infection, animals, and tobacco smoke exposure.
- Nearly one half the world's population live in the tropics and owing to long-term adaptation of the immune system to helminthic infections could be at a much greater risk of developing asthma than those from more temperate climates.

Over the last 10 to 20 years, rapid advances in DNA technologies have allowed an exponential expansion in the number and variety of studies investigating the genetics of disease. With respect to respiratory disease, the great majority of studies have been directed at asthma, chronic obstructive pulmonary disease (COPD), and cystic fibrosis. Cystic fibrosis is very different from asthma and COPD in that it is a single gene defect disease and its genetics are covered in Chapter 61. Asthma and COPD are polygenic diseases with many genes contributing to their susceptibility. As an example of a polygenic disease, asthma is the most instructive, partly because the investigations into its genetic background have been carried out on a longer time scale and on a much greater scope than in COPD. This chapter will focus on the genetics of asthma because this best illustrates the importance of interactions between genes and environment with respect to genetics and respiratory disease.

CURRENT KNOWLEDGE OF GENETIC INFLUENCES ON RESPIRATORY DISEASE

Since the first studies of the genetics of asthma that utilized DNA analysis started nearly 20 years ago, steady progress has been made in understanding the genetics of asthma and more recently COPD. During this period, several findings with respect to asthma have become well established (Box 56-1). To summarize Box 56-1, after 20 years of research into the genetics of asthma, studies have established that asthma is a polygenic disease, with no major susceptibility genes discovered to date, and also thus far asthma genetics studies have made no major contribution to the understanding of the mechanisms of asthma. This situation is a long way from the optimistic predictions made when these studies started. There are several reasons for the slow progress; perhaps the most important of these is the very strong relation between asthma, genes, and environment. The important role of the environment in this triad has been clarified recently, because without an environmental influence, a genetic susceptibility will not be present.[1] A further factor complicating analyses of gene by environment interactions is the paradoxical nature of some of the relationships, with a given allele showing an association with a low level of an environmental load in one region or population, but with the other allele in another population.[2] Another complex relation between an allele and an outcome involves age. For the association between the CD14 C-159T genotype, atopy, and age, one allele was a susceptibility allele for atopy in children but only within a particular age range.[3]

CURRENT KNOWLEDGE OF ENVIRONMENTAL INFLUENCES ON RESPIRATORY DISEASE

Before considering gene by environment interactions, the current state of knowledge of environmental influences on asthma should be taken into account. This subject has been summarized in Chapter 2. Many environmental factors are now known to significantly affect risk factors for the development of asthma. These include: the protective effects of exposure to animals, including farm animals, cats, and dogs,[4,5] respiratory infections in early life;[6] and day care in infancy.[7]

BOX 56-1 Major Findings of Asthma Genetics Studies to Date

Many genes have variations that contribute to the susceptibility to asthma.
Many other genes have variations that affect the severity of asthma.
No single gene provides a substantial contribution to genetic susceptibility or severity, and each of the known genes provides less than 10% of a population's asthma susceptibility.
No genotypes have been found that are consistently related to an asthma phenotype in all populations studied.
Most genes and genotypes for which there is evidence of involvement in asthma were studied because their known function suggested they would be candidate genes for asthma.
In genome-wide screening studies, only a few new genes with a recognized involvement in asthma genetics have been found to date.
Several genotypes have been well substantiated in a broad range of populations and are undoubtedly important in increasing susceptibility.
Asthma genetics studies done to date have led to some important gains in knowledge of asthma but no major advances into its etiology.

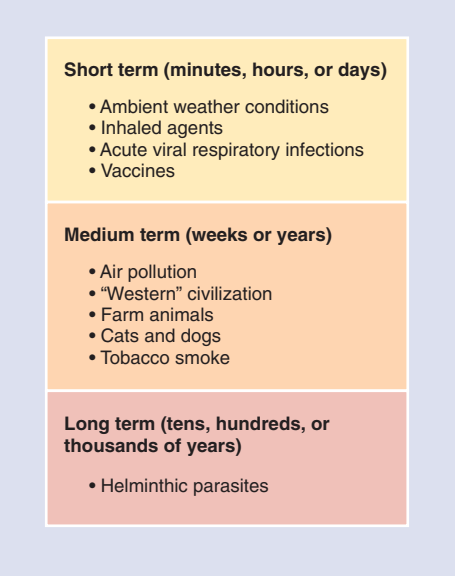

Figure 56-1 Gene by environment interactions. Evidence has been reported for the following short-, medium- and long-term interactions between genes and environment

They also include the increased risk of asthma conferred by tobacco products.[8]

However, despite this valuable body of knowledge, the most important environmental influences are still unknown. This is well demonstrated by the complete lack of a plausible hypothesis for the environmental factors responsible for the increase in asthma seen in the 1980s and 1990s and also perhaps for the decrease in asthma rates and severity seen since the turn of the millennium.[9-11] Part of the decrease may be due to better treatment,[11] but this would appear unlikely to be the major cause of the decrease in some locations, as in these the use of asthma medications decreased at the same time as the decrease in asthma prevalence.[9] The powerful influence of the environment is also shown by the substantial differences in wheezing rates in children between the developing and developed world.[12] A further excellent example of highly differing environments acting to affect asthma-related phenotypes in populations with substantially the same ethnic background is the Karelian study[13] in which children on the Finnish side of the border had an atopy prevalence that was four times higher than that of children on the Russian side. To summarize the effects of environment on asthma susceptibility, several risk factors have been identified, but the most important factors are still unknown.

DIFFICULTIES IMPOSED BY THE POOR CURRENT STATE OF KNOWLEDGE OF ENVIRONMENTAL INFLUENCES ON ASTHMA

This profound lack of knowledge on the most critical and powerful environmental factors has almost certainly impaired the ability of researchers to gain good insight into gene by environment interactions. Indeed, the broad lack of reproducibility of findings between different populations for asthma genetics studies is plausibly related to variations in these factors between different populations. A lack of appreciation of this issue was evident in early asthma genetics studies in which the absence of a significant relation between a linkage site or genotype and an asthma-related phenotype was held up as evidence that the site or genotype had "failed" to influence asthma,[14] and this view persists in some current studies.[15] An alternative, and in many cases more plausible, explanation is that the absence of a relation between a genotype and an asthma phenotype is due to the absence of the necessary environmental factor. Thus, the presence of powerful, unknown, and highly variable environmental influences on asthma susceptibility may be behind the lack of reproducibility of gene by environment findings. An opposing view that there are many type one statistical errors in studies reporting positive associations between genotype and asthma phenotype is also, however, highly likely to be true, as is the likelihood that many negative studies have type two statistical errors.

GENE-ENVIRONMENT INTERACTIONS—CURRENT KNOWLEDGE

Despite these major unsolved methodological issues, there is now good evidence for specific polymorphisms and haplotypes affecting asthma susceptibility, and the rest of this chapter will concentrate on this rapidly evolving area of research. In describing current knowledge on this issue, three areas will be discussed. These are the short-, medium-, and long-term interactions between genetics and environment (Fig. 56-1). In this context, *short-term* is the immediate or acute effects of an environmental exposure, *medium-term* refers to exposures that take place over days, weeks, or years, and *long-term* refers to environmental influences that affect

populations over tens, hundreds, thousands, or tens of thousands of years. In Chapter 2, the need to consider environmental influences as more than simply the external physical environment was argued. In the following sections, this theme is continued and environment is considered as any influence outside those intrinsic to the individual. Thus, environment in this context includes the physical environment, substances present in food and fluid, inhaled substances, proximity to other life forms, infectious agents, and social and household factors.

Short-Term Exposures to Environmental Influences

ATMOSPHERIC CONDITIONS

Short-term changes in climatic conditions or air pollutants have been associated with increased presentations of asthmatics to acute medical care and are likely to be under genetic influence. An association between respiratory symptoms, ozone levels, and glutathione-S-transferase (GST) M null and GSTP1 Val/Val genotypes has been reported from Mexico.[16]

Airway Responsiveness

Acute changes in airway caliber have been associated with factors related to the physical environment including dry or cold air, but have also been associated with provocative agents such as methacholine and histamine. Polymorphisms in several genes have been shown to be associated with the latter, including the genes in the chromosome 5q cytokine region,[17] and the genes for interleukin-13 (IL-13),[18] IL-4,[19] tumor necrosis factor alpha (TNF-α),[20] the β2 adrenoreceptor,[21] and CD14 in mid-childhood but not adulthood.[3] Allergen inhalation challenge has been associated with several polymorphisms, but almost all of these studies have been in mice.

