Leukotrienes (LT) are biologically active fatty acids derived from the oxidative metabolism of arachidonic acid.[111] Several forms exist: LTA_4, which is formed and then rapidly converted to LTB_4; and the cysteinyl LTs, LTC_4, LTD_4, and LTE_4, which are potent constrictors of human airways. LTs can be produced by mast cells (cLT and LTB_4), eosinophils (cLT), and neutrophils (LTB_4). Epithelial cells and macrophages have also been shown to produce leukotrienes. Immunoreactive LTC_4 has been recovered from the plasma of children with severe asthma; the amounts recovered are significantly greater than those recovered from the plasma of normal children.[112] In addition, treatment of asthma is associated with a decrease in the amount of immunoreactive LTC_4 recovered from plasma. LTC_4 is detectable in significant amounts in the BAL fluid of patients with chronic stable asthma in the absence of a specific challenge.[113] Both LTD_4 and LTE_4 have been reported to increase airway hyperresponsiveness[105,114] and may play an important role in asthma. LTB_4 is a potent chemokine: it acts at accumulating and activating inflammatory cells (mostly neutrophils and eosinophils).[115] Although it has been found in BAL of asthmatic subjects,[101] the role of LTB_4 in asthma remains unclear. LTC_4, LTD_4, and LTE_4 bind to the same receptor (LT_1) on the bronchial smooth muscle. Most leukotriene antagonist drugs that have been developed block this receptor.[116] The relatively poor clinical response of children with moderate to severe asthma to leukotriene receptor antagonists raises questions about the true role of these mediators in chronic asthma.

Platelet-activating factor (PAF), like prostaglandins and leukotrienes, is formed by the action of phospholipase A_2 on membrane phospholipids and may be produced by several of the inflammatory cells implicated in asthma (i.e., macrophages, eosinophils, and neutrophils). Inhaled PAF causes bronchoconstriction and a small increase in airway hyperreactivity[117] in normal subjects. Once PAF is rapidly inactivated in vivo, it apparently triggers a chain of inflammatory events that lead to increased bronchial responsiveness. Release of PAF is apparently associated with increased accumulation of eosinophils in the lungs[118] and skin of atopic subjects.[119] PAF makes eosinophils adhere more easily to endothelial surfaces, a property that may be involved in the recruitment of eosinophils into tissues.[120] Because eosinophils are a source of PAF, they can attract more eosinophils and perpetuate an inflammatory reaction. PAF stimulates eosinophils to release basic proteins, which are known to cause tissue damage. PAF also causes an increased expression of low-affinity IgE receptors on monocytes.[121] In addition, PAF induces microvascular leakage[122] and increases airway secretions and epithelial permeability.

Bradykinin is derived from kininogens in the plasma by the action of kininogenases (including kallikrein and tryptase from mast cells). Inhaled bradykinin causes bronchoconstriction in asthmatics but not in normal subjects[123,124] inducing a sensation of dyspnea and coughing spells similar to those observed during asthmatic attack. This supports the idea that bradykinin acts as an activator of sensory nerves in the airways.[125] Mucus hypersecretion and airway edema are main features of asthma. Bradykinins could contribute to both these phenomena by dilating blood vessels, increasing vascular permeability, and stimulating ion transport. Kinins can also activate inflammatory cells and amplify the release or production of other putative mediators in asthma, notably histamine, lipid-derived mediators, and neuropeptides.[126] Bradykinin may also contribute to bronchial obstruction by mechanisms other than spasmogenesis. Bradykinin increases mucus production[127] and elicits airway edema with microvascular leakage.[128] The presence of kinins, tissue kallikrein, and kininogen in the airways at the time of either provoked

or naturally occurring asthmatic attacks has been documented.[129] Bronchial responses to bradykinin are strongly correlated with airway eosinophilic inflammation,[130] perhaps explained by damage to the airway epithelium.[131,132] Eosinophils may damage the airway epithelium, thus impairing the production of two major bronchial peptides, neutral endopeptidase (NEP) and kinase II.[133] These peptides are mainly produced by the airway epithelium, and they degrade bradykinin, thus limiting its bronchoconstrictive effects.[129,132-134] Prostaglandin E_2 is also released by the airway epithelium, and it has a strong bronchodilating effect that also balances the effect of bradykinin.[134]

Many inflammatory cells produce **oxygen-derived free radicals** such as superoxide anions which may contribute to epithelial damage.[135] These free radicals induce an oxidative stress response in the airways that appears to play an important role in the pathogenesis of asthma. Increased levels of hydrogen peroxide and nitric oxide have been reported in the exhaled breath of asthmatic patients.[136] Air pollutants have the ability to drive free radical reactions, inducing oxidative stress in the lung when endogenous antioxidant defenses are overwhelmed.[136,137] The resultant inflammatory response appears to be particularly strong among susceptible individuals, including asthmatics. "Gene + environment" interaction seems to be important in determining the increased asthma risk in children exposed to traffic-related pollutants.[138,139] Children with a genetic deficiency in their ability to neutralize oxygen-free radicals are more likely to have low lung function, respiratory symptoms, and asthma.

Oxygen radicals react with polyunsaturated fatty acid residues in phospholipids, resulting in the production of reactive aldehydes. The most abundant of these, malondialdehyde (MDA),[140] has been used as a biomarker of pulmonary oxidative stress in occupational settings.[141-143] As part of an inflammatory response in the airways, activated neutrophils, eosinophils, monocytes, mast cells, and alveolar macrophages release free radicals, which in turn provoke bronchoconstriction and changes in receptor function, which could influence airway reactivity.[144] Superoxide anion generation by eosinophils appears to be an important factor in both host defense and inflammation, and the presence of an eosinophil infiltrate in the airway of asthmatic patients can provide a potent mechanism for tissue damage.

Cytokines such as IL-5, GM-CSF, and IL-3, which are able to prolong eosinophil survival in vitro, are found in a biologically active state in the circulation of asthmatic subjects.[145] Overtly atopic and apparently non-atopic patients with asthma have been shown to have different cytokine production patterns.[145-147] Table 57-1 summarizes the functions and cell origin(s) of some of the most important cytokines involved in the airway inflammation in asthmatic subjects.

Chemokines with specific leukocyte-selective chemotactic activity are also increased in asthmatics. IL-8 is a CXC chemokine and is a chemotactic factor for neutrophils and T lymphocytes, and under some conditions for eosinophils. Other members of the CXC subfamily are MGSA/Gro-α, CTAP-III, and NAP-2, and they have similar chemotactic activities. The CC subfamily has proteins that are chemotactic for monocytes, but not neutrophils. One such cytokine is RANTES, which has been shown to be a chemoattractant for memory T cells.[146] RANTES also stimulates the migration of eosinophils across IL-1–stimulated endothelium.[147] This suggests that RANTES has an important role as a selective chemoattractant pathway for eosinophils and memory T cells in asthma.

Inflammatory Cells in the Asthmatic Airways

EOSINOPHILS

The importance of eosinophils in the pathogenesis of asthma is related to its central role in the airway inflammatory process.[148,149] To stress this role, some authors have described asthma as "chronic eosinophilic bronchitis," a concept that perhaps underestimates the importance of the contribution of many other, interconnected cells in the development and persistence of asthma. An increase in eosinophil counts is found in sputum,[150] BAL fluid,[151,152] airway epithelium and submucosa,[153,154] and commonly in blood[155] of asthmatic subjects. Although both lymphocytes and eosinophils often infiltrate the airway mucosa of asthmatics, eosinophils seem to play a major role. Eosinophils are now believed to be the cells responsible for the development of many features of asthma, such as damage and desquamation of the respiratory epithelium,[156] allergen-induced LAR,[157] and airway hyper-responsiveness.[90]

Eosinophils are derived from bone marrow precursors. After allergen challenge, eosinophils appear in BAL fluid during the LAR,[151] and this is associated with a decrease in peripheral eosinophil counts and with the appearance of eosinophil progenitors in the circulation.[157] This signal for eosinophil recruitment probably originates in the inflamed airway. The recruitment initially involves adhesion of eosinophils to vascular endothelial cells in the airway circulation, their migration into the submucosa, and their subsequent activation.

This process involves interactions between specific adhesion molecules expressed in the endothelium and their complementary ligands expressed in the leukocytes. These adhesion molecules are classified into families of related molecules: one of these families is that of the selectins.[158] E-selectin is present in cell surface glycoproteins and glycolipids of many leukocytes, including eosinophils, neutrophils, monocytes, and some lymphocytes; P-selectin[159] responds to the stimuli of histamine; L-selectin[160] is present in lymphocytes and also in eosinophils and neutrophils. There are two other large families: the immunoglobulin gene superfamily[161] and the integrins. ICAM-1 (intercellular adhesion molecule-1)[162] belongs to the immunoglobulin gene superfamily and is expressed in the vascular endothelium. It binds to two integrins that are expressed in many types of leukocytes. VCAM-1 (vascular cell adhesion molecule-1)[163] is also a member of the same family and mediates leukocyte adhesion via an integrin present on eosinophils, monocytes, and basophils. The selectins mediate central contact between the eosinophils and the endothelium, whereas the integrins and their ligands ensure a stable adhesion, following which the eosinophils transmigrate into the submucosa.

IL-1 and TNF-α increase the expression of ICAM-1 and VCAM-1, whereas IL-4 is selective for VCAM-1 and IFN-γ for ICAM-1.[164,165] Although both ICAM-1 and E-selectin appear to be involved in the process of eosinophil adhesion, the specific upregulation of VCAM-1 by IL-4 may play a

Table 57-1
Cytokines and Their Role in Airway Inflammation Reaction in Asthmatics

Cytokine	Cell Source	Functions
Interleukin-2 (IL-2)	T cells	T cell growth factor Eosinophil chemoattractant
Interleukin-3 (IL-3)	T cells Mast cells Eosinophils	Granulocyte (eosinophil and neutrophil) differentation activation in vitro survival enhancement primary chemotaxis (eosinophil)
Interleukin-4 (IL-4)	T cells Mast cells	Essential for IgE synthesis (isotype switch of B cells) Inhibition of IFN-γ-mediated responses T cell growth factor Inhibits macrophage-activated inflammatory cytokines Survival enhancement (eosinophils)
Interleukin-5 (IL-5)	T cells Mast cells Eosinophils	Eosinophil differentiation and maturation activation transmigration endothelial adhesion chemotaxis (eosinophilis) survival enhancement Basophil differentiation priming Cofactor for IgE synthesis
Interleukin-1 (IL-1a and b) Tumor necrosis factor (TNF-α) Interleukin-6 (IL-6)	Many cell types	Increased endothelial adhesion molecule expression T cell activation costimuli Macrophage activators Eosinophil activators
Granulocyte/macrophage colony-stimulating factor (GM-CSF)	T cells Mast cells Macrophages Epithelial cells Eosinophils	Granulocyte (eosinophil and neutrophil) differentation activation in vitro survival chemotaxis (eosinphils)
Interferon-γ (IFN-γ)	T cells	Inhibition IgE isotype switch Inhibition of Th-2 cell growth Eosinphil activation (late acting) Macrophage activation
Interleukin-8 (IL-8)	Monocytes T cells Fibroblasts	Neutrophil and T cell chemoattractant Neutrophil activator Inhibition of IgE synthesis Primes for eosinphil chemotaxis
RANTES	T cells Platelets	Memory T cell and eosinophil chemoattractant
Interleukin-10: human (IL-10)	T cells Monocytes Macrophages	Inhibition of Th-2 and Th-1 cytokine production Inhibition of macrophage-activated inflammatory cytokines Inhibition of eosinphil survival Inhibition of IgE synthesis
Interleukin-12 (IL-12)	T cells	Natural killer cell, T cell growth Inhibition of IgE synthesis
Interleukin-13 (IL-13)	T cells Mast cells	Induces isotype B cell switch to IgE Inhibition of macrophage-activated inflammatory cytokines
Platelet-derived growth factor b (PGDF-b)	Monocytes Macrophages	Fibrosis Th-2 cytokine inhibition
Transforming growth factor b (TGF-b)	Monocytes Macrophages	Fibrosis Th-2 cytokine inhibition

Modified from Robinson DS, Durham SR, Kay AB: Cytokines. 3. Cytokines in asthma. *Thorax* 48(8):845-853, 1993.

crucial role in this process. The role of individual cytokines and mediators in coordinating these responses is not yet fully understood. Eosinophils can respond to cytokines but are also able to produce cytokines themselves.[166,167] Attention has also been focused on the production of growth factors by eosinophils. TGF-α mRNA has been detected in eosinophils of patients with high eosinophil counts.[168] If these findings are confirmed in bronchial tissue from asthmatics, they would suggest that TGF-α and also TGF-β may be important in the epithelial regeneration, myofibroblast proliferation, and subepithelial collagen deposition that are characteristic of chronic asthma.

Eosinophils can be activated in a number of different ways, including by allergen exposure, PAF, and cytokines such as GM-CSF and IL-5. Eosinophils release a variety of mediators, including LTC_4, PAF, 15-HETE, and oxygen-derived free radicals. Eosinophils also release four basic proteins that are toxic to the airway epithelium: MBP, eosinophil cationic protein (ECP), eosinophil-derived neurotoxin, and eosinophil peroxidise.[149,169] These basic proteins are involved in such

actions as bronchoconstriction, mucus hypersecretion, increased vascular permeability, and epithelial desquamation, causing damage to the respiratory epithelium, which ultimately leads to the clinical features of asthma.

A number of tissue leukocyte-induced eosinophil surface proteins act to regulate airway eosinophilic inflammation. ICAM-1 was demonstrated on the surface of eosinophils in sputum. Blood eosinophils also show ICAM-1 after incubation with TNF-α and eosinophil survival factors. By these and other pathways, the eosinophil is able to maintain eosinophil-lymphocyte and eosinophil-eosinophil interactions to directly influence its own accumulation and activity and that of other inflammatory cells.[170] The same cytokines that are responsible for eosinophil production also have an important role in the priming of eosinophils.

MAST CELLS

Mast cells are widely distributed in the body and are part of its defense against harmful agents. They can also be found in the connective tissue of the lamina propria in the airways.[171] Mast cells can also be found in association with airway smooth muscle cells in the airways of adult asthmatics in greater numbers than seen in patients with eosinophilic bronchitis or nonasthmatic controls,[172] suggesting that these cells are involved in the airway dysfunction characteristic of chronic asthma. Whether similar infiltration occurs in asthmatic children is not known.

Mast cells release a variety of preformed and newly synthesized mediators that could be responsible for many of the clinical expressions of asthma.[90] Moreover, mast cells are one of the only cell types carrying the high-affinity receptor for IgE (FcGRI), suggesting that this cell plays an important role in signaling the presence of antigen in its vicinity. An important feature in asthmatic patients is the presence, density, and degranulation of mast cells within the epithelium. Once activated, mast cells release a number of mediators. Histamine, neutral proteases, and proteoglycans are preformed and stored in granules, whereas the lipid mediators, PGD_2, LTC_4, and PAF, are all newly synthesized. As discussed earlier, histamine is a bronchoconstrictor that may also mediate vasodilation, increase vascular permeability, and increase mucus secretion. PGD_2 is a potent bronchoconstrictor; LTC_4 and its metabolites also contract smooth muscle and increase vascular permeability.

Mast cells synthesize and release cytokines.[173] Murine cell lines when activated have been shown to secrete a large number of cytokines: GM-CSF,[174,175] IL-3,[175] IL-4,[176] IL-5, and IL-6,[177] IL-1, IL-2, IFN-γ, and four members of the chemokine family. It is also known that human mast cells release TNF-α when activated.[178] This molecule is believed to play an important part in the recruitment of inflammatory cells from the peripheral circulation, and the proportion of mast cells expressing this cytokine has been found to be increased in asthmatics.[179] Human mast cells also produce IL-4, and the proportion of mast cells expressing IL-4 has also been found to be increased in asthmatics.[176]

MACROPHAGES

Macrophages can be activated by allergen via a low-affinity IgE receptor (FcGR1).[180] They are derived from blood monocytes and are the cells found in largest numbers in the BAL fluid. Macrophages are found in increased numbers after allergen challenge in asthmatic patients.[180] Macrophages from asthmatic subjects release increased amounts of oxygen-derived free radicals,[181] indicating that they have been activated by some endogenous mechanisms. Macrophages produce a great number of mediators, with more than 100 secretory products identified.[182] One important feature of the macrophage is to help determine the characteristics of the inflammatory response. After allergen exposure, alveolar macrophages release a number of inflammatory mediators (LTB_4, PGF_2, thromboxane B_2, and PAF).[183,184] They are also able to release a great number of cytokines.[185] These cytokines include IL-1, IL-8, IL-10, GM-CSF, histamine-releasing factors, and TNF-α.[186,187]

Macrophages normally have a suppressive role on lymphocyte function, but this function may be impaired in asthma after allergen exposure.[188,189] Dendritic cells, which are specialized macrophages in the airway epithelium, are professional antigen-presenting cells[190] and have a very important role in the initiation of allergen-induced responses (see earlier).

NEUTROPHILS

Neutrophils may have a role in asthma because they contain many destructive proteases, are able to secrete arachidonic acid metabolites and leukotrienes, and can produce active oxygen metabolites and cytokines such as IL-8 and IL-1. Several earlier studies have failed to find any difference in baseline neutrophil numbers between asthmatic and nonasthmatic subjects in BAL fluid.[191,192] However, a distinct subtype of asthma has been identified, characterized by neutrophilic inflammation.[91-93] This type of asthma is characterized by the presence of increased concentrations of IL-8 and free neutrophil elastase activity in induced sputum, rather than the increased levels of the matrix metalloproteinase MMP-9 seen in eosinophilic asthma. In addition, neutrophils appear to be present in the sputum of adults[193,194] and children[195] with severe asthma and steroid-resistant asthma.

EPITHELIAL CELLS

The airway epithelium appears to play an important regulatory role in the inflammatory mechanism of asthma. In addition to its function as a barrier to the outside environment, the epithelial lining of airways has a number of metabolic functions. These include regulation of fluid and ion transport, production, secretion, and movement of mucus, and presentation of antigen and foreign substances to immunologic cells within the airway. It has been recently proposed that the epithelium also regulates airway caliber by secreting substances that alter smooth-muscle reactivity.

Bronchial epithelial cells (BECs) also appear to play a direct role in immune modulation.[196] Increasing evidence shows that the BECs from asthmatics show a different secretion pattern in response to various stimuli. Asthmatic BECs secrete more IL-8, GM-CSF, and sICAM-1 than BECs from nonasthmatics in response to exposure to diesel exhaust particles—a key component of traffic-related pollution.[197] In addition asthmatic BEC also secreted RANTES in response to diesel exhaust particles, a response that was lacking in nonasthmatic BECs.[197] Similarly, BECs from asthmatics

secreted increased amounts of IL-8, GM-CSF, TGF-β, IL-4, and IL-13 than BECs from nonasthmatics when exposed to house dust mite allergen.[198] In addition to cytokine secretion, BECs interact with RTDC and seem capable of influencing the way in which these cells interact with T cells.[199]

Injury caused by environmental insults or other stimuli inhibit the ability of the epithelium to produce mediators that regulate airway responsiveness and caliber. After an acute asthmatic exacerbation, cells and mediators of airway inflammation persist within the airway and submucosa, providing a continued stimulus to the epithelium both to produce factors that may enhance reactivity and to disrupt the production of factors that could normally downregulate reactivity. BECs are also able to produce the cyclooxygenase products PGE_2 and $PGF_{2\alpha}$, influencing bronchial smooth muscle tone in either direction, depending on their relative levels of production, which may, in turn, be influenced by other factors such as bradykinin, histamine, and PAF.[200] Increased epithelial permeability to inhaled irritants appears to be responsible for the increased airway responsiveness seen following viral LRI.[201,202]

Interaction between Airway Inflammation and Neural Responses in Asthma

The fact that neural mechanisms are involved in the regulation of airway tone convinced many researchers in the past that neural abnormalities could be involved in the pathogenesis of asthma. This idea has been all but abandoned, but there is now significant evidence that points to important interactions between neural and immunologic mechanisms of inflammation Specifically, it is now established that neural nonadrenergic, noncholinergic peptide neurotransmitters interact with inflammatory mediators during the airway inflammatory process that is characteristic of asthma.[203] These peptide neurotransmitters are stored and released from nerve endings that have a more classic primary function as cholinergic or adrenergic neurons.

Two main types of NANC neurotransmitters exist: inhibitory and excitatory. NO appears to be the most important inhibitory neurotransmitter in the airways. Several enzymes (NO synthases) contribute to its production, and inhibition of these enzymes blocks the neural bronchodilator response in vitro. However, NO may have the undesired effect of increasing airway inflammation by increasing blood flow to the airway, with consequent plasma leakage. Other neurotransmitters such as vasoactive intestinal polypeptide (VIP) and peptide histidine isoleucine (PHI) are also abundant in the lung but seem not to have a physiologic role in airway bronchodilation.[203,204]

The excitatory NANC neurotransmitters are co-localized at the nerve endings of afferent nerves, or C-fibers, and include tachykinins-substance P (SP), neurokinin A (NKA), and neurokinin B (NKB)—named as such because of their rapid spasmogenic effect on smooth muscle; calcitonin gene-related peptide (CGRP), and gastrin-releasing peptide. An increased population of SP-containing nerves may be identified in the airways of subjects who died with severe asthma, suggesting a neural tropism is concomitant with chronic inflammation. Once released, the effects of these neuropeptides are regulated, in part, by distinct peptidases, such as NEP and angiotensin-converting enzyme.[203] Disruption of the airway epithelium (either mechanically or by viral infection) increases the bronchoconstrictor effect of tachykinins, presumably by limiting its degradation.[205]

Bronchial Hyper-responsiveness

Bronchial hyper-responsiveness—exaggerated responses to a variety of seemly harmless stimuli—is a characteristic feature of asthma. However, the relation between asthma and BHR to chemical stimuli, such as methacholine (MCh), is complex.[206] Although both the prevalence and severity of BHR are increased in children with asthma, BHR also exists in nonasthmatic and non-atopic children. The mechanism(s) underlying BHR in children are not well understood. Airway remodeling is thought to play an important role in adults with chronic asthma[207-209]; however, this may not be the case in children and adolescents, especially because most have lung function within the normal range when asymptomatic.[210] Recent work has suggested that different mechanisms may underlie BHR in atopic and non-atopic teenagers, with BHR to inhaled histamine related to classic Th-2 mechanisms in atopic subjects but more closely related to production of IL-10 and interferon gamma (IFN-γ) by T cells in non-atopic subjects.[82] However, Humbert and coworkers[211] have pointed to more similarities than differences in the airway immunopathology in adults with atopic and non-atopic asthma, with infiltration of eosinophils and Th-2 cells secreting IL-4 and/or IL-5 being observed in both variants.

Although some studies show a relation between eosinophils and BHR, it is not clear whether they directly contribute to BHR. Eosinophil cationic proteins can increase cholinergic discharge at the airway smooth muscle neuromuscular junction by disrupting the normal feedback inhibition mediated by muscarinic (M_2) prejunctional receptors,[212] and the cationic proteins, major basic protein, and poly-L-lysine, increase immunoreactive kinins and kallikrein-like activity in vivo.[202] Both these mechanisms could potentially contribute to BHR. We have recently reported that eosinophils play an important role in driving BHR in adolescents with asthma, independent of atopy. This relation was much stronger in girls, raising the possibility that female sex hormones may be involved.

SUMMARY

There is still a lot that we do not know about the mechanisms underlying the initiation and persistence of asthma in children. A genetic predisposition(s), which results in both a delayed postnatal maturation of the immune system and an increased risk of lower respiratory viral infections in early life, appears to markedly increase the risk of developing asthma. The onset of allergic sensitization by 2 years of age and the development of more severe atopy appear to be important risk factors. We still lack data to determine whether the inflammatory mechanisms demonstrated in the airways of adult asthmatics, together with the structural remodeling that occurs, are present in young children with asthma and when this begins. More research is required to understand these mechanisms so that more effective treatments and preventive strategies can be developed.

CHAPTER 58 Clinical Features, Outcomes, and Prognosis

Andrew H. Liu and Ronina A. Covar

TEACHING POINTS

- There are three common clinical scenarios for asthma in children:
  1. Recurrent coughing and/or wheezing in preschool children
  2. School-age children with asthma
  3. Difficult-to-control asthma
- A diagnostic test for asthma is lacking. Diagnosis depends on clinical patterns of recurrent cough and/or wheeze with confirmatory physical exam findings and diagnostic tests.
- Recurrent cough and/or wheeze in early childhood is common; this is the age when most asthma begins. Prognosis for persistence into later life varies, and is predictable.
- Allergy in early childhood, especially the combination of indoor allergen sensitization and exposure, predicts the persistence and severity of asthma.
- A good assessment of asthma impairment and risk is essential to determine if good control is being achieved and maintained, and will simultaneously educate children and their families on the expectations of good control.
- When assessing asthma control in school-age children, question the child as well as the parent/caregiver.
- Spirometry is an important clinical tool for assessing lung function and asthma control in children. Experience is required to obtain accurate information from spirometry and to interpret the findings in children of different ages.
- Identify children at increased risk of severs attacks, morbidity, and death due to asthma for heightened management.
- Exhaled nitric oxide is a new clinical marker of airway inflammation in asthma that may help practitioners asses control and confirm the diagnosis.

OVERVIEW

Although there are hallmark pathologic features of asthma (e.g., airways inflammation, narrowing, and obstruction), many clinical aspects are quite variable from individual to individual (e.g., disease severity, hyperresponsiveness, natural history, type of inflammation, allergic sensitizations). One approach to this clinical variability is to build on a common foundation of understanding with tailored considerations for the three most common manifestations of childhood asthma: (1) preschooler with recurrent cough/wheeze; (2) school-aged child with asthma; and (3) difficult-to-control or severe asthma in childhood.

There are distinct considerations in clinical features, outcomes, and prognosis that are specific for each of these scenarios. The following introduction briefly overviews some of these key considerations.

Recurrent coughing and/or wheezing in preschool children is common and accounts for much of the morbidity and hospitalizations for asthma. Preschool children have frequent exacerbations and severe events, incurring the highest hospital admission rate of all other age groups for asthma. From a retrospective analysis of children with asthma admitted to a community-based pediatric intensive care unit over a 10-year period, 75% were 6 years and younger.[1] The diagnosis of asthma in young children is challenging in that they are too young to report more subtle symptoms of asthma or the frequency of symptoms, and to perform currently available confirmatory tests (e.g., spirometry). The clinical course in young children is often more episodic: periods of mild symptoms or wellness punctuated by exacerbations. Importantly, the prognosis for younger children with recurrent wheezing to have persistent asthma into later childhood and adulthood varies, such that most young children with recurrent wheezing will grow out of their symptoms by the end of their lower school years; others will persist and ultimately compose most of the children and adults with persistent asthma. Clinical management of these two divergent groups is aided by predictive risk factors that distinguish young children with recurrent wheezing who are likely to persist versus those who will gradually improve on their own.

The *school-age child with asthma* is perhaps the common "bread-and-butter" presentation of asthma in children. Most have mild to moderate disease severity, have associated atopy with inhalant allergen sensitization and allergic rhinitis, and can achieve good control and outcomes with adherence to the national and international guidelines for asthma management. It is generally believed that the large majority of children with asthma can normalize their lives to the extent that the goals of the U.S. National Asthma Education and Prevention Program should be achievable (Box 58-1).

Children may have *difficult-to-control asthma* for a variety of reasons that affect response to therapy, ranging from inadequately addressed comorbid conditions, occult masquerad-

BOX 58-1 Goals of Asthma Management and Control

Minimal or no chronic symptoms day or night
Minimal or no exacerbations; step-wise early intervention to prevent exacerbations from becoming severe
No limitation of activities; have physically active lives
No missed school and/or work due to asthma
Near normal pulmonary function
Minimal use of inhaled short-acting β_2-agonists
Minimal or no adverse effects from medications

From the National Asthma Education and Prevention Program Expert Panel Report II: Guidelines for the Diagnosis and Management of Asthma. National Institutes of Health/National Heart, Lung, and Blood Institute, NIH Publication No. 97-4051, 1997; and Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention. 2005 Update: Workshop Report (http://www.ginasthma.com).

ers of asthma, persistent environmental exposures that increase asthma severity and reduce the effectiveness of therapy, inherent biological variation in disease processes and their response to existing therapies, and the often-present challenges of adherence to controller therapy and exacerbation management.

DIAGNOSING ASTHMA

Without a diagnostic test for asthma, five criteria are typically used to identify asthma in a child (Box 58-2).

General Clinical Features

MEDICAL HISTORY

The most common asthma symptoms are coughing and/or wheezing that can worsen to chest tightness, shortness of breath, tachypnea and/or retractions (Box 58-3). Asthma symptoms often worsen with sleep, typically manifest as diurnal variation with increased symptoms at night and upon awakening in the morning. Asthma symptoms are also commonly triggered and worsened by common exposures and activities. These exposures include irritants (e.g., tobacco smoke, air pollutants, wood-burning, cleaning agents, perfumes, cold air) and inhaled allergens in those with allergen-specific hypersensitivity. Common respiratory viral infections (e.g., rhinovirus, RSV, metapneumovirus) are frequent causes of exacerbations in children with asthma. Activities that commonly trigger asthma include exercise, laughing, and hyperventilation. Common conditions that can also manifest with recurrent coughing and are often comorbid with asthma include rhinitis, sinusitis, gastroesophageal reflux disease, and prolonged postinfectious laryngotracheobronchitis (e.g., pertussis).

BOX 58-2 Diagnosing Asthma

Five criteria are typically used to identify asthma in a child:
Coughing and/or wheezing are recurrent
Other causes of coughing/wheezing are excluded
Risk factors for asthma are identified
The child improves with asthma therapy
Confirmatory physical examination findings and/or diagnostic tests

BOX 58-3 Asthma History

Symptoms
Recurrent coughing and/or wheezing
Symptoms of increasing severity:
- Chest tightness and/or pain
- Shortness of breath
- Tachypnea
- Retractions

Episodic exacerbations

Diurnal Variation
Worsens with sleep/worse at night and upon awakening

Common Triggers
Exercise, cold air, hyperventilation (laughing, crying)
Tobacco smoke and inhaled irritants
Inhaled allergens
Exacerbations: common respiratory viruses

BOX 58-4 Physical Examination for Suspected Asthma

Coughing and/or wheezing:
- Expiratory, polyphonic, high-pitched wheezing
  - Wheezing often not heard
- Resolution or improvement in cough/wheeze with asthma therapy:
  - Inhaled beta-adrenergic agonist (e.g., albuterol, salbutamol)
  - Corticosteroids: oral/systemic or inhaled (2 to 4 weeks' response)

Signs of increasing severity:
- Tachypnea
- Retractions
- Respiratory distress
- Cyanosis

Comorbid findings:
- Atopic dermatitis rash
- Allergic rhinitis, sinusitis

Rule out asthma masqueraders: examination findings NOT consistent with asthma
- Clubbing
- Fine rales
- Failure to thrive

PHYSICAL EXAMINATION

The findings summarized in Box 58-4 can support and, when present, confirm the diagnosis of asthma. During clinical evaluations in the office setting, one often has to rely on the

BOX 58-5 Confirmatory Tests for Asthma

Spirometry
- Airflow limitation
  - Low FEV_1 (relative to percentage of predicted norms)
  - FEV_1/FVC ratio <0.80
- Bronchodilator response (to inhaled β-agonist):
  - Improvement in/resolution of coughing and/or wheezing
  - Improvement in $FEV_1 \geq 12\%$ (or at least 200 mL)*
- Bronchial hyper-responsiveness to a provocative agent*
- Exercise challenge:
  - Worsening in $FEV_1 \geq 15\%$*

Daily peak flow or FEV_1 monitoring:
- Morning-to-PM variation ≥20%*

Exhaled nitric oxide
- Elevated*

*Main findings consistent with asthma.

medical history and patterns of disease to support a tentative diagnosis of asthma because most children may be relatively asymptomatic and without physical signs of asthma during the visit unless they are poorly controlled and are having an acute exacerbation.

Confirmatory tests (Box 58-5) can strengthen the diagnosis of asthma. Standard diagnostic tests that help to confirm the diagnosis of asthma include: (1) bronchodilator response ≥12% (which is greater than normal); (2) bronchial hyperresponsiveness greater than normal, evident during bronchoprovocation challenges (e.g., with methacholine, histamine, exercise, hyperventilation/cold air, mannitol); and (3) diurnal variation in peak flow (i.e., early morning-to-evening) more than 20% (greater than normal). A new "breath test" that measures nitric oxide in exhaled air, a biomarker of airways inflammation, is a useful and increasingly available confirmatory test for asthma. Several recent studies have demonstrated high statistical accuracy for exhaled nitric oxide as a confirmatory test for distinguishing asthma from other causes of chronic cough in adults and children (see Advances in Clinical Assessment of Asthma in Children, later). Induced sputum to detect an increased percentage of eosinophils could also serve as a confirmatory diagnostic test, although the practicality of its implementation in the clinic setting is limited, and consistent, valid results are not obtainable in younger children.[2]

Preschooler with Recurrent Cough/Wheeze: Diagnosis

Preschoolers present some diagnostic challenges because of their young age. It is obvious that infants and young children are unable to provide a medical history themselves and that clinicians are limited to observations made by parents/caregivers. Preschoolers are usually too young to reliably perform spirometry, peak flows, exhaled nitric oxide, and induced sputum, thereby limiting the use of current asthma confirmatory tests in the clinical setting.

Another challenge is that there are several different clinical patterns of recurrent coughing/wheezing that develop in young children and have different prognoses. These clinical patterns implicate differing disease processes underlying the outcomes of disease persistence versus resolution. Indeed, many infants and young children will experience symptomatic bronchitis/bronchiolitis with respiratory viral infections (i.e., "transient wheezer" or "wheezy bronchitis" patterns), without leading to a chronic recurrent condition. Given this scenario, perhaps it is not surprising that asthma in young children may be both overdiagnosed and underdiagnosed, and often not appropriately managed.

The five criteria for diagnosing asthma can be applied to the preschool child:

1. *Coughing and/or wheezing are recurrent:* a typical pattern begins some months after birth with recurrent symptoms, instigated by common respiratory viral infections, with variable symptoms in between. Some infants and toddlers cough, some wheeze, and some do both. The nature of the cough can vary, often presenting as a dry, persistent cough, but it can also be a wet, gagging cough, sometimes with post-tussive emesis. As asthma exacerbations worsen, young children may manifest tachypnea, retractions, and hypoxemia requiring urgent care. The patterns of recurrence or persistence are essential. For example, a single episode of bronchiolitis in the winter months does not forebode persistent disease unless the episode is severe or accompanied by pneumonia. A pattern of recurrent coughing/wheezing episodes with common respiratory viral infections, extending outside of the winter months,[3] and persistence of coughing/wheezing apart from colds,[4] are presentations of recurrent or persistent disease compatible with asthma. It is not uncommon for young children to present with recurrent pneumonias, atelectasis, or bronchitis before symptoms and patterns of persistent asthma become apparent.
2. *Other causes of coughing/wheezing are excluded:* the differential diagnosis for young children with a clinical picture of asthma is particularly broad and deserves special emphasis, in part because of a number of asthma masqueraders that typically manifest in infancy and early childhood; they are listed in Box 58-6. Neonatal onset of symptoms, associated failure to thrive, diarrhea or vomiting, and even focal lung or cardiovascular findings suggest an alternative diagnosis and require further investigations.
3. *Risk factors for persistent asthma are identified:* a series of risk factors identifies young children who are likely to persist with asthma symptoms: allergic manifestations (clinical and/or biological); parental asthma, and patterns of wheezing apart from common colds. The Asthma Predictive Index (API) is a statistically optimized algorithm that was developed via the Tucson Children's Respiratory Study (CRS) to predict which toddlers with a pattern of recurrent wheezing are most likely to have persistent asthma into the school-age years.[4] A modified version of the API incorporates other risk factors for persistent asthma (Table 58-1).[5] Indeed, toddlers who meet these modified API criteria essentially have the clinical picture

BOX 58-6 Asthma Masqueraders (Differential Diagnosis)

Upper respiratory tract conditions
- Allergic rhinitis*
- Chronic rhinitis*
- Sinusitis*
- Adenoidal or tonsillar hypertrophy
- Nasal foreign body

Middle respiratory tract conditions
- Laryngotracheobronchomalacia*
- Laryngotracheobronchitis (e.g., pertussis)*
- Laryngeal web, cyst, or stenosis
- Vocal cord dysfunction*
- Vocal cord paralysis
- Tracheoesophageal fistula
- Vascular ring, sling, or external mass compressing the airway (e.g., tumor)
- Foreign body aspiration*
- Chronic bronchitis from environmental tobacco smoke exposure*
- Toxic inhalations

Lower respiratory tract conditions
- Bronchopulmonary dysplasia or chronic lung disease of preterm infants
- Viral bronchiolitis*

Causes of bronchiectasis
- Cystic fibrosis
- Immune deficiency
- Allergic bronchopulmonary mycoses (e.g., aspergillosis)
- Chronic aspiration
- Immotile cilia syndrome, primary ciliary dyskinesia

Medications associated with chronic cough
- Acetylcholinesterase inhibitors
- β-adrenergic antagonists

Other
- Gastroesophageal reflux*
- Bronchiolitis obliterans
- Interstitial lung diseases
- Hypersensitivity pneumonitis
- Pulmonary eosinophilia, Churg-Strauss vasculitis
- Pulmonary hemosiderosis
- Tuberculosis
- Pneumonia
- Pulmonary edema (e.g., congestive heart failure)

*More common asthma masquerading conditions.

of school-age children with asthma and might be considered to have early-onset asthma (see Outcomes, Prognoses, and Predictors, later). In comparison, there are other additional risk factors for chronic or persistent wheezing in preschoolers, distinct from common persistent asthma: these include small for gestational age; male gender; environmental and in utero tobacco smoke exposure; and pneumonia with bronchiolitis in infancy.

Table 58-1
Modified Asthma Predictive Index

Toddler-aged children (2-3 years old) with a history of recurrent cough/wheeze in the past year and either one major *or* two minor criteria have an increased risk for asthma in later life (school-aged years).

Major Criteria	Minor Criteria
Parent with asthma	Allergic rhinitis
Atopic dermatitis	Wheezing apart from colds
Inhalant allergen sensitization	Eosinophils >4% (blood)
	Food allergen sensitization

Data from Castro-Rodriguez JA, Holberg CJ, Wright AL, Martinez FD: A clinical index to define risk of asthma in young children with recurrent wheezing. Am J Respir Crit Care Med 162:1403-1406, 2000; and Guilbert TW, Morgan WJ, Zeiger RS, et al: Atopic characteristics of children with recurrent wheezing at high risk for the development of childhood asthma. J Allergy Clin Immunol 114:1282-1287, 2004.

4. *The child improves with asthma therapy:* without confirmatory diagnostic tests for asthma in preschoolers, reliance on response to conventional asthma therapy and management is often used to support a tentative diagnosis of asthma. An appropriate response to therapy might include overt clinical improvement in the clinic to an inhaled beta-agonist (e.g., albuterol, salbutamol), or clinical improvement following a course of daily controller pharmacotherapy and/or oral corticosteroids.
5. *Confirmatory physical examination findings and diagnostic tests:* confirmatory physical examination findings in young children can be helpful, especially if they improve with asthma therapy (e.g., bronchodilator in the clinic). Key parameters of the physical assessment of the young child include: (1) general respiratory status and grading of respiratory distress if any observed; (2) respiratory rate, air exchange, presence and character of coughing and wheezing if detected, and other pulmonary findings by auscultation (e.g., rhonchi, rales); and (3) surveying other body systems for evidence suggestive of other disease processes besides or comorbid with asthma: failure to thrive, clubbing, eczematous rash, nasal patency versus congestion or obstruction, oropharyngeal abnormalities (e.g., palatal defects, lack of tonsillar tissue), cardiac findings suggesting anomalies, or lymphadenopathy/hepatosplenomegaly. Children with asthma rarely, if ever, develop clubbing.

School-Aged Child with Asthma: Diagnosis

The five diagnostic criteria for asthma in children, as described in Box 58-2, also apply to the school-aged child:

1. *Coughing and/or wheezing are recurrent:* In school-aged children, in addition to wheezing and cough, other symptoms emerge as the ability of the children to perceive and verbalize symptoms improves (e.g., chest tightness/pain, shortness of breath, exercise intolerance). Other asthma symptoms in children can be subtle and nonspecific, including self-imposed limitation of physical activities, general fatigue, and difficulty keeping up with peers in physical activities.

BOX 58-7 Asthma Triggers

Common viral infections of the respiratory tract:
rhinovirus, respiratory syncytial virus, parainfluenza and influenza viruses, metapneumovirus
Aeroallergens in sensitized asthmatics:
Animal dander: cats, dogs, rodents, horses
Indoor allergens: dust mites, cockroaches, molds
Seasonal aeroallergens: pollens (trees, grasses, weeds), seasonal molds (*Alternaria, Cladosporium*)
Environmental tobacco smoke
Air pollutants: ozone, sulfur dioxide, particulate matter, wood- or coal-burning smoke, endotoxin, mycotoxins
Strong or noxious odors or fumes: perfumes, hair sprays, cleaning agents
Occupational exposures: farm and barn exposures, formaldehydes, cedar, paint fumes
Cold air, dry air
Exercise
Hyperventilation: crying, laughter
Comorbid conditions: rhinitis, sinusitis, gastroesophageal reflux

BOX 58-8 Common Comorbid Conditions

Upper airway disease
Allergic rhinitis
Chronic rhinitis
Recurrent/chronic sinusitis
Atopic disorders of the "atopic march" of childhood
Allergic rhinoconjunctivitis
Atopic dermatitis
Food allergy
Gastroesophageal reflux disease
Vocal cord dysfunction

Most school-aged children with asthma manifest typical patterns and triggers. Symptoms apart from colds are reported more often. Nocturnal awakenings and early morning worsening of symptoms are not uncommon in poorly controlled patients or during prolonged exacerbations triggered by respiratory infections or inhalant allergens. The typical child has asthma symptoms triggered by viral infections, physical exertion, and hyperventilation (e.g., laughing), cold or dry air, and airways irritants (e.g., smoke) (Box 58-7). Most children with asthma are likely to be allergic and, therefore, a variety of inhalant allergens are additional triggers (see Identifying Asthma Triggers, later).

2. *Other causes of coughing/wheezing are excluded:* several medical conditions are comorbid with asthma, can make asthma worse, and can be difficult to distinguish from asthma (Box 58-8):
   - *Allergic rhinitis* is reported in 85% to 90% of children with asthma.[6] Recurrent or chronic sinusitis is often coincident with asthma. Several mechanisms may explain how uncontrolled allergic rhinitis can provoke or worsen asthma: the release of mediators via nasal allergen exposure can cause bronchoconstriction and eosinophil influx into the lungs by neural and immune mechanisms; postnasal drip may cause coughing, bronchial smooth muscle contraction, and lower airway inflammation; and mouth breathing (i.e., lack of nasal breathing) leads to poor air preparation for the lungs, by bypassing the air warming, humidification, and filtration processes that breathing through the nasopharynx provides.
   - *Food allergy and atopic dermatitis*. These conditions, with allergic rhinoconjunctivitis and asthma, comprise a subset of atopic conditions that compose the "atopic march" of childhood. These conditions tend to cluster in families and individuals, beginning with atopic dermatitis and food allergy in infancy, followed by airways allergic disease and asthma in later childhood. Both food allergen sensitization and atopic dermatitis in infants with recurrent wheezing are recognized risk factors for the subsequent diagnosis of asthma.
   - *Gastroesophageal reflux disease (GERD)* can cause episodic coughing and sometimes wheezing that mimics asthma. GERD is believed to worsen asthma through inflammatory and reflex neural mechanisms related to distal esophagitis, as well as microaspiration. Additionally, GERD may be provoked or caused by asthma, especially when asthma is poorly controlled, during asthma exacerbations, or by the medications used to treat asthma.
   - *Vocal cord dysfunction (VCD)* in adolescents can manifest as intermittent, sudden-onset daytime wheezing. In this condition, the vocal cords close inappropriately during inspiration and, sometimes, exhalation, producing shortness of breath, coughing, throat tightness. The wheezing of VCD is often audible laryngeal wheezing and/or stridor. The monophonic wheeze of VCD generally differs from the polyphonic wheeze of asthma, although asthma can also manifest a monophonic wheeze. In most VCD cases, spirometric lung function testing will reveal "truncated" and inconsistent inspiratory and expiratory flow-volume loops, a pattern that differs from the reproducible pattern of airflow limitation in asthma that improves with bronchodilators. Asthma, allergic rhinitis, sinusitis, and GERD, can be underlying causes of VCD.

   Special procedures are sometimes necessary to evaluate for these conditions because symptoms can be subtle or unreliable. For example, GERD can be without any gastrointestinal manifestations, hence, clinically silent in children. Children with chronic sinusitis often do not report sinusitis-specific symptoms such as localized sinus pressure or tenderness, and may have only a lingering cough.
3. *Risk factors for asthma are identified:* Numerous studies have consistently identified atopy to be a risk factor for asthma; therefore, a history of other allergic conditions (allergic rhinitis, allergic conjunctivitis, atopic dermatitis, and food allergies) or parental asthma and atopy is supportive of the diagnosis of asthma.
4. *The child improves with asthma therapy:* It is believed that the majority of children with asthma should obtain good control of their condition with a conventional approach to

asthma management, as described in different national/international guidelines (see Chapter 59, Asthma Treatment). Prior experience with asthma medications (i.e., bronchodilators) may provide a history of symptomatic improvement that supports the diagnosis of asthma. A lack of response to bronchodilator treatments and corticosteroid therapy is inconsistent with underlying asthma and an investigation for other disorders should be initiated. For children presenting with acute symptoms, treatment with a bronchodilator and, if needed, a short course of an oral corticosteroid might bring quick relief and support the diagnosis of asthma. For children presenting without acute symptoms, but with a historical pattern suggestive of asthma, good improvement in symptoms with a conventional course of daily controller pharmacotherapy of adequate duration (e.g., inhaled corticosteroids for 1 to 2 months) along with other measures to reduce airways inflammation, would support the diagnosis of asthma.

5. *Confirmatory physical examination findings and diagnostic tests:* On physical examination, the general approach applies (see Box 58-4), with special emphasis on the common comorbid conditions (e.g., rhinitis, sinusitis, GERD) that can mimic and/or worsen asthma (see Box 58-8). It is common for asthma in children to manifest in the regular clinical setting without diagnostic physical signs of asthma (e.g., expiratory wheezing). The chest examination is often normal but, sometimes, forced expiratory breaths can elicit otherwise undetectable wheezing. Chest radiographs, typically viewed as normal or with minimal bronchial wall thickening in children with asthma, are often obtained at initial evaluation to screen for causes of persistent coughing and wheezing that are not asthma (e.g., tuberculosis, pneumonia, bronchiectasis).

MEASURES OF LUNG FUNCTION

Beginning in school-age years, children develop the ability to perform the confirmatory tests for asthma that are based on measurements of forced expiratory airflow (see Box 58-5). The conventional measure of airflow for diagnosing and assessing asthma is spirometry. For asthma assessments, spirometry measures maximal forced expiratory airflows and lung volumes to determine if either are limited or smaller than adjusted norms, based on height, gender, and ethnicity. In asthma, airway obstruction results in reduced airflow with forced exhalation and smaller partial expiratory lung volumes, such as FEV_1 (Fig. 58-1). Because children with asthma are often hyperinflated and can have larger than normal lung volumes, FEV_1 is adjusted for full expiratory lung volume—the forced vital capacity (FVC)—with an FEV_1/FVC ratio. An FEV_1/FVC ratio less than 0.80 indicates significant airflow obstruction (see Box 58-5).

Airflow limitation in itself is not a hallmark of asthma in children; however, bronchodilator-induced improvement in airflow, or bronchodilator reversibility (traditionally calculated as a percent of change: [{postbronchodilator FEV_1 – prebronchodilator FEV_1}/prebronchodilator FEV_1] × 100) of ≥12% is greater than normal and considered to be confirmatory evidence of asthma (see Box 58-5). Bronchodilator reversibility correlates with and can be viewed as a surrogate marker of airway inflammation and bronchial hyperresponsiveness, and may even be a predictor of irreversible airflow limitation.[7,8] Because airways obstruction can be caused by inflammation and edema that will not improve rapidly with bronchodilator, anti-inflammatory therapy (e.g., an oral and/or inhaled corticosteroid therapeutic trial) may be needed to improve airflow significantly.

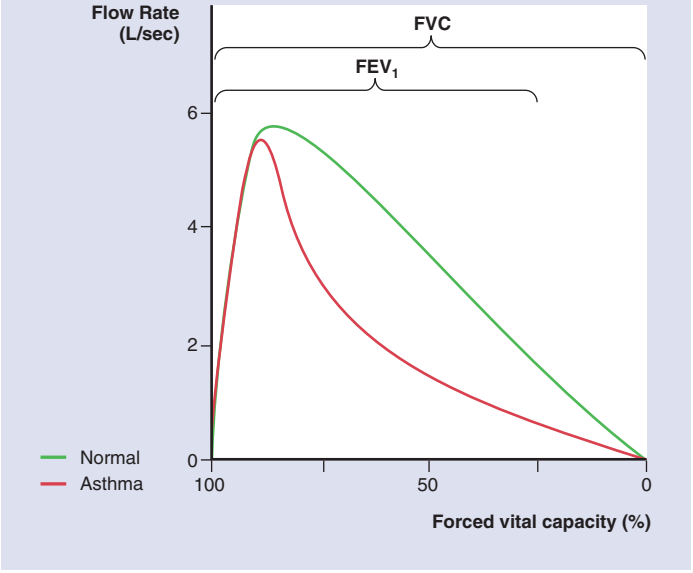
Children with asthma often have normal lung function in the resting state, yet are characteristically hypersensitive to a number of provocative stimuli. This lability in lung function is likely a reflection of underlying bronchial hyper-responsiveness (BHR)—another characteristic feature of asthma. Broncho-provocation challenges (using exercise or inhaled methacholine, histamine, adenosine, hypertonic saline, or cold or dry air) can be helpful not only in diagnosing asthma but also in assessing asthma severity and optimizing asthma management.[9] The degree of airway hyper-responsiveness to these exposures correlates to some extent with asthma severity and airways inflammation.[10,11] Broncho-provocation challenges using inhaled broncho-provocative agents are carefully dosed and monitored. For example, using gradually increasing inhaled doses of methacholine, BHR can be demonstrated when an abnormally low dose induces a decline in FEV_1 of ≥20% from baseline. As such, their use in a general practice setting is limited. Exercise challenges (i.e., aerobic exertion or "running" for 6 to 8 minutes) can help to identify children with exercise-induced bronchospasm (EIB). Although the airflow response of non-asthmatics to exercise is to increase functional lung volumes and improve FEV_1 slightly (5% to 10%), exercise can elicit airflow obstruction in children with uncontrolled asthma corresponding to at least a 15% reduction in FEV_1 during or after exercise (see Box 58-5). The onset of EIB is usually within 15 minutes after a vigorous exercise challenge and can spontaneously resolve within 30 to 60 minutes. Exercise challenges can provoke severe asthma exacerbations in at-risk patients; therefore, careful patient selection for exercise challenges and readiness for severe asthma exacerbations are necessary when performing this test.

Also typical of asthma is exaggerated variation in airflow, demonstrable by differences in peak flows of greater than 20%, both diurnally (i.e., AM on awakening compared with PM) and day-to-day (see Box 58-5). Non-asthmatics do not have variability in airflow to this degree. Such variability in airflow or peak flows is indicative of more severe and inadequately controlled asthma.

Last, it is necessary to recognize that peak flows, as well as spirometric measures, are completely effort and technique-dependent; the validity and reliability of these measures requires trained and proficient personnel as well as the reproducibility of repeated measures. At least three FEV_1 values or peak flows within 5% is ideal, and the best of three acceptable efforts is used as the final result (*NOT* the average of three acceptable results). Importantly, when asthma is unstable, poorly controlled, or exacerbating, forced expiratory maneuvers such as those generated by spirometry or peak flows can induce bronchospasm and worsen asthma; therefore, one must be wary of performing spirometry or peak flows in a patient with poorly controlled or exacerbating asthma; wary of a patient whose spirometry or peak flows are declining with each effort; and prepared to administer bronchodilator therapy in case of bronchospasm.

	Asthma	Normal
FEV_1 (L)	2.1 (55% predicted)	3.8 (100% predicted)
FVC (L)	4.0 (93% predicted)	4.3 (100% predicted)
FEV_1/FVC	0.53	0.88

A



B

Figure 58-1 Spirometry. A, Volume-time curves. Note how the FEV_1 and FVC lung volumes are obtained. FEV_1 is the volume of air exhaled in the 1st second of a forced expiratory effort. FVC is the total volume of air exhaled during a forced expiratory effort. Both FEV_1 and FVC can be compared with predicted norms (% predicted). The FEV_1 and FEV_1/FVC ratios of the child with asthma are smaller than those of the non-asthmatic child, indicating airflow limitation. The asthmatic child's FVC is close to what is expected. **B,** Expiratory flow-volume loops. Note how peak expiratory flow rates are obtained. Also note the concave or "scooped" appearance of the asthmatic expiratory flow-volume loop when compared with normal; with increasing obstruction, there is greater "scooping." L, liters; L/sec, liters/sec.

Difficult-to-Control Asthma in Childhood: Diagnosis

The child with difficult-to-control asthma can be viewed as a failure of conventional asthma management. Such cases often benefit from a careful review and reassessment of the child, a return to the dogged diagnostician.

If coughing and/or wheezing are recurrent: more rigorous efforts to better understand the coughing or wheezing patterns may help, such as challenges to provoke and observe reported symptoms (e.g., exercise challenges) or overnight observation if the symptoms typically recur at night.

If other causes of coughing/wheezing are excluded: failure to respond to conventional asthma management may be the result of unaddressed comorbid conditions or an occult asthma masquerader. A systematic reconsideration of the differential diagnosis may help to identify such asthma confounders or masqueraders (see Box 58-6):

1. Common comorbid conditions that can worsen or mimic asthma—rhinitis, sinusitis, GERD, VCD—are described earlier.
2. In particular locales, children may be susceptible to develop hypersensitivity pneumonitis (e.g., farming communities, homes of bird owners), pulmonary parasitic infestations (e.g., rural areas of developing countries), or tuberculosis.
3. Uncommon conditions that can mimic childhood asthma include cystic fibrosis, bronchiolitis obliterans, interstitial lung diseases, primary ciliary dyskinesias, humoral immune deficiencies, allergic bronchopulmonary mycoses, atypical mycobacterial disease, congestive heart failure, mass lesions in or compressing the larynx, trachea, or bronchi (e.g. lymphadenopathy), and medication-induced coughing and/or wheezing.

Testing to diagnose or rule out such masquerading diagnoses should be considered: high-resolution CT scans of the chest

or sinuses, pH probe studies for GERD, rhino-laryngoscopy, and/or bronchoscopy.

Risk factors are identified: Ultimately, if potential masqueraders and comorbid conditions have been ruled out, and adherence with therapy has been assured, then children may have severe asthma due to a number of underlying causes, discussed in more detail in the following section on different phenotypes of severe asthma. Briefly, these risk factors include:

1. Pulmonary: fixed airflow obstruction, severe lability in airflow, neutrophilic inflammation
2. Environment: allergen sensitization with high levels of exposure; occupational-like exposures (e.g., ambient endotoxin); aspirin/NSAID hypersensitivity
3. Poor pharmacotherapeutic responders: corticosteroid insensitivity; poor responders to long-acting bronchodilators

The child improves with asthma therapy: Ascertaining adherence with conventional asthma medications can be quite challenging but essential when contending with children with asthma who appear to be treatment failures. A study using digital metered-dose inhaler chronologs to ascertain adherence to conventional inhaled corticosteroid (ICS) controller therapy in children with asthma revealed that, of those who demonstrated treatment failure with an asthma exacerbation, adherence to ICS controller was only 17%, which was far lower than the 55% adherence observed among controlled asthmatics, and even further from the 95% self-reported adherence levels.[12] Extra measures may be needed to enhance compliance and to determine if adequate, prescribed trials of pharmacotherapy have occurred, such as: calendars for tracking all dates and times when medication is taken; enlisting the support of a parent, caregiver, teacher or friend as an asthma "coach" to help support daily adherence and monitoring; and even daily clinic visits or hospitalization to assure daily administration of therapy to determine if the patient is indeed a treatment failure.

Confirmatory physical examination findings and diagnostic tests: The physical examination is used to determine if the physical signs of asthma are consistent with its reported severity, if findings are consistent with a diagnosis of asthma or if asthma masqueraders should be considered. More involved diagnostic tests that support or refute asthma may be necessary (see Box 58-5). Broncho-provocation testing may not only help to confirm the diagnosis of asthma, but can also provide insight into symptom progression and unusual manifestations. For example, an asthmatic who develops upper airway tightness and audible wheezing might, during methacholine challenge, show onset of these symptoms concurrent with truncation of inspiratory flow-volume loops; flexible laryngoscopy might reveal inappropriate vocal cord closure and dysfunction. If severe nocturnal asthma is described, then careful observation overnight might confirm this pattern and, in so doing, confirm the diagnosis of asthma.

ASSESSING ASTHMA SEVERITY AND CONTROL

National guidelines for asthma management recommend the assessment of severity as the basis for patient management. In these guidelines (i.e., National Asthma Education and Prevention Program, National Institutes of Health), asthma severity is categorized into four groups (mild intermittent, mild persistent, moderate persistent, and severe persistent) by ascertaining the frequency of day and nighttime symptoms, spirometric assessment of airflow limitation (i.e., FEV_1 % predicted), and peak flow variability assessed day-to-day (Table 58-2). While these severity criteria have a role in the initial assessment of asthma, there are limitations of this approach as the basis for managing children in clinical practice. These limitations include:

1. Variability of asthma: Determination of asthma severity can fluctuate using these measures.[13]
2. Day and night symptoms: whom do you ask for accurate information, the child and/or parent/caregiver?[14,15]
3. Spirometry and peak flows: challenging to obtain valid measurements in children younger than 6 to 8 years of age. As well, lung function abnormalities change with age in children with asthma such that FEV_1 % predicted is not abnormally low for a large majority of children with asthma.[16]
4. Accounting for controller therapy: for example, how does one designate a severe asthmatic who becomes well controlled on controller therapy?
5. Accounting for exacerbation frequency and severity: a key element of disease severity in children is the frequency and severity of their exacerbations. But how does one classify, for example, a preschooler with a history of

Table 58-2
Classifying Asthma Severity*

	Days with Symptoms	Nights with Symptoms	FEV_1 or Peak Flow	Peak Flow Variability
Severe persistent	Continual	Frequent	≤60% predicted	>30% (day-to-day)
Moderate persistent	Daily	>1 night/week	<80 to >60% predicted	>30%
Mild persistent	>2 days/week but <once daily	>2 nights/month	≥80% predicted	20 to 30%
Mild intermittent	≤2 days/week	≤2 nights/month	≥80% predicted	<20%

*Classification based on clinical features before treatment. The patient's severity classification is determined by the most severe feature.

National Institutes of Health/National Heart, Lung, and Blood Institute, NIH Publication No. 97-4051, 1997; National Asthma Education and Prevention Program Expert Panel Report: Guidelines for the Diagnosis and Management of Asthma—Update on Selected Topics 2002; National Institutes of Health/National Heart, Lung, and Blood Institute, NIH Publication No. 02-5075, 2003; Global Initiative for Asthma. Global Strategy for Asthma Management and Prevention. NIH Publication No 02-3659 (original 1995, updated 2002); and 2005 Update: Workshop Report (http://www.ginasthma.com).

several severe exacerbations requiring hospitalization, but infrequent day or night symptoms or rescue medication usage in the two months following hospitalization? A history of severe exacerbations such as life-threatening episodes or requirement for hospitalization, and prior frequent or prolonged use of systemic corticosteroids, should elicit a higher level of concern.

6. Activity limitation and quality of life outcomes: if a child with asthma refrains from participating in physical activities so as not to trigger asthma symptoms, their asthma would be inadequately controlled but not detected by the standard questions.

More recently, asthma control has been introduced as an approach to assess the adequacy of current treatment, and to improve care and outcomes for children with asthma. The U.S. National Asthma Education and Prevention Program (NAEPP)[17] and the Global Initiative for Asthma (GINA)[18] define the goals of asthma control as summarized in Box 58-1. These well-accepted goals imply that the assessment of asthma control is, at best, multidimensional and should include evaluation of these different domains of asthma outcomes: frequency of daytime symptoms, nighttime awakenings, and usage of quick reliever and exacerbation reliever medications; functional status (e.g., exercise tolerance); health care utilization (e.g., urgent visits, emergency department [ED] visits, hospitalizations); missed school or work; quality of life aspects; lung function; and assessment of airways inflammation. Additionally, an understanding of potential exposures that can worsen asthma, current controller medication usage, adherence and the technique used with inhaled controller medications completes a working understanding of an individual's asthma from which a tailored and effective management plan can be derived. Inadequate control of asthma indicates to the clinician the necessity of refining assessments of exposures, triggers, comorbid conditions, and adherence—as well as the possibility of the need to step up the level of therapy to gain control.

Preschool-Aged Children: Assessment

For preschool children up to approximately 7 years of age, the assessment of asthma severity and control is based primarily on symptoms, medication usage, and exacerbations because young children cannot perform the maneuvers required for conventional lung function measurements. The history of asthma is acquired almost completely from the parent(s) or caregivers as preschool-aged children are generally limited in describing their symptoms, their accuracy of symptom frequency and their placement in the context of time. A "3 strikes" rule is a practical concept for determining if a child with asthma is inadequately controlled (Box 58-9). Although this and other simplified algorithms have not been validated as a measure of asthma control in children, they incorporate many of the dimensions of asthma control that are identified in national and international guidelines.

School-Aged Children: Assessment

The general approaches and challenges to assessing asthma severity and control, described earlier, are applicable to the school-aged child with asthma.