Acute Respiratory Virus Infections

The most common and important cause of asthma exacerbations is acute viral respiratory infection. Over recent years, several studies have shown that the majority of children presenting with acute asthma have viral antigen present in their airway secretions and the most common viral infective agent is rhinovirus (RV).[22] Respiratory syncytial virus (RSV) is also found in this situation, but much less frequently. Recent studies have also shown that RV is more commonly associated with bronchiolitis than RSV in cases diagnosed in the community,[23] whereas the reverse is true for infants admitted to hospital with bronchiolitis. RV was also commonly associated with lower respiratory symptoms in young children.[22]

Understanding the genetic susceptibility to acute viral infection and its link to asthma would be key to providing important new information into mechanisms involved in asthma exacerbations, but very few studies have been reported in this area. One study has shown that the severity of an acute asthma episode was related to presence of the C allele of CD14 C-159T and the A allele of Clara cell 16 (CC16) A38G.[24] This study showed that a potentially important basic mechanism that predisposes to the development of asthma is the failure of an increase in soluble CD14 that is seen in those homozygous for the C allele, whereas those with one or more T alleles had significant increases in CD14 levels and less severe asthma (Fig. 56-2).[24] From the same study, a preliminary analysis has not found any genetic variations in innate immunity genes that could explain an increased susceptibility to acute viral infections in asthmatics.[25] Further genetic studies in this area are likely to be highly productive because a defective Th1 response has been implicated as an underlying feature of increased susceptibility of asthmatics to acute viral respiratory infections.[26-28]

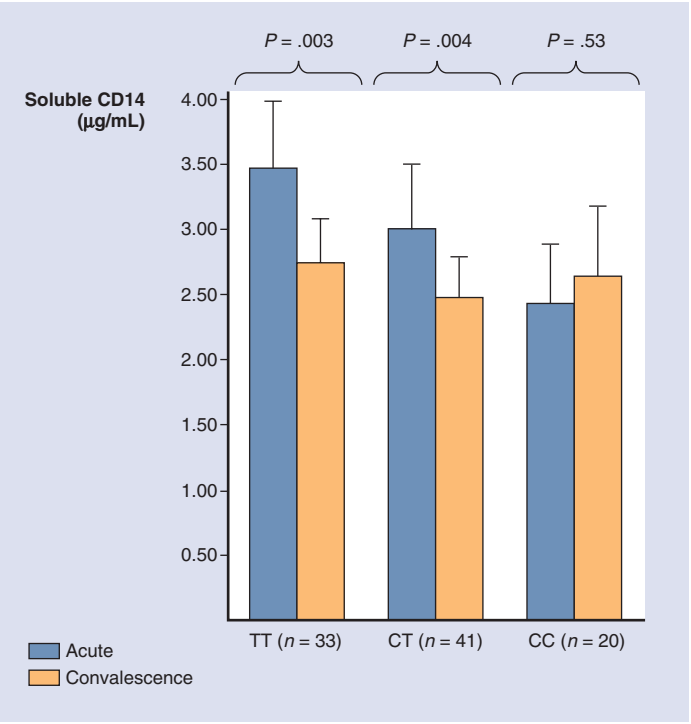

Figure 56-2 Relation between plasma levels of soluble CD14 and genotypes of CD14 C-159T. Subjects homozygous for the C allele failed to increase CD14 levels during acute asthma and were more likely to have severe asthma. (Redrawn from Martin AC, Laing IA, Khoo SK, et al: Acute asthma in children: Relationships among CD14 and CC16 genotypes, plasma levels, and severity. Am J Respir Crit Care Med 173[6]:617-622, 2006.)

VACCINES

The responses of young infants to vaccines are of interest because these represent the immune system's response to a discrete, precise, controlled dose of either an antigen or an infective agent. A vaccine, therefore, can be seen as well-characterized environmental exposure that offers strong insight into an individual's response to the natural environment. With respect to infants at risk of atopy, studies some years ago showed that there were significant differences in the way that atopic and non-atopic infants responded to regular vaccines. Examining young children's responses to tetanus toxoid and diphtheria antigens illustrates this point.

Both Th1 and Th2 responses are produced by tetanus vaccination. Young children with a family history of atopy have delayed development of Th1 responses and a predominance of Th2 responses.[29] Children with Th2 predominance exhibit a slower development of protective levels of response against the infective pathogens targeted by the vaccine.[30] Indeed, vaccine responses early in life appear to be impaired

in children with a genetic bias toward Th2 responses. At one year of age, a higher total serum IgE was associated with lower concentrations of diphtheria-specific IgG, and at 2 years of age, an inverse correlation was noted between total serum IgE levels and cellular immunity to tetanus toxoid as assessed by lymphoproliferation.[31] Thus, Th1 and Th2 lymphocyte responses are intimately involved with the responses to vaccines in early life and evidence suggests that increased Th2 responses may impair or delay the response to vaccines. Variations in genes involved in determining the rate of maturation of Th1/Th2 responses, the deviation of these responses, or the level of Th1 and Th2 responses themselves may influence responses to vaccines.

Given this situation, examining vaccine responses with respect to Th1 or Th2 gene polymorphisms would be of interest. Based on the data just mentioned, one would expect to see that alleles associated with either increased Th2 or perhaps decreased Th1 responses would be associated with reduced vaccine antibody production and reduced cytokine responses following stimulation of T cells by the vaccine antigen. This does appear to be true and recent studies have shown associations between decreases in specific IgG antibody production for each antigen of the 7-valent pneumococcal vaccine and the pro-Th2 response allele for CD14,[32] IL-4, IL-4 receptor alpha chain (Ralpha) and IL-13 (Fig. 56-3).[33] A further study has shown that the "pro-Th2" alleles in IL-4, IL-4 Ralpha, and IL-13 are also associated with decreases in specific IgG against tetanus toxoid and diphtheria vaccine antigen, but only in infants with at least one parent who was a smoker.[34] In this study, pro-Th2 alleles were also associated with altered cellular responses because PBMC stimulated with tetanus toxoid showed reduced cytokine responses for interferon-gamma and IL-10 and IL-13 for individuals with at least one R allele for IL-4 Ralpha Q551R and again, only in individuals exposed to parental smoking.[34] These findings are striking because genes related more to antibody production are likely to be important in vaccine responses to both killed vaccines and live attenuated vaccines, but genes that contribute to cell-mediated immunity are more likely to be important in responses to live viral vaccines.[35]

These vaccine response genetic studies have broad implications to gene by environment interactions, as they suggest that there may be a basic problem with both specific IgG and cellular responses to foreign antigens that is independent of the IgE system of antibodies. Taken further, they also suggest that part of the problem with asthma might be a relative impairment of the immune system toward hostile environmental threats. Given that acute asthma is triggered most frequently by viral respiratory infections rather than allergic responses, the possibility is raised that atopy may be of much less importance in asthmatics than the accompanying impairment of the immune system toward respiratory viral infections. Clearly, further studies are needed to determine the importance of these aberrant immune responses.

Medium-Term Exposures to Environmental Influences

AIR POLLUTION

Medium-term exposure to air pollution variables has been shown to affect individuals with particular genotypes more than others. In a study of Taiwanese children from three districts with different air pollution levels in southern Taiwan, those homozygous for GSTP1 Ile-105 had a weakly significant association with asthma.[36] However, when air pollution was accounted for, a significant gene-environmental interac-

Geometric mean (error bars = standard errors) IgG titers against seven pneumococcal serotypes versus CC, CT, and TT. (Redrawn from Wiertsema SP, Khoo SK, Baynam G, et al: Association of CD14 promoter polymorphism with otitis media and pneumococcal vaccine responses. Clin Vaccine Immunol 13[8]:892-897, 2006.)

tion was apparent, with Ile-105 homozygotes in the high air pollution district having an adjusted odds ratio of 5.52, 95% confidence interval (CI) = 1.64 to 21.25 for asthma.[36] This association of GSTP1 is not unexpected because this enzyme is important in the detoxification of products of oxidative stress. The same enzyme has also been linked to the development of lung cancer.[37]

"WESTERN SOCIETY"

As indicated earlier, knowledge of the most critical and powerful environmental factors that act within "Western society" is lacking. The existence of a broad range of environmental exposures that are included in this general term is supported by very strong evidence. In the ISAAC study, with few exceptions asthmatic symptoms are most common in the most affluent Western countries and least common in developing countries.[12] Asthma-related phenotypes are also more common in Russian Karelia compared with Finnish Karelia.[13] In developing countries that are making rapid economic progress, asthma is increasing in prevalence fastest in the most affluent areas. For example in India, Bangalore has made remarkable economic advances in recent years, but has at the same time seen rates for asthma in children increase faster than in the rest of India.[38] In general, exposure to a Western environment results in high rates of atopic sensitization, allergic diseases, and asthma. Several theories have been put forward to explain this situation, the "hygiene hypothesis" being the best known of these[39,40] and one of the most controversial.[41] This hypothesis contends that Western society has experienced a marked reduction in exposure to infectious and potentially noxious agents. However, there are many contradictions to this theory, the most striking being the large number of populations in developing countries, especially in South America, with high rates of asthma despite exceedingly poor social circumstances and endemic parasitic disease.[42]

The majority of the genome-wide screens done to detect asthma genes have been performed in Western countries. Remarkably, not many of the linkage sites detected in these studies have been replicated in more than a few of these studies.[43] Sites that have been most reproducible include 5q31-33, 6p21, and 12q13–q24.[44] In the absence of any better concept, the best and, unfortunately, the least remarkable explanation for these findings is that the environmental interaction is with "Western society" and the variability in the results from these studies is due to variability in the environmental factors that contribute to Western society. From an environmental point of view, this is a disappointing summary of how much progress has been made with the issue of gene by environment interactions after nearly 2 decades of studies using the best technologies available.

A recent summary of asthma genotypes has noted that 118 genes have shown associations with asthma-related phenotypes, 79 of which have had findings replicated in two or more publications and 10 of which have had findings replicated in at least 10 reports.[44] Again, for the majority of this large number of reports, the environmental factors responsible for producing the genetic association were not identified.