BOX 58-9 Indicators of Inadequate Asthma Control

The presence of *any* of the following indicates inadequate asthma control:

Three or more times/week
- Asthma symptoms
- Rescue reliever medication use (e.g., albuterol to treat symptoms)

Three or more times/month
- Night awakenings due to asthma

Three or more times/year
- Quick-relief inhaler fill/refills
- Asthma exacerbations requiring urgent medical visits, prednisone courses, emergency department visits, hospitalizations

ASKING QUESTIONS ABOUT ASTHMA CONTROL

It is believed that optimal history-taking from lower school-aged children (e.g., 5 to 12 years of age) should include input from both the parent and child. Children can accurately recognize asthma symptoms, their common triggers, and their impact on daily activities; although younger children may be unable to accurately quantify the frequency of their symptoms or place them in the context of time. In a study by Lara and colleagues assessing the validity of exercise-related symptom reporting by children with asthma compared with their parents, child-reported coughing and wheezing correlated with lung function changes and observed symptoms due to exercise; in contrast, parent-reported symptoms did not correlate.[14] Guyatt and coworkers observed in children younger than 11 years of age that their symptom reports correlated strongly with changes in quality of life measures, whereas parents' ratings of asthma symptoms showed moderate correlations with FEV_1 and asthma control, but not quality of life measures.[15] Thus, clinicians are likely to obtain important and complementary information from children and their parents.

For children with asthma, there are several guidelines,[18,19] as well as health-related quality of life instruments, clinical diaries, and questionnaires for assessing asthma severity and control: About My Asthma[20] Childhood Asthma Questionnaire,[21] "How Are You?" questionnaire,[22] Pediatric Asthma Quality of Life Questionnaire (PAQLQ),[23] Pediatric/Adolescent Asthma Therapy Assessment Questionnaire (ATAQ),[24] Children's Health Survey for Asthma,[25] Asthma Assessment Questionnaire for Your Child,[26] Rules of Two,[27] and Asthma Control Test (ACT).[28]

Within the numerous questionnaires noted above for assessing asthma control, there are key questions that capture most of the relevant information. The Asthma Control Test (ACT) for children 12 years of age and older, and the Childhood ACT for children 4 to 11 years of age, are two examples of self-administered questionnaires that have been developed and validated with the objective of identifying the most relevant questions (Table 58-3). In the development of both questionnaires, questions about all of the domains of asthma

Table 58-3
Key Questions When Assessing Asthma Control in Children

Questionnaire Examples	Childhood Asthma Control Test*	Asthma Control Test†
For ages	4 to 11 years	12 years and older
Who replies	Child and parent/caregiver	Teenager
Recall period	Past 4 weeks (parent/caregiver only)	Past 4 weeks
Response format	Child: 4-point scale Parent/caregiver: 6-point scale	5-point scale
Questions	**For child:** How is your asthma today? How much of a problem is your asthma when you run, exercise, or play sports? Do you cough because of your asthma? Do you wake up during the night because of your asthma? **For parent/caregiver:** How many days did your child have any daytime asthma symptoms? How many days did your child wheeze during the day because of asthma? How many days did your child wake up during the night because of asthma?	How would you rate your asthma control? How much of the time did your asthma keep you from getting as much done at work, school, or at home? How often have you had shortness of breath? How often did your asthma symptoms (wheezing, coughing, shortness of breath, chest tightness or pain) wake you up at night, or earlier than usual in the morning? How often have you used your rescue inhaler or nebulizer medication (such as albuterol)?

Questionnaire examples from http://www.asthmacontroltest.com.

control were included, and key questions were selected via logistic regression analyses as predictors of asthma control.[28,29] These two questionnaires are similar in that each question provides a score such that the sum of the scores constitutes the total test score, and lower scores indicate poorer control. Generally, a total score of 19 or less indicates inadequate control. The key questions that compose these questionnaires appeared to differ slightly, but were generally consistent with NAEPP and GINA guidelines. The optimal combination of seven questions for the Childhood ACT includes four questions for the child and three questions for the parent/caregiver, whereas the five questions for the ACT are all directed toward the older child with asthma.

Measures of Airflow Limitation

Pulmonary function testing is particularly helpful in children with asthma whose symptoms are nonspecific, who are poor perceivers of airflow obstruction, or in whom physical signs of asthma do not manifest until airflow limitation is severe. Forced expiratory airflow measures, such as spirometry, are helpful in diagnosing and monitoring asthma and in assessing efficacy of therapy. However, the validity of spirometric measures is dependent on trained personnel to conduct and interpret the tests, and a patient's ability to properly perform a full, forceful, and prolonged expiratory maneuver, usually feasible in children older than 6 years of age (with some younger exceptions).

Normative values for FEV_1 have been determined for children, based on height, sex, and race. FEV_1 as a percentage of predicted is one of four criteria used to define asthma severity in standard clinical asthma guidelines.[19] FEV_1 measurements are conventional means of assessing airflow limitation and airway obstruction; however, they do not discriminate children who display clinical characteristics of mild, moderate, and even severe asthma. The NAEPP guidelines set >80% FEV_1 % predicted for patients with mild persistent asthma, 60% to 80% predicted for moderate asthma, and <60% predicted for severe persistent asthma. In a comparison of asthma severity in children based on symptom frequency or medication use, Bacharier and colleagues found that the mean FEV_1 was 97.5%, 101.1%, 99.9%, and 95.1% predicted values for children with mild intermittent, mild persistent, moderate persistent, and severe persistent asthma, respectively.[16] In this study, only 6.5% of children with moderate persistent asthma had $FEV_1 < 80\%$ predicted, and only 3.5% of those with severe persistent asthma had $FEV_1 < 60\%$ predicted. Although FEV_1 % predicted did not differ by level of asthma severity, FEV_1/FVC ratios decreased as asthma severity worsened (means of 0.88, 0.86, 0.83, and 0.79, respectively; $P < 0.0001$), and was abnormal in 17%, 20%, and 51% of children with mild, moderate, and severe persistent asthma, respectively. This suggests that FEV_1/FVC is a more sensitive and reliable measure of airflow limitation for assessing asthma severity in children, by accounting for the hyperinflation manifest by many of these children.

ASTHMA EXACERBATIONS IN CHILDREN

An important component of the evaluation of asthma severity and control is exacerbations. In the United States, childhood asthma is the most common cause of childhood ED visits and hospitalizations, accounting annually for 867,000 ED visits and 166,000 hospitalizations. Considering this high frequency of ED visits and hospitalizations for asthma, death caused by asthma is relatively uncommon (0.3 deaths per 100,000 population per year). In the United States, in 2000, asthma was responsible for 223 deaths of children.

A disparate increase in the frequency of severe asthma exacerbations in children living in inner city communities, especially of African-American ethnicity, has persisted in the United States over the past 25 years. A scenario of biological, environmental, economic, and psychosocial risk factors underlie severe asthma exacerbations (see Severe Asthma in

BOX 58-10 Severe Asthma Types in Children

Corticosteroid response

Corticosteroid-responsive: marked improvement in lung function with a 1-week course of oral corticosteroids

Corticosteroid-insensitive:

Chaotic lung function: wide variability in lung function, persisting despite oral corticosteroid course

Non-chaotic lung function: fixed airflow obstruction

Character of inflammation: while on oral and high-dose inhaled corticosteroids

Remodeling without inflammation

Neutrophilic inflammation

Persistent eosinophilic inflammation

Life-threatening exacerbations

Sudden asphyxic: abrupt onset, loss of consciousness or respiratory arrest associated with extremely high $PaCO_2$ (e.g., 113 mm Hg); rapid recovery in hours; neutrophilic inflammation

Gradual progressive: gradual worsening, increased work of breathing over days, respiratory failure due to fatigue, associated with near normal $PaCO_2$; mechanical ventilation for days with gradual recovery over weeks; eosinophilic inflammation

Childhood: Prognoses and Predictors, later). Although a previous hospitalization for asthma is a strong predictor of future severe exacerbations, they can occur in children with all levels of asthma severity (mild, moderate, or severe).

The onset of severe asthma exacerbations can be prolonged or rapid (Box 58-10).[30,31] These exacerbation types can be remarkably distinct. Some exacerbations escalate over days into severe airflow obstruction resulting from progressive inflammation, epithelial sloughing, and cast impaction of small airways. When extreme, respiratory failure due to fatigue develops and typically necessitates mechanical ventilation for numerous days. In contrast, some children experience abrupt onset of severe symptoms from extreme airway reactivity and physiologic susceptibility to airways closure. Such sudden, asphyxic exacerbations usually occur outside of medical settings, are initially associated with extreme hypercapnia (i.e., mean $PaCO_2$ 116 mm Hg), and tend to require relatively brief periods of supportive ventilation (i.e., 34 hours).[30] Sudden asphyxic asthma also appears to have distinct histopathologic features, most notably increased neutrophils and reduced eosinophils when compared with fatal episodes of gradual onset.[32,33] Fatal asthma attacks of sudden onset have also been associated with increased CD8+ T lymphocytes[34] and increased airway mucous glands.[33]

With either type of severe exacerbation, controller therapy should be reinforced, but recognition of the specific type of exacerbation helps to optimize early exacerbation management in order to keep it from becoming life threatening. For example, progressive-onset exacerbations can likely be interrupted with oral corticosteroids. Preparedness for managing such exacerbations should include keeping an oral corticosteroid at home to administer early in the course of a developing exacerbation. In comparison, optimal management of abrupt-onset exacerbations includes any measures to reduce bronchial lability, consideration of daily measures of lung function such as peak flows to identify any subclinical lability or reduction in lung function, and, in extreme cases, having supplemental oxygen, Epi-pens, and providing CPR training for parents and caregivers.

Several studies have revealed that a discriminating risk factor in children who experience severe asthma exacerbations is food allergen sensitization.[35] A relevant question that remains unsettled is whether or not this implicates food allergens as a common trigger of severe exacerbations, or if food allergen sensitization is a biological marker that results from immunologic processes that concurrently render the lungs susceptible to severe exacerbations (e.g., early-onset atopy with food allergy).

PHENOTYPES OF SEVERE ASTHMA IN CHILDREN

Various clinical and/or pathophysiologic phenotypes can be identified in patients whose asthma is more difficult to control, also called severe or refractory asthma, after suboptimal adherence and other confounders are ruled out. There is general information on the characteristics of this subgroup of children, but limited information on why and how the evolution to a severe state occurs. Typically, these are the patients whose medication requirement is escalated without achieving optimal control of symptoms or acute exacerbations. Bratton and coworkers reported on the outcome of almost 100 children with severe asthma (mean age 11 years, range 9 months to 18 years) referred for treatment in a multidisciplinary day program based at National Jewish Medical and Research Center.[36] There were features indistinguishable from pediatric epidemiologic asthma studies: 56% male, 17% minority, and 25% of lower socioeconomic status; median age of asthma onset was 2 years; approximately 80% were classified as atopic by skin testing and 65% were living with a cat or dog in the home at the time of admission. However, several measures of severity and poor control were distinct (Box 58-11): median lifetime hospital admissions per patient were 6.5. Features of severe, life-threatening exacerbations were prominent: 64% had experienced cyanotic episodes, 30% had loss of consciousness and 25% had been intubated for respiratory arrest. Sixty percent of patients were taking oral corticosteroids on admission, with a median dose of 10 mg/day for adolescents, 6.3 mg/day for school-age children, and 0.6 mg/day for preschoolers. Corticosteroid adverse effects were reported in 79%. Nearly one half of the children in the cohort were morbidly obese (body mass index [BMI] ≥95th percentile) or at risk of obesity (BMI ≥ 85th percentile). Marked physical deconditioning was notable with a median functional endurance of 8% of predicted for age. BMI was significantly associated with corticosteroid dose at admission ($r = 0.42$; $P < 0.0001$) and inversely correlated with functional endurance ($r = -0.66$; $P < 0.0001$). Median absence from school due to asthma for the previous school year was 26.5 days.

A separate retrospective review of 164 consecutive school-aged children admitted (median age 14.0 years, median dura-

BOX 58-11 High-Risk Factors for Asthma Morbidity and Mortality

Biophysical
- Previous severe asthma exacerbation(s):
  - Hospitalization for asthma
  - Exacerbation(s) with cyanosis, loss of consciousness, seizure, respiratory arrest, intubation, mechanical ventilation
  - Severe airflow obstruction
  - History of rapidly occurring attacks
- Severe bronchial hyper-responsiveness
- Increasing and large diurnal variation in peak flows
- Decreased chemosensitivity and perception of dyspnea
- Poor response to systemic corticosteroid (CS) therapy
- Routine oral corticosteroid requirement
- Food allergy
  - Frequent missed school due to asthma (≥20 days per year)
  - Obesity
  - Male gender
  - Low birth weight
  - Nonwhite (especially black) ethnicity

Environmental
- Allergen exposure in sensitized patients
- Environmental tobacco smoke exposure
- Air pollution exposure
- Urban environment

Economic/psychosocial
- Poverty
- Crowding
- Mother <20 years old
- Mother with less than high school education
- Inadequate medical care:
  - Inaccessible
  - Unaffordable
  - No regular medical care (only emergent)
  - No care sought for chronic asthma symptoms
  - Delay in care of asthma exacerbations
  - Inadequate hospital care for asthma exacerbation
- Psychopathology in the parent or child
- Family problems
- Alcohol or substance abuse

tion of asthma 11.9 years) to National Jewish for refractory asthma revealed interesting and important clinical phenotypes based on response to oral corticosteroid treatment (see Box 58-10).[37] All were on high-dose inhaled corticosteroid (median 1500 μg/day) and more than 50% were receiving chronically administered oral corticosteroid (median dose 15 mg/day) on admission. Fifty-three percent of these patients received a 7-day course of oral corticosteroid therapy secondary to poor asthma control on admission: 24% were deemed corticosteroid-insensitive based on failure to respond to a 7-day course of oral glucocorticoids by ≥15% improvement in AM prebronchodilator FEV_1. In comparison, the 76% who were corticosteroid-sensitive demonstrated a median improvement in FEV_1 of 45%. Two distinct patterns in the daily spirometry of corticosteroid-insensitive patients were noted in light of a poor FEV_1 response after a 1 to 2 week burst: a "chaotic" pattern characterized by marked variability in lung function; and a "nonchaotic" pattern displaying limited diurnal variability that might be due to a fixed airway obstruction. The risk factors associated with corticosteroid-insensitivity included need for oral corticosteroids at an earlier age, need for higher maintenance oral corticosteroid dose, and black ethnicity—the latter possibly related to a genetic or immune predisposition.[38] Last, although speculative, these two patterns of lung dysfunction in children with corticosteroid-insensitive asthma may represent different underlying disease mechanisms that may be better managed with different interventions.

IDENTIFYING ASTHMA TRIGGERS

Asthma symptoms can be triggered by a range of ubiquitous exposures: respiratory viruses, allergens, tobacco smoke, air pollutants, other airway toxicants, and cold or dry air (see Box 58-7). Exposures that induce airways inflammation, such as viral infections and inhaled allergens, can induce prolonged asthma exacerbations and increase airways hyperresponsiveness to irritant exposures for subsequent weeks. Common air pollutants and tobacco smoke can worsen asthma, especially in those who are predisposed by ongoing airways inflammation and/or genetic factors (e.g., glutathione-*S*-methyltransferase [GST]-null genotypes). Numerous exposures known to incite asthma in some adults in occupational settings (e.g., endotoxin) are currently being recognized as similar triggers of asthma in exposed children. Aspirin sensitivity, also recognized in some adults with asthma, has perhaps been under-recognized in children. Accordingly, a good environmental exposure history is essential for optimal asthma assessment and management.

Common Respiratory Viral Infections

Viral infections (e.g., respiratory syncytial virus [RSV], rhinovirus, parainfluenza and influenza viruses, metapneumovirus) are strongly associated with wheezing episodes in young children. It is uncertain if these infections contribute to aberrant lung growth and/or development or chronic asthma in later childhood, independent of atopy.[39,40] Severe RSV bronchiolitis in infancy (i.e., resulting in hospitalization) has long been suspected and is a risk factor for asthma as well as allergy in adolescence (e.g., animal dander sensitivity).[41] An unsettled question is whether or not severe viral bronchiolitis provides an enhanced pro-allergic Th2 response locally by overexpression of IL-4 or IL-13, or if delayed Th1 function underlies the susceptibility to severe bronchiolitis, allergic sensitization, and persistent asthma. In an emergency department study of respiratory viral pathogens in wheezing children, RSV was the predominant pathogen of wheezing infants, detected in 68% of wheezing children younger than 2 years of age versus 6% of older children.[42] In contrast, rhinovirus was detected in 41% of wheezing infants and 71% of older wheezing children; an emergent wheezing episode in children was most likely in those who had rhinovirus and atopy (positive RAST), nasal eosinophilia, or elevated nasal eosinophil cationic protein.

Two longitudinal birth cohort studies further our understanding of the relationship of common respiratory viral infections and subsequent recurrent wheezing and asthma outcomes. In the Childhood Origins of Asthma Study (COAST), although RSV and parainfluenza were associated with respiratory illnesses of increased severity, the most commonly identified respiratory virus with wheezing episodes was rhinovirus.[3] Many species of rhinovirus underlie its perennial presence such that rhinovirus-associated infantile wheezing episodes in March through November were strongly associated with reported wheezing in the third year of life, more so than RSV-associated wheezing. In the Tucson CRS, lower respiratory tract infections (LRTI: manifest as wheezing, deep or wet chest cough, hoarseness, stridor, shortness of breath) were cultured for common pathogens in the first 3 years of life.[43] Ninety-one percent of LRTIs were cultured: 44% were RSV-positive, 14% were parainfluenza-positive, 14% were culture-positive for other respiratory pathogens, and 27% were culture-negative (rhinovirus was not easily detectable in this study). Followed prospectively, infants with RSV LRTI were more likely to have wheezing symptoms at 6 years of age, but not at later ages (i.e., 11 and 13 years old). None of the other LRTI groups was different from non-LRTI children in the prevalence of asthma symptoms at these follow-up time points. There were also no differences in prevalence of allergen sensitization or lung function among the RSV group, other LRTI groups, and the non-LRTI group at later time points. However, young children who had radiographic evidence of pneumonia or croup symptoms accompanying wheezing were more likely to have persistent asthma symptoms and lung function impairment at 6 and 11 years of age.[44,45] This further supports the premise that individuals with lower airways vulnerability to common respiratory viral pathogens are at risk for persistent airways disease.

Risk factors for recurrent wheezing episodes in early childhood include smaller airways at birth (associated with male gender, small size for gestational age, and tobacco smoke exposure beginning in utero) and reduced IFN-γ (T-helper 1 type) responses in early life. The following linkage of reduced IFN-γ responses with recurrent wheezing episodes, lung dysfunction, and asthma has been observed in multiple studies and may indicate susceptibility owing to impaired antiviral immune responses:

1. Reduced PHA-induced IFN-γ production by cord blood samples was associated with more respiratory viral infections in the first year of life.[46]
2. Following RSV bronchiolitis in infants, reduced IL-2-induced IFN-γ production by peripheral blood cells was associated with persistent asthma, reduced airflow, and bronchial hyper-responsiveness.[47]
3. In experimental rhinovirus infection of adults with allergic rhinitis or asthma, increased symptoms and prolonged viral shedding were associated with lower IFN-γ/IL-5 ratios in induced sputum.[48]

Allergen Sensitization and Exposure

Sensitization to inhaled allergens is expected in children with asthma in the United States. In the Childhood Asthma Management Program (CAMP) that included 1041 5- to 12-year-old children with asthma from eight different U.S. and Canadian centers, 88% of the children were already sensitized to at least one common aeroallergen, and 56% were exposed to high levels of at least one allergen to which they were sensitized.[6] Similarly, in a study of inner-city children with asthma (Inner-City Asthma Study), 94% were sensitized to at least one inhaled allergen, with nearly 80% sensitized to at least two allergens.[49]

A cardinal feature of asthma in children is the association of sensitization and exposure to higher levels of perennial allergens, especially in the home, with disease severity and persistence. In the CAMP study, the combination of allergic sensitization to dog, *Alternaria*, or cat was associated with more severe disease as measured by BHR to methacholine.[6] In contrast, in the National Cooperative Inner-City Asthma Study, the combination of cockroach or rat allergen sensitization and high-level exposure was associated with more hospitalizations, unscheduled medical visits, more days of wheezing, more missed school days, and more nocturnal awakenings owing to asthma.[50,51] Interestingly, a similar pattern of asthma severity was not seen with dust mites or cat allergy in this cohort. Mouse allergen sensitization and exposure is also expected to increase asthma severity in some inner-city locales, although studies have not been able to disentangle the effect of mouse allergen from that of cockroach allergen because of their high correlation.[52-54] It has been shown that poor lung function in children with asthma is longitudinally associated with indoor allergen sensitization and exposure (i.e., cat, dog, mites), suggesting that asthma persistence in childhood is allergen-driven in homes.[55] Another longitudinal birth cohort study observed that sensitization and exposure to cat, dog, and/or dust mite allergens in the home were associated with poorer lung function (i.e., increased airways resistance) as early as 3 years of age.[56]

Determining allergen sensitization and exposure in children: Allergen sensitization in children via IgE can be determined in vivo by skin sensitization and in vitro by detection of allergen-specific IgE in serum or plasma. Skin prick allergy testing is relatively inexpensive and provides results quickly.[57] Tests should be carried out using standardized methods and standardized allergen extracts. The panel of allergens tested will depend on the age of the child and individual case history, and should vary depending on local environment-specific allergens. Perennial allergens that may be in high levels in the home should be prioritized.

Optimally, allergy skin testing should be performed by qualified health care professionals with training and demonstrable proficiency. Results from skin prick tests depend on a series of variables, including extract potency, use of drug treatment by the patient, skill of the tester, and the device used to puncture the skin. There is a very low risk of adverse allergic symptoms due to skin prick testing aside from local itching. Nevertheless, skin test personnel and their clinical sites of operation should be prepared to manage the very rare but unpredictable adverse event. Interpretation of the results and assessment of their clinical significance should be performed by an experienced clinician. Skin prick testing can be performed in children of all ages.[58]

In vitro testing for allergen-specific IgE may be useful if skin prick testing cannot be performed because the child has severe atopic dermatitis, urticaria or dermographism, is

Table 58-4
Indicators of Significant Allergen Exposure in Households*

Allergen	Home Environment History	House Dust Analysis for Major Allergen Content
Cat	Cat(s) in home	Fel d 1 > 8 μg/g dust
Dog	Dog(s) in home	Can f 1 > 10 μg/g dust
Dust mite	In dry climates, increased humidity (home dampness, mold, humidifier or evaporative cooler usage)	Der p 1 + Der f 1 > 2 μg/g dust
Cockroach	Sighting in home	Bla g 1 > 2 U/g dust; Bla g 2 > 10 U/g dust
Fungi	Mold, mildew, water damage, or water collection in home	Mold plate from house dust >25,000 colonies
Rat†	Sighting in home of rats or mice	Rat n 1 > 4 ng/g dust
Mouse‡	Sighting in home of mice	Mus m 1 > 1.6 μg/g dust

unable to discontinue antihistamine therapy, or has had a dangerous allergic reaction to a food. In vitro IgE testing can be conducted at any age using a validated method such as the CAP system fluoroenzyme-immunoassay (FEIA).[59]

Elevated indoor allergen levels associated with asthma severity in sensitized individuals can sometimes be determined via environmental history, although this can be inaccurate. Laboratory-based measurement of major allergen content in house dust samples is available commercially on a limited basis (Table 58-4).

Tobacco Smoke and Air Pollutant Exposure

Environmental tobacco smoke (ETS), air pollutants (e.g., ozone, sulfur dioxide), and endotoxin and mycotoxins aggravate airways inflammation and increase asthma severity. ETS is a risk factor for wheezing problems at all ages. Prenatal ETS exposure is associated, in a dose-dependent manner, with wheezing manifestations and decreased lung function in infancy and early childhood.[60-62] Postnatal ETS exposure is associated with a greater likelihood of transient wheezing in infancy[63] and persistent asthma in childhood.[64] Cigarette smoking has also been strongly associated with persistent asthma and asthma relapses in adulthood.[23] ETS exposure is also associated with food allergen sensitization,[65] allergic rhinitis, hospitalization for lower respiratory tract infections, BHR, and elevated serum IgE levels.[66,67] In a 7-year prospective study, ETS exposure was associated with greater inhalant allergen sensitization and reduced lung function.[68]

Other indoor exposures that have been associated with worsening asthma include wood-burning, nitrogen dioxide (e.g., from gas-burning stoves, kerosene space heaters), endotoxin, and mycotoxins. Outdoor air pollutants associated with worsening asthma include particulate matter, ozone, sulfur dioxide, and diesel exhaust. Some children may be particularly susceptible to common air pollutants (e.g., ETS, ozone, diesel exhaust) such that these exposures might not only make existing asthma worse, but they may also have a causal role. For example, polymorphisms in genes that detoxify oxidant stress products may be relevant to asthma manifestations owing to common exposures. Asthmatic children with common loss-of-function mutations in the glutathione-*S*-transferase M1 and P1 enzymes (GSTM1, GSTP1) are susceptible to ubiquitous inhaled exposures that cause oxidant stress, such as environmental tobacco smoke,[69,70] diesel exhaust,[71] and ozone.[72-74]

Aspirin-Sensitive Asthma

Aspirin-sensitive asthma (ASA) in children has not been studied as extensively as in adults and has perhaps been under-recognized in children. Based on an oral provocation challenge, one study found that 5.0% of children with asthma had a positive challenge, and 15.5% of those with a history of aspirin sensitivity reacted.[75] In contrast to adults with ASA, children with ASA were mostly male (2 : 1), more than 80% were atopic, and although nasal polyposis was rare, urticaria was more common than in adults. The primary mechanism of the pharmacologic action of and intolerance to aspirin and other nonsteroidal anti-inflammatory medications is thought to involve inhibition of the cyclo-oxygenase enzyme, subsequent prostaglandin synthesis, and activation of the leukotriene pathways in the respiratory tract; however, the relation between aspirin sensitivity and airway disease is not clear.

Occupational Exposures

Although occupational exposures that cause or worsen asthma are much more recognized in adults, some children might have chronic exposure to environmental endotoxin or similar airway proinflammatory agents in their home environments. Such exposures, often measured by endotoxin levels in house dust, have been associated with increased asthma symptoms and severity[76,77] and increased wheezing in infancy.[78,79] A recent large U.S. survey revealed that house-dust endotoxin levels were associated with increased asthma prevalence in a dose-dependent manner,[80] suggesting that the association of endotoxin with asthma may be common and not limited to rural settings.

AIRWAY INFLAMMATION AND HISTOPATHOLOGY

Preschooler with Recurrent Cough/Wheeze: Inflammation and Histopathology

Airway inflammation is a critical component in asthma, yet, similar to the assessment of airflow limitation, evaluation of airway inflammation in young children remains a challenging field of research. Research bronchoscopy and markers of airway inflammation studies in very young children with recurrent wheeze have revealed generalized inflammation with no predominant cellular pattern, unlike a primary eosinophilic feature apparent in older children or adults (Box 58-12). Bronchoalveolar lavage (BAL) studies from children with asthma (4 to 15 years), infantile wheeze (5 to 46 months), chronic cough (10 months to 13 years), cystic fibrosis (2.5 to 15 years), and controls (1.5 to 15 years) were undertaken by Marguet and colleagues.[81] Infantile wheezers have few eosinophils in BAL fluid compared to asthmatic children. Two thirds of children with asthma had increased BAL eosinophils, whereas less than one third of infantile wheezers did. An interesting finding in this study was the increase in neutrophils (i.e., BAL neutrophils >10%) in one half of the wheezing infants and in one third of the children with asthma. In another bronchoscopy study by Krawiec and coworkers of preschool children (mean age 14.9 months) with at least two episodes of wheezing or prolonged wheezing for at least 2 months, BAL inflammatory cells and mediators were generally increased compared with healthy controls: total BAL cells/mL, lymphocytes, macrophages/monocytes, polymorphonuclear cells, epithelial cells, and eosinophils.[82] BAL fluid levels of 15-HETE, PGE_2, LTE_4, and LTB_4, but not in PGD_2 and tryptase, were also greater in wheezing children compared with controls. In a retrospective study, the BAL cell profile of children younger than 3 years of age with severe recurrent wheezing (at least three moderate to severe episodes) compared with healthy controls revealed a higher percentage of neutrophils (mean 9% versus 2.1%, $P = 0.003$).[83] The larger number of neutrophils was not associated with detectable bacterial or viral infection, age, sex, or atopic status. These three studies show that, unlike prominent eosinophil and mast cell involvement in adults and older children, the airways inflammation in very young children with recurrent wheezing involves generalized immune upregulation, and tends toward neutrophilic inflammation. It is likely that these studies comprise a mixed group of infantile wheezers, from whom a subgroup will evolve into typical atopic asthma with eosinophil and mast cell involvement, whereas others may have different forms of pulmonary disease (i.e., transient wheezers, non-atopic wheezers).

Evaluation of airway remodeling in young children remains a challenging field of research due in part to ethical constraints of biopsy studies in this age group. Children younger than 2 years of age with severe wheeze and/or cough, accompanied by decreased specific airway conductance and/or bronchodilator reversibility, did not have evidence for cellular or immunologic alterations or thicker epithelial reticular basement membranes on endobronchial biopsy suggestive of airway remodeling when compared to healthy controls and established asthma subjects.[84] In this study, the only participant with a thickened reticular basement membrane on biopsy also had airway eosinophilia. These findings have significant implications: (1) in young children who are symptomatic and have airflow limitation, clinical features do not necessarily correlate with structural changes of airway remodeling or eosinophilic inflammation typical of associations seen in older children and adults with asthma; and (2) other studies of airway injury or aberrant repair are needed to provide more insights into the relation between inflammation and remodeling.

School-Aged Child with Asthma: Inflammation and Histopathology

Our knowledge substantiating the role of airway inflammation in asthma comes primarily from studies of adults with mild to moderate asthma in the absence of inhaled corticosteroid therapy who underwent bronchoscopy with bronchoalveolar lavage with or without endobronchial biopsies. These studies in corticosteroid-naïve subjects have demonstrated characteristic findings: airway epithelial desquamation with varying degrees of inflammatory cell infiltration consisting primarily of eosinophils, mast cells, and activated T lymphocytes[85,86] (see Box 58-12 and Fig. 58-2). A few studies have characterized inflammatory and structural changes in the airways of children with mild to moderate atopic asthma, compared with atopic non-asthmatic and non-atopic wheezing children.[87,88] Prominent BAL eosinophils and mast cells and elevated ECP were found in atopic asthmatics, whereas increased histamine levels were found in asthmatics, regardless of atopic status. Biopsy findings show higher alveolar eosinophils in children with allergic asthma compared to non-allergic asthma.[89] This suggests eosinophil recruitment into the airways in atopy-associated asthma. Another study confirmed typical histopathologic features (i.e., airway eosinophilia and reticular basement membrane thickening) in children with mild to moderate asthma, but perhaps surprisingly, these findings were also present in atopic

BOX 58-12 Histopathologic Findings in Children with Recurrent Wheezing/Asthma

Preschooler with Recurrent Cough/Wheeze

Generalized immune response: increase in neutrophils, lymphocytes, macrophages, and epithelial cells; rarely, increase in eosinophils

School-Aged Child with Asthma (mild to moderate severity)

Similar to adults with asthma: increased eosinophils, mast cells, activated T lymphocytes, epithelial desquamation, basement membrane thickening

Difficult-to-Control or Severe Asthma in Children

Remodeling with minimal inflammation: Smooth muscle hypertrophy, basement membrane thickening, goblet cell and submucous gland hyperplasia

Few eosinophils or neutrophils (patients generally on oral and high-dose inhaled corticosteroids at time of biopsy)

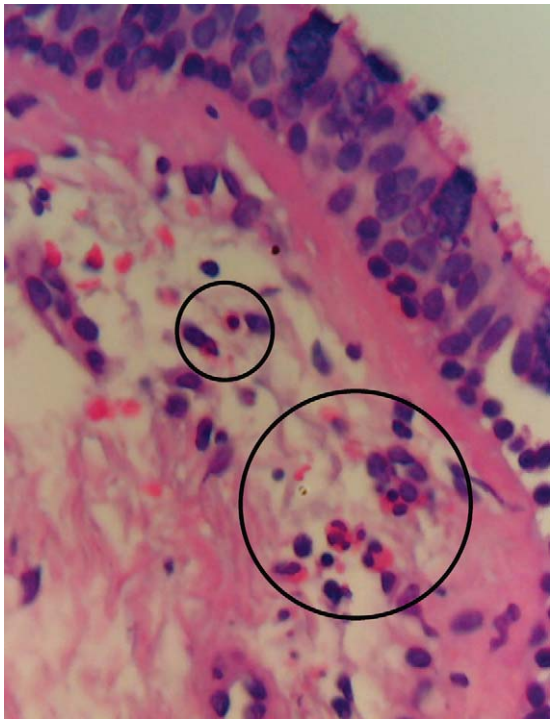

Figure 58-2 Eosinophilic airway inflammation in asthma. Endobronchial biopsy from a child with asthma reveals submucosal eosinophils (*circled*). Hematoxylin-eosin staining. (Courtesy of Dr. Carlyne Cool, National Jewish Medical and Research Center, and University of Colorado Health Sciences Center, Denver, Colo.)

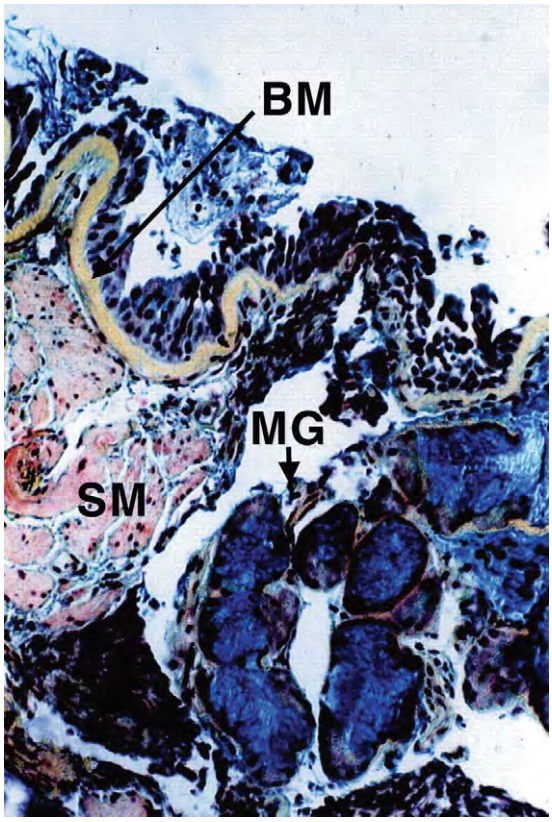

Figure 58-3 Airway remodeling in asthma. Endobronchial biopsy from a 12 year-old male with severe asthma. Pentachrome staining delineates the features of a remodeled airway by staining smooth muscle (*red*), collagen (*yellow*), mucus (*turquoise*), and elastin (*black*). BM, basement membrane thickening; SM, smooth muscle hypertrophy; MG, mucous gland hypertrophy. (Modified from Jenkins HA, Cool C, Szefler SJ, et al: Histopathology of severe childhood asthma: A case series. Chest 124:32-41, 2003.)

non-asthmatic children.[90] However, decreased subepithelial TGFβ-RII expression was found only in asthmatics and not in atopic non-asthmatic children or healthy control subjects. In asthmatic children, the number of eosinophils correlated negatively with TGFβ-RII expression and positively with symptom duration. This study suggests that: (1) downregulation of TGFβ-RII may be a more specific finding than airway eosinophilia and reticular basement membrane thickening in childhood asthma; (2) pathologic changes of airway inflammation in atopic subjects precede the development of persistent asthma symptoms and airway obstruction; and (3) an undetermined threshold has to be reached before clinical features of asthma are manifest. It is also possible that the functional changes occur independent of, or partially related to, histopathologic findings. In moderate asthma in childhood, endobronchial biopsy findings from six children showed typical features of basement membrane thickening and hyalinization, epithelial barrier breakdown, lymphocytic infiltration, and intra-arteriolar platelet aggregation.[91] However, only two subjects had goblet cell hyperplasia and only one subject had eosinophilic infiltration. On electron microscopy, evidence of fibroblast activation, increased submucosal collagen fiber deposition, and mast cell degranulation was found.

Severe Asthma in Childhood: Inflammation and Histopathology

Most of the histopathologic information from BAL and biopsy samples from subjects with severe disease have likely been affected by ongoing treatment. These are patients in whom a clinical or research indication for the procedures would have included evaluation for other conditions because they have been symptomatic despite conventional therapy for severe asthma. In addition, control groups are often composed of children with other clinical indications for bronchoscopic evaluation of the airway or have other medical conditions requiring intubation for surgical procedures; therefore, they cannot be considered healthy controls. To further complicate these comparisons, different histochemical techniques and measurements are employed in different studies.

In recent years, biopsy findings in children with refractory asthma have been reported in several studies. In a case series of six children (6 to 17 years old) with severe refractory asthma, the following histopathologic findings were seen: thickening of the basement membrane, smooth-muscle hypertrophy, and varying degrees of goblet-cell and submucous gland hyperplasia (see Box 58-12 and Fig. 58-3).[92] In five of six subjects, there was minimal to no histologic evidence for airway inflammation, with only mild and patchy submucosal lymphocytic infiltration noted; eosinophils and neutrophils were not present. It is important to note that these subjects were all on high-dose inhaled corticosteroids and routine oral corticosteroids—befitting of their severe asthma status. Payne and colleagues have compared findings in children with difficult-to-control asthma treated with sys-

temic corticosteroids with adults with either mild or severe asthma and adult and pediatric control subjects. Children with severe asthma had reticular basement membrane thickness similar to that seen in the adults with either mild or severe asthma, and significantly greater than both the adult and pediatric control subjects.[93,94] No correlation between reticular basement membrane thickness with age, duration of asthma, FEV_1 (before and after a course of prednisone), exhaled nitric oxide, or mucosal eosinophilic inflammation was found in children with difficult-to-control asthma.[94] Asthmatic subjects with persistent airflow limitation ($FEV_1 < 80\%$ predicted) had higher CD4+ T lymphocyte density than those without, such that CD4+ T cells were inversely correlated with FEV_1. Severe asthmatic children had similar inflammatory cell composition and gene expression for IL-4, IL-5, and RANTES as subjects with other non-asthmatic respiratory symptoms. Furthermore, no tissue differences were found between symptomatic and asymptomatic severe patients after a course of systemic corticosteroids.

Collectively, these studies, albeit limited by small sample size, provide valuable information regarding the pathogenesis of severe asthma. In these studies, findings of airway remodeling are prominent in children, despite treatment with inhaled and systemic corticosteroids, with only minimal evidence for cellular infiltration particularly in the more severe group. It is possible that corticosteroid therapy is sufficient to inhibit eosinophilic inflammation but inadequate to prevent the airway remodeling features seen in these severe cases. Alternatively, airway remodeling proceeds independent of, or only partially attributable to, airway inflammation.

IMMUNOHISTOPATHOLOGIC PHENOTYPES OF SEVERE ASTHMA IN CHILDREN

Two recent studies evaluating the features of airway inflammation in children with refractory asthma following systemic courses of prednisolone suggest different phenotypes of severe asthma based on immunohistopathologic outcomes.[93,95] Payne and colleagues showed minimal active airway inflammation in the majority of children after 2 weeks of prednisolone therapy. There was no difference in the median airway eosinophil scores between the children with severe asthma after prednisone therapy and non-asthmatic children. The investigators found a significant correlation between levels of eNO and tissue eosinophils ($r = 0.54$; $P = 0.03$), with the strongest relation found among the small group of children who remained symptomatic following the prednisolone course.

De Blic and associates investigated two distinct clinical phenotypes—symptomatic and pauci-symptomatic—in 28 children with difficult-to-control asthma (defined as persistent obstructive pattern [i.e., $FEV_1 < 80\%$ predicted] regardless of symptoms) who failed to show an improvement in lung function despite combination treatment with high-dose inhaled corticosteroids (beclomethasone equivalent dose 800 µg/day), inhaled long-acting beta-agonist, and prednisone treatment for 2 weeks.[95] Biopsy and BAL were performed 4 to 6 weeks after the last oral corticosteroid dose. Although both groups had large numbers of eosinophils and neutrophils and Th2-type profiles despite high dose anti-inflammatory therapy, distinctive histologic correlates were found. The symptomatic group had a higher percentage of BAL neutrophils, less percentage of BAL lymphocytes, higher epithelial (but not submucosal) eosinophil and neutrophil counts, higher BAL eosinophil cationic protein, and lower IFN-γ and IFN-γ/IL-4 ratio compared to the pauci-symptomatic group.

In contrast to the phenotypes of severe asthma in the above studies based primarily on persistence of symptoms and/or airflow limitation, Wenzel and colleagues, in her studies of adults with severe asthma, distinguished phenotypes beginning with histologic findings: those with airway eosinophilia (eosinophil [+]) and those without airway eosinophilia (eosinophil [–]).[96] The eosinophil + group were noted to have elevated numbers of T lymphocytes (CD3+, CD4+, and CD8+ cells), mast cells, and macrophages, and thicker sub-basement membranes compared to the eosinophil – group. The eosinophil + refractory asthmatics had more severe disease features with higher prevalence of intubation secondary to respiratory failure. Airway neutrophilia was found to be a remarkable feature in all of the corticosteroid-dependent asthmatics irrespective of their eosinophil status. These studies demonstrate heterogeneity of severe refractory asthma. Although reticular membrane thickness does not distinguish different groups of subjects with asthma, smooth muscle hypertrophy can be a prominent feature.

OUTCOMES, PROGNOSES, AND PREDICTORS

The natural history of childhood asthma reveals that approximately 80% of asthmatics of all ages have disease onset before 6 years of age.[97] However, of all young children who experience recurrent wheezing, only a minority will go on to have persistent asthma in later life. The most common form of recurrent wheezing in preschool children occurs primarily with viral infections. Most are "transient wheezers" or "wheezy bronchitics" who are not at an increased risk of having asthma in later life (Box 58-13 and Fig. 58-4). Transient wheezing is associated with airways viral infections, smaller airways and lung size, male gender, low birth weight, and prenatal ETS exposure.

Persistent asthma commonly begins and coexists with the larger groups of transient and non-atopic wheezers (see Box 58-13 and Fig. 58-4). In early life, the clinical pattern of episodic wheezing, primarily triggered by common respiratory viral infections, generally does not distinguish persistent from transient or non-atopic wheezers. Persistent asthma is strongly associated with allergy, which is evident in the early childhood years as clinical conditions (i.e., atopic dermatitis, allergic rhinitis, food allergies) or by testing for allergen sensitization to inhalant and food allergens (e.g., IgE, allergy skin testing).[4,98] In particular, toddlers with perennial inhalant allergen sensitization and higher levels of exposure in the home are most likely to have persistent asthma in later life.[55] A parental history of asthma is also associated with persistent asthma; with allergy, these risk factors formulate a predictive index for persistent asthma (see Table 58-1).[44] Severity of childhood asthma, determined clinically or by lung function impairment, also predicts asthma persistence into adulthood. These and other "types" of childhood asthma to be discussed in this chapter are not exclusive and may be related in various ways. One pattern of recurrent wheezing in early childhood

BOX 58-13 Recurrent Coughing/Wheezing Patterns in Childhood, Based on Natural History

Transient Early Wheezing
Common in early preschool years
Recurrent cough/wheeze, primarily triggered by common respiratory viral infections
Tends to resolve during the preschool years, without increased risk for asthma in later life
Reduced airflow at birth, suggestive of relatively narrow airways. Improves by school-age

Persistent Atopy-Associated Asthma
Begins in early preschool years
Associated with atopy in early preschool years:
- Clinical (e.g., atopic dermatitis in infancy, allergic rhinitis, food allergy)
- Biological (e.g., early inhalant allergen sensitization, increased serum IgE, increased blood eosinophils)

Highest risk for persistence into later childhood and adulthood
Lung function abnormalities:
- Those with onset before 3 years of age acquire reduced airflow by school age.
- Those with later onset of symptoms, or with later onset of allergen sensitization, are less likely to develop airflow limitation in childhood.

Non-atopic Wheezing
Wheezing/coughing beginning in early life, often with RSV infection; resolves in later childhood without increased risk of persistent asthma
Associated with bronchial hyper-responsiveness near birth

Asthma with Declining Lung Function
Children with asthma with progressive increase in airflow limitation
Associated with hyperinflation in childhood, male gender

Late-Onset Asthma in Females, Associated with Obesity and Early-Onset Puberty
Onset between 8 to 13 years of age
Associated with obesity and early-onset puberty, specific for females

Occupational-Type Asthma in Children
Children with asthma associated with occupational-type exposures known to trigger asthma in adults in occupational settings (e.g., endotoxin exposure in children raised on farms)

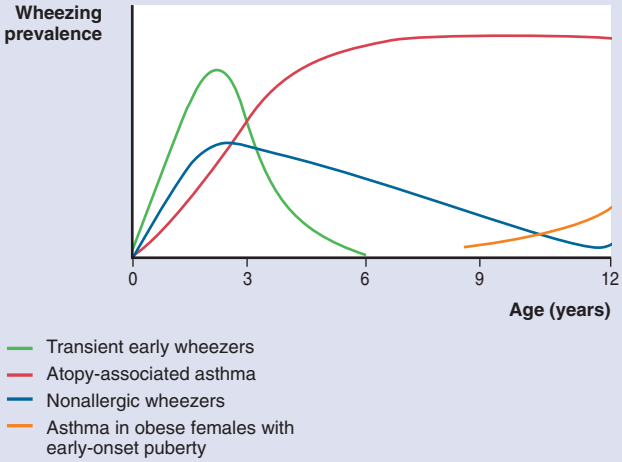

Figure 58-4 Common patterns of recurrent wheezing in childhood. Hypothetical yearly prevalence for four different patterns of recurrent wheezing in childhood (Tucson Children's Respiratory Study, Tucson, Arizona). These patterns differ in their age of onset and prognosis of persistence. This classification does not imply that the groups are exclusive. (Modified from Stein RT, et al: Thorax 52:946-952, 1997; and Castro-Rodriguez JA, et al: Am J Respir Crit Care Med 163:1344-1349, 2001.)

may appear to lead to or be supplanted by another—or different types may seem to occur concurrently in the same individual.

Preschooler with Recurrent Cough/Wheeze: Prognoses and Predictors

The heterogeneity of recurrent wheezing in young children has been well recognized and characterized in longitudinal epidemiologic studies, supportive of the common dictum "Not all that wheezes is asthma."[64,99,100] From the Tucson CRS in which more than 1200 unselected newborns were enrolled, different wheezing phenotypes were identified based on age of onset and persistence. By age 3 years, approximately one third of the cohort had wheezed.[64] Only 40% of these children continued to wheeze by age 6 years (persistent wheezers), representing 14% of the entire cohort having wheezing both before 3 years and at 6 years (see Fig. 58-4). The persistent wheezers were more likely to have a positive maternal history of asthma, elevated IgE levels with normal lung function in infancy, and low lung function with elevated IgE levels at 6 years (see Box 58-13). In contrast, 20% of the total group had at least one episode of wheezing associated with a respiratory tract infection during the first 3 years of life, but had no wheezing at 6 years (transient wheezers). These children were more likely to have diminished airflows in infancy and a history of maternal smoking, and less likely to be atopic. Fifteen percent of the children did not wheeze during the first 3 years of life, but they experienced wheezing by 6 years (late-onset wheezers). These children were likely to be atopic, similar to the persistent wheezers, and were also likely to have mothers with asthma, but did not acquire lung dysfunction by age 6 years as did the persistent wheezers in the cohort.

PREDICTORS FOR PERSISTENT ASTHMA

To distinguish preschool-aged children who are likely to have persistent asthma versus transient wheeze, an *asthma predictive index* was developed based on analyses of the Tucson CRS (see Table 58-1).[4] Two similar versions of the indices were used to classify the children: stringent and loose. The stringent index required *recurrent* wheezing in the first 3 years of life plus one major (parental history of asthma, or

physician-diagnosed eczema) or two of three minor risk factors (eosinophilia, wheezing without colds, allergic rhinitis); the loose index required *any episode* of wheezing in the first 3 years plus the same one major or two of three minor risk factors as the stringent index. Six percent of the preschool children had a positive stringent index and they were predominantly boys, whereas 23.6% had a positive loose index. Preschool children with a positive index were at least 2.6 times more likely to have active asthma in school age than those with a negative index. The positive predictive values for either the positive stringent or loose index for active asthma in school age were 76% and 59%, respectively. In contrast, at least 90% of young children with a negative "loose" or "stringent" index did not develop "active asthma" in school age. Hence, these simple predictive indices are clinical useful means of identifying preschool children at risk for persistent asthma.

ATOPY

Essentially all of the current natural history studies have found that allergic disease or evidence of pro-allergic immune development are significant risk factors for persistent asthma. In the Tucson CRS, early atopic dermatitis, allergic rhinitis, elevated serum IgE levels in the first year of life, and peripheral blood eosinophilia were all significant risk factors for persistent asthma.[4,64] In the Berlin Multicentre Alllergy Study, additional risk factors for asthma and BHR at age 7 years included persistent sensitization to foods (i.e., hen's egg, cow's milk, wheat and/or soy) and perennial inhalant allergy (i.e., dust mite, cat), especially in early life.[55,101,102] In particular, the combination of perennial inhalant allergen sensitization by age 3 years and exposure to high levels of these allergens in the home was a strong predictor of asthma persistence into the teen years.[55] In the Kaiser-San Diego study, milk or peanut allergen sensitization were risk factors for asthma.[103] With these additional considerations, a modified version of the previously described asthma predictive indices adds inhalant allergen sensitization as an additional major risk factor, and food allergen sensitization as an additional minor risk factor (see Table 58-1).[5]

LUNG DYSFUNCTION

The association between early childhood lung function and the different wheeze phenotypes (i.e., transient, persistent, and late onset) has also been explored. In the Tucson CRS, the transient wheezers had lower airflows (using maximal airflow at functional residual capacity [VmaxFRC]) in infancy (2.4 months of age) compared to never wheezers, and remained so at ages 6, 11, and 16 years.[64,104] Persistent wheezers had normal lung function in infancy, but by age 6 years, they had developed lower lung function compared to never wheezers, that persisted as abnormal through age 16 years. The late-onset wheezers did not show significant reductions in airflow measurements when compared with never wheezers.

Other longitudinal studies of smaller cohorts have revealed additional insights to the natural course of asthma. In contrast to the observations reported in the Tucson CRS, Turner and colleagues found reduced lung function in their subgroup of persistent wheezers as early as 1 month of age; their transient wheezers had airflows similar to their never wheezers.[105] In another study from a hospital-based pediatric pulmonary clinic, 129 children with history of wheezing before age 2 years were followed 4 years later and 38% of these children were still wheezing.[99] Persistent wheezers had the lowest lung function (using VmaxFRC) when measured at 17 months of age when compared to intermittent wheezers, coughers, and asymptomatic children. In the National Asthma Campaign Manchester Asthma and Allergy Study, interviewer-administered questionnaire and lung function (specific airway resistance (measured in kPa/second) were obtained at age 3 and 5 years of age. Children in this cohort were classified as never wheezers, transient early wheezers, late-onset wheezers, or persistent wheezers.[100] Similar to the Tucson CRS, transient and persistent wheezers had reduced lung function compared to never wheezers; persistent wheezers had significantly poorer lung function when compared with other groups. In children who had wheezed by age 3 years, using a multivariate analysis, increased airway resistance (OR 5.5, 95% CI 1.2 to 25.9; $P = 0.03$) and especially allergic sensitization (OR 2.8, 95% CI 1.3 to 5.8; $P = 0.008$) were significant predictors of persistent wheezing. There was no association between lung function at age 3 years and late-onset wheeze in children.

Despite strong associations between wheezing patterns and lung function measures in each study, it is unclear if significant discrepancies between lung function and wheezing patterns exist between these studies. Possible explanations include differences in constitutional properties of the airways, timing of injury to the airways, inherent characteristics of the cohorts, and/or group definitions used. Nevertheless, lung function in infancy may not be all that reliable as a predictor of persistent wheeze—particularly with respect to the significant variability of VmaxFRC values between the groups of very young children.

SCHOOL-AGED CHILD WITH ASTHMA: PROGNOSES AND PREDICTORS

School-age children with persistent asthma are at risk for disease persistence into adulthood. This is exemplified in a cohort of asthmatic 7-year-olds living in Melbourne, Australia, who were re-studied for persistence and severity of asthma at 10, 14, 21, 28, 35, and 42 years of age. At age 35 and 42 years, about 70% of the asthmatics and 90% of the severe asthmatics continued to have asthma symptoms.[106,107] In comparison, 38% of "wheezy bronchitics" (i.e., wheezing only with colds) and 15% without asthma in childhood reported asthma symptoms at these ages of adulthood. These observations—that many asthmatic children experience disease remission or improvement in early adulthood, but that severe asthma persists with age—are remarkably similar to those of several other natural history studies of childhood asthma into adulthood (i.e., Aberdeen, Scotland,[108] Tasmania, Australia,[109] and a national British study).[110]

Objective measures of lung function validate and bring further insights to these natural history studies. Longitudinal spirometric measures of lung function in the Melbourne study initially revealed that asthmatic children ages 7 to 10 years old, especially severe asthmatics, had reduced airflow, while wheezy bronchitics (i.e., transient wheezers) had lung function that was not different from non-asthmatics (Fig. 58-5).[111] Over the ensuing years (to age 42 years), these

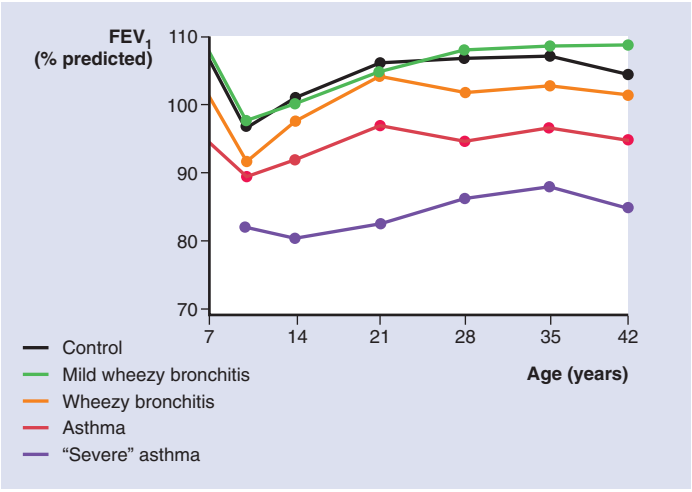

Figure 58-5 Natural history of lung function from childhood to adulthood. Children ages 7 to 10 years were followed to the age of 42 years (Melbourne Longitudinal Study of Asthma, Melbourne, Australia). At age 7, the children were classified into the following groups: Control (never wheezed); Mild wheezy bronchitis (<5 episodes of wheezing, always associated with bronchitis or respiratory infections); Wheezy bronchitis (≥5 episodes of wheezing with bronchitis or respiratory infections); Asthma (wheezing unassociated with respiratory infections); "Severe" asthma (onset of asthma symptoms before 3 years of age, persistent symptoms at 10 years of age, and barrel chest deformity and/or reduction in FEV_1/FVC ratio to ≤0.50). Mean values are shown. (Adapted from Oswald H, et al: Peds Pulmo 23:14-20, 1997; and Horak E, et al: BMJ 326:422-423, 2003.)

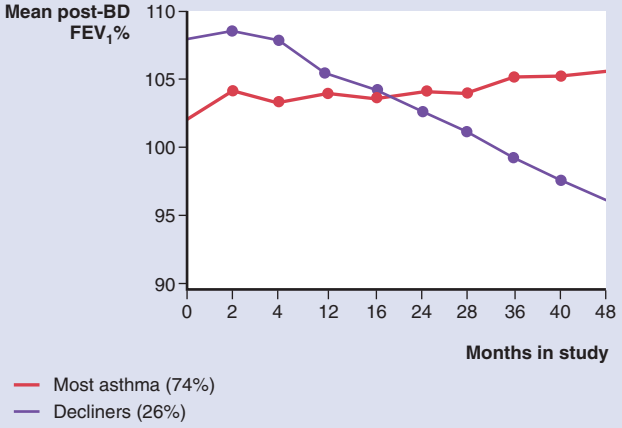

Figure 58-6 Progressive decline in lung function in a sub-group of children with asthma. Repeated measures of lung function (post-bronchodilator FEV_1 % predicted as an indicator of airflow limitation independent of airway smooth muscle tone) were obtained in 990 children, 5 to 12 years of age, with mild to moderate persistent asthma (Childhood Asthma Management Program study, National Institutes of Health/National Heart, Lung and Blood Institute). A sub-group of the asthmatic children (26%) demonstrated a significant and progressive decline in their lung function over this 4-year period (mean reduction of 2.9% per year). In comparison, most asthmatic children (74%) had no significant reduction in lung function over time (mean increase 0.6% per year). Mean values are shown. (Adapted from Covar RA, et al: Am J Respir Crit Care Med 170:234-241, 2004.)

differences in lung function impairment between groups persisted in parallel, without a greater rate of decline in lung function in any group (see Fig. 58-5). In the longitudinal Aberdeen study, greater airflow limitation in asthmatics versus wheezy bronchitics or controls was complemented by a greater proportion of asthmatic subjects with BHR when compared with the wheezy bronchitis or control groups.[108] These findings, consistent in these and other studies, support the importance of the early childhood years in asthma development—the establishment of chronic disease and lung function impairment in lower school-aged children appears to predict persistent asthma in adulthood.

CHILDREN WITH PROGRESSIVE DECLINE IN LUNG FUNCTION

The concept of asthma as a progressive disease has become apparent based on pathologic changes of airway remodeling and from adult longitudinal studies that have shown that adult asthmatics lose lung function at a greater rate than non-asthmatics.[112,113] In children, a somewhat different course has been shown. In community-based studies of school-aged children with asthma, most had mild disease and no further loss in lung function over time when compared with children without asthma.[114,115] This was also reported in the NIH-sponsored Childhood Asthma Management Program (CAMP) in which 1041 children with mild to moderate persistent asthma demonstrated no significant change in post- or pre-bronchodilator FEV_1 % predicted during the 4-year treatment period with controller therapy (budesonide or nedocromil) or placebo, regardless of treatment group.[116] However, 25% of the CAMP participants had progressive reduction in airflow (i.e., postbronchodilator FEV_1 % predicted) throughout the treatment phase (Fig. 58-6 and see Box 58-13).[117] This occurred in a similar proportion of participants in the active treatment and placebo arms. Predictors of progressive decline in lung function included younger age, male gender, and hyperinflation at the start of the study.

Most children with asthma will not have progressive loss of lung function or worsening of disease state, but a minority of children with asthma appear to be susceptible, even those with mild to moderate disease. This underscores the importance of objective monitoring of lung function over time, even in children with mild disease or those who appear well controlled. The etiology of the reduction in lung function in children may be reflective of reduced lung growth, persistent airway inflammation, or airway remodeling.

ADOLESCENT ASTHMA

Apart from those who develop asthma in early childhood that persists into later life, another epidemiologic pattern emerges in later childhood. Males account for most children with asthma in the prepubertal ages, whereas new incident cases of asthma in adolescence are predominantly females. In the Dunedin Multidisciplinary Health and Development study, an association between obesity with asthma and atopy, and an inverse correlation with FEV_1/FVC ratio (but not airway reactivity), was female gender specific.[118] After 9 years of age, 28% of asthma developing in women could be attributed to being overweight. A similar pattern was observed in the

Tucson CRS. Prepubertal females who were overweight were at increased risk for wheezing in adolescence; the strongest association between obesity and asthma risk was among girls with early-onset puberty (i.e., puberty started before 11 years of age; see Box 58-13).[119] In another study by Varrraso and coworkers the combination of early menarche and high body mass index (BMI) was associated with more severe asthma in women.[120] These associations between obesity, early-onset puberty, asthma, and female gender are consistent and provide cursory evidence for a complex interaction between genetic and hormonal influences underlying a subgroup of children with onset of asthma in adolescence.

Severe Asthma in Childhood: Prognoses and Predictors

A disparity in asthma outcomes links high rates of asthma hospitalization and death with poverty, ethnic minorities, and urban living. Over the past two decades, African-American versus white children had three to four times more ED visits, hospitalizations, and deaths due to asthma.[121] This large disparity in poor outcomes for African-American children with asthma has persisted despite broad improvements in asthma therapies and management over the past 25 years.

A combination of biological, environmental, economic, and psychosocial risk factors is believed to increase the likelihood of severe asthma exacerbations (see Box 58-11). Clinical and crucial psychosocial variables have been associated with fatal asthma events, including conflicts between family members and hospital staff regarding medical management of the patient, inappropriate self-care, depressive symptoms and suicidal ideation, and disregard of asthma symptoms.[122] Severe asthma exacerbations, resulting in respiratory distress, hypoxia, hospitalization, intensive care unit management, seizures, and/or respiratory failure, are the best predictors of future life-threatening exacerbations or a fatal asthma episode.[123] Bloomberg and associates observed that prior hospitalization(s) is the strongest predictor of subsequent hospitalization for asthma, with the probability of readmission increasing from 30% after the first admission, 46% after a second, and 59% after a third.[124] Marquette and colleagues observed the asthma mortality rate following mechanical ventilation for an asthma exacerbation was 10.1% after 1 year, 14.4% after 3 years, and 22.6% after 6 years.[125] Severity of previous asthma exacerbations appears to be the best predictor of severe, life-threatening exacerbations.

Some children are at risk for severe exacerbations because their perception of airways obstruction is notably poor. Poor perception of hypoxia, dyspnea, and resistive loads to breathing has also been associated with near-fatal asthma exacerbations (see Box 58-11).[126,127] Reduced lung elastic recoil pressure, usually accompanied by profound hyperinflation, has also been associated with near-fatal asthma attacks, suggesting that properties intrinsic to the lung parenchyma can render the airways susceptible to severe airflow limitation.[128] Whether or not these are intrinsic or acquired states that are reversible is unclear. Severe, life-threatening exacerbations can be characterized as being rapid or gradual in onset and have other distinguishing characteristics that are described earlier (Assessing Severity and Control: Severe Asthma Exacerbations in Children) and in Box 58-10.

ADVANCES IN CLINICAL ASSESSMENT OF ASTHMA IN CHILDREN

Lung-specific measures of dysfunction and inflammation have an essential role in diagnosing and assessing asthma, and following its course over time. Standard measures, generally spirometric, are limited in part by the age and developmental ability of young children to perform valid, reproducible measures. Yet, because the early childhood years appear to be a critical and dynamic period of lung and asthma development, investigators have sought to identify meaningful measures of lung dysfunction and inflammation that can be obtained noninvasively in children at the earliest possible ages.