A complicating factor in gene by environment is the problem that a given allele can be associated with a particular asthma-related phenotype in one environment, but the opposite allele can be associated with the same phenotype in another environment.[1] Another difficulty is that some genotypes are related to phenotype in an age-related manner. For example, in a longitudinal data set of nonselected children followed frequently from age 8 to 25 years of age, the C allele of CD14 C-159T was associated with the development of atopy in mid-childhood, but this effect disappeared completely by 25 years of age.[3]

EXPOSURE TO FARM ANIMALS

For some years, the relation between proximity to farm animals and a protective effect against asthma in children has been known. This relation appears to be particularly strong for children raised on farms in which the animals lived under the same roof as the humans.[13,45] Lipopolysaccharide (LPS) has been implicated as the principal causative agent in this relation.[5] An in vitro study of PBMC taken from Swedish farm children has reported an association between PBMC responses to LPS and a polymorphism in Toll-like receptor 4 (TLR4).[46]

A few studies have been able to isolate specific genes likely to be involved in vivo. The first of these studies was an investigation into TLR2 polymorphisms in children of farmers; those with a TLR2-16934T allele compared with children with TLR2-16934AA were less likely to have a diagnosis of asthma (3% versus 13%, respectively; $P = .012$), current asthma symptoms, atopic sensitization, and current hay fever symptoms.[45] The association between asthma and TLR2 C-16934T in this population was independent of atopy. A similar protective relationship between farm exposure and the development of allergy has been shown for those with CD14-159TT.[47] A polymorphism in the gene for caspase recruitment domain protein (CARD) has also been reported to affect the relation between farm exposure and allergy, with a strong protective effect being found for children homozygous for the CARD4-21596T compared with those with a CARD4-21596C allele.[48]

EXPOSURE TO CATS AND DOGS

An interesting paradox is the observation that allergies to cats and dogs are much more common in allergic asthmatics, but that exposure to these animals early in life is associated with protection from the development of asthma in those predisposed to atopy. Several studies have shown this. For example in a study from Tucson, children exposed from early life to a dog had less wheeze, although not less atopy.[49] This appears to be true in otherwise very different environments, as the presence of a dog in Finland (OR, 0.57; 95% CI, 0.35 to 0.95) or a cat in Russia (OR [odds ratio], 0.43; 95% CI, 0.24 to 0.80) in the adjacent Karelian areas of these two countries was associated with protection from the development of atopy.[13] These two Karelian regions are very similar with respect to the natural environment, but very different with respect to the socioeconomic environment.

The genotypes that might be involved in the mechanism of this childhood cat exposure–related tolerance include IL-1A and IL-10 polymorphisms.[4] IL-13 may also be involved, as those homozygous for Gln form of the R130Q polymorphism in the IL-13 gene had higher levels of specific IgE to dog ($P = .003$).[50] Similar findings have been made for RANTES G-401A with the A allele being significantly associ-

ated with IgE sensitization to cat (OR 2.35; 95% CI 1.15 to 4.77).[51] However, finding genotypes associated with specific skin responses to cat, dog, or other allergens, although interesting, is not necessarily important. Rather, the findings may be nonspecific in that a genotype would need to be specifically associated with reduced disease prevalence or severity in those exposed to either cats or dogs, compared with individuals who have not been exposed, to be seen as a genotype interacting with an environmental factor.

EXPOSURE TO TOBACCO SMOKE

A large number of studies over the last 20 to 30 years have reported associations between parental smoking and respiratory disease in children.[8,52,53] More recently, genetic variants have been associated with tobacco-related effects on respiratory status or disease. One of the first of these studies was an investigation into the effects of a glutathione-S-transferase (GSTM1) genotype, tobacco product exposure during pregnancy, and environmental tobacco smoke (ETS) exposure in early life on asthma and wheezing in 2950 children aged 6 to 12 years in 12 communities in Southern California.[54] The adverse effects of in utero exposure with respect to the development of asthma and wheezing were substantially determined by the presence of the GSTM1 null genotype. Subjects with this genotype and in utero exposure had an increased prevalence of several asthma-related phenotypes including early-onset asthma, asthma with current symptoms, persistent asthma, wheezing with exercise, or requiring medication and emergency room visits in the past year (OR 3.7, 95% CI 1.9 to 7.3). These associations were not present in the group of children exposed to smoking in utero but with the GSTM1^{+} genotype.

These striking findings have been confirmed in several other studies. In more than 3000 German school children, associations were sought between GSTM1 and GSTT1 genotypes and asthma with respect to current and in utero ETS exposure.[55] Children with GSTM1 null allele exposed to current ETS had a greatly increased risk for current asthma (OR 5.5, 95% CI 1.6 to 18.6) as well as wheeze ever, current wheezing, and shortness of breath compared with GSTM1-positive individuals not exposed to ETS. In utero tobacco product exposure in children deficient in GSTT1 was associated with reduced lung function compared with GSTT1-positive children not exposed to ETS.[55] A further study supporting the importance of the GST genes in preventing harm from tobacco smoke used a placebo-controlled, crossover study designed to demonstrate that individuals with ETS exposure and GSTM1-null or GSTP1 Ile105 showed larger responses to nasal allergens, but also that IgE levels were greatest in subjects with both the GSTM1-null and GSTP1 Ile homozygotes.[56]

Additional evidence linking genetics and an adverse effect of parental smoking comes from a genome-wide screening study in 200 families in which a site on chromosome 5q was linked to bronchial hyper-responsiveness for children with ETS exposure.[17] This linkage was not present for children not exposed to ETS (Fig. 56-4).

The foregoing results related to the GST polymorphisms, and the data previously presented on the relation between vaccine responses, Th2 response alleles, and parental smoking provide evidence that tobacco smoke is the most important known environmental factor in gene by environment studies in respiratory disease in children.

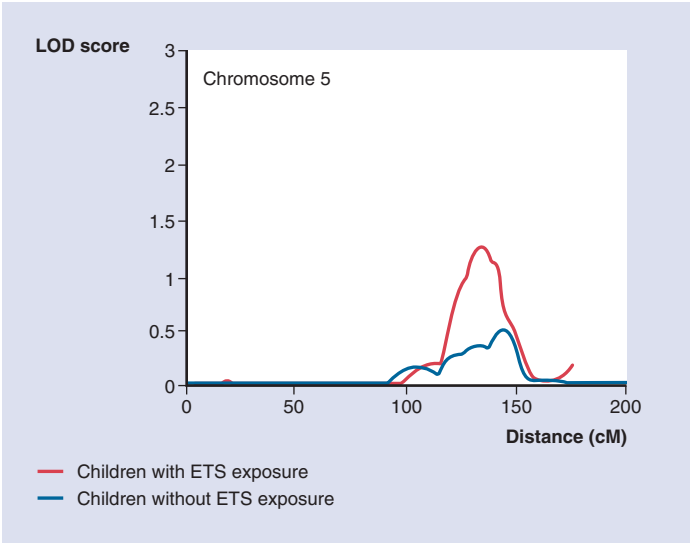

Figure 56-4 Evidence linking genetics and parental smoking from a genome-wide screening study in 200 families with significant LOD score for a site on chromosome 5q showing linkage to bronchial hyperresponsiveness for children with ETS exposure (*red line*). This linkage was not present for children not exposed to ETS (*blue line*). LOD, logarithm of the odds. J Allergy Clin Immunol 2005;115[6]:1169-1175, 2005.)

Long-Term Exposures to Environmental Influences

Genes and environment also interact over a very long period via Darwinian selection. Although investigations into the extent of this interaction with respect to allergy and asthma are still few, there is now strong evidence suggesting that current function of the immune system has been determined by environmental factors.[57,58] Given that various regions on the planet have hostile infective agents that require robust Th2 responses for defense, populations with long-term ancestry in such regions could be expected to show selection in favor of alleles that promote Th2 responses. The available data suggest that this is the case, as pro-Th2 alleles are consistently more frequent in populations that originate from equatorial regions compared with those from regions of higher latitude.[42] Current evidence supports an important role for strong Th2-biased responses in defense against helminthic parasites and that these parasites are more prevalent in hot, moist conditions.[42] The lower frequency of pro-Th2 alleles in populations with long-term ancestry in temperate or cold climates could be due to a small but significant decline in competitiveness in individuals with excessive Th2 responses. Having over-reactive Th2 responses could lead to allergic diseases, asthma,[42,59] and both an increase in mortality and a decrease in general competitiveness for survival or reproduction. However, there is no direct evidence to suggest why pro-Th2 alleles are less frequent in populations away from the tropics.

The evolutionary gene/environment interactions that have resulted in the current differences in pro-Th2 allele frequen-

*Genes that are listed have been reported to be associated with an asthma-related phenotype in at least six publications.
From Koppelman GH: Gene by environment interaction in asthma. Curr Allergy Asthma Rep 6(2):103-111, 2006.

cies are of more than anthropologic interest because they have direct consequences toward current disease patterns.[60,61] For example, African Americans originate substantially from tropical west Africa and, for genes for which data are available, pro-Th2 alleles have higher frequencies in these populations than in European-Americans.[57] In the United States, when environmental differences between African Americans and European Americans are controlled for, African Americans also have a higher prevalence of allergy and asthma.[58] Approximately 2 billion people have tropical ancestry up to current times and these people may all be at risk of much higher rates of asthma and allergy than those with their most recent ancestry from more temperate climates (Box 56-2). People with tropical ancestry may also be at risk of infectious diseases due to inadequate responses to immunization.