Lung Physiology in Young Children

Traditional pulmonary function testing is challenging in preschool children. Spirometry and peak flow measurements can be reliable between 5 to 8 years of age. Impulse oscillometry (IOS) is a pulmonary function measure of respiratory system resistance and reactance at different frequencies. Forced oscillation involves the application of sine waves through a loudspeaker to the airway opening via a mouthpiece—through which the subject breathes normally for short periods of time. Measurements are carried out during tidal breathing over a 30-second interval and are easily performed with at least three efforts recorded. Given its relative ease of use (e.g., does not require forced exhalation), it is a reproducible and suitable measure of lung function in younger children.[129] Marotta and coworkers performed pre- and post-bronchodilator spirometry and IOS in 4-year-old children at risk for asthma.[130] Young children with asthma had increased reduction in IOS resistance to bronchodilator; no difference in baseline FEV_1 or IOS resistance was observed. Some investigators believe that reactance at low frequencies is a reflection of peripheral airways function.[131]

Using three different lung function measures, Nielsen and Bisgaard evaluated the bronchodilator response of 92 children 2 to 5 years old, 55 of whom had asthma.[132] Compared to non-asthmatic controls, children with asthma had increased specific airway resistance (sRaw) using whole body plethysmography, increased respiratory resistance using an interrupter technique, and increased respiratory resistance using IOS at 5 Hz. All children, including non-asthmatics, responded to terbutaline, although children with asthma improved to a significantly greater extent. The investigators found sRaw via body plethysmography was the best pulmonary function measure for distinguishing the asthmatic from non-asthmatic children based on bronchodilator response.

As with measurements of airflow limitation, procedures to assess BHR in infants and young children have unique challenges. Measurement of BHR indirectly using cold air (4 minutes of isocapnic hyperventilation) or dry air (6 minutes of eucapnic hyperventilation) challenge with sRaw as an outcome may be useful and practical alternatives to pharmacologic challenges in young children.[133] Using a dry air challenge, magnitude of response was found to be associated with wheeze phenotype. Persistent wheezers had a larger increase in sRaw following eucapnic hyperventilation challenge compared with never wheezers, but no significant differences between never wheezers, late-onset, or transient wheezers were seen.[100]

Exhaled Nitric Oxide (eNO)

Nitric oxide is produced by at least three distinct nitric oxide synthases (NOS): constitutively expressed NOS (cNOS 1 and 3) from the endothelium and inducible NOS (iNOS 2), upregulated by proinflammatory cytokines. Its exact role (i.e., as a mediator, immune modulator, or marker of epithelial damage and/or allergic inflammation) in airway inflammation is not clearly understood. However, hundreds of studies have been published on eNO in humans, including those demonstrating associations between eNO and other measures related to asthma in children, such as bronchodilator response, BHR, atopy indicators (e.g., skin test reactivity and serum IgE), and other biomarkers such as serum eosinophil cationic protein and sputum eosinophilia.[134,135]

Measurement of eNO, in parts per billion (ppb), is a noninvasive procedure that can easily be performed in children. Guidelines for standardized eNO measurement have been developed and published jointly by the American Thoracic Society and the European Respiratory Society.[136] Normal reference values with the recommended technique are available for children 4 to 17 years old.[137] eNO can be obtained in children as young as 2 years of age using online[138] and offline methods.

Noninvasive biomarkers support the presence of inflammatory changes in young children with recurrent wheeze. eNO levels are elevated in patients with asthma,[139] increase during acute exacerbations,[140] decrease after oral or inhaled corticosteroid therapy,[141,142] and correlate with other markers of inflammation, particularly eosinophilic inflammation.[11,135] Infants and young children with recurrent wheezing episodes presenting with acute wheeze had higher mean eNO levels (14.1 ppb) compared to first-time viral wheezers (8.3 ppb, $P < 0.05$) and healthy matched controls (5.6 ppb, $P < 0.001$).[142] In addition, their eNO levels were reduced by ~50% after corticosteroid therapy to a level comparable to the other two groups. This is evidence for airway inflammation during exacerbations in infants with recurrent wheeze, but what specific inflammatory feature(s) elevated eNO is uncertain.

Several studies have shown high diagnostic accuracy of at least 80% of eNO for asthma.[143-145] This relates to the combined consistency of having high eNO for patients with diagnosed asthma and low eNO for patients without asthma. Two studies have demonstrated the diagnostic accuracy of eNO in young children as well.[146,147] One study determined that eNO had better diagnostic accuracy compared to IOS-measured lung function and bronchodilator response: an eNO cut-point of 1.5 standard deviation above predicted distinguished children with probable asthma from healthy controls (sensitivity 86%, specificity 92%).[146]

In addition to studies that have evaluated the diagnostic potential of eNO levels, studies have also included applications for clinical use of eNO to assess asthma control. Assessing asthma control based on beta-agonist use, day- and night-time symptoms, and spirometry, an eNO value >21 ppb was a reliable predictor of poor asthma control, whereas eNO levels of 11 and 15 ppb corresponded with good and acceptable control, respectively.[148] A similar study also demonstrated lower eNO levels in children with good compared with poor asthma control (29 ± 11 and 86 ± 56 ppb, respectively; $r = -0.51$, $P = 0.001$).[149] The eNO levels also tracked well with assessment of asthma severity according to the NHLBI guidelines ($r = 0.44$, $P = 001$) and adherence to controller therapy ($r = -.75$, $P = 001$). Studies in adults[150,151] and children[152] have also supported the use of eNO (and also sputum eosinophilia) to predict loss of asthma control using an inhaled corticosteroid reduction model. In addition, eNO has been shown to be a useful tool to strategize treatment. In an adult study, the strategy using eNO allowed for greater ICS reduction without an increase in asthma exacerbations.[153] In a pediatric study that integrated eNO in the treatment algorithm, incorporating eNO allowed for greater improvement in bronchial responsiveness and reduction of eNO levels, without increasing cumulative ICS usage.[154]

In conclusion, eNO measurement holds promise as a useful clinical tool for diagnosing and assessing asthma in children. eNO measurements are easily performed, completely noninvasive, and reproducible and reliable in children. eNO correlates with several clinical parameters and may be a clinically useful predictor of response to therapy and/or loss of asthma control. It has also been shown to be helpful as a treatment strategy tool. Some limitations of its usage are: correlations with other measures of disease severity are modest; once corticosteroid therapy is instituted, associations with disease severity are weaker; tobacco smoking reduces eNO levels; and it is unclear if certain subgroups of children with asthma are not well characterized by their eNO measures. If used prudently, eNO measurement can probably best serve asthma patients as an additional assessment tool, along with symptom reporting and lung function measurement.

Induced Sputum

Induced sputum analysis has gained favor especially in pediatric asthma research because of its ability to directly measure airway inflammatory cells and mediators with fair association with BAL samples, without the risks of bronchoscopy. Although the relation between induced sputum and BAL can be robust, sputum is relatively rich in neutrophils and with fewer lymphocytes when compared with BAL; sputum fluid is likely reflective of larger airways. Nevertheless, in children with mild to moderate asthma, technical and ethical issues limit the application of bronchoscopy/bronchoalveolar lavage in the assessment of airway inflammation. Hence, sputum induction is an attractive alternative to bronchoscopy.

Children with controlled or uncontrolled asthma have higher sputum eosinophils compared to normal subjects, even in the presence of normal lung function.[155] Sputum eosinophil count correlates with various measures of chronic and current asthma control, such as prednisone use, beta-agonist rescue use, and frequency of nocturnal symptoms. In addition, it also correlates with the degree of atopy, BHR, bronchodilator reversibility, and markers of inflammation including eNO; it inversely correlates with airflow obstruction as measured by the FEV_1/FVC ratio.[11] Both elevated eNO and sputum eosinophil count indicate an increased risk of failed ICS reduction in children.[152] In adults, two studies have shown that the incorporation of sputum eosinophil count as a treatment strategy tool versus clinical guidelines approach led to a significant reduction in severe exacerbations and hospitalizations without a requirement for higher ICS dose.[156,157]

Although sputum induction is a relatively safe, noninvasive procedure that allows for a direct assessment of cellular and molecular mechanisms that may be used as a diagnostic or monitoring tool, the procedure can be time-consuming and demands standardization in collection, processing, and interpretation of samples; hence, its current application in pediatric asthma is confined to research. Sputum induction involves inhalation of hypertonic saline (3% to 5%) for 12 to 30 minutes after pretreatment with albuterol inhalation. It is time-consuming, requiring 20 to 30 minutes to collect the sample and 2 hours to process in the laboratory. Variable success rates ranging from 68% to 100% have been reported,[158] which could be due to differences in sputum induction methods such as induction with or without a bronchodilator pretreatment, or differences in criteria to define a satisfactory sample. Marked bronchospasm can occur in 8% of patients despite pretreatment with a bronchodilator.

CHAPTER 59 Treatment

Louis I. Landau and Fernando D. Martinez

TEACHING POINTS

- There are age-related patterns of disease, drug treatment, and use of devices.
- Effective patient and family education is critical.
- Make the correct diagnosis, abolish symptoms, and maintain optimal lung function.
- Address environmental measures where appropriate.
- Individualize drug treatment with relievers, preventers, and controllers.
- Ensure correct use of inhaler devices.
- Any attack of asthma is a failure of prophylaxis and treatment should be reviewed.
- Use the minimum drugs necessary to maintain a child free of symptoms during all normal activities.
- Work with the child, the family, and the schools to optimize treatment.
- A cure is not yet available, but research at this time looks promising.

DIAGNOSIS

Appropriate treatment is dependent on the correct diagnosis being made. As described in the previous section, this is primarily determined by evaluation of accurate and appropriate historical information. Physical examination may help support the diagnosis, define severity, and exclude alternative diagnoses. Diagnostic tests are of limited value in most children with asthma. Lung function measurements will be useful in older children, particularly when historical events are not clear. Objective measures of the degree of airway obstruction with response to bronchodilators is then helpful. Most children who are old enough should have spirometry performed. In those with severe disease, spirometry will be repeated at each visit. A small group of those with troublesome asthma may be improved with peak flow monitoring at home,[1] some for a short period until symptoms are controlled, whereas others with persisting unstable asthma may continue regular peak flow monitoring to document early deterioration and the need for increasing medication.

A chest radiograph may be helpful for very young infants in whom alternative diagnoses are more common, for those with severe disease, and for those with localizing signs on physical examination. However, chest radiographs are not necessary, or useful, for all children with mild asthma.

Skin allergy testing, RAST testing, and total IgE measurements may be useful additional tests to document atopy in those with an uncertain diagnosis. Rarely will they provide additional information to identify specific environmental allergens responsible for symptoms. Children with such reactions usually have a clear history. One can predict that most children will show a skin and RAST response to house dust mites in those areas where they are prevalent, grass and tree pollens, molds, and cat fur. Some will respond to various food agents, but without a history of relevant symptoms, this need not necessarily indicate clinically significant allergy to that substance. Production of specific IgE is a normal phase in the development of tolerance to many foods. More than 90% of those with respiratory symptoms caused by food allergens will also have an associated skin disorder. Occasionally, these tests may be quite helpful in convincing the parents that the child is not allergic to a particular substance and does not require elimination of that substance from the diet.

The assessment of asthma is usually based on the pattern of wheeze and breathlessness. Cough is usually associated with these symptoms. Some have argued that asthmatics may present with cough alone and have called this entity *cough variant asthma*. Evidence would suggest that cough without wheeze is reasonably uncommon in childhood asthma.[2] Those children with cough alone are less atopic and less responsive to challenges with cold dry air, exercise, or methacholine and more responsive to capsaicin, suggesting that they have what could be called a *hypersensitive cough receptor syndrome*, which is not particularly responsive to asthma medication.

Some children present with recurrent atelectasis incorrectly diagnosed on chest radiograph as recurrent pneumonia.[3] This appears to be related to increased mucus production leading to plugs of eosinophils and mucus which can form casts of the airways. This pattern is sometimes called *hypersecretory asthma*.

The diagnosis of asthma is particularly difficult during the first year of life. Wheezing associated with lower respiratory illness occurs in more than 30% of infants during this period. Uncommonly, it may be due to conditions such as cystic fibrosis, milk aspiration, or congenital structural abnormalities. In many cases it may relate to smaller airway caliber as a result of a respiratory infection on top of intrinsic factors, which include a familial predisposition, male gender, or maternal smoking during pregnancy. In approximately one third to one half of infants the wheezing will represent the early onset of asthma. These children often have more fre-

quent wheezing and are atopic, but it may be difficult to differentiate those with smaller airways and viral-induced wheeze from those with early-onset asthma.

SEVERITY

The asthma severity of each child should be assessed so that treatment can be individualized. Most of the information can be obtained from an accurate history of symptoms, although some cases will require supporting objective evidence with lung function measurements. Children must be asked specifically if they have a wheeze and/or cough and whether this occurs regularly or intermittently. This can often be determined by asking (1) whether the child wakes at night because of cough or wheeze; (2) whether he or she has cough or wheeze on waking first thing in the morning requiring urgent bronchodilator therapy; (3) whether the child's sport or physical activity is limited by cough, wheeze, or tightness in the chest; (4) how frequently the child requires bronchodilator for symptom relief; (5) whether a metered-dose inhaler lasts for less than 4 to 6 weeks (i.e., used more than twice daily); and (6) whether school attendance has been affected by symptoms. Information regarding the use of medication should be sought because inappropriate medications such as antibiotics, antihistamines, and nonprescription medications may be given for symptoms that are actually caused by asthma.

Poorly controlled asthma will be recognized by the presence of these symptoms, excessive use of reliever medication, inadequate length of response to reliever medication, and supporting evidence of abnormal lung function.

Treatment will be based on the pattern of symptoms, which can be classified as infrequent episodic (50% to 75% of childhood asthmatics), frequent episodic (20% to 30%), and persistent (5% to 20%). The latter can be defined as mild persistent, moderate persistent, or severe persistent. Criteria for this classification are shown in Table 59-1.

Patients at high risk for life-threatening asthma may be recognized by (1) repeated visits to the doctor or emergency department or admissions to a hospital, especially the intensive care unit; (2) previous life-threatening attacks; (3) poor compliance with treatment, especially in teenagers and young adults; (4) poor perception of symptoms; (5) persistently abnormal lung function measurements; (6) denial of asthma; and (7) overt psychosocial problems. However, it must be recognized that, although low, there is a risk of dying from asthma in every child with asthma, and every child should be carefully assessed and appropriately managed to minimize that risk.

PRINCIPLES OF MANAGEMENT

Asthma is a disease associated with airway inflammation and characterized by hyper-responsiveness of the airways with reversible airway obstruction. There are many differences between children and adults with asthma, and management in children cannot be extrapolated from adult care. About 30% of children will have respiratory symptoms consistent with asthma during childhood, and many will cease to wheeze. Because two thirds of children with asthma have mild symptoms that can be easily controlled and are not necessarily associated with increasing morbidity in adult life, aggressive treatment cannot be justified at this time in this group. In those with moderate to severe symptoms, there is certainly sufficient evidence that better control of symptoms, usually with inhaled corticosteroids, can be supported.

Most children who wheeze are young and are not able to coordinate well enough to use metered-dose inhalers (MDIs) or dry powder inhalers (DPIs) effectively. However, spacer devices and other aids ensure that children from the first year of life can still be treated with aerosol medications, provided the method of delivery is suited for the age of the patient.

There appears to be an age-related difference in response to medications, with younger children less responsive to β-agonists and rarely responding well to high-dose steroids. This should be taken into account when planning treatment regimens so that unnecessary excessive doses of medication that would cause side effects without benefit are avoided. The immediate aims of treatment are (1) to make the correct diagnosis; (2) to abolish symptoms; and (3) to maximize lung function.

In the long term, one should aim for the following:

1. Maintain the child symptom free.
2. Maintain best lung function at all times. Those with persistent asthma will have spirometry at each consultation. Those with troublesome symptoms may have a peak flow meter at home. The aim is to ensure lung function remains within normal limits for each individual child and that diurnal variation in peak flow is less than 10%.
3. Avoid need for extra bronchodilators.
4. Prevent the restriction of normal childhood activities.

Table 59-1
Severity of Asthma

Pattern	Infrequent Episodic	Frequent Episodic	Persistent
Wheeze, tightness, cough infection, or exercise	Occasional (e.g., with viral)	Most days	Every day
Nocturnal asthma	Usually absent	<Once per 4-6 wk	>Once per wk
Asthma on waking	Usually absent	<Once per 4-6 wk	>Once per wk
Hospital admission in past year	Absent	Usually not	Usually
Previous life-threatening attack	Absent	Usually not	May have a history
Bronchodilator use	Infrequent	Needed most wk	Needed most days
FEV_1 (% predicted)	Normal	Normal/low	Usually low
Mean peak flow variability* over 2 wk	10-20%	20-30%	>30%

*Mean peak flow variability % = (highest – lowest)/highest × 100

5. Prevent the development of irreversible airway obstruction.
6. Reduce risk of death from acute attacks of asthma.
7. Avoid unnecessary side effects from medications.

GINA and Asthma Foundations in many countries provide guidelines to management.[4]

PATIENT EDUCATION

An extensive education program involving the child, the parents, other health professionals, and the physician in co-management is vital to ensure complete understanding of the natural history of the disease and the roles of particular medications. Without this understanding, adherence will be severely compromised.[5] It is also important that health professionals address real concerns of the parents that may not be related purely to the symptoms presented at consultation. Written material in the form of action plans with detailed personalized information as illustrated in Figure 59-1 may be useful to improve adherence, although Cochrane reviews reported too few results available to confirm their value. Peak flow meters may be of additional value for those with troublesome asthma and poor perception of symptoms. However, peak flow meters are not necessary to improve control of symptoms in the vast majority of children.[6] Support groups can help with information and encouragement.

Recent studies have shown that less than 50% of patients adhere to daily prescribed medication.[7] Physicians cannot predict, better than chance, which of their patients will comply. Good control of *frequent* asthma symptoms requires physicians to assume the role of teachers developing a complete plan with active participation by patients. Clinicians

ASTHMA MANAGEMENT PLAN FOR YOUNG PEOPLE

Name: _____ Date: _____ Best peak flow _____
(6 years and over)

WHEN WELL — **PEAK FLOW**

Take preventer (if prescribed): _____ Above:

Dose: _____ How often: _____

Take reliever: _____ Dose: _____ _____

(Take only when necessary for relief of symptoms)

Before exercise, take: _____

WHEN NOT WELL — **PEAK FLOW**

At the first sign of a cold or if asthma symptoms get worse:

Take reliever: _____ Between:

Dose: _____ How often: _____ _____

Take preventer if prescribed: _____ And

Dose: _____ How often: _____ _____

When your symptoms get better, return to the treatment when well.

IF SYMPTOMS GET WORSE — **PEAK FLOW**

Extra steps to take:

- _____ Less than
- _____
- _____ _____
- Emergency medication: _____ Dose: _____
  Take: _____
  _____
  _____

If you follow this plan but your symptoms get worse, see a doctor immediately or call an ambulance.

AMBULANCE **DOCTOR** **HOSPITAL**

Figure 59-1 Asthma management plan for young people.

must make it possible for patients to tell them what they are and are not willing to do, so that it is more likely that the prescribed drugs are used effectively.[8]

From the very beginning of a patient visit, an equal physician-patient partnership should be promoted. Good or effective communication and health education are critical to the success of the physician-patient interaction and both should begin at the start. The presenting complaint is often not the patient's chief concern. It is important to identify and deal with major concerns. A direct question (which cannot be answered with just a "yes" or "no") like "What really concerns you?" is one way of giving parents or families permission to tell their concerns even though often they are embarrassed to do so.

Patient education should begin with a description of the pathogenesis of asthma in plain language, emphasizing how airway inflammation, mucus production, and bronchoconstriction can each contribute to airway obstruction. Patients are confused by the multiple terms used to describe asthma, including *bronchitis*, *asthmatic bronchitis*, *wheezy bronchitis*, *reactive airways disease*, and *hyper-reactive airways disease*. What patients and families really want to know is, "will this condition impair or interfere with a normal active life," but they rarely ask the question directly. Emphasizing that there is a wide spectrum of severity in children and adults with asthma but that most are able to lead active and productive lives sets the right tone and provides motivation for the patient to play an active role in controlling and managing asthma. It is often worthwhile to point out that there are many Olympic athletes with asthma who manage to win gold medals.

Setting goals for preventive therapy is important. Many families do not like the idea of giving their child medicine over a long period, particularly if the child seems well. It is important to set the goal of gradually reducing inflammation and, once good control is established, to try to reduce the amount of medication needed to maintain the child in that state. Thus parents can be encouraged to take any appropriate practical environmental control measures as a way of reducing the need for medication. It is important to establish criteria, such as experiencing a cold without asthma symptoms, that let parents know how to assess how well controlled are their children's airways.

With respect to drug therapy, it is important to be explicit about how the medicines work; how to take the medicines correctly, including the use of spacers; and the potentially harmful effects of drugs. The latter is essential to identify specific patient or family concerns. Most patients are very concerned about drug toxicity whether or not they articulate this concern. Some confuse muscle-building or anabolic steroids with anti-inflammatory steroids. Others have seen patients with considerable facial swelling following systemic doses of corticosteroids and may be terribly worried about their use. They need to be reassured that in the conventional inhalation doses currently recommended, the risks of serious asthma far outweigh the side effects of the medication, including inhibition of growth, and that the regimen that is being recommended represents the most favorable risk-to-benefit ratio. Following an extensive meta-analysis, Allen and colleagues[9] concluded that children treated with inhaled beclomethasone were more likely to reach predicted or normal heights than children whose asthma was not treated with preventive medication. Since that report, there have been reports in adults indicating risks to be considered including an increased incidence of cataracts in those receiving moderate to high doses of *inhaled* corticosteroids.[10] Because there is still considerable controversy about the possibility that inhaled steroids may inhibit growth, even when used in conventional doses, it is reassuring for patients to know that once the asthma is brought under *good* control, the dosage of inhaled steroids will be reduced. It also helps for patients and families to understand that poorly controlled asthma can lead to impaired growth as well and that risks and benefits have been weighed carefully in developing the treatment plan. The physician's task is to recommend a regimen that maximizes prevention and the use of the least medication over the long haul consistent with good control of asthma.

The physician should provide a plan of action in case of deterioration and especially in an emergency. Before presenting the actual drug regimens being recommended, it is worth stressing that once families understand how the chart is constructed, they can easily follow the clinician's directions for changing dosages or medications in response to a variety of conditions that are likely to occur. Although the actual drug regimen will no doubt change with newer and presumably more effective therapeutic or preventive agents, the *method* of communicating or writing out the recommendations is core. The format can be adapted for use by clinicians who may wish to use different drug regimens as part of a long-term treatment plan.

When indicating the first sign of a cold, it is important to emphasize that this refers to the *earliest* signs, such as a scratchy throat and not waiting until there are full blown signs and symptoms, such as thick nasal mucoid discharge, prominent cough, or wheeze. Once there is cough or wheeze, the treatment is given up to every 4 hours. When there has been no cough or wheeze for 1 week, the revised medication regimen can be discontinued.

The basic strategy for this plan is to eliminate the symptoms of asthma quickly with an intensive regimen and then to decrease the number or dosage of medications. From a psychological point of view, patients are more motivated to adhere to a regimen if they believe they are improving. This is reinforced if they see that some medications are either being reduced or discontinued. Finally, it is easier for patients to follow a set routine. Some compromise in this optimal regimen may be needed if cost of medication or compliance is an important issue.

Developing a long-term plan and teaching a patient or a family to follow it will probably require several visits. These visits will be necessary to get patient feedback, provide the additional health education, adjust the pharmacologic regimen, and also correct any misunderstandings. In applying the regimens as outlined, the aim is to make the patient as symptom free and as physically active as possible. With respect to inhaled corticosteroids, the strategy of aggressively treating asthma early may, in fact, lead to less use of this medication long-term.

Following the recommendations of the Expert Panel Report Guidelines for the Diagnosis and Management of Asthma,[11] an increasing respiratory rate, breathlessness, use of accessory respiratory muscles, alertness, and change in

color (cyanosis) to assess severity of a wheezing episode have been used to recommend a short-acting β_2-agonist by nebulizer or 4 to 8 puffs by metered-dose inhaler in a spacer, up to every 20 minutes, if needed. If there is no response, emergency care must be sought immediately.

Tailoring the therapeutic plan to the family's routine or lifestyle is essential to encourage adherence to the therapeutic programs. For example, for children who have a long school day and find it difficult to take the medication at school, it may occasionally be preferable to introduce a long-acting β-agonist earlier than usual.

The image of a clogged nose has been used as a way of communicating how airway inflammation, swelling, and mucus lead to airway clogging or obstruction. Persuading families to start or increase treatment early is a key to successful management. Many families treat asthma as they would a headache; if it is mild, ignore it and hope it will disappear. It is important to teach them a better metaphor: treat asthma as if it were a fire. If you saw smoke in your kitchen, would you sit down and say, "Let's see what develops"? This question usually elicits a smile, indicating that patients and families get the message.

TRIGGER FACTORS

Continued exposure to allergens and other trigger factors may be associated with worsening of asthma. Avoidance of trigger factors should be considered at all times to maximize potential for improvement of the asthma.

Sensitization in utero does appear to occur, but most studies do not show any benefit from restrictive diets during pregnancy, and severe restriction can be detrimental with impaired nutrition to the mother and the fetus. At present, apart from avoidance of maternal smoking, there are no other proven strategies for prenatal avoidance.

Some avoidance measures may be justified after birth in those at high risk. It is not easy to accurately identify those at risk. Although cord blood IgE levels have been found by some to be elevated, albeit at very low levels, in those with a risk of asthma and atopy, many who become asthmatic do not have high levels, so this is not a clinically useful test for prediction of atopic disease. At present, the family history is the most useful criterion, with increasing probability of atopy when one parent, and especially two parents, or siblings have such a history.[12] The season of birth has been associated with increased airway responsiveness, especially in Finns exposed to birch pollen allergen.[13] Exposure to high levels of house dust mites in the first year of life has been reported to be associated with troublesome asthma symptoms over the next 8 years.[14]

Some foods and additives may trigger attacks of asthma. There are no foods that affect all asthmatics, therefore their role needs to be considered individually in each patient. A common trigger is the preservative sodium metabisulfite, commonly present in dried fruits, sausages, wines, and other drinks, which releases sulfur dioxide, especially in the presence of acid drinks. Cold drinks may lead to increased airway responsiveness, especially in Asian children. There are anecdotal reports of asthma attacks caused by monosodium glutamate and tartrazine, but no consistent findings. Occasionally foods such as nuts, shellfish, strawberries, eggs, and cow's milk will produce an acute response, but this is usually associated with generalized anaphylaxis and is obviously recognized. If uncertain, a double-blind challenge in a recognized clinic may be necessary.

Attempts have been made to influence the induction of asthma in early childhood by dietary modification. Maternal restriction of cow's milk, eggs, and nuts during pregnancy and postnatally with subsequent breastfeeding followed by soy supplements and a restrictive infant diet without cow's milk, eggs, or fish has been reported to be associated with some decrease in eczema and gastrointestinal symptoms[15] but rarely with a decrease in asthma.[16] Wheeze has been noted to be less with breastfeeding in the first few months,[17] but more so in non-atopics,[18] possibly related to reduced respiratory infections in nonasthmatic early wheezers. The effect on asthma is not consistent, and the observations have been associated with multiple changes in the environment, and these need to be sorted out before any restrictive diets can be recommended. There is no evidence that soya replacement is significantly better than cow's milk formula. At present, one could suggest that those infants born to parents with a strong family history of atopy should be breastfed during the first year of life and that in the latter half of the first year of life foods be introduced carefully, one at a time, with a particular preference for less allergenic foods such as rice, vegetables, and noncitrus fruits and avoidance of eggs and nuts.

Aeroallergens are the agents to which most asthmatics develop long-term sensitization, and this sensitization is associated with persistence of symptoms. A direct causal relation is not always clear, and further studies must be done to clarify this association between sensitization and symptoms. It is very likely dose dependent.[19] Exposure to animals such as dogs and cattle during the prenatal period and early postnatal life is associated with reduced asthma and atopy.[20] The German Multicenter Allergy Study did not find any relation between early indoor allergen exposure and the prevalence of asthma, wheeze, and bronchial responsiveness at 7 years.[21] In fact, long-term and early life exposure to stables and farm milk induces a strong protective effect against development of asthma, hay fever, and atopic sensitization.[22] This may be induced by a subject's exposure to endotoxin leading to tolerance to allergens.[23] However, it may be reasonable to exclude furry pets in those who are already sensitized, particularly cats whose fur is often coated with saliva with enzymes that assist passage across the epithelial surfaces. It may take many months for the environment to clear of cat fur allergens.[24] There is no evidence that particular dogs are nonallergenic.

Even though house dust mite sensitization is one of the more common associations with continuing asthma,[25] avoidance measures have rarely proved successful. In a 5-year controlled study from birth, house dust mite avoidance measures resulted in a 61% reduction in mite allergen concentration, but no difference in asthma/atopy prevalence with an increase in prevalence of eczema.[26] Methods for reducing allergen levels in laboratory may not work in the home and may not result in clinical benefit: studies are ongoing.[27] Extreme measures such as admitting subjects to a hospital or living in alpine environments does appear to be associated with a decrease in sensitization to house dust mite and improvement in symptoms and lung function. Less extreme

measures do not often work. Murray and Ferguson[28] have shown benefit with pillows encased or replaced regularly, mattresses encased with thick plastic, bedding warm washed, and humidity kept at less than 50%. Pulling up carpets, high-grade filters, ascaricides, and special vacuum cleaners have not consistently shown significant benefit. In inner-city children with asthma, reductions in the levels of cockroach and dust mite allergens were significantly correlated with reduced complications of asthma.[29] The Cochrane review concludes that chemical and physical methods aimed at reducing exposure to house dust mite allergens cannot be uniformly recommended.[30]

Pollens, particularly in some environments, have been shown to be important allergens, but it is difficult to do much that will influence exposure. Molds, particularly *Alternaria*, are again important inducers of sensitization, but they are outdoor allergens, and little can be done except ensuring that the humidity in the house is decreased. Cockroach allergens may also be important, and cockroach eradication may be helpful in some inner-city environments.

Exposure to environmental tobacco smoke is associated with increased asthma symptoms, and maternal smoking has been documented to be associated with increased wheeze in infancy, decreased lung function, and increased airway responsiveness, and to be responsible for up to 20% of acute attacks of asthma and for an increase in emergency room visits.[31,32] An improvement has been documented with cessation of parental smoking.[33] Active smoking becomes an important trigger for progression of symptoms and should be discussed with all children at around the age of 10 years.

Although external pollution is an important cause of lower respiratory symptoms, particularly bronchitis, and for the triggering of asthma symptoms, it has not been shown to be a major factor associated with an increased prevalence of asthma.[34] Ozone[35] and traffic pollutants[36] have been reported to be associated with increased airway responsiveness and atopy to local allergens and may initiate exacerbations in those with asthma. Public health measures to reduce pollution will be of benefit. Filters and ionizers have not been found to have any clinically significant benefit.

Drugs are not a common cause of asthma attacks in children. Aspirin and other nonsteroidal anti-inflammatory drugs and some complementary medicines very occasionally cause symptoms in younger children. β-Blockers, taken orally or as eye drops, should be avoided or used with caution because these can certainly cause severe asthma in children.[37] Paints and other fumes can usually be avoided. Gastroesophageal reflux has been reported to be associated with exacerbations of asthma, but this has not been found to be common in children. Obstructive sleep apnea and rhinitis have also been associated with increased asthma symptoms, but this does not seem to be a particularly common association in children. It is recommended that children with chronic asthma receive influenza vaccination. The benefits for this in children with asthma have not been documented.

Exercise is an important trigger of asthma but should not be avoided. With appropriate warm-up sprints (so that tachyphylaxis can be induced) and premedication with β_2-agonists or sodium cromoglycate if necessary, a more sustained period of exercise will not cause significant symptoms. Approximately 30-second sprints every 2 minutes for 10 to 20 minutes have been shown to be a useful warm-up.[38] Physical training improves cardiopulmonary fitness, but has little impact on lung function. It is likely that improved fitness will lead to better quality of life.

Physiotherapy is used in asthma for specific purposes. Those with mucous plugging and subsequent atelectasis will benefit with physiotherapy as well as adequate treatment of their asthma. This group often needs steroids to reduce the mucus hypersecretion. Physiotherapists have an important role as part of the health care team in educating the children on useful exercises and the correct techniques in use of their aerosol devices.

The association of asthma with obesity,[39] particularly in adolescent girls, may justify consideration of dietary advice. Adequate trials to document benefit have not been done.

DRUG TREATMENT

It is being increasingly demonstrated that many different genetic polymorphisms can contribute to asthma susceptibility and asthma severity (see Chapter 56). These polymorphisms also influence the variability in the patient's response to drugs, both therapeutic and adverse (pharmacogenetics). Polymorphisms can impact on drug metabolism, target receptors, or unintended targets. Polymorphisms in the β_2 adrenergic receptor, particularly the 16th and 27th amino acid positions, may affect the response to β-agonists so that good responders or those who may have adverse effects with regular β-agonist use can be identified. Differences in interaction with the Arg 16 allele have been reported in different ethnic groups (Puerto Rican versus Mexican).[40] The mechanism is unknown. Polymorphisms on leukotriene C4 synthase or 5-lipoxygenase enzyme sites may identify variation in response to leukotriene modifiers. There is genetic variation in response to steroids, their metabolism, and the susceptibility to adverse events—such as a decrease in bone density.[41]

Current concepts on the use of drugs in asthma are based on the treatment of the underlying inflammatory disease as well as prevention and treatment of acute attacks of asthma associated with environmental triggers.[42] These attacks of asthma may be treated with reliever medications such as β_2-agonists, ipratropium bromide, and theophylline. The underlying disease process is generally controlled with inhaled corticosteroids, sodium cromoglycate, nedocromil sodium, leukotriene modifiers, and rarely theophylline. Maximum efficacy/safety is usually achieved by use of inhaled medications.

Inhaler Devices

Inhaler devices for children include MDIs with or without spacer, DPIs, or nebulizers (Table 59-2) (see Chapter 17). Clear instructions are essential. Children must be observed repeatedly using these devices to ensure their technique is satisfactory because they will often revert to bad habits despite careful instructions. Most children older than the age of 7 years can use an MDI, a DPI, or the breath-activated autohaler. Some may be helped with a large volume (750 mL) spacer, which will improve deposition and may, in some cases, allow larger doses to be given to have an effect similar to a nebulizer during an acute attack. Some children will need

Table 59-2
Medication Delivery for Young Children

Route of Administration	Less Than 4 Yr	4-6 Yr	7 Yr and Older
Nebulizer	Yes	Yes	Yes
MDI/small volume spacer/mask	Yes		
MDI/large volume spacer		Yes	Yes
DPI		Sometimes	Yes
MDI			Yes

Always assess compliance and delivery technique when symptom control or response to medication is poor.
DPI, dry powder inhaler; MDI, metered dose inhaler.

a nebulizer if they have severe acute attacks of asthma or troublesome chronic asthma.

Children from 4 to 7 years can use an MDI with the large volume spacer. The aerosol can be inhaled through the mouth as a single breath or with panting tidal maneuvers—both being equally effective. Only 1 to 2 actuations at a time should be used because any larger number significantly allows deposition and reduces the available respirable particles.[43] Spacers should be washed with detergent and left to dry, not wiped, to minimize electrostatic forces that cause increased aerosol fallout. Some can use the DPI, but deposition is unreliable in those younger than 5 years old,[44] especially during symptomatic periods when inspiratory flow rates are low. For many DPI devices, a rate of at least 30 L/minute is required for optimal de-aggregation and appropriate deposition of particles. It is not clear whether the breath-actuated autohaler is of significant benefit in this age group.

In children younger than age 4, MDIs with a small volume spacer and face mask can provide adequate deposition and similar therapeutic response to that seen with nebulizers.[45,46] In some societies, access to and cost of these devices are a particular problem, and a large plastic coffee cup or half of a 1-liter plastic soft drink bottle may be modified to produce a reasonable spacer device.

Nebulizers are effective because large doses can be administered and breathing pattern does not have as significant an effect on deposition. They can be used with oxygen if needed, but they are bulky and expensive and not necessary for most asthmatics. An MDI and spacer with up to 10 puffs of β_2-agonist will produce the same or better result than a nebulizer.[47] Nebulizers with a venturi design to drive air or oxygen through the fluid and with a separate expiratory valve provide a better dose of drug. Use of novel incentive spacer devices such as the Funhaler (Visiomed, Nedlands, Western Australia, Australia) appear to be associated with improved adherence and likely efficacy.[48]

RELIEVER MEDICATIONS

β_2-Agonists

The initial treatment for children with a mild episode, which if it recurs, does so less than every 2 months and there are no symptoms between attacks, is with intermittent short-acting aerosol β_2-agonists such as salbutamol/albuterol or terbutaline. β_2-Agonists act through the β_2-receptor, which is a G protein–linked receptor in the cell membrane. Stimulation causes activation of adenyl cyclase, which opens K^+ channels and catalyzes the production of cyclic adenosine monophosphate (cAMP). β_2-Agonists relax smooth muscle, decrease vascular permeability, increase mucociliary clearance, and decrease mucus secretion. They may modulate mediator release from mast cells. There appears to be an age effect, with these agents having little effect in normal infants under the age of 12 months and increasing effect from 1 to 5 years.[49] They have a greater effect in infants born preterm than others in the first year of life, and this may be related to the greater amount of smooth muscle seen more peripherally in the airways of these infants. Receptors are certainly present, and β_2-agonists in the early months of life can block the response to mediator challenge.[50] The drugs are safe and effective. They produce acute bronchodilation and prevent exercise-induced bronchoconstriction. They should almost always be used by aerosol. Once again, there may well be significant differences in deposition with age, although these have not been well defined. Inhalation of agents through the nose and breathing patterns of infants lead to reduced deposition in younger infants. However, a lack of response rarely justifies increasing the dosage in infants because it is unlikely that they will respond to the higher dosages. It is important to use the minimum dosage needed to produce the beneficial effect without side effects.

Salbutamol/albuterol and terbutaline have similar β_2 selectivity, although fenoterol may be somewhat less selective. Duration of action is normally up to 4 to 6 hours, with maximum effect for 1 to 2 hours, and an onset of action between 3 and 10 minutes.

MDIs are available as salbutamol 100 μg and terbutaline 250 μg. Usually 1 to 2 puffs are used in normal symptomatic periods, but up to 10 puffs in a spacer may be used during a severe acute attack. DPIs usually contain the equivalent of two puffs. Nebulizing solutions contain the equivalent of 2.5 mg or 5 mg of salbutamol, or 10 mg of terbutaline per mL and approximately 0.02 to 0.03 mL/kg of these solutions is usually used.

Common side effects of the β_2-agonists include tremor, tachycardia, headache, and hyperactivity.[51] Large doses may be associated with hypokalemia and alteration of the ST segment on electrocardiograms. In vitro tolerance or tachyphylaxis to β_2-agonists is seen with long-term use. Tolerance to both side effects such as tremor and to protection against inhalational challenge is also shown with regular use. The clinical significance is not clear, especially because the bronchodilator response does not appear to be significantly affected. Some epidemiologic studies have documented an association between long-term use (more than four times daily) and increased morbidity and mortality,[52,53] but this relationship is not consistent and has not been proved to be causal, clinically significant, or a particular problem in children. However, increased airway responsiveness has been shown with withdrawal of β_2-agonist after long-term use,[54] and this observation in association with the metabolic and cardiac effects that can be seen with these agents provide biological plausibility for a potential risk. Thus, it appears reasonable to attempt to ensure minimal use of β_2-agonists to the level that will control symptoms. It must be remem-

bered that some children will still require β_2-agonists long-term and that, in these situations, the benefit outweighs the potential risks.

Long-Acting β_2-Agonists

Long-acting β_2-agonists such as salmeterol, eformoterol, and bambuterol have lipophilic side chains, which ensure tighter binding to receptor sites and action up to 12 hours. They generally have a slightly slower onset of action than short-acting β_2-agonists, hence short-acting agents are usually necessary for bronchodilation during acute episodes and for protection against challenges,[55] although formoterol onset of action is not much longer than short-acting agonists and is being suggested for rescue as well as maintenance therapy.[56] Some anti-inflammatory activity is argued, although this has not been confirmed, and long-acting β_2-agonists must be used with inhaled corticosteroids and not alone. They are available as MDIs; salmeterol has 25 μg/puff and eformoterol has 6 μg/puff and are usually administered as two puffs twice daily. Side effects are the same as for short-acting β_2-agonists.[57] There have been concerns regarding the risk of long-acting β_2-agonists in view of the studies regarding regular short-acting β_2-agonist use and occasional reports of increased exacerbations and deaths with their use, but the studies are confounded by severity of asthma and access to health care services. No clinically significant tachyphylaxis has been observed and it is recommended that they should be used only in association with inhaled corticosteroids. Reports suggest that the combination of the long-acting β_2-agonist and regular-dose inhaled corticosteroids may be more effective than higher-dose inhaled corticosteroids, and they are currently used for long-term management in that situation. In adults with inadequately controlled asthma on lower-dose inhaled corticosteroids, added long acting β-agonist is superior to added leukotriene receptor antagonist.[58]

PREVENTIVE AGENTS

Preventive agents are used to prevent exacerbations and are thought to do this by control of the inflammatory process. Inhaled corticosteroids are used in those with continuing asthma, whereas sodium cromoglycate, nedocromil sodium, or a leukotriene modifier may be used in those with mild to moderate asthma, even though a long-term effect on the inflammatory process is not well documented. Indications for the introduction of preventive agents are not clear-cut, but most would agree that any of the following: continuing symptoms; the need for β-agonists more than twice weekly; attacks of asthma more than every 2 months; any life-threatening attack of asthma; abnormal lung function in the interval phase; and interference of normal lifestyle because of symptoms would justify the introduction of preventive agents. There is argument whether to use a low dosage of inhaled corticosteroids and increase if necessary or to start with a high dosage to gain maximum control and to define an effective baseline and then reduce the dosage while maintaining the effect. Both are probably appropriate—those with mild to moderate symptoms could start at a low dosage inhaled corticosteroid because it is unlikely that any increase will be required; those with moderate to severe disease should be brought under best control with a high dosage or oral corticosteroid then weaned to the minimum required to maintain that state.

Inhaled Corticosteroids

Inhaled corticosteroids are anti-inflammatory agents that exert their effect after binding to a glucocorticoid receptor in the cytoplasm, which then moves into the nuclear compartment where it regulates the transcription of target genes, leading to a number of actions including the modification of arachidonic acid metabolism, synthesis of prostaglandins and leukotrienes, as well as restoring disrupted epithelium, decreasing vascular leakage, inhibiting cytokines, preventing activation and migration of inflammatory cells, and augmenting β_2-receptor responsiveness. Inhaled corticosteroids lead to a reduction in the eosinophil numbers and eosinophilic cationic protein concentration and in numbers of activated CD4+ T cells. The anti-inflammatory effect is accompanied by a reduction in exhaled nitric oxide (eNO).[59] Inhaled corticosteroids are associated with decreased airway responsiveness to histamine and the late reaction to allergens, but they do not alter the early allergen response; do not modify the disease process; and do not induce permanent cure because these responses may return after cessation of treatment—even when used for many years.[60-63] Inhaled corticosteroids are available or are being developed as beclomethasone dipropionate, budesonide, fluticasone propionate, flunisolide, mometasone furoate, ciclesonide, and triamcinolone acetonide in doses of 50, 100, 250, 400, and 500 μg per puff. Rapid topical biotransformation reduces the amount of active metabolite absorbed. Budesonide and fluticasone are more potent and lipophilic than beclomethasone, triamcinolone, or flunisolide—and this is associated with increased activity, decreased absorption, and first-pass hepatic cytochrome P-450 metabolism. This tends to allow improved effect with smaller doses and decreased side effects.[64] Mometasone and ciclesonide are very potent with predicted fewer adverse effects.[65,66] In childhood, most physicians aim to obtain a response on less than 400 μg/day beclomethasone equivalent because the maximum improvement is seen between 100 and 400 μg and this dosage limits potential for side effects. When taking more than 800 μg/day, the dose-response curve flattens with less significant improvement for the same increase in dosage and greater risk of side effects. The agents are administered via MDIs, PDIs, and nebulizers. A large-volume spacer with an MDI will decrease side effects as a result of raining out of larger particles, which are then swallowed or deposited in the mouth.[67] A mouth rinse following PDIs will decrease absorption and side effects. Some have documented increased deposition with PDIs and recommend a reduction in dosage when changing to this form of administration.[68] Budesonide is available as a nebulizer solution. This is rarely needed, although it may be helpful in some infants with troublesome symptoms. In this case, goggles and face cream should be used and/or the face washed after administration to decrease topical side effects. If possible, attempts are made to administer these drugs in young infants through MDI, small volume spacer, and face mask.

Some studies have suggested that a greater improvement in lung function is achieved if steroids are introduced sooner

after a diagnosis of asthma is made, suggesting prevention of irreversible changes.[69] Selection bias cannot be ruled out in these studies, and the CAMP and PEAK studies suggest that presymptomatic introduction of steroids in young children is not justified.[63,70] Biopsy studies in infants have not confirmed consistently present asthma inflammation in this age group.[71]

Side effects have been reported with all dosages, although they appear to be clinically insignificant below 400 μg/day. Suppression of the hypothalamic-pituitary-adrenal (HPA) axis with reduced cortisol levels[72] has been reported, but few studies show a clinically significant effect below 800 μg. Cushingoid appearance can be seen in some children following the use of inhaled corticosteroids, but there appears to be significant individual variation. The effects on bone turnover and growth are inconsistent but a potential concern. The problem is confounded by the fact that asthma itself will have an effect on growth and pubertal development and it becomes difficult to separate the two. Some investigators have not documented any effect on growth, serum calcium and phosphorus, bone density, or osteocalcin levels,[73] but others have shown delayed puberty with subsequent catch-up[74]; some have found reduced osteocalcin levels,[75] and some documented decreased growth, measured by knemometry,[76] at dosages above 400 μg/day.[77] At present, there are no indications that long-term use of modest dose inhaled corticosteroids is associated with clinically significant reduced bone density. A significant effect on growth has been demonstrated in mild asthmatics given 400 μg/day. This evidence of a systemic effect on growth appears to be temporary with no effect on adult height reached.[78,79] Linear growth was not affected in young children at 200 μg/day, but was reduced temporarily at 400 μg/day and especially 800 μg/day. Hoarseness, oral thrush, and cough are relatively common and can usually be minimized by using spacers. Purpura, bruising, psychological disturbances, and posterior subcapsular cataracts have been reported occasionally.

Corticosteroids are usually given twice daily, although some clinicians have documented benefit when used once daily[80]; others would suggest that they should be given around 3 PM because this has been documented to produce maximum effect with oral corticosteroid medications.[81] One should aim to reduce the dosage to the minimum needed with occasional increases for intercurrent exacerbations. Consideration of reduction in dosage should be given every 6 months if the patient is symptom free. It has been suggested in adults that satisfactory control can be achieved with episodic *as needed* administration in mild asthma but further studies are required in children.[82]

If there is no response to a regular dosage of inhaled corticosteroids, a variety of options are available, none of which has been consistently proved to be superior.[83] Most would add long-acting β_2-agonists. Combination products are now available. Others would consider leukotriene-receptor antagonists or theophylline as appropriate. Some increase the dosage of inhaled corticosteroid, but further benefit with dosages above 800 to 1000 μg/day is difficult to demonstrate. It may be preferable to use a more powerful locally acting corticosteroid. Troleandomycin (TAO) has been suggested to be steroid sparing. It does increase the half-life,[84] but it also increases the side effects.[85] Some children appear to be steroid resistant. The mechanism is uncertain, although changes in receptor binding have been suggested. It is important to recognize this phenomenon to avoid unnecessary side effects with overuse when the drug is not likely to be effective.

Sodium Cromoglycate

Sodium cromoglycate has been shown to be an effective preventive agent in some children and is good particularly for preventing the bronchoconstriction associated with exercise. It also decreases both the immediate and late response following an allergen challenge. It is a mast cell stabilizer but stronger mast cell stabilizers such as β-agonists do not block the late allergen response. It may influence cytokine production and release, and it appears to have some effect on nonadrenergic, noncholinergic nerve endings and neuropeptides. Long-term treatment may lead to reduced airway responsiveness, but this is not consistently found. It must be used by aerosol and is usually given as two puffs of 5 mg per puff MDI two or three times daily or in a nebulizer solution with 20 mg of sodium cromoglycate for wheezy infants.[86] In some countries, only a 1 mg per puff MDI is available. It is generally free of side effects, although some complain of the taste and develop cough following inhalation. It is no longer widely used.

Nedocromil Sodium

Nedocromil sodium is similar to sodium cromoglycate. No significant differences between sodium cromoglycate and nedocromil sodium have been reported[87-89] and neither is as effective as modest-dose inhaled corticosteroids.[78] It is now rarely used.

Leukotriene Modifiers

Viruses may lead to increased airway responsiveness associated with mucosal damage and the presence of cysteinyl leukotrienes in airway secretions.[90] Leukotriene modifiers have been found to produce some symptomatic relief in infants and toddlers with viral-induced wheeze.[91] The availability of leukotriene-receptor antagonists (Zafirlukast, Montelukast) and leukotriene-synthesis inhibitors (Zileuton) provides new mediator-specific therapy for asthma. Their specific role is not yet clear. They have been shown to block airway response to challenge and, in chronic asthma, to lead to improved lung function, reduced symptoms, and some steroid sparing. They appear less effective than steroids,[92-94] with 17% of an asthmatic cohort showing increased FEV_1 with use of both steroids and leukotriene modifiers; 23% to inhaled corticosteroids only; and 5% to leukotriene receptor antagonist only.[95] They are well tolerated, although hypereosinophilia as a part of Churg-Strauss syndrome has been reported, but rarely in children. It is not certain whether this is or is not due to the antileukotrienes or is a consequence of steroid withdrawal. Specific recommendations are not yet clearly defined, but inhaled corticosteroids remain first-line therapy for most children with moderate persistent asthma, whereas leukotriene modifiers may prove useful in mild asthma especially if an oral preparation is required. They may be useful for viral-induced wheeze in young children.[96] They

appear to increase the number of symptom-free days, ED visits, and parental time at work in the months following a diagnosis of viral-induced wheeze. In occasional patients, leukotriene modifiers may be tried with inhaled corticosteroids as an alternative to the combination of inhaled corticosteroids and long-acting β-agonists and possibly in those in whom steroid reduction is sought.

Oral Steroids

Oral prednisolone or methylprednisolone may be used in a very small group of children as a trial to diagnose asthma, for acute management of a severe attack, and in some with troublesome chronic asthma for long-term treatment. High dosages of 1 to 2 mg/kg may be used to achieve control, but it should then be reduced to the lowest possible dosage, and this may be as low as 1 to 2 mg/day. In those with severe disease, most will use oral prednisolone intermittently for episodes of acute deterioration. Long-term treatment can be associated with reduced growth, HPA axis suppression, hypertension, posterior subcapsular cataracts, and psychological changes.

Nonsteroidal Anti-inflammatory Agents

Many other anti-inflammatory agents have been tried in those not responding to moderate dosages of steroids. Methotrexate appears to help some but it is not uniformly effective.[97] Changes seen with cyclosporine are small and of doubtful clinical significance. Gamma globulins have been used, but consistent benefit has not been confirmed.[98] It has been noted that gold may have a steroid-sparing effect.[99] Nifedipine has been associated with a reduction in circadian peak flow variation.[100] PAF antagonists[101] and inhaled diuretics are being tried experimentally, but as yet have no clinical application.

Omalizumab is a recombinant humanized monoclonal antibody directed against IgE to inhibit the immune response to allergen exposure. Omalizumab is directed against the binding site of IgE for its high affinity Fc receptor. It prevents free serum IgE from attaching to mast cells and other effector cells and prevents IgE-mediated inflammatory changes. A Cochrane review[102] reports that omalizumab is significantly more effective than placebo in enabling more patients to reduce or withdraw inhaled corticosteroids, but the level of clinical value is debatable. It is approved in some countries for use in children 12 years and older with evidence of asthma and atopy not controlled by inhaled corticosteroids. It is administered by regular subcutaneous injection, is well tolerated, and reduces asthma exacerbations. It is expensive. Further assessment is necessary.

Theophylline

Theophyllines have been widely used in the past. They are inexpensive but have a low therapeutic benefit to potential toxicity ratio. They are bronchodilators with considerable extrapulmonary effects. Some have argued that they have an effect on the late response to allergen challenge and that they have anti-inflammatory activity as a result of more selective phosphodiesterase inhibition in small doses.[103] They produce some muscle relaxation, increase mucociliary clearance, inhibit mediator release, suppress edema, stimulate ventilation, and reduce diaphragmatic fatigue. With long-term use they do not lead to a reduction in the inflammatory infiltrate or nonspecific airway hyper-responsiveness. They are used in some intensive care units in severe acute attacks to reduce diaphragm fatigue and to produce central nervous system stimulation. They are usually given at dosages of approximately 5 mg/kg of regular theophylline up to six doses hourly, or 7 to 8 mg/kg of the slow-release preparation every 12 hours, but are rarely used today. Side effects are seen even at therapeutic doses. Some are due to direct irritation of the gastrointestinal tract, such as nausea and vomiting, whereas others are associated with increased serum levels and include vomiting, hematemesis, tachycardia, and dysrhythmia. With long-term use, headache, learning difficulties, sleep disturbance, and behavioral problems[104] have been reported, but theophyllines are more likely to exacerbate these symptoms in those predisposed. Uncommonly, convulsions and death may occur.

Anticholinergic Agents

Anticholinergic agents such as ipratropium bromide and tiotropium bromide block the postganglionic efferent vagal pathways leading to bronchodilation associated with decreased vagal tone.[105] They block reflex bronchoconstriction to irritants but have no effect on the early or late response to antigen challenge or on the inflammatory response. Some would suggest that these agents have an additive effect to β_2-agonists with acute attacks of asthma and should be used for anyone with moderately severe symptoms, and some would consider that they be used occasionally for long-term management. They may be useful for those who have significant side effects such as tremor with high-dose β_2-agonists. They are administered as an MDI using two to four puffs of 20 μg/puff, or as a nebulizer with 250 μg/dose. They have a slow onset of action, with maximum effect at 30 to 60 minutes. They have few systemic side effects, although paradoxical bronchoconstriction has been reported possibly owing to the effect on M1 and M2 receptors, which may cause increased acetylcholine release as well as the block of M1 receptors at the neuromuscular junction and of M3 receptors on smooth muscle and mucous glands. High dosages given frequently to young infants cause significant skin vascular dilation. Currently, they are used in some centers in association with β_2-agonists for the acute management of asthma.[106] A Cochrane systematic review suggests that ipratropium bromide was of no additional benefit in children with mild to moderate acute asthma and should be considered only in school-aged children with severe acute asthma.[107] They may very occasionally be used long-term in those requiring high-dose corticosteroids or those who experience significant side effects with β_2-agonists. Some reported better response in infants under 18 months of age,[108] although this has not been confirmed. Some investigators consider that they may have a role in infants with chronic lung disease of prematurity.

Other Agents

Ketotifen is a potent oral H_1-antagonist that was shown to increase β_2 receptor density on lymphocytes with reduced

levels, and it has been suggested that this agent was a useful preventive agent in asthma.[109,110] Benefit has been reported but not consistently with oral antihistamines[111]—there being a small effect compared with placebo and potential side effects such as drowsiness and dry mouth.

Antihistamines may be used for many of the associated symptoms that occur in asthmatics such as rhinitis, eczema, and conjunctivitis but currently have no role in the management of the asthma. Cough suppressants and demulcents should not be used in the treatment of asthma. Antibiotics are rarely needed because bacterial infections, except for *Mycoplasma*, *Chlamydia*, and pertussis, do not cause asthmatic wheezing and secondary infections are uncommon in children in developed countries.

DIET

There are reports of reduction in both asthma symptoms and improved lung function with exposure to pollutants in asthmatics taking antioxidants in the diet[112] as well as a potential for reduced development of asthma in those who are atopic with the use of lactobacillus[113] or omega-3 fatty acid supplements. Further studies are needed to confirm the role of these dietary interventions.

ALTERNATIVE THERAPIES

Many asthmatics resort to alternative health therapies.[114] Most have not been found to be effective when appropriately controlled trials have been undertaken. Ionizers[115] and acupuncture[116,117] were shown to be ineffective in controlled trials. Most studies of chiropractic, herbal medicines, homeopathy, yoga, specific breathing exercises, and hypnosis have also been disappointing, although suggesting some individuals may gain nonspecific benefit. The Cochrane reviews concluded that recommendations on their use cannot be made because of the limited evidence available.

IMMUNOTHERAPY

The role of immunotherapy in asthma continues to be debated. At present, avoidance of known triggers and pharmacotherapy are more appropriate initial approaches to management because they give good control without significant side effects. This makes immunotherapy with its moderate benefit and significant side effects less justified as an early intervention. Efficacy has been documented,[118] but the effect is mild and less than that obtained with anti-inflammatory agents and associated with more side effects, including death. It will be considered occasionally in highly selected children who are sensitive to a single allergen such as grass pollen, mites, or *Alternaria* and when it can be done under specialist supervision and safe conditions. Usually it must be given for at least 3 years. Some argue that it reduces the number of children that progress from rhinoconjunctivitis to asthma.

ONGOING TREATMENT

Specialist and multidisciplinary clinic referral should be considered in anyone who has a life-threatening attack of asthma, frequent hospital admission, poor parental management, uncertainty of diagnosis, and poor response to regular treatment and regular doses. The natural history of childhood asthma is usually for improvement, and the possibility of a decrease in drug treatment or cessation of therapy should be considered every 6 months.

MANAGEMENT OF ACUTE ATTACKS

In spite of the availability of good preventive treatment, acute attacks still occur and are responsible for considerable hospital admissions and missed school days.

Assessment of Severity

Good management will be based on accurate assessment of each attack. Historical information is vital with clear documentation of the duration of symptoms, cause of the exacerbation, severity of symptoms, current medication, prior hospitalization, and past history of events such as syncopal episodes. Physical examination for tachycardia, tachypnea, cyanosis, changes in demeanor, silent chest, use of accessory muscles, subcutaneous emphysema, and pulsus paradoxus of greater than 20 mm Hg should be undertaken to categorize severity as mild, moderate, or severe (Table 59-3). Attempts to develop reliable and predictive asthma scores have not been successful. Few extra investigations are needed. A chest radiograph is not routinely done but should be considered with differential chest signs that may indicate a complication such as lung collapse or pneumothorax. It may also be justi-

Table 59-3
Initial Assessment of Severity of Acute Asthma in Children

Symptoms	Mild—Probably Manage at Home	Moderate—May Need Hospital Admission	Severe—Admission Required
Altered consciousness	No	No	Yes
Physical exhaustion	No	No	Yes
Speaks in:	Sentences	Phrases	Words
Pulsus paradoxus	Not palpable	May be palpable	Present
Central cyanosis	Absent	Absent	Present
Wheeze on auscultation	Present	Present	Present
Use of accessory muscles	Absent	Moderate	Marked
Sternal retraction (in young children)	Absent	Moderate	Marked
Initial PF or FEV_1 (% predicted or % child's best)	>60%	40-60%	<40%
Oximetry on presentation before treatment (SaO_2)	>95%	92-94%	<91%

fied with unexplained deterioration or failure to respond to treatment. Peak flow or spirometric measurements can be made in older children without severe distress and should be performed when possible. Oximetry has proved to be a good predictor of subsequent progress.[119] Those with oxygen saturation of greater than 95% are likely to respond rapidly and be discharged. Those at 91% or less are very likely to require admission to a hospital and this should be considered in the context of other clinical indicators. Those between 92% and 94% should be given aggressive therapy to achieve the most satisfactory response. These measures should be used with other indicators to determine the need for hospitalization. Each acute attack of asthma is a failure of prophylaxis and preventive treatment should be reviewed at follow-up.

Treatment

Treatment will usually be initiated at home with regular β-agonist treatment. Repeated β_2-agonists should be given for an acute attack of asthma not responding to standard treatment in the community while seeking medical attention. Failure to respond should make one consider an alternative diagnosis such as inhaled foreign body but, if thought to be due to asthma, lead to a visit to the emergency room or doctor's office where a β_2-agonist would be given through a nebulizer with oxygen if necessary (Table 59-4). Mild to moderate episodes can be treated with an MDI and spacer using 6 to 10 puffs, which can be given with 30 seconds between each actuation or 2 puffs every 5 minutes. Some centers use additional ipratropium bromide, suggesting that this results in a 10% increase in response and a greater duration of response.[120] If the child responds to this treatment, he or she should be observed for 1 to 4 hours and then sent home with continuing treatment. If the child does not respond optimally, steroids should be added.[121] Oral prednisolone may be used, or when severe, intravenous hydrocortisone in a dose of 4 mg/kg or either prednisolone or methylprednisolone in doses of 1 to 2 mg/kg will generally be used. There is some evidence that high-dose inhaled corticosteroids may be equally effective for mild asthma in the emergency department, but a combination of inhaled and oral corticosteroids does not provide additional benefit.[122] Although there has been controversy regarding the effects of steroids, their benefit in moderately ill patients has been documented.[123] The optimal dose is not known. An effect can usually be documented between 4 and 12 hours. Some clinicians have recommended a single dose of corticosteroids in the emergency department,[124] whereas others have not shown that this significantly alters the natural history.[125] It does appear that if the child needs oral or intravenous corticosteroids for an acute attack of asthma, then a short course should be given. Very large doses may be associated with side effects such as peptic ulceration, hypertension, behavioral disorder, and myopathy.

Those not responding to treatment over 1 to 4 hours will require admission to a hospital. Admission criteria are based on duration and severity of clinical signs, peak flow, SaO_2, and lack of response to bronchodilator, but admission is often influenced by health service access, social circumstances, past history, and comorbidities. The mainstay of treatment is repeated β_2-agonist (Table 59-5) in various dosing regimens, depending on response. Addition of ipratropium bromide will be considered in those with more severe attacks either initially or only in those who do not show a good response to β_2-agonist and steroids.

Careful clinical monitoring is essential with peak flow measurements in those able to perform the maneuver and SaO_2 in those with moderate to severe disease. If there is a continued deterioration or failure to respond, blood gases may be justified to document the level of $PaCO_2$. Supplemental oxygen should be given to maintain SaO_2 above 93%.