BOX 56-2 Potential Consequences of Long-Term Exposure to a Tropical Climate

- Increases in frequency of pro-Th2 response alleles in genes affecting immunologic function
- Increased susceptibility to develop allergies and asthma
- Impaired ability to limit airway inflammation from acute respiratory viral infections
- Impaired humoral and cellular responses to vaccines

CONCLUSION

In conclusion, after nearly 20 years of research, much new information has been obtained on the genetics of respiratory disease, and on asthma in particular. This information has shown that there are a great number of genes associated with asthma, some of which have shown reproducible associations with asthma phenotypes (Table 56-1), but none of these on their own have been found to exert a strong influence. More careful analyses have shown that several immunologic and inflammatory pathways have many genetic variations that contribute to asthma susceptibility. Ethnic differences in the frequency of these variations have probably been caused by geoclimatic influences and these differences may be responsible for the current differences in respiratory disease susceptibility that have been observed between different ethnic groups. A great deal more research is needed before the relationships between genes, environment, and respiratory disease can be properly understood.

CHAPTER 57 Disease Mechanisms and Cell Biology

Peter D. Sly, Patrick G. Holt, Renato Stein, and Fernando D. Martinez

TEACHING POINTS

- Asthma is a developmental disease in which the normal development of the respiratory and immune systems is altered by the impacts of environmental exposures acting on underlying genetic predispositions.
- The developmental stage of environmental exposures is an important determinant of their effects.
- Slow maturation of the immune system after birth is a major risk factor for both viral lower respiratory infections in early life and for allergic sensitization.
- While atopy is a significant risk factor for the development of persistent asthma, not all asthmatic children are atopic and the true relation between asthma and atopy is poorly understood.

DEVELOPMENT OF ASTHMA

Asthma is essentially a developmental disease, in which the normal development of the respiratory and immune systems is altered by the impacts of environmental exposures acting on underlying genetic predispositions (see Chapter 56 for further details). When considered from this point of view, it makes sense to briefly review the basics of normal respiratory and immune system development and then consider how alterations of these by genetic and environmental factors result in the development of asthma.

Normal Development of the Respiratory System

Although the lungs at birth are immature, the basic structure is formed in utero, which means that normal lung growth is susceptible to alteration by adverse exposures before birth. Knowledge of the phases of normal development of the lung (Fig. 57-1) allows an understanding of how the timing of adverse environmental exposures produces adverse effects on lung structure. Airway development is essentially complete before birth. Airway branching is complete to the terminal bronchioles by 16 weeks' gestation and the pulmonary vasculature develops along with the airways. Airway smooth muscle development begins around 8 to 10 weeks' gestation and has extended to respiratory bronchioles by 26 weeks' gestation. Cartilage development is essentially complete by 28 weeks. Alveolar development begins around 24 weeks' gestation and at birth approximately 30% to 50% of the final complement of alveoli is present. Lamellar bodies, the structures responsible for secreting and storing surfactant, appear within type II alveolar epithelial cells by 24 weeks' gestation.

After birth, alveolarization continues rapidly for the first 18 to 24 months. Although the timing of cessation of alveolar development is not known with certainty and may continue until 5 to 8 years of age, the rate of alveolar formation is most rapid in early postnatal life. The pulmonary microvasculature develops mostly during this secondary phase of alveolarization. Lung volume increases along with somatic growth, with the lung volume approximately doubling from birth to 18 months, doubling again by 5 years of age, and doubling again by adult life. The lungs continue to grow longer in boys, continuing into the early 20s, whereas lung growth appears to stop in the late teen years in girls.[1,2] Boys are thought to have relatively smaller airways for the size of their lungs than girls in early life,[3] and this is thought to contribute to the increased prevalence of wheezing in boys during infancy and the preschool years.[4] Lungs grow along trajectories set in early life, similar to percentiles for somatic growth.[1] This means that adverse influences on lung growth in early life, such as maternal smoking during pregnancy (see later), have lifelong consequences.

Normal Development of the Immune System

The immune system has two major arms, the innate immune system and the adaptive immune system. The innate immune system in the lungs represents the first line of defense against invading organisms, consisting of nonspecific responses triggered by recognition of conserved molecular patterns carried on the surface of microorganisms (pathogen-associated molecular patterns or PAMPs). This response is generated by macrophages resident in the airways, which secrete cytokines and chemokines that recruit inflammatory cells to the lungs. The innate immune system relies on a limited number of pattern recognition receptors (PRRs) to identify PAMPs. Secreted PRRs, such as CD14 or LPS-binding protein, bind to microbes and facilitate their destruction by phagocytosis or the complement system. Toll-like receptors (TLRs) induce antimicrobial genes and inflammatory cytokines within a variety of cells while activating dendritic cells (DCs), the major professional antigen presenting cells in the airways, to initiate adaptive immune responses. Mesenchymal cells, in particular airway epithelial cells, can also utilize some of these innate immune mechanisms, including TLR-mediated cytokine secretion, to signal the presence of invading microorganisms.

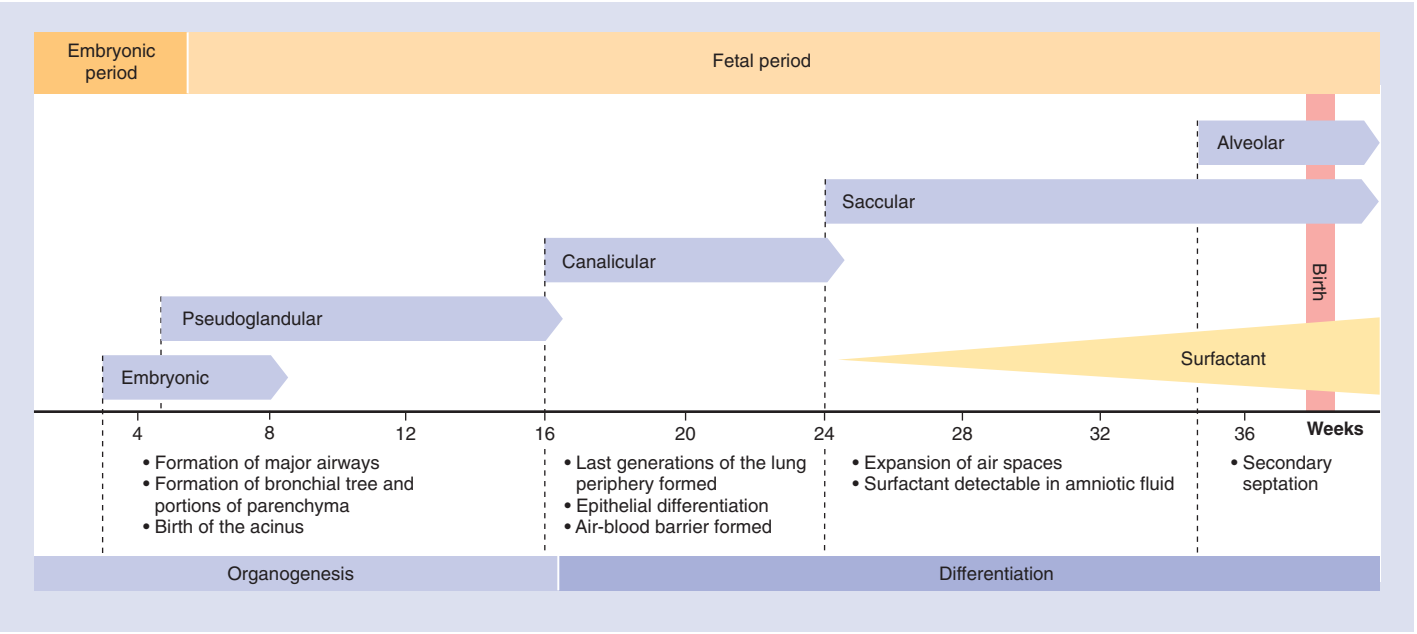

Figure 57-1 Schematic representation of the stages of lung development. These periods outline periods of vulnerability of different components of the lungs to environmental exposures.

The adaptive immune system adds specificity to host defense responses by recognizing specific antigens and producing both a humoral and cell-mediated response involving activation B and T cells. A fundamental characteristic of the adaptive immune system is the development of immunologic memory, in which a rapid response is mounted on subsequent reinfection with individual pathogens. Although the strengths of such a mechanism in providing resistance to infection is important for survival in the face of infectious diseases, immunologic memory is also the basis for immunopathology in allergic disease.

Both the innate and adaptive immune systems undergo considerable development in utero but both are immature at birth.[5] Studies of the normal development of T cells have shown that circulating T cells can be demonstrated by 15 weeks' gestation and that these are capable of proliferating in response to mitogen stimulation in vitro by 17 weeks' gestation. Surface markers characteristic of T cells (i.e., CD3, CD4, and CD8, have been demonstrated by 18 weeks' gestation) as has the surface expression of the major histocompatibility complex class II. T cell responses to antigen have been reported, using ex-vivo stimulation protocols as early as 22 weeks' gestation; however, as discussed later, considerable doubt exists over the specificity of these responses.[6] Fetal and placental tissues secrete cytokines in utero and measuring these in cord blood can give an indication of the maturational state of the fetal immune system.[7]

Considerable maturation of both the innate and adaptive immune systems occurs after birth. although a thorough review of this topic is beyond the scope of this chapter and the interested reader is directed to a recent review by Holt and colleagues,[8] a brief overview is warranted. As reviewed by Holt and coworkers,[8] monocytes circulating in neonates respond less well to a variety of bacterial and viral signals than do adult monocytes. Dendritic cell function is immature at birth in several important ways.[9-15] Neonatal DCs have reduced ability to present antigen[8] and reduced ability to induce T cell differentiation.[9-11] Their ability to secrete bioactive interleukin (IL)-12, a key cytokine for inducing T cells to differentiate into T-helper (Th)-1 cells, is deficient at birth and matures slowly through childhood.[8] DCs also show a reduced ability to secrete type I interferons, an important part of the innate antiviral response.

Circulating T cell numbers are increased in infancy relative to later life[16] but many of these show characteristics of being functionally immature cells known as *recent thymic emigrants* (RTEs), including the expression of the surface markers CD1[17] and CD38,[18] coexpression of T cell markers CD4 and CD8,[19,20] whereas very few express classic activation markers, such as CD25, CD69, or CD154.[19] T cells from neonates and infants appear to be incapable of sustaining responses to stimuli in vitro. Although initial rapid proliferative responses are seen[21,22] and are associated with cytokine production, these responses are not maintained and most appear to undergo apoptosis.[6,18] An inability to generate true memory responses has also been reported[23]—further questioning the specificity of allergen-induced T cell responses in early life.

The T cell responses in early life are characterized by the production of Th-2 cytokines, which appears to be related to an active suppression of secretion of Th-1 cytokines in utero and an inability of neonatal DCs to induce Th-1 differentiation in early life.[24-27] The ability to produce a wide variety of Th-1 cytokines is reduced in early life and maturation is not complete until late adolescence (Fig. 57-2).

Postnatal maturation of the immune system is driven by environmental exposures, especially to microbial products.[28-33] Postnatal colonization of the gut and skin with bacteria is thought to provide potent maturational signals. Other maturational signals are thought to be provided by exposure to components of microbial cell walls, such as lipopolysaccharide (LPS) from gram-negative organisms, lipoteichoic

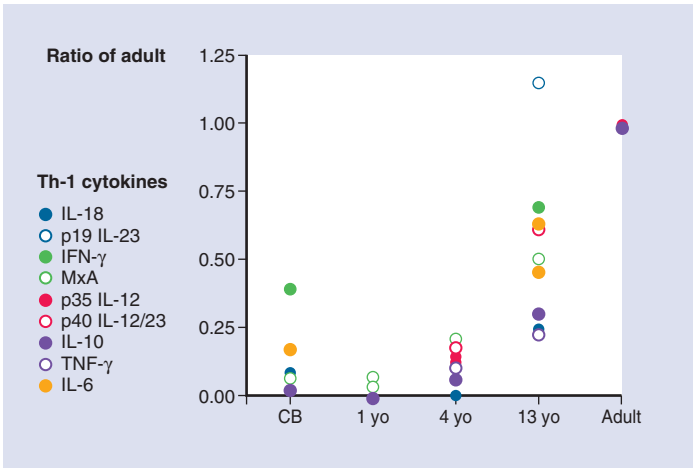

Figure 57-2 Maturation profile of a number of markers of Th-1 cytokine capacity. Data are derived from a variety of studies in which peripheral blood mononuclear cells were stimulated ex vivo with relevant stimuli. Data from cells harvested from children at various ages are shown and expressed as a ratio of the cytokine production capacity of cells harvested from adults and simulated under identical circumstances.

acids from gram-positive organisms, glucans from fungi, and many others. These maturational signals result in an increased expression of MHC class II on DC and an increased ability of T cells to produce Th-1 cytokines with age.

Mechanisms Underlying the Development of Allergic Sensitization

When a protein antigen is encountered at a mucosal surface, such as the airway epithelium, for the first time, a series of events is initiated that result in the development of either immunologic memory or tolerance to that antigen. In the lungs, respiratory tract dendritic cells (RTDCs) form a network within the epithelium (Fig. 57-3) with dendrites protruding between epithelial cells like snorkels that "sample" the luminal environment. Protein antigens are taken up by the RTDCs through these snorkels by endocytosis and are processed. The RTDCs then undergo a transformation from cells specializing in uptake of antigen to cells specializing in antigen presentation, and at this stage they leave the lungs, trafficking to the regional lymph nodes via the lymphatic system. On the first occasion that protein antigens are encountered they are presented to naïve T cells, together with maturational signals from the RTDCs that determine how the T cells differentiate. If the protein antigen is completely inert and contains no motifs recognizable by PRRs, and the RTDC containing the protein has not recently encountered any microbially related inflammatory signal and thus is (functionally) in a baseline "resting" state, the RTDCs will trigger the induction of a state of immunologic unresponsiveness to that program by stimulating the differentiation of populations of T-regulatory cells. If however the RTDCs have been exposed to an environmental signal that alerts their PRR system (e.g., via TLRs stimulation), they will provide a strong IL-12 signal in conjunction with the processed antigen, the recipient T cells will differentiate as Th-1 cells and produce Th-1 cytokines. Some of the progeny of these activated Th-cells differentiate further into long-lived "memory" cells. In the absence of a strong IL-12 signal or in the presence of an IL-10 signal (which is the default signal delivered by resting DCs), the T cells will be more likely to differentiate into Th-2 cells and produce Th-2 cytokines, such as IL-4 and IL-5 and will give rise to Th-2 memory cells. Interestingly, an initial Th-2 response is usually observed during the early stages of tolerance induction, including in non-atopic human infants,[23] indicating that Th-2 memory programming is potentially reversible.

When the same protein antigen is encountered on subsequent occasions and presented to T cells in individuals who did not develop tolerance at first exposure, a rapid expansion of the antigen-specific T-memory cells occurs, together with the rapid production of cytokines. Antigen is also presented to B cells, which triggers the production of antibodies directed against the antigen. B cells require "T-cell help" for the efficient production of antibody. The default response of B cells is to produce IgG antibodies, especially IgG_1 subclass antibodies; however, in the presence of IL-4, class switching can occur—resulting in the production of IgG_4 and IgE antibodies.

During fetal life active suppression of Th-1 cytokine production leads to Th-2 biased T cell responses.[34,35] This Th-2 bias persists into early postnatal life and, in those who do not develop allergic sensitization, switches to a low-level Th-1 bias as the immune system matures under the influence of environmental exposures (as earlier). In those who develop allergic sensitization to protein antigens from the environment during this period, the Th-2 bias remains imprinted in specific areas of their immune response repertoire, into later life. Viewed in this light, allergic sensitization can be considered as a maladaptive response to exposure to protein antigens, generally known as *allergens*.

Genetic predisposition is recognized as an important component of risk for development of allergic sensitization (see Chapter 56). This predisposition is manifest in the observation that allergies run in families. Children at high risk of developing allergies, based on a strong family history of allergy, show sluggish postnatal immune maturation, as evidenced by decreased T cell proliferation to stimulation in vitro[36] and decreased ability to secrete cytokines, especially Th-1 cytokines.[37] In addition, sluggish postnatal immune system maturation is a major risk factor for the development of allergic sensitization and atopic asthma in later life.[8]

Impact of Intrauterine Exposures on Respiratory and Immune System Development and the Risk of Asthma

The intrauterine environment is the first environment a child is exposed to and adverse exposures have the potential to alter the development of the respiratory and immune systems. The most well-studied adverse intrauterine exposure is maternal smoking, although there is increasing interest in maternal exposure to other toxic substances, including heavy metals, pesticides, and persistent toxic substances in our environment.

Maternal smoking during pregnancy results in the direct exposure of the developing fetus to nicotine and carbon monoxide (CO). These components of cigarettes are thought to be responsible for the adverse effects of maternal smoking on the fetus. Nicotine is concentrated in the fetal circulation, reaching concentrations many times higher than present in the maternal circulation. Nicotine and CO result in constriction of the uteroplacental circulation, compromising oxygen delivery to the fetus. The adverse consequences of maternal smoking on fetal development include: alteration in airway growth resulting in lower lung function at birth[38]; increased deposition of collagen in both large and small airways[39]; decreased immune maturation demonstrated by lower levels of cytokines in cord blood[7]; and lower birth weight and abnormal control of breathing with blunted ventilatory responses to hypoxia.[40] Maternal smoking during pregnancy is a major risk factor for wheeze in infancy and is an independent risk factor for asthma in childhood.[7]

Maternal smoking during pregnancy also increases the risk of asthma in grandchildren born to mothers exposed to maternal smoking during pregnancy through epigenetic mechanisms.[41] When the maternal grandmother smoked but the mother did not, the risk of developing asthma was 80% higher in children (odds ratio 1.8, 95% CI 1.0 to 3.3). This risk increased to 2.6-fold (odds ratio 2.6, 95% CI 1.6 to 4.5) if the mother also smoked during pregnancy. This can be explained by an effect of the tobacco smoke products on ova development in fetal girls; this effect takes place in utero and is an example of an epigenetic phenomenon that increases the risk of asthma.

Impact of Postnatal Exposures on Respiratory System Development and the Risk of Asthma

As discussed earlier lungs grow along trajectories. However, exposure to inflammatory or irritant stimuli can retard lung growth. Lung function can also be damaged by postnatal exposures, such as environmental tobacco smoke or viral infections, in early life. Inflammatory stimuli from environmental exposures (e.g., to allergens, air toxics, or pollutants) could also limit lung growth. Woodcock and colleagues[42] used a strict environmental control regimen to reduce house dust mite (HDM) allergens to very low levels. They demonstrated that children in the clean environment had better lung function at 3 years of age than children in a control group. Lung function was not different between the groups at 4 weeks of age, showing that this was a postnatal effect.