Inadequate response to these regimens will warrant admission to the intensive care unit and may justify the addition of intravenous aminophylline. This is usually given as a single dose of 6 mg/kg over 30 minutes followed by 1 mg/kg/hour to maintain serum levels in the therapeutic range. The loading dose may be reduced or omitted if the child is on theophylline. The effects of aminophylline are not clear. An effect can be detected on lung function within 6 hours. Apart from bronchodilation, it may help by stimulating ventilation and decreasing diaphragmatic fatigue. Aminophylline has been required less frequently because regular or even constant β_2-agonist inhalation has been used. In fact, some argue that it increases the toxicity without significant benefit.[126,127] Some

Table 59-4
Initial Management of Acute Asthma in Children

Treatment	Mild—Probably Manage at Home	Moderate—May Need Hospital Admission	Severe—Admission Required
MDI and spacer or nebulized short-acting β-agonist	Single dose	3 doses at 20-min intervals if required, and 1 to 4 hourly thereafter	Continuous initially then hourly; when stable, decrease to second hourly
Oxygen	No	Up to 8 L/min by face mask to achieve $SaO_2 > 93\%$	Up to 8 L/min by face mask to achieve $SaO_2 > 93\%$
Nebulized ipratropium with β-agonist	No	Optional	250 μg/4 hr may be used (1 mL of 0.025%)
Corticosteroid	No	Consider	Yes; oral or IV
Aminophylline	No	No	Possible
Observation	For 1 hr, if improvement maintained—discharge home	1 Hr after last dose, if improvement maintained—discharge home; if not, admit	Continuous and admit

Table 59-5
Recommended Dosages for Bronchodilators for Acute Exacerbations

Treatment	Formulation	Dosage	Comment
Albuterol/ salbutamol	Metered-dose inhaler (MDI) (90 μg/actuation or 100 μg/actuation)	2 actuations inhaled, may be repeated every 1 to 5 min for a total of 6 to 10 actuations if necessary. Then repeat between 20 min and 4 hr as required.	Monitor response via peak flows or spirometry, if possible. If improved, decrease frequency of administration, if not improved, switch to nebulizer.
	Nebulizer solution 0.5% (5 mg/mL) or more dilute preparations.	0.05-0.15 mg/kg/dose up to 5 mg inhaled via nebulizer every 20 min for 1-2 hr if required. 0.5 mg/kg/hr by continuous nebulization	If improved, decrease to 1 treatment every 1-6 hr, if not improved, use continuous inhalation.
Terbutaline	MDI (200 μg/actuation or 250 μg/ actuation)	2 actuations inhaled, may be repeated every 5 min for total of 12 actuations if necessary. Then repeat 20 min and 4 hr as required.	Maximum 15 mg/hr
	Nebulizer solution (5 mg/2 mL)	0.2 mg/kg/dose to a maximum of 2 mL/4 hr as required.	
	Injectable solution 0.1 mg/mL in 0.9% sodium chloride or 0.5 mg/mL	0.01 mg/kg up to 0.3 mg injected subcutaneously every 2-6 hr as needed. 10 μg IV over 10 min as loading dose, then 0.4 μg/kg/min increased as needed by 0.2 μg/kg/min.	Inhaled bronchodilator preferred. Should expect to use 3-6 μg/kg/min for final maintenance dose.
Epinephrine/ adrenalin	Injectable solution: 1 : 1000 (1 mg/mL)	0.01 mL/kg up to 0.3 mL injected subcutaneously every 20 min for a total of 3 doses.	Inhaled bronchodilator preferred.
Ipratropium bromide	MDI (18 μg per puff or 21 μg per puff)	2 Puffs up to 4 times daily.	
	Nebulizing solution (250 μg/mL)	0.5 to 1.0 mL diluted to 2-3 mL up to 4 times daily.	

report benefit of intravenous magnesium sulfate for severe acute asthma[128]—but there are inadequate data to justify routine use.

Continuous nebulized β_2-agonists[129] or intravenous β_2-agonists will generally be used in those with continuing severe airway obstruction.[130] Experience with continuous nebulized β_2-agonists has been encouraging with reduced need for other interventions. Sedation or antibiotics is rarely required. Repeated assessment is important, and occasionally the child may require intubation and ventilation[131] if the $PaCO_2$ continues to rise and the child tires. Intubation and ventilation should be performed by experienced pediatric practitioners because children with severe acute asthma can be very difficult to manage during induction and maintenance. Air leaks and hypoxic ischemic encephalopathy may occur. Administration of β-agonists into the ventilator circuit can be difficult.

LONG-TERM MANAGEMENT

Successful long-term management is achieved by adherence to a treatment strategy by the family, health care providers, and temporary caregivers such as teachers. Recently published guidelines provide algorithms that recommend currently agreed-upon good clinical practice (Tables 59-6 through 59-8). However, treatment must be individualized, and the ideal for each child will differ; choice provides an opportunity to find the most suitable regimen based on initial assessment and to then move up or down the protocol depending on the response. The proportion of children in each classification of severity will vary with age.

INFREQUENT EPISODIC ASTHMA

Children with infrequent episodic asthma (50% to 75%) will usually require only intermittent inhaled short-acting β_2-

Table 59-6
Maintenance Medication for Children

Classification of Severity	Common Features	Maintenance Therapy
Infrequent episodes	Episodes more than 6-8 wk apart. Attacks generally not severe and short. Physical examination and spirometry between attacks normal.	Nil preventive treatment; prn use of short-acting β-agonist.
Frequent episodes	Attacks <6-8 wk apart. Attacks more troublesome. Increasing symptoms between attacks. Abnormal spirometry when symptomatic.	Consider sodium cromoglycate/nedocromil sodium/leukotriene modifier. Use inhaled corticosteroids in minimum effective dose plus prn use of short-acting β-agonists.
Persistent	Symptoms most days. Nocturnal asthma >3/wk. Attacks <6-8 wk apart. Daily use of short-acting β-agonist. Abnormal lung function. History of A&E visits or hospital admissions.	Inhaled corticosteroid using minimum effective dose. If high dosages of inhaled steroids are required long-term, consider specialist referral. In this situation, consider other drugs to minimize corticosteroid dosage (e.g., long-acting β-agonists, leukotriene modifiers, or omalizumab.)

A&E, admissions and emergency (department).

Table 59-7
Recommended Dosages for Bronchodilators for Long-Term Care

Drug	Formulation	Dosage
Albuterol/salbutamol	Metered-dose inhaler (MDI) (90 μg/actuation) (100 μg/actuation)	2 Actuations inhaled up to every 4-6 hr
	Dry powder inhaler (DPI) (200 μg/capsule)	Contents of 1 capsule inhaled every 4-6 hr
	Nebulizer solution 0.5% (5 mg/mL)	0.10-0.15 mg/kg up to 5 mg in 2 mL sodium chloride inhaled via nebulizer every 4-6 hr
Terbutaline	MDI (200 μg or 250 μg per actuation)	2 Actuations up to every 4 to 6 hours
	DPI (500 μg per actuation)	1 Actuation up to every 4 to 6 hours
Formoterol	MDI (21 μg per actuation)	1 Actuation 12 hourly
	DPI (12 μg per capsule)	1-2 Capsules 12 hourly
	DPI (50 μg per blister)	1 Blister 12 hourly
Ipratropium bromide	MDI (18 μg/actuation or 20 μg/actuation)	2 Actuations inhaled up to 4 times daily (maximum 12 actuations/day)
	Nebulizer solution (250 μg/mL)	1 mL up to 4 times/day in older children
Salmeterol xinafoate	MDI (25 μg/actuation)	0.5 mL up to 4 times/day in younger children
	DPI (50 μg/actuation)	2 Actuations twice daily
		1 Actuation twice daily

Table 59-8
Recommended Dosages for Inhaled Glucocorticoids and Other Preventers

Drug	Formulation	Dosage
Beclomethasone dipropionate	Metered-dose inhaler (MDI) (42, 50, 100, 250 μg/actuation)	1-2 Actuations inhaled twice daily
	Dry powder inhaler (DPI) (100 μg/actuation)	Dose dependent on severity of asthma and previous response
Flunisolide	MDI (250 μg/actuation)	2 Actuations inhaled every 12 hr up to 15 yr
		4 Actuations inhaled every 12 hr if required over 15 years
Triamcinolone acetonide	MDI (100 μg/actuation with spacer included)	1-2 Actuations inhaled twice daily and increased if needed
Fluticasone	MDI (50, 250 μg/actuation)	1-2 Actuations twice daily
	DPI (100, 500 μg/actuation)	
Budesonide	MDI (50, 100, 200 μg/actuation)	1-2 Actuations twice daily; dose dependent on severity of asthma and previous response
	DPI (100, 200 μg/actuation)	1 Actuation twice daily
	Nebulizer suspension (250 μg/mL, 500 μg/mL)	250 or 500 μg twice daily for severe chronic asthma where an MDI with spacer or PDI not effective
Fluticasone/salmeterol	MDI with salmeterol (25 or 50 μg) and fluticasone (100 μg, 125 μg, 250 μg or 500 μg)	1 Twice daily
Budesonide/eformoterol	DPI with budesonide (100 μg, 200 μg or 400 μg) and eformoterol (6 or 12 μg).	1 Twice daily
Sodium cromoglycate	MDI (1 mg or 5 mg per actuation)	2 Twice daily or before exercise
	Nebulizing solution (20 mg in 2 mL)	1 Ampule 2 to 4 times daily
Nedocromil sodium	MDI (2 mg per actuation)	2 Twice daily or before exercise
Montelukast	4 or 5 mg chewable tablets	Once or twice daily
	4 mg granules	
	10 mg tablets	
Zafirlukast	10 mg and 20 mg tablets	Twice daily

agonists. The parents should be aware of signs such as runny nose, itchy throat, or cough for early recognition of an attack so that treatment can be instituted early. Treatment is usually continued until free of symptoms for at least 48 hours.

FREQUENT EPISODIC ASTHMA

Children with symptoms at least every month but with clear periods in between (10% to 20%) should be given a regular preventive agent. This will usually be low-dose inhaled corticosteroids, but may be sodium cromoglycate or a leukotriene modifier. Choice will depend on the pattern of asthma and patient preferences.

PERSISTENT ASTHMA

Children with troublesome symptoms on most days (5% to 20%) will require inhaled corticosteroids once or twice daily with added bronchodilator as required. The starting dosage of inhaled steroids will depend on asthma severity. If symptoms are not well controlled, then regular peak flow measurements may be needed to monitor response to additional treatments that could be higher-dose inhaled corticosteroids, added long-acting β_2-agonist, theophylline, ipratropium bromide, oral steroids, leukotriene-receptor antagonists, or other preventive agents. With inhaled corticosteroid used by an MDI, a spacer device should be used, and mouth rinsing and spitting out when dry powder devices are used. There is some evidence that eNO monitoring may assist in optimizing inhaled corticosteroid treatment in children with persistent symptoms,[132,133] but its clinical usefulness has not been confirmed.

The family must be aware of action to take if the child does not respond to the regular bronchodilator or if the

response does not last 3 to 4 hours. This may be related to the normal circadian rhythm—the family must be comfortable that they can cope at that time. The reason for decreased peak flow and increased symptoms at night is not certain, but factors that may contribute include reduced catecholamines, reduced cortisol levels, increased vagal tone, cold dry air, allergens such as house dust mites, gastroesophageal reflux, and sleep state. Asthma has a tendency to interfere with activities at school, and efforts should be made to minimize any disruption. Teachers must be informed about asthma symptoms and how to respond. Schools should have an asthma-friendly policy regarding administration of drugs. The family should provide the teacher with details of treatment that may be required at school.

In the past, long-stay special schools and residential units were required for troublesome asthmatics. This is rarely necessary today because children can be managed in a mainstream school program and can achieve excellence in study and sport and not be held back by their asthma.

SPECIFIC PROBLEMS

Infants

The wheezing infant is more difficult to manage because the diagnosis is often uncertain and response to therapy is decreased. Many have a transient wheezy illness associated with viral infections, which settles over the first 1 to 3 years and is not associated with risk factors considered to be important for the development of asthma. Some will have other diagnoses such as viral bronchiolitis, cystic fibrosis, milk inhalation, and congenital abnormalities. Others will have chronic lung disease of prematurity or bronchopulmonary dysplasia. Some of these may be associated with asthma, and some may require the same treatment, although each must be considered individually as they may respond differently to various therapeutic interventions. Referral to a specialist may be justified.

The pathophysiology of wheezing in this age group is associated with smaller absolute size of the airways, decreased collateral channels, more peripheral airway smooth muscle, decreased static elastic recoil, and a mechanically disadvantaged chest wall so that wheezing is noted with milder degrees of airway obstruction. Due to less developed collateral ventilation and other developmental factors, hyperinflation occurs more readily, and carbon dioxide level rises earlier in the course of the disease, so artificial ventilation will not be required at levels that may justify assisted ventilation in older children. Lung function measurements are not easy in this age group. Arterial oxygen saturation may help, but decisions regarding the progress of the disease are generally dependent on clinical observation of alertness, feeding, cry, chest movement, and signs of hypoxia.

β_2-Agonists will generally be used, although response will be decreased. In the first year of life there is a negligible response in most infants, although some may respond, and a therapeutic trial may be justified, especially in the second 6 months. Some will show a significant decrease in Sa_{O_2} that may be related to shunting by vascular dilation in unventilated zones or bronchoconstriction to the tonicity or acidity of the aerosol. Anticholinergic agents are favored by some, although significant benefit has not been documented. For the spectrum of wheezy infants younger than 2 years of age, inhaled corticosteroids have been reported to produce a transient improvement in Vmax but no benefit sustained at 3 months.[134] Inhaled corticosteroids and sodium cromoglycate can be effective, although not consistently, in those with early onset asthma and are tried in those with persistent disease. There is early evidence that leukotriene modifiers may be effective, but more long-term studies in young infants are needed.[135] The metabolism of theophylline is decreased in this age group and dosage adjustments need to be made.

Adolescents

Adherence with treatment during adolescence as a result of perceptions related to drug taking, body image, and being seen to be different is a problem, and this is associated with a significantly higher death rate from asthma in this age group. Smoking is common in those with asthma, and unfortunately the number is no less than in the general community in spite of the potential for significant deleterious effects on subsequent lung health. It appears to be part of the risk-taking behavior that is normal in this age group. It is an important time for establishing rapport, improving educational techniques, and providing guidelines for better care. Denial is associated with a significant increase in the risk of death.

Severe Persistent Asthma

Rarely in children, asthma may appear resistant to standard therapies. Alternative diagnoses such as inhaled foreign body and structural abnormalities need to be excluded. Compliance/adherence as well as the appropriateness and correct technique of aerosol devices must be evaluated and addressed. Genetic and acquired steroid-resistant patterns of asthma have been described and may be related to abnormal steroid receptor activity, continued environmental exposure to irritants or allergens, and/or the presence of a neutrophilic rather than eosinophilic inflammation. Treatments to consider for these possibilities include environmental adjustment, leukotriene modifiers, other anti-inflammatory agents, and, very rarely, long-term subcutaneous β-agonist infusions.[136]

CESSATION OF TREATMENT

Because asthma symptoms subside in 60% of childhood asthmatics, cessation of treatment should be regularly considered. Every 6 months, weaning could be considered if the child has remained asymptomatic. This should be gradual and with the assistance of lung function measurements.

FUTURE MANAGEMENT

The future for the management of asthma will be prevention of the disease. Asthma prevalence has increased in the last 25 years, so it should certainly be possible to reduce the prevalence by at least one half. Environmental manipulation may help; however, it is likely that it will be more important to identify those at risk and consider early intervention with environmental modification, anti-inflammatory agents, or vaccination to modulate immunologic maturation during the

critical period in early infancy when the predisposition to asthma appears to be set. Although asthma cannot be cured at present, the increasing understanding of the development of asthma symptoms in early childhood may mean that early intervention in the future will lead to a cure.

CHAPTER 60 Overview

Mark A. Anselmo and Larry C. Lands

TEACHING POINTS

- Cystic fibrosis is the most common autosomal recessive life-limiting illness in North American whites.
- The estimated incidence of cystic fibrosis in the United States is 1 in 2906 white and 1 in 10,338 nonwhite live births.
- Affected humans demonstrate dysfunction of a multifunctional cyclic-AMP regulated ion-channel protein, the cystic fibrosis transmembrane conductance regulator (CFTR).
- There has been a consistent and significant improvement in birth-year cohort patient survival.
- Although respiratory difficulties remain the most common suggestive complaint, failure to thrive and gastrointestinal complaints also frequently lead to diagnosis.
- The diagnosis is based on typical phenotypic findings and/or history accompanied by laboratory confirmation of CFTR dysfunction or identification of two CFTR mutations.
- Quantitative pilocarpine iontophoresis test (QPIT) remains the most discriminatory initial test.
- Mutation analysis has supplanted nasal potential difference as the next step for confirmation in a symptomatic but sweat-test–negative child.
- Access to carrier screening is now available to couples of all racial and ethnic groups, recognizing that the sensitivity of screening is reduced in these groups.
- Enhanced nutritional status is the principal benefit in patients diagnosed via newborn screening.
- With improved median survival, diabetes, bone disease, multiresistant pathogens, hormone dysregulation, and cancer are significant problems for the adult cystic fibrosis population.

Pediatric pulmonology training centers differ in many aspects; however, all trainees, past and present, are linked by a common fiber: the care of the patient with cystic fibrosis (CF). Cystic fibrosis is a chronic multisystem disease and the most common autosomal recessive life-limiting illness in North America. Although the primary cause of morbidity and mortality in CF is related to the respiratory system, disease can manifest itself in the digestive, reproductive, and integumental systems. There are approximately 60,000 persons with CF worldwide, with an estimated incidence of 1 in 2906 white and 1 in 10,338 nonwhite live births in the United States.[1-3] Specifically, the incidence of CF in Hispanic and African-American births is 1 in 9200 and 1 in 15,000, respectively.[4]

Affected humans demonstrate dysfunction of a multifunctional cyclic-AMP regulated ion-channel protein, the CFTR. The gene encoding the 1480 amino-acid polypeptide spans 230 kilobase pairs on the long arm of chromosome 7.[5] Although primarily a chloride channel, CFTR has been implicated in the regulation of other membrane channels, such as the epithelial sodium channel (ENaC)—as well as calcium-activated chloride and potassium channels.[6-8]

Inherited in an autosomal recessive manner, affected individuals require deleterious mutations in both alleles of CFTR, whereas carriers are asymptomatic. There are more than 1400 mutations presently known and this number is continually growing as the disease is being investigated in previously under-represented ethnic groups and mildly affected individuals.[9] The most common mutant allele results from a deletion of a nucleotide triplet encoding for phenylalanine at amino-acid position 508 in the normal protein. This ΔF508 mutation accounts for approximately 66% of mutations worldwide.[10] The frequency of ΔF508 in CF disease varies with ethnicity: in Hispanics (46%), Jews (30%), African Americans (48%), and native Americans (less than 5%). After the ΔF508 mutation, substitution mutations such as G542X (2.4%) and G551D (1.8%) are the next most common mutations in the United States (Table 60-1).

CFTR dysfunction can be grouped into one of six general classes (Fig. 60-1). In class I defects, such as G542X, the transcription of the mRNA is either prematurely stopped or out-of-frame and no protein is synthesized. In class II mutations, such as ΔF508, N1303k, G85E, and G91R, premature degradation of CFTR occurs secondary to defective protein processing. Class I and II patients are typically severely affected and experience pancreatic insufficiency. Class III and IV abnormalities demonstrate altered CFTR regulation and conductance, respectively. Mutations such as G551D (III) and R117H (IV) have residual activity and patients tend to be pancreatic sufficient, although pulmonary disease is variable. Class V mutations lead to abnormal splicing of the CFTR mRNA without alteration of the nucleotide sequences. These mutations can vary widely in severity, depending on the efficiency of translation from mRNA to protein. A severe splicing error mutation, 621 + 1G > T, produces no functional mRNA, whereas intervening sequence 8 (IVS-8) mutations, which affect exon 9 splicing, demonstrate variable severity. Class VI mutations promote early degradation of membrane-associated CFTR.[8]

Defective CFTR alters transepithelial movement of ions and water in the respiratory, gastrointestinal, hepatobiliary,

epidermal, and reproductive systems. One widely supported hypothesis contends that CFTR function below a certain threshold releases ENaC from regulation. Unfettered ENaC actively absorbs sodium; chloride and fluid follow, altering the airway surface liquid layer (ASL), thereby dehydrating the airway. Accumulation of thick viscous secretions further impairs mucociliary clearance leading to chronic pulmonary infection and airways obstruction. This volume hypothesis has been strengthened by a mouse model in which increased sodium absorption by the airways epithelium produces a phenotype similar to CF.[11] The airway epithelium is also the site of intense inflammation and neutrophil recruitment. Inflammatory molecules including interleukins-6 and 8, tumor necrosis factor alpha, and leukotriene B_4 are found in elevated levels in CF airways and/or in vitro studies of CF epithelial cells. Therefore, it is surmised that CF airway pathology results from a combination of ASL alteration, chronic infection, chronic inflammation, and diminished innate immunity. In other organ systems, level of CFTR activity generally correlates with disease manifestations (Table 60-2).

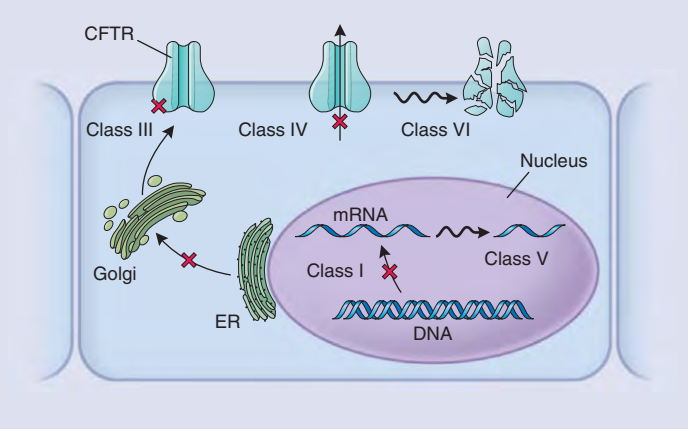

Figure 60-1 Classes of cystic fibrosis transmembrane conductance regulator (CFTR) dysfunction.

SURVIVAL IN CYSTIC FIBROSIS

There has been an astonishing improvement in CF patient life expectancy since the mid-20th century. Between 1940 and 1964, U.S. patient survival was 20% by age 5 years, 10% by 10 years, and there were no adults. By 2001, the average life span was estimated at 33.4 years and by 2004, the predicted median survival was 35.1 years.[1,12] Canadian survival curves, as grouped by birth-year cohort, demonstrate the consistent and significant improvement in patient survival, culminating in 100% survival for patients born recently (Fig. 60-2). The birth-year cohort improvement in survival has been mirrored by an equally impressive improvement in average cohort weight, with children born after year 2000 demonstrating an average weight percentile of more than 40% predicted (Fig. 60-3). Although nutritional status is an independent prognostic factor, an improved body mass index (BMI) correlates with an improved FEV_1 (Fig. 60-4). Not surprisingly, percent predicted FEV_1 per age has improved since 1990 (Fig. 60-5). These impressive statistics imply that children diagnosed today will continue to benefit from innovative treatments and therapies and survival will continue to improve. In 2004, the percentage of registered patients 18 years or over increased to 41.8% in the United States.

CYSTIC FIBROSIS CARE CENTERS AND FOUNDATIONS

The care for the CF patient has evolved from a few specialty centers caring independently for this orphan disease to highly integrated and complex networks active in the United States, Canada, the United Kingdom, Europe, and Australia. Through these national programs, we meet on an international level to efficiently exchange knowledge and strategy on how to improve care and control of CF while improving patient quality of life. CF foundations provide research grants, training in quality improvement, and updated care guidelines and have become instrumental in therapeutic development. This international level of coordination has been paramount in the constantly improving survival curves as demonstrated by our patients.

HISTORICAL ACCOUNTS OF CYSTIC FIBROSIS

Although first regarded as a unique disease by American pediatric pathologist Dorothy Andersen in 1938, we can surmise that CF has a long human history. Using coalescence theory, Wiuf and colleagues have determined that the age of the ΔF508 mutation is 11,000 to 34,000 years.[13] Using standard population genetics modeled on the overall frequency of CF alleles, Reich and Lander have also estimated that the ΔF508 mutation may predate the expansion of anatomically modern humans.[14] Historical references from medieval times describe the salty-when-kissed infant who was hexed and therefore, soon to die.[15] In 1595, Peter Pauw described an autopsy of a bewitched 11-year-old girl with a swollen, hardened, and gleaming white pancreas.[15] In 1606, Alonso y de los Ruyzes de Fonteca, professor of medicine at Henares in Spain, wrote that it was known that the fingers tasted salty after rubbing the forehead of the bewitched child.[16] Emilia Chopin, a young sister of the great French-Polish composer, suffered chronic cough, hemoptysis, and weight loss. She succumbed to a massive gastrointestinal hemorrhage at 14 years of age. Frederic Chopin (1810-1849) himself was described as sickly and delicate after birth.[17] He suffered from respiratory complaints, recurrent diarrhea, and fatty food intolerance. Despite an intense 11-year relationship, Chopin fathered no children.[18] Chopin's death was attributed to laryngeal and pulmonary tuberculosis. However, Cruveilhier, an authority on tuberculosis, reportedly said to Chopin's sister Ludovika, "The autopsy did not elucidate the cause of death—enlarged heart—no pulmonary tuberculosis—pulmonary alterations—a disease which has never been seen before."[19] Although unconfirmed, it is possible that Chopin had CF.

The modern history of CF has involved scores of talented investigators, too many to provide due credit in this modest review, who have pursued this disease from pathologic description to physiologic studies, on to molecular genetics and culminating in proteomic investigations. An abridged timeline of discovery follows:

1905, Landsteiner publishes case of pancreatic abnormalities with delayed passage of meconium.[20]

1933, Blackfan and Wolbach present pancreatic pathology and suppurative lung disease in 13 infants who were suspected of having vitamin A deficiency.[21,21]

1936, Renowned Swiss pediatrician Guido Fanconi describes familial fibrotic pancreatic lesions and bronchiectasis.[22]
1938, Dorothy Andersen describes neonatal intestinal obstruction, intestinal and respiratory complications of 49 patients, and coins the term *cystic fibrosis* of the pancreas.[23]
1945, Farber coins and prefers the term *mucoviscidosis* as he hypothesizes that the disease is caused entirely from thickened mucus.[13,24]
1946, Andersen and Hodges present the first hard evidence that CF is inherited in an autosomal recessive manner.[25]
1948, Paul di Sant'Agnese, a pediatrician, notices that a high number of CF patients presented in heat prostration.
1953, Di Sant'Agnese presents to the American Pediatrics Society data demonstrating a great difference in the sodium concentration between the sweat of children who suffered from CF and healthy controls, leading to the sweat test.[26]

Of equal significance, CF was now more than simply a state of thickened mucus, but an error in the transport of electrolytes across epithelial surfaces. This was of paramount importance because there was a paradigm shift to investigate CF as a disease with dysfunctional electrolyte transport at its very core. This single observation of an astute clinician researcher changed the very way CF was viewed!

1959, Gibson and Cooke publish the method of iontoelectrophoresis, to be the basis for the modern quantitative pilocarpine iontoelectrophoresis test (QPIT), the standard diagnostic test for CF.[27]
1981, Knowles demonstrates that the CF airway epithelium was ineffective in secreting chloride ions.[28]
1983, Quinton reports that the general defect of the CF sweat gland was impermeability to the return of chloride anions.[29,30]
1985, Evidence accumulates in favor of aggressive intravenous antibiotic treatment.[31]
1985, Organ transplantation becomes possible for patients in terminal stages.[32]
1985, Genetic linkage between the putative CF gene and serum paraoxonase, as well as two random fragments of complementary DNA, is discovered.[33]
1985, Knowlton and colleagues assign the gene to chromosome 7.[34] In Toronto, Canada, Tsui localizes the CF gene to an area of 1% of the human genome.[35] Wainwright further localizes the gene to a specific band of chromosome 7.[36]
1989, Tsui, with Collins and Riordan, report the location and genetic analysis of the CF gene in a triumphant triplicate publication.[5,37,38]

Advances in understanding the molecular biology and function of CFTR have occurred since 1989. Although there is a relation between pancreatic function and genotype, linking mutation to severity of lung disease is not evident.[39] Because genotypically similar patients follow disparate courses, the presence of other genes that modify disease severity has recently drawn attention. Rate of *Pseudomonas aeruginosa* infection varies with polymorphisms in mannose-binding lectin.[40-42] Two polymorphisms of the transforming growth factor beta-1 gene are associated with more severe lung disease in patients homozygous for ΔF508 and more putative modifying genes are presently being investigated.[43] Additionally, environmental influences, including treatment regimens, interact significantly with genetic predisposition. Although genetic mutations in CF are still being discovered, attention has turned to protein function and action. Presently, many trials looking at improving nascent CFTR function are underway, as are studies improving action of other chloride channels.

CLINICAL AND LABORATORY DIAGNOSIS

Presenting Signs and Symptoms

CF is most commonly diagnosed after clinical suspicion is confirmed by a diagnostic test. There were 909 newly diagnosed CF patients in the United States in 2004, and the median age of diagnosis was 6 months.[1] Chronic respiratory difficulties remain the most common suggestive complaint leading to diagnosis (Table 60-3). A history of chronic cough, chronic production of sputum, recurrent pneumonia, asthma not responsive to care, and the presence of typical CF organisms such as *Staphylococcus aureus* and *P. aeruginosa* require further investigation. The sinuses are affected in children with CF; therefore, documented recurrent sinusitis in children requires investigation for underlying disease. The respiratory examination can be entirely normal or demonstrate one of many nonspecific abnormalities. Nasal polyps are rare in healthy children and indicate a need for testing. Schamroth sign, colloquially known as *digital clubbing*, never occurs in asthma and signifies the need for further investigation.

Alongside pulmonary complaints, patients usually present with signs and symptoms of gastrointestinal disease. In the neonatal period, meconium ileus and cholestatic jaundice can lead to an early diagnosis. Outside of the neonatal period, infants and children often demonstrate a lower BMI and failure to thrive, despite a voracious appetite. Pancreatic

Table 60-3
Reason for Diagnostic Testing

Diagnosis Suggested by:	Number in U.S. Registry	Percent of Total
Acute or chronic respiratory symptoms	11,015	48.49
Failure to thrive/malnutrition	9026	39.74
Steatorrhea/abnormal stools/ malabsorption	7174	31.58
Meconium ileus/other intestinal obstruction	4663	20.53
Family history	3082	16.74
Neonatal screening	1159	5.10
Electrolyte imbalance	1070	4.71
Genotype	858	3.78
Rectal prolapse	786	3.46
Nasal polyps/sinus disease	742	3.27

Liver problems	269	1.18
Edema	156	0.69
Unknown	272	1.20
Other	665	2.93

*Patient may have more than one symptom at diagnosis.

insufficient patients present especially foul smelling, bulky, and greasy stools. Pancreatic function, although not entirely normal, is sufficient in 15% of CF patients—thereby complicating the clinical diagnosis. Such patients may present with recurrent pancreatitis. A high index of suspicion in cases of rectal prolapse, allergic formula intolerance, or severe gastroesophageal reflux is required if patients are to be diagnosed in a timely fashion. Hepatosplenomegaly can be documented in patients with CF-related liver dysfunction, which presents mainly in the first decade of life.[44]

Patients can rarely present with sequelae of fat-soluble vitamin deficiency. Hypovitaminosis A can lead to xerophthalmia or pseudotumor cerebri.[45,46] Unexplained hemolytic anemia or hemorrhagic disorders owing to vitamin E or K deficiencies, respectively, can be the manifesting signs of cystic fibrosis.[47] Because CF patients lose relatively large amounts of salt in their sweat, they are susceptible in hot temperatures to hyponatremic hypochloremic metabolic alkalosis. Even in the 21st century (although rare), children are diagnosed after the parent tasted salt when kissing the child on the forehead.