Studies performed in rhesus monkeys[43] reared in controlled laboratory conditions show that postnatal exposures to the irritant stimuli O_3 and house dust mite allergen can alter airway growth. Infant monkeys were exposed to filtered air, house dust mite aerosol (HDMA), O_3 or HDMA + O_3 over a 6-month period. One half of the monkeys were previously sensitized to HDM. O_3 exposure had little effect on airway structure or on airway resistance. Similarly, in sensitized monkeys, exposure to HDMA or O_3 alone had minimal effects, whereas repeated exposures to HMDA and O_3, either sequentially or simultaneously, resulted in exaggerated structural and functional changes in airways. Although these data support the concepts presented, no detailed assessments of lung growth have been undertaken and the effects of early life viral infections have not been studied by direct measurement.

Air pollution, both outdoor and indoor, has been identified as a potential risk factor for both the initiation/induction and the exacerbation of asthma. One potential mechanism is through the induction of pulmonary inflammation, with the resultant effects on postnatal lung growth. Pollutants or irritants that may induce pulmonary inflammation include: combustion-related products formed by the burning of organic fuels, including nitrogen dioxide, particulate matter, and diesel exhaust particulates; bioaerosols including molds, allergens, and bacterial products (e.g., LPS), and air toxins including formaldehyde and other volatile organic compounds.

Recurrent viral lower respiratory infections (LRIs) may also alter lung growth. Although no definitive data exist demonstrating the adverse effects of recurrent viral infections on lung growth, this concept is not fanciful. Recurrent LRIs in early life are a major risk factor for the subsequent development of asthma.[44-47]

Virus-Induced Wheezing during Childhood

Wheezing with viral infections is a very common occurrence during childhood. One fifth of all children have at least one episode of LRI with wheezing (wLRI) in the first year of life, and up to 70% of these cases are associated with documented viral infections.[48] Up to 30% of all children have one or more episodes of wheezing during LRIs.[49] Such episodes are mainly caused by rhinoviruses (RV), respiratory syncytial virus (RSV), parainfluenza viruses and—to a lesser extent—adenoviruses, human meta-pneumovirus, and influenza virus.[50,51] In older children RVs are most commonly associated with triggering episodes of asthma.[52-54] Certain factors are common to all forms of virus-associated childhood wheezing. In general, male children tend to develop wheezing more commonly than female children,[3,50] as do children of lower socioeconomic status and of less educated and younger mothers.[55,56] Children who spend several hours each day in settings where several other children are taken care of also tend to develop more wheezing illnesses than other children.[44,57] Therefore, both factors that increase the likelihood of becoming infected with viruses and factors associated with the nature of the response to the virus tend to increase the likelihood of wheezing.

Whereas much of the epidemiologic data have focused on the relation between RSV infection in early life and asthma (see later), wLRI associated with RV also increases the risk of asthma in later childhood. The number and viral associations with LRI in the first year of life have been studied in a cohort of children at high risk of developing asthma in Perth,

Australia[50] and the asthma outcomes were assessed when the children were 5 years old. RV was responsible for more wLRI (46%) than RSV (16%). In addition, RV-associated wLRIs were significant risk factors for both current asthma (odds ratio 2.8 [95% CI 1.2 to 6.6], $P = 0.02$) at age 5 and persistent wheeze (2.8 [1.2 to 6.6], $P = 0.02$) throughout early childhood. The risk factors for current asthma and persistent wheeze for RSV-associated wLRI were 2.7 (0.7 to 9.6), $P = 0.10$ and 3.5 (1.1 to 12.1), $P = 0.04$, respectively. RV and RSV are very different viruses and use different mechanisms to infect epithelial cells. These data raise the possibility that host-response factors rather than virus-specific factors are responsible for the asthma risk associated with LRI in early life.

Recent data suggest that asthmatics have a decreased ability to make type 1 interferons, in particular IFN-β and IFN-λ.[58,59] These cytokines form a vital part of the host antiviral response and aid viral clearance. It is not known whether this is a congenital or an acquired defect or what the mechanisms underlying the defect may be. However, it does raise the possibility that a primary defect in antiviral immunity may play a part in the initiation of asthma. Studies in early life, especially in the first year of life, will be needed to clarify this.

Mechanisms of Virus-Induced Airway Obstruction

Considerable advances have been made in recent years in our understanding of the alterations that may be associated with bronchial obstruction during viral infections in childhood. Two main areas of knowledge have been extensively explored: the possibility that intrinsic characteristics of the lungs may enhance airway obstruction during viral infections and the possibility that altered immune reactions to the virus may enhance bronchial obstruction in certain children.

It is now apparent that infants and young children whose airway function is in the lower percentiles of the population distribution at birth are at increased risk of developing wheezing during lower respiratory tract illnesses.[60,61] If not associated with other risk factors for asthma, this condition is transitory and not characterized by persistence of symptoms beyond the preschool years. For this reason, it has been called *transient early wheezing*.[49] RSV-wLRI in these children is not associated with an increased incidence of atopy in later life.[62-64]

Children hospitalized with bronchiolitis show persistent reductions in lung function[62] lasting into later life.[63] Several studies have found that these children had lower flows, increased inspiratory or expiratory resistance, or increased gas volume months or years after the initial event.[62-64] Several studies have demonstrated that children who will go on to wheeze during the first 3 years of life have diminished levels of lung function that precede the development of the wheezing illnesses.[60,61,65] It has thus been suggested that these lower levels of lung function are a predisposing factor for airway obstruction during viral infections. The nature of the alteration in airway dynamics present in these "transient infant wheezers" is not known. It is possible that diminished airway function may be associated with narrower airway diameter for a given airway generation.[61] The internal diameter of an intrapulmonary airway is determined by the balance between pressures that tend to keep it open (airway resistive pressure, elastic recoil pressure of the airway, and alveolar pressure) and the transmural pressure, which tends to compress the airway during expiration,[66] and elastic recoil pressure of the lung, which tethers the airway.[66]

Because of developmental immaturity, the infant's lung is stiff and has a low content of elastin and collagen.[67] Also, the chest wall is quite compliant during the first years of life.[68,69] The stiff lung and decreased chest wall stiffness combine to set the elastic equilibrium point of the infant's lung at a lower relative volume than that of the adult.[70] The elastic equilibrium volume may be very close to, or even below, the closing volume of the infant's airways, making the infant particularly vulnerable to airway closure during tidal breathing.[71] Genetic factors or environmental exposures such as maternal smoking during pregnancy[38,72] may further decrease elastic recoil pressure of the lung and resting airway diameter. In children with any of these alterations, mucus deposition and airway edema occurring during viral infections may cause sufficient narrowing to allow the airways to reach a critical diameter. This may predispose these children to airway obstruction and wheezing. Interestingly, although these children tend to outgrow their symptoms with age, their mean levels of lung function remain lower than those of children without any history of wheezing.[63]

Synergism between Allergic Sensitization and Virus-Induced Wheeze in the Initiation of Asthma

Although allergic sensitization is a major risk factor for asthma the relation between allergic sensitization and asthma is not invariably close. A community-based longitudinal birth cohort study in Perth, Australia, has shown that approximately 40% of 6-year-old children were sensitized to inhalant allergens; however, only one half of these children had current asthma.[44-47] This target-organ selectivity is poorly understood. Atopic sensitization to one or more inhalants during the preschool years doubled the risk for current asthma in these children at age 6 years. However, if this was accompanied by severe (wheezing) LRI during infancy, odds ratios for persistent asthma rose to more than 9 (Fig. 57-4). This synergistic interaction between allergic sensitization and viral infections in early life depends critically on when the sensitization occurs. Data from a high-risk birth cohort study in Perth, Australia have shown that viral LRIs are only a risk factor for asthma at 5 years of age if the children were sensitized to aeroallergens at or before 2 years old and not in those sensitized between 2 and 5 years of age.[73]

These findings form the basis for the "dual hit" model for asthma etiology proposed by Holt and Sly (Fig. 57-5).[8] While the early acquisition of allergic sensitization is a risk factor for the subsequent development of asthma, a second "hit," sensitization that is associated with pulmonary inflammation, is required for the development of persistent asthma. Theoretically, other inflammatory stimuli (e.g., exposure to air toxics, combustion-related products, and vehicle exhaust emissions), could also provide the second hit.[74-78] The key target of the second hit is postnatal growth and development of the lungs.[8] The important aspects of these processes are

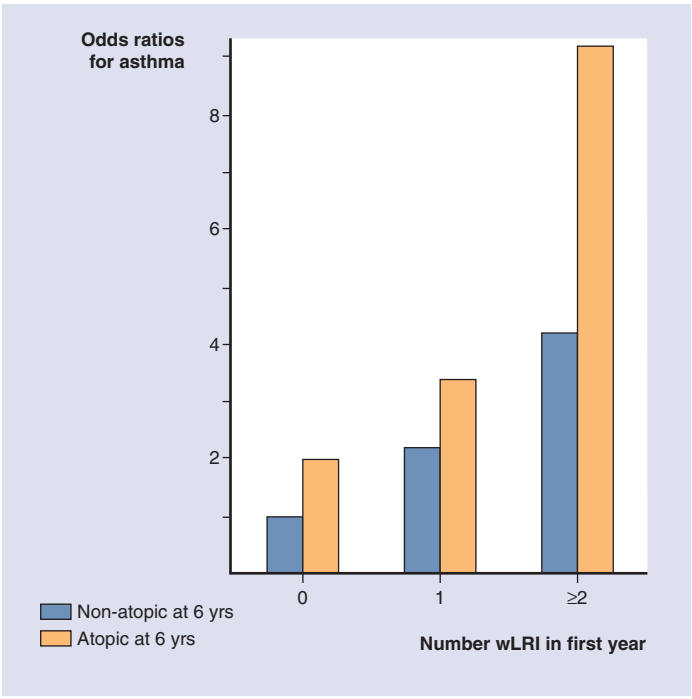

Figure 57-4 Synergistic interaction between atopy, defined as having a positive skin-prick test to at least one aeroallergen at the age of 6 years and the number of wheeze-associated lower respiratory illness (wLRI) in the first year of life and the risk for current asthma at the age of 6 years.

that (1) infancy is a period of intensive growth and differentiation of lung and airways tissue, and (2) lung function "tracks" from early childhood into later life.

In this context, it is important to point out the potential dual role that airway inflammation may play. On one hand, airway inflammation related to viral LRI results in symptoms that we recognize as asthma. On the other hand, airway inflammation has been thought to underlie structural changes in the airway wall, including deposition of collagen beneath the basement membrane, increase in smooth muscle bulk, and inflammatory infiltrates in the airway wall. A lung function deficit is seen in children with persistent asthma and is seen in the earliest measurements available in longitudinal studies.[79] The failure of recent studies postulating that using inhaled corticosteroid to show true disease-modifying action, in spite of achieving good symptom control, questions the long-held belief that airway inflammation results in both asthma symptoms and airway remodeling. As postulated by Martinez,[79] it is possible that asthma symptoms and airway remodeling result from different mechanisms and that the relation between altered lung growth and asthma is both complex and not "steroid responsive."

ESTABLISHED OR PERSISTENT ASTHMA

In the earlier sections in this chapter we have been discussing risk factors for the development of asthma. We will now turn

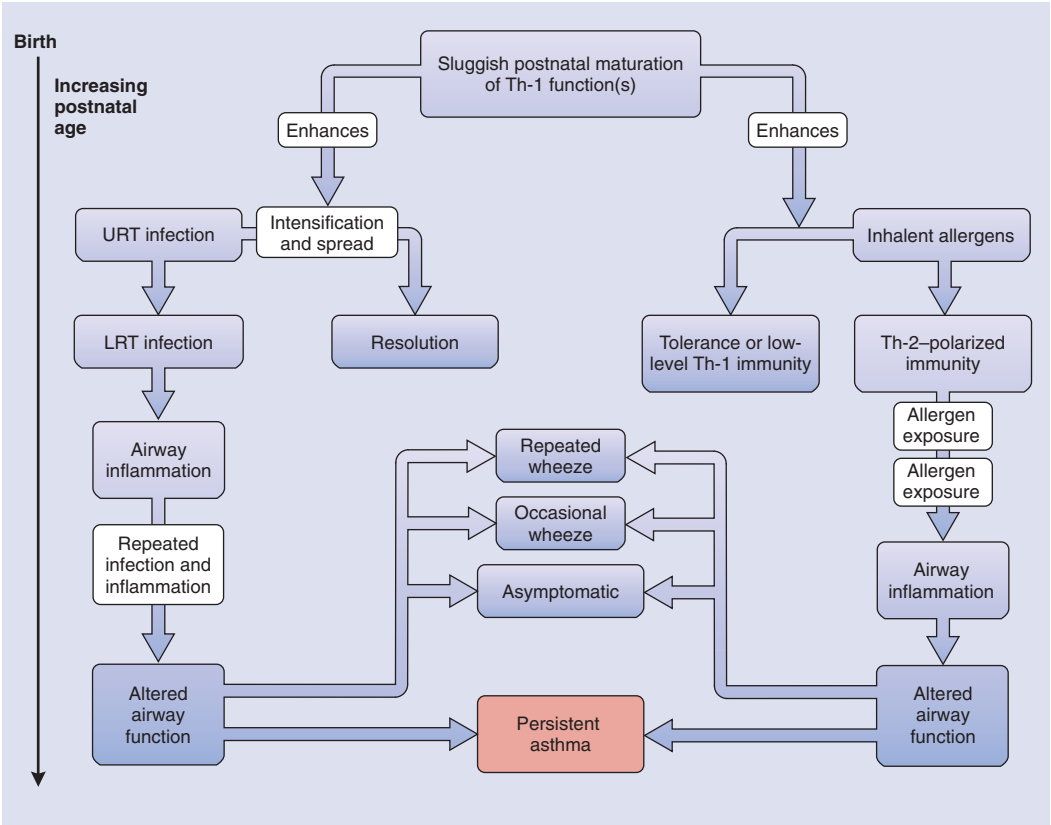

Figure 57-5 Schematic representation of the "dual-hit" model for the development of persistent asthma. The model proposes a common genetic susceptibility resulting in sluggish postnatal maturation of Th-1 function that results in both an increased risk of lower respiratory tract infections (LRTI) in early life and an increased risk of allergic sensitization. A child traveling down either the pathway of repeated LRTI or allergic sensitization alone has an increased risk of wheeze. The increased risk of persistent asthma is conveyed to children who travel down both pathways simultaneously.

to discussing mechanisms underlying persistent asthma. The bulk of the epidemiologic literature indicates that the type of asthma that is most likely to persist into adult life is the type associated with allergic sensitization, known as atopic asthma, and this chapter will concentrate on this. For a discussion on other types of wheezing, the interested reader is directed to other chapters in this book and to an excellent review.[4]

Non-atopic Asthma

Although there is a strong association between atopy and persistent asthma, especially in older children, a significant proportion of asthmatic children are non-atopic. In a longitudinal cohort study conducted in Perth, Australia, atopy was a strong predictor of persistence of asthma from 6 years of age to 14 years of age. However, only approximately one half of the asthmatic children at age 6 years were atopic[44] and only two thirds were atopic at age 14 years (unpublished observations). The association between atopy and childhood asthma is even less strong in low-income developing countries, where lower respiratory infections in early life are major risk factors for persistent asthma in later childhood.[80]

The mechanism(s) underlying non-atopic asthma are not well understood. As outlined earlier, viral lower respiratory infections can result in airway inflammation and heightened bronchial responsiveness. Animal studies in which activated T cells are adoptively transferred into naïve animals can increase airway responsiveness in the total absence of IgE antibodies[81]; however, the direct relevance of these studies to asthma in children is not known. Recent data point to some differences but also similarities in the inflammatory factors driving atopic and non-atopic asthma. In one small cohort, the T-cell responses to stimulation with the mitogen PHA were seen to differ in atopic subjects and non-atopic subjects with bronchial hyperresponsiveness (BHR). Asthma and BHR in atopic children were most strongly related to peripheral blood eosinophil counts and to TH-2 cytokine responses, whereas the strongest relation seen in the non-atopic children was with the regulatory cytokine IL-10 made by stimulated T cells.[82]

In a larger cohort of teenaged children the peripheral blood eosinophil count was strongly associated in both atopic and non-atopic children. This effect was particularly strong in non-atopic girls (unpublished observations). Eosinophils are generally thought of as being part of an atopic inflammatory response and are responsive to secretion of the TH-2 cytokine IL-5. However, eosinophils also have surface receptors for estrogen and are increased in the peripheral blood of girls during the mid-stage of the menstrual cycle. These data show the mechanistic complexity underlying asthma; we are a long way from understanding the true link between asthma and atopy in children.

Airway Inflammation

Our understanding of the characteristics of airway inflammation in chronic asthma has been considerably enhanced by the availability of bronchoalveolar lavage (BAL) and bronchial biopsies. Although the majority of these data have come from studies in adults, they are instructive. We do not know when the chronic changes seen in adult asthma begin, and considerable doubt exists as to whether these same changes are present early in the course of childhood asthma in those who are destined to develop persistent asthma. Few studies directly addressing this issue have been performed in children. Indeed, bronchial biopsies from children with asthma do not invariably show the eosinophilic inflammation characteristic of adult asthma.[83] In addition, the reservations about the link between chronic airway inflammation and airway remodeling and abnormal lung growth in children raised by Martinez[79] (see earlier) should be noted.

Various studies in adults have consistently shown the presence of increased numbers of ciliated epithelial cells often in clumps, mast cells, and eosinophils,[84-86] whereas others have revealed increase in lymphocytes[87,88] and epithelial cells[89,90] in the BAL of asthmatic patients. More recently, sputum analyses have shown that a noneosinophilic type of asthma may be present in adults[91-93] in which the predominant cell type is neutrophils. In mild asthmatics, numbers of T lymphocytes (CD3+) and their subclasses (CD4+ helper, CD8+ suppressor/cytotoxic) are not increased, although using activation markers there is accumulating evidence of T cell activation. Macrophage and neutrophil function are also enhanced; even in mild disease, macrophages have been shown to respond to allergen by generating cytokines such as IL-8 and IL-1β, and this may reflect an important change in the phenotype of these cells in asthmatics. Both mast cells and eosinophils are also present in airway secretions. A variety of different mediators from many cell types have been described, but some of the most important are: histamine, prostaglandin D_2 (and other prostanoids), 15-hydroxyeicosatetraenoic acid (15-HETE), leukotrienes B_4, C_4, D_4, and E_4, lysosomal enzymes, and a number of basic proteins from the eosinophil. Many of these mediators originate from activated mast cells and eosinophils, but platelets, macrophages, and monocytes also contribute to the autacoid pool.

Some aspects of the inflammatory response in asthma can be modeled by the early and late asthmatic reactions (EARs, LARs) to inhaled allergen challenge (Fig. 57-6).[94] After bronchial provocation with an allergen to which the subject is sensitized, a rapid bronchoconstriction usually occurs, which lasts for about 1 hour (EAR). This is often followed by a more prolonged phase of airway narrowing (LAR) that starts 2 to 3 hours after exposure, reaches a maximal airway response by 4 to 8 hours, and resolves in 12 to 24 hours. Similar patterns are seen in young children with atopic asthma.[95] LAR occurs in parallel with an increase in airway responsiveness to bronchoconstrictor agents, such as methacholine and histamine, and this heightened responsiveness may persist for days after the LAR has resolved.

The EAR is mostly characterized by activation and degranulation of the mast cell with release of mediators, although the direct evidence for this in humans is scant. After inhalation of challenging allergens there is rapid airway narrowing, presumably due to airway smooth muscle contraction following the release, among others, of the lipid-derived mediators prostaglandin PGD_2, $9\alpha11\beta P\text{-}PGF_2$, thromboxane, leukotriene LTC_4 and 15-HETE, and kinins,[96] as well as proteases, lysosomal hydrolases, and proteoglycans that will, in a later phase, act on tissue damage and repair.

The LAR expresses itself in the airways with an important edema component, and BAL fluid during this phase contains

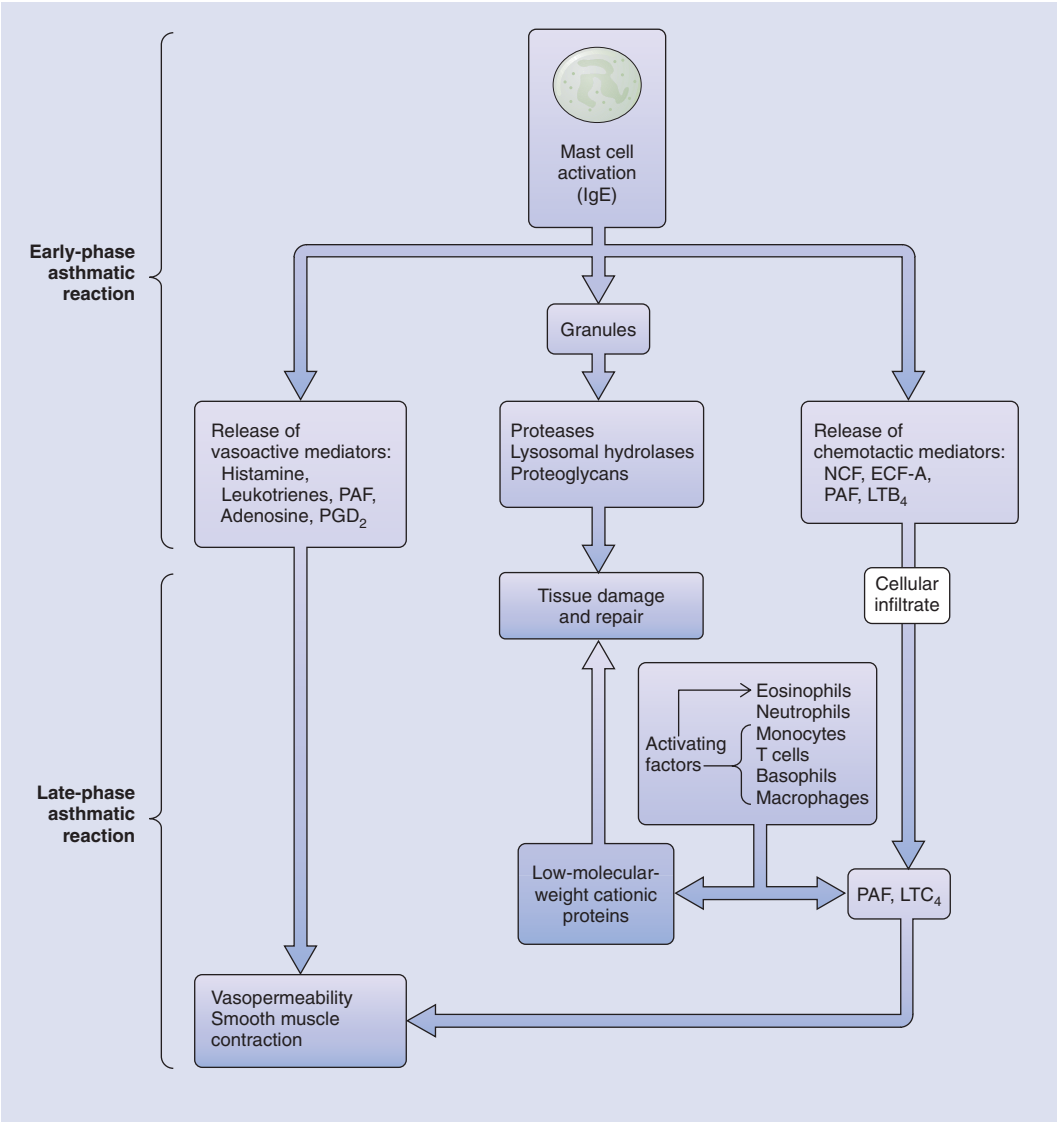

Figure 57-6 Early- and late-phase asthmatic reaction (EAR, LAR) model. ECF-A, eosinophilic chemotactic factor of anaphylaxis; PAF, platelet-activating factor; LT, leukotriene; PG, prostaglandin. (From Malo JL, Cartier A: Late asthmatic reactions. In Weiss EB, Stein M [eds]: Bronchial Asthma: Mechanisms and Therapeutics, 3rd ed. Boston, Little, Brown, 1993, p 140.)

increased numbers of eosinophils.[97] Some studies have shown increased numbers of neutrophils and lymphocytes after antigen challenge; these changes were not seen in subjects with an EAR only.[96] Patients who demonstrate both EAR and LAR show increased levels of eosinophil-derived major basic protein (MBP) and neurotoxin (EDN), but LTC_4 is seen only in patients who have a LAR. The second inflammatory "wave" represented by LAR may be important in asthma, because it may lead to proliferative and repair responses, including the targeted destruction of the bronchial epithelium, the expansion and activation of fibroblasts, hypertrophy and hyperplasia of the smooth muscle, and proliferation of neuropeptide-containing nerves.

It is clear from the preceding description that many inflammatory mediators and cells are involved in the disease process in chronic asthma. The model of EAR and LAR has been very useful in expanding an understanding of the immunopathology of hyperreactive airways. However, consensus has been reached today that there is overlap between the two responses. Interaction among cells and mediators in the airway inflammatory response could be responsible for airway bronchial hyper-responsiveness.

The relation between allergic sensitization and atopic asthma is not a simple one. Many epidemiologic studies consider atopy to be a binary variable, based on a positive skin prick test to inhalant allergens. However, recent data suggest that the degree of allergic sensitization is important. Joseph-Bowen and coworkers[98] derived a composite index based on the wheal sizes of inhalant allergens. They reported that serum levels of ECP were higher in those with more severe atopy and that more severe atopy was related to more severe asthma in 6-year-old children.[98] In addition, Douglas and colleagues[95] have demonstrated that a wheal size of >4.5 mm is highly predictive of a positive response (both EAR and LAR) to inhalational allergen challenge in young children.

Inflammatory Mediators in Atopic Asthma

Histamine is probably one of the most widely studied inflammatory mediators in asthma. A rise in plasma histamine concentrations is seen minutes after allergen inhalation,[99-101] and the subsequent increase in urinary *N*-methylhistamine[102] indicates that histamine is responsible at least in part for the early asthmatic response. Mast cells are the main source of this mediator,[90] as demonstrated by the increased levels of histamine seen in BAL from stable asthmatics, together with increased mast-cell activation.

Three types of histamine receptors are known to be present in the airway:[103] H_1, H_2, and H_3. H_1 receptors mediate histamine-induced bronchospasm in asthmatics as well as in normal subjects in higher concentrations. Histamine also elicits activation of sensory reflexes, vasoconstriction, and vasodilation of bronchial vessels through H_1 receptors.[103] H_2 receptors mediate mucus secretion and vasodilation, whereas H_3 receptors are responsible for the regulation of cholinergic and sensory nerve function. Most histamine receptors also mediate feedback inhibitory mechanisms for histamine secretion by mast cells.

Although there is evidence indicating that histamine contributes to the EAR, a direct role for histamine in the LAR has not been well established.[104] Antihistamines have not proved to be very effective in the treatment of asthma.[105] Despite the improvement in symptom scores and airway caliber measurements, studies involving continuous treatment for 2 to 7 weeks with antihistamines have not shown any significant change in airway responsiveness when assessed by methacholine inhalation challenge.[106,107] This suggests a limited role for histamine in the chronic inflammation present in asthma.

Prostaglandins or prostanoids are one of a group of local mediators believed to play a role in the asthmatic inflammatory process. After immunologic or nonimmunologic stimulation, cytosolic phospholipase A_2 (PLA_2) is activated, causing cleavage of arachidonic acid from the cell membrane phospholipid. Arachidonic acid is then metabolized in either of two pathways: the cyclooxygenase pathway, leading to the formation of prostaglandins, thromboxane, and prostacyclin, and the 5-lipoxygenase enzyme system pathway, to form leukotrienes. To become active, this PLA_2 enzyme requires the action of another protein called 5-lipoxygenase activating protein (FLAP).[108]

Alveolar macrophages also generate various prostaglandins (PG_2, PGE_2, and PGF_2-B_5) and thromboxanes. In humans, prostanoids (except those of the E series) contract airway muscle.[109,110] PGF_2-B_5 causes increased airway secretions with the production of glycoproteins.[110] Prostaglandins cause contraction of airway smooth muscle by activating the thromboxane receptor. The role of thromboxane and prostaglandins in chronic asthma is not well understood.