A negative family history does not rule out CF because only 17% of CF patients have a family member diagnosed before them.[12] *S. aureus* sepsis has occurred in patients who were diagnosed with CF after the event. Men can present with azoospermia; however, debate exists as to whether bilateral congenital absence of the vas deferens without other organ involvement should be considered as CF. In any event, a patient demonstrating signs and symptoms of CF, or siblings of newly diagnosed patients, should undergo diagnostic sweat testing.

Persistent abnormalities on chest radiographs and/or the presence of bronchiectasis are indications for further testing. Pulmonary function testing can be nonspecific, although obstruction on spirometry that may or may not be reversible with bronchodilator can be documented before diagnosis. Older children and adults may present with a history of recurrent bronchitis, asthma, pancreatitis, infertility or nonspecific gastrointestinal complaints.

Laboratory Evaluation of CFTR Function

Diagnosis of CF requires clinical evidence in addition to laboratory confirmation (Table 60-4). Typical phenotypic findings or siblings of confirmed patients must be accompanied by laboratory confirmation of CFTR dysfunction or identification of two CFTR mutations. Prenatal and newborn screening present special situations where a diagnosis of CF is provided with laboratory evidence alone.

THE SWEAT TEST

Before 1959, the laboratory diagnosis of CF was exceedingly difficult. Suspected children would first provide two stool specimens to confirm the absence of proteolytic enzymes followed by duodenal intubation for the presence of trypsin. After di Sant'Agnese's discovery in 1948, noninvasive diagnosis became possible, but was limited by difficulties and inconsistencies in sweat collection.[26] In 1959, Gibson and Cooke used the electrical properties of iontophoresced pilocarpine to stimulate sweating, using gauze or filter paper to collect the sweat and send for chemical examination.[27] The test has been modified from the initial description and one variation, the QPIT remains the most discriminatory diagnostic sweat test today as 98% of known CF patients have had a positive sweat test.[48] The QPIT is a diagnostic test and should be performed on all patients suspected of having CF.

A sweat chloride ($SwCl^-$) result greater than 60 mmol/L is consistent with CF.[49] A result between 40 and 60 mmol/L is borderline and indicates a need for further investigation—initially genetic testing. A $SwCl^-$ result less than 20 mmol/L is accepted as negative. Levels between 20 and 40 mmol/L are normal with a high degree of certainty, however, $SwCl^-$ values increase with age; therefore, some clinicians have suggested that the cutoff for a positive result in infants should be 30 mmol/L, as opposed to 40 mmol/L, to decrease the chance of a false-negative result.[49-51] There are causes of false-positive and false-negative sweat testing (Table 60-5). If present in a homozygous or heterozygous fashion, there are a number of mutations that can manifest with symptoms yet provide a truly normal sweat test (Table 60-6). There are other sweat-testing devices and protocols including conductivity and osmolarity; however, they have not been accepted

Table 60-4
Diagnostic Criteria for Cystic Fibrosis

Clinical Features (Phenotype)
Chronic cough and sputum production
Persistent infection with characteristic pathogens (*Staphylococcus aureus, Pseudomonas aeruginosa*)
Airflow obstruction on spirometry, with or without response to inhaled bronchodilator
Chronic chest radiographic abnormalities, including bronchiectasis
Sinus disease; nasal polyps
Gastrointestinal and Nutritional Abnormalities
Pancreatic exocrine insufficiency; recurrent pancreatitis
Meconium ileus; distal intestinal obstruction syndrome
Obstructive Azopermia in Males
One or More of Above Clinical Features Plus
Laboratory Evidence of CFTR Dysfunction
Elevated sweat Cl^-
Deleterious mutation in both CFTR alleles
Characteristic bioelectric abnormalities in nasal epithelium in vivo

CFTR, cystic fibrosis transmembrane conductance regulator. Adapted from Rosenstein BJ, Cutting GR: The diagnosis of cystic fibrosis: A consensus statement: Cystic Fibrosis Foundation Consensus Panel. J Pediatr 132:589-595, 1998.

Table 60-5
Selected Causes of False-Positive and False-Negative Sweat Test Results

Causes of False-Negative Sweat Test Results	
Technical Problem with test	Skin edema
Malnutrition	Mineralocorticoids
Causes of False-Positive Sweat Test Results	
Malnutrition	Fucosidosis
Atopic dermatitis	Mucopolysaccharidosis
Hypothyroidism, hypoparathyroidism	Glycogen storage disease type I
Adrenal insufficiency	Glucose-6-phosphate dehydrogenase deficiency
Munchausen-by-proxy	Hypogammaglobulinemia
Klinefelter syndrome	Familial hypoparathyroidism
Technical issues	Autonomic dysfunction
Anorexia nervosa	Familial cholestasis syndrome

H199Y	ΔF508-R553Q

as diagnostic tests, leaving confirmation via QPIT. Any positive test should be repeated and further confirmation is sought by genetic mutation analysis.

GENETIC MUTATION ANALYSIS

The single gene abnormality in CF is theoretically ideal for genetic testing; however, with more than 1400 known deleterious mutations of CFTR, testing can be inconclusive, especially in ethnic groups with less disease prevalence and mildly affected patients. There are four major roles for genetic testing: (1) it should be performed after the diagnosis is made because the information adds to epidemiologic studies of CF and can provide information regarding pancreatic function; (2) identification of mutations allows for prenatal and family-specific carrier screening; (3) molecular genetics can move into first line testing in the case of a patient with convincing symptoms and a borderline or normal QPIT result; and (4) mutation analysis improves sensitivity when coupled with immunoreactive trypsinogen testing (IRT) as part of a newborn screening (NBS) program.[52] In many countries and continents, there are regional differences with respect to common mutations and most screening programs require a tailored local screening genetic analysis that covers a large percentage of mutations in the indigent population. If the initial screen is noncontributory, extended analysis, by either a research laboratory or by a private for-profit laboratory, is often required. Quality control is always a significant factor and diligence is required with results. Genetic testing may not always confirm the diagnosis and care must be taken with interpretation of results, such as in the case of the R117H mutation where phenotype depends on the length of the polythymidine (poly T) tract of intervening sequence 8 (IVS8). Individuals with a 5T polymorphism produce less CFTR than those with 7T and 9T alleles. If paired with a second CFTR mutation, the R117H/5T allelic combination will usually cause classic CF, whereas R117H/9T will not cause any disease. There are reported patients homozygous for the 5T allele who demonstrated nonclassic CF.[53]

NASAL POTENTIAL DIFFERENCE

Patients with clinical features of CF and a borderline or normal SwCl result can present as a significant diagnostic dilemma because even genetic testing may not uncover both mutations. An examination for characteristic bioelectric abnormalities of the nasal epithelium can be performed at certain specialized centers. The test is performed in vivo. After the basal potential is read, sodium conductance is blocked with amiloride and the site is irrigated with a chloride-free solution containing isoproterenol, which will stimulate CFTR. Unlike normal airway epithelium, CF epithelium will not respond with chloride ion secretion to isoproterenol challenge. The test requires a high level of technical expertise and is simply not an effective diagnostic test at centers that do not perform it regularly. Large gene screen analysis has supplanted nasal potential difference as the next step for confirmation in a symptomatic but sweat test–negative child.

Preconceptual Screening

Despite incredible advances in CF care and improved median survival, many couples who already have a child with CF often decide to avoid having another child with CF.[54,55] Traditionally, couples with an immediate family history of CF are offered preconceptual screening for mutations. In 1999, the National Institutes of Health advocated that CF carrier screening be offered to all couples either pregnant or planning to become pregnant, but not to the general population.[56] The American College of Obstetricians and American College of Medical Genetics published cooperative guidelines supporting this policy and introduced a 25-mutation screening panel.[57] The ACOG guidelines recommend offering CF screening to individuals with a personal or family history of CF, and also to any couple in whom one or both partners are white and are planning a pregnancy or seeking prenatal care. Access to screening is now available to all North American couples, recognizing that the sensitivity of screening is reduced in low carrier frequency groups. The panel includes disease causing mutant alleles with a frequency in CF patients of >0.1%.[58]

General Carrier Screening

With an estimated white CF carrier frequency of 1 in 26, no currently available cure and accessible genetic testing, some have championed general population carrier screening.[3,59,60] Massie and colleagues estimate that a 12-mutation screen in Australia would identify 85% of carriers.[61] If instituted, a general population screen theoretically would decrease the incidence of CF. In Canada, the CF birth rate in 1988 was 1 in 2714 but declined by 25% to 1 in 3608 in the ensuing 12 years. The decline coincides with the discovery of the CF gene and the authors contended that increased use of carrier screening and prenatal diagnostic services is responsible for the CF birth rate decline.[62] In Brittany, France, a 15.7% reduction in CF prevalence at birth was attributed to the introduction of a newborn screening program (NBS) for CF and prenatal diagnosis leading to termination of subsequent pregnancies.[63] Opponents to general carrier screening argue that such a program would offset the economic benefit of an NBS program because the incidence of CF would decline.[64] Concurrent general population screening and newborn screening programs do not make economic sense. More importantly, general population screening brings a deeper ethical question for jurisdictions: Is CF a disease that should be treated and eventually cured, or should CF be eradicated by genetic selection? There is no easy answer.

Prenatal Diagnosis

The ability to sample genetic material from the developing placenta and amniotic fluid has enabled the early diagnosis of

certain genetic conditions before 20 weeks of gestation, thereby providing the ability to make informed reproductive choices. With respect to CF, if both parents are carriers of identifiable CFTR mutations, they can be provided the genotype of the developing fetus. This group includes couples with a child with CF, family history of CF, or those identified through preconceptual or general carrier screening. There are two methods presently available: chorionic villous sampling (CVS) and amniocentesis. CVS can be done transcervically and safely between 10 and 13 weeks of gestation and, in very experienced hands, it carries a miscarriage procedure risk of 1 in 200. The procedure-induced chance of miscarriage in experienced hands following mid-trimester (16 to 20 weeks) amniocentesis appears to be 1 in 300. Early amniocentesis (≤13 weeks) has been found to carry a risk of loss rate near 1 in 50 and carries further risk of talipes equinovarus of 1% to 2%, therefore CVS is preferred for pregnancies 13 weeks or less. There is no evidence to support CVS over amniocentesis between 14 and 16 weeks.[65] CVS and amniocentesis for CF are not suggested for parents of unknown genetic potential because the risk for CF is much less than the miscarriage risk (1 in 3000 versus 1 in 300). As of 2004, 507 CF patients in the U.S. registry had been diagnosed prenatally, indicative that parents do not always consider abortion. Advance knowledge facilitates the acceptance of the new baby and allows for preparation in perinatal and neonatal management. The involvement of a genetic counseling team is indispensable during such periods for CF parents planning a subsequent pregnancy.

Newborn Screening Programs

In most countries, the diagnosis of CF depends on the presence of symptoms in the patient and recognition by the clinician before diagnostic testing is performed. According to the Canadian CF Foundation Patient Data Registry in 2000, 40% of patients were diagnosed after 1 year, 9.6% after 10 years, and 2% after 30 years of age.[66] Unfortunately, these children were often markedly symptomatic at the time of diagnosis, many with growth delay and evidence of pulmonary disease. Accordingly, a strong effort to determine the effect of early diagnosis on outcomes has been undertaken. Newborn screening (NBS) for CF involves the quantification of serum trypsinogen from the regularly obtained dried blood spot; no separate specimen collection is required. An elevated serum trypsinogen level is an indirect indication of pancreatic injury, which is present in most newborns affected with CF. In most programs, newborns demonstrating an abnormally high level of immunoreactive trypsinogen (IRT) are flagged for complementary genetic mutation analysis using a tailored local screen. Infants with a positive IRT and who are subsequently found to carry at least one CFTR mutation are referred for confirmatory QPIT. Some jurisdictions employ a "failsafe" protocol where an elevated IRT alone will lead to an investigational QPIT, presumably in patients who carry rare mutations not on the local screen. In 2003, the Centers for Disease Control (CDC) and the U.S. CF Foundation (CFF) co-supported the clinical utility of newborn screening in cystic fibrosis. Newborn screening in the United States is associated with diagnosis at a median age of 0.5 months, whereas the median age for diagnosis in non-meconium ileus patients is 14.5 months.[67] Certainly growth and cognitive development (in those patients who demonstrated low plasma vitamin E levels) were improved in patients diagnosed by newborn screening.[68,69] The evidence for pulmonary outcomes has been mixed and survival benefit evidence depends on retrospective analyses.[70] Lai and colleagues retrospectively segregated CF patients in the registry from 1986 to 2000 as to whether they were diagnosed by meconium ileus, newborn screen, family history alone, or by symptoms. They contend that the children diagnosed by symptoms had a statistically significant shortened survival versus those who were diagnosed by screening. The cost-benefit analysis of neonatal screening using an immunoreactive trypsin/DNA two-stage screening protocol supports the use of screening if patients were to be diagnosed 6 months before becoming symptomatic. The cost-effectiveness data assumed patients would be less ill if diagnosed with newborn screening. The decision by the CF foundation and the CDC to endorse screening is not simple, as there are negative aspects to NBS. First, as with any screening program, there will be false negatives. Combining overlapping data from Wisconsin, Colorado, and Massachusetts, there was a total of 20 babies missed by newborn screening out of 553 known CF children born between 1994 and 2003. Therefore, care providers must maintain a high index of suspicion, even in the era of newborn screening.[52,71,72] Second, depending on their perceptions about the likelihood of CF, depressive symptoms in parents can occur during the waiting period between a positive NBS result and a diagnostic sweat test.[73] Third, the possibility of exposing asymptomatic babies to pathogens in the clinic setting is concerning. As a result of these negatives, the CDC recommends the involvement of a CF specialty center, available genetic counseling, and strict infection control measures be an integral part of a CF NBS program. Present evidence indicates moderate benefits versus a low risk in the case of NBS for CF.[74]

Fecal Elastase Testing

In 2004, 89.9% of patients in the U.S. CF Registry were prescribed enzyme supplements, though most patients do not have a recorded test of pancreatic function.[75] Historically, the percentage of absorbed fat after 3 days of stool collection was used to determine pancreatic sufficiency. Recently, a single random stool sample test that determines the amount of stool elastase has been introduced, simplifying collection and analysis. Elastase is one of more than 20 enzymes produced by the pancreas and it is secreted in response to cholecystokinin.[76] Elastase is stable in the intestinal tract and the concentration increases in the colon owing to water adsorption allowing quantification in egested stool. In patients with CF, 87% had a fecal elastase level less than 100 μ/g stool with the mean value of 1.6 μ/g.[77] An additional 1.5% of patients studied had a level between 100 and 200 μ/g. Therefore, the positive predictive value for pancreatic insufficiency using a cut-off value less than 100 μ/g stool is excellent in patients with CF. Levels of > 100 μ/g stool are indicative of pancreatic sufficiency. Performing fecal elastase testing on 1074 patients, Borowtiz found 24 patients with pancreatic insufficiency not on pancreatic enzyme supplement. Additionally, of 141 patients with normal elastase levels, 81 were on enzyme

supplements.[77] Determination of fecal elastase in CF is quick, has demonstrated good sensitivity and specificity for identifying CF patients with pancreatic insufficiency, and functional pancreatic status should be determined in all patients. Centers in the United Kingdom recommend twice yearly assessment of pancreatic function in children found to be pancreatic sufficient until 2 years of age, and yearly thereafter to ensure continuity of pancreatic function.[78]

EMERGING TRENDS

Improvement in patient survival has permitted the emergence of health issues unique to an aging CF population. Diabetes, bone disease, multiresistant pathogens, hormone dysregulation, and cancer have affected the adult CF population and programs have established routine protocols for some of these emerging problems.[79] Many of these problems have their origin or can manifest in the pediatric population, thereby requiring awareness and treatment before transition to adult centers.

CYSTIC FIBROSIS–RELATED DIABETES

The 2004 CF patient registry stated 16.1% of U.S. CF patients had either glucose intolerance or CF-related diabetes (CFRD) (Fig. 60-6).[1] As expected, the prevalence of CFRD increases with age; consequently, there will be a parallel increase in the total number of patients with CFRD as the average age of the patient population increases.[80] Despite differences in etiology from non-CF diabetes, microvascular complications such as diabetic retinopathy and nephropathy are evident in CFRD and will likely increase in prevalence as CF patients are living longer.[81] They may affect potential for transplant. Of particular concern to CF care-providers, there is a decrease in pulmonary function and BMI in the 2 to 4 years preceding the diagnosis of CFRD, and the development of CFRD has been found to accelerate the decline in pulmonary function and overall clinical status—and possibly increase mortality.[82-85]

There is a strong association between exocrine pancreatic dysfunction and risk of developing CFRD as insulin secretion and end organ response is intact in most pancreatic-sufficient patients.[86,87] The pathophysiology of CFRD likely involves many factors. Histologic examination of pancreatic tissue from CFRD patients demonstrates a significant reduction in the proportion of beta-cells in pancreatic islets owing to progressive fibrosis.[88,89] This structural abnormality is accompanied by functional changes. A 41% reduction in peak plasma insulin concentration along with a delayed time to reach peak levels after oral glucose challenge indicates a dual dysfunction of insulin secretion by CFRD patients.[90] Finally, patients with CFRD have evidence of target organ resistance to insulin.[91] Therefore, CFRD is characterized by hyperglycemia caused by a combination of poor insulin secretion and target organ insulin insensitivity. CF patients are at risk for complications from diabetes, therefore yearly screening is indicated after age 10 years. Additionally, glucose intolerance or diabetes should be investigated in a patient demonstrating one of the following: abnormal random blood glucose, abnormal HbA1c, weight loss, or symptoms of hyperglycemia. Symptoms include polyuria, polydipsia, poor weight gain or growth velocity, decline in pulmonary function, or delayed puberty.[85]

Symptom control and risk reduction of later complications are aims of treatment which includes maintenance of optimal nutritional status and healthy glycemic control. Oral hypoglycemics such as Repaglinide are used in some centers, although further investigation and evidence is required before such therapies can be part of national guidelines. Initiation of insulin therapy reversed the deterioration in body mass and pulmonary function in patients with CFRD.[92] All patients with CFRD should be screened annually for microvascular complications, with a dilated eye evaluation and a urinalysis for microalbumin measurement.[80]

BONE DENSITY

In 1979, Hahn and Mischler separately reported that the bones of CF patients were demineralized as compared to non-CF controls.[93,94] This finding seemed to be of academic interest; however, because patient survival has improved steadily and consistently over the last 40 years, we are begin-

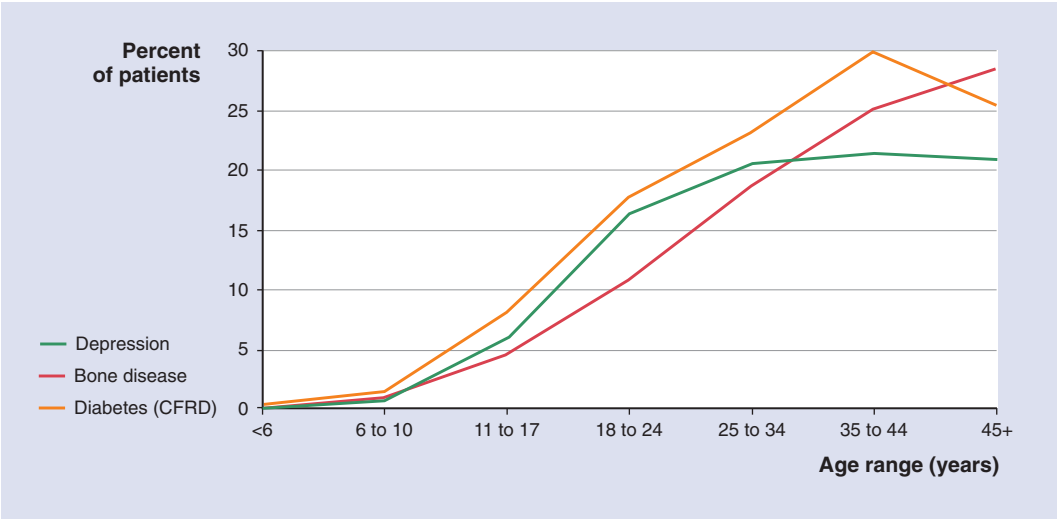

Figure 60-6 Complications versus age. CFRD, cystic fibrosis–related diabetes. (Redrawn from Cystic Fibrosis Foundation, 2006 Patient Registry, Bethesda, MD.)

ning to see long-term problems associated with the disease that were heretofore unknown. Decreased bone density, fractures, and kyphosis occur earlier in CF patients than in healthy controls.[95-97] Although CF bone disease is present in 10.3% of CF patients older than 18 years of age (see Fig. 60-6), good bone health starts in the early adolescent years.[1] In 1996, Henderson and Madsen reported that children affected with CF achieve a lower peak bone mass than their non-CF counterparts.[97] To make matters worse, adults with CF tend to lose bone mineral density 3 to 5 times faster than non-CF controls.[98]

The term *CF bone disease* is purposely nondescript because the exact pathophysiology of the problem is, at this point, unknown.[98] Because the disease begins near or during the growth spurt, there is a failure to achieve optimal "banking" of minerals in the bone and there is a loss of mineral reserves. Contributing factors include delayed pubertal maturation, physical inactivity, poor overall nutritional status, specific vitamin D malabsorption, hypogonadism, and glucocorticoid therapy. The expert committee on bone health reached a consensus that CF patients have inadequate absorption of vitamins D, K, and calcium. Additionally, chronic pulmonary infection increases bone resorption while suppressing bone formation.[95,97,99-104] The state of the art in bone disease is in flux presently as many centers are investigating this relatively new problem. Recently, ΔF508, male sex, poorer nutritional status, and more severe lung disease were found in one study to be independently associated with reduced bone mineral density. The mechanism of action of ΔF508 in reducing bone density in cystic fibrosis remains to be elucidated.[105]

Taken together, data suggest that bone disease begins near or during the growth spurt and is characteristically more pronounced in patients with more pulmonary disease.[98] Recently, bone health has become a priority in CF care. In 2004, the U.S. CF Foundation convened an expert panel to provide guidelines for bone health and identified patients who require screening and subsequent investigations and therapy for patients with CF bone disease.[98]

EMERGING PATHOGENS AND INFECTION CONTROL

In 2004, pediatric CF patients in the United States were most commonly culture positive for *P. aeruginosa*, *S. aureus* and *Haemophilus influenzae*. *P. aeruginosa* is the most significant pathogen in CF, found on positive culture in 57.3% of all patients and approximately in 80% of patients in the 25- to 34-year age range (Fig. 60-7). Historically, acquisition of *P. aeruginosa* at a young age presented an adverse factor in terms of morbidity and mortality.[106] Early and aggressive anti-*Pseudomonas* eradication programs targeting children demonstrating intermittent positive cultures have been so successful that in 2001, no Danish CF patient younger than 14 years of age was chronically infected with *P. aeruginosa*.[107] Eradication of nonmucoid *P. aeruginosa* in children with CF is possible and can delay infection from noneradicable mucoid strains.[108] Aside from these usual suspects, there are other organisms notable for wide-spectrum antibiotic resistance. *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, and *Burkholderia* spp demonstrate resistance to multiple antibiotics with variable impact on infected patients. Additionally, nontuberculous mycobacteria are being found in a significant number of CF patients.

Stenotrophomonas maltophilia

S. maltophilia is an opportunistic nosocomial pathogen that has been isolated from chronically ill or immunocompromised patients on wide-spectrum antibiotics or on ventilatory support. In 2004, 11.6% of CF patients grew *S. maltophilia* on one occasion.[1] During a course of 6 months, 30% of subjects enrolled in the tobramycin solution for inhalation trial grew *S. maltophilia* on one occasion.[109] *S. maltophilia* is soil based and can be found in moist areas including sinks and faucets. The virulence of *S. maltophilia* in the setting of CF is not presently clear. A retrospective review in 2002 concluded that the acquisition of *S. maltophilia* occurs in the setting of more severe disease but does not in itself lessen survival. Although independent association with decreased

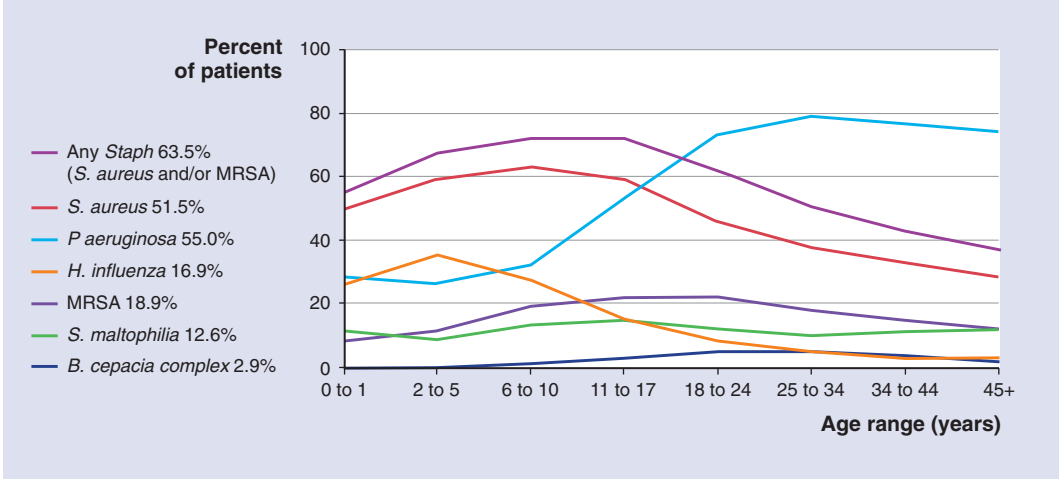

Figure 60-7 Respiratory infections versus age. MRSA, methicillin-resistant *Staphylococcus aureus*. (Redrawn from Cystic Fibrosis Foundation, 2006 Patient Registry, Bethesda, MD.)

survival with *S. maltophilia* infection is not presently evident, many CF teams will treat patients demonstrating positive cultures and symptom progression not attributable to other causes. Treatment is difficult owing to antibiotic resistance and, unlike *Burkholderia* spp and multidrug resistant *P. aeruginosa*, studies of combination testing are lacking. Cross-infectivity has not been identified as a problem, although universal precautions are appropriate.[110]

Achromobacter xylosoxidans

Like *S. maltophilia*, *A. xylosoxidans* also infects severely ill hospitalized patients and the virulent potential of this bacterium in CF is not fully understood. No deterioration in clinical status was noticed in 13 CF patients chronically infected with *A. xylosoxidans* over 2 years as compared to 544 controls.[111] Presently, treatment is case specific and multiple antibiotics are sometimes necessary.[112] Patient cohorting is not presently recommended.[113]

Burkholderia cepacia Complex

The genus *Burkholderia* has been found to chronically infect CF patients. The *Burkholderia cepacia* complex (Bcc) contains at least nine phylogenetically closely related yet distinct species, previously known as *genomovars*.[114] The difficulty in accurately identifying the proper species has required the services of specialized laboratories. Only 3% of CF patients in the United States are infected with a *B. cepacia* complex organism and infection has been found to be typically of one strain.[1,115] The prevalence may be misleading as most infections are in adults, making it a significant pathogen in adult CF centers. The ability of Bcc species to cross-infect patients makes it an important issue in some centers. Bcc is an infection control issue because some strains within certain species have an ability to spread easily between CF patients.[116]

Another issue with infection control is that virulence is variable within a species, indicating that cohorting of "C*epacia* patients" should not supersede universal precautions and that unrestricted contact between such patients should be avoided.[117] Certainly, Bcc infection has been associated with pulmonary decline[118] and pretransplant infection with certain strains of Bcc has been associated with poorer outcome post-lung transplantation.[119-121] However, phenotypic response does vary and there is variability in virulence. Local laboratories in the United States, Canada, and Europe can be found through the International *Burkholderia cepacia* Working Group website at http://go.to/cepacia.

Nontuberculous Mycobacteria

Aside from the emergence of typically resistant bacteria, a significant number of CF patients are infected with nontuberculous mycobacteria (NTM). Historically, patients considered immunodeficient presented with disseminated disease, however, *Mycobacterium avium-intracellulare* complex (MAC), a group of NTM, are rapidly becoming a significant cause of pulmonary disease in immunocompetent patients.[122] NTM are found in soil and drinking water and there is little evidence for person-to-person transmission.[123] In CF patients, infection may be due to a number of reasons including abnormal anatomy, such as cavitary lesions or bronchiectasis, as well as selective pressure from wide-spectrum antibiotics.[124] Unlike tuberculosis, NTM infection is not a reportable disease, therefore, overall prevalence is unknown. Additionally, diagnosis can be difficult in regular sputum samples because bacterial overgrowth and decontamination procedures decrease the yield for NTM. Laboratories are continually improving culture techniques for NTM.[125,126]

The American Thoracic Society (ATS) guidelines suggest disease is present if (1) there are clinical signs and symptoms of cough, fever, fatigue, weight loss, hemoptysis, and dyspnea, with exclusion of other disease; (2) there are radiographic findings on chest radiography (infiltrates, nodules, or cavitation) or high-resolution computed tomography (HRCT) of chest abnormalities (nodules and/or multifocal bronchiectasis); and (3) there is bacteriologic isolation of the NTM organism on sputum/bronchial washings or tissue biopsy. Confirmation of infection by ATS bacteriologic standards requires either one positive smear with two positive cultures, or in the event of smear-negative samples, three positive cultures. If only a washing is available, a high level of AFB on smear can suffice.[127]

Age-related prevalence and distribution of NTM species among 385 CF patients aged 1 to 24 years was determined by a French multicenter prospective study.[128] Overall prevalence was 8.1% and the mean age of first culture was 14.6 years, with a range from 1 to 22 years. *Mycobacterium abscessus* was found in 39% of positive patients, whereas MAC was found in 21%, followed by *Mycobacterium gordonae* and others. Of considerable interest, all of the patients with MAC were older than 15 years of age, whereas *M. abscessus* was found in all ages up to 22 years. In the United States, a multicenter study of patients older than 10 years found an overall prevalence rate of 13% with considerable variation between centers, ranging from 7% to 24%.[129] Of the positive cultures, 20% of patients demonstrated criteria positive for pulmonary disease. In contrast to the French data, MAC was the most common NTM (72%), followed by *M. abscessus* (16%). Other NTM such as *Mycobacterium gordonae*, *M. kansasii*, *M. lentiflavum*, and *M. peregrinum* were rarer. For pediatricians, the French data are unsettling because rapidly growing mycobacteria, such as the difficult to eradicate *M. abscessus*, may be of more importance in children than slow-growing NTM.[130,131]

Therapy involves multiple medications because macrolide monotherapy can lead to resistance. In 2004, 49% of CF patients in the United States were prescribed a macrolide at least once and although there was no NTM emergence during the macrolide trials in CF, induced sputum for NTM should be performed in all patients before and yearly after the initiation of chronic macrolide therapy. Additional testing should occur in a setting of symptoms. NTM infections are also common after lung transplantation (6.5%, 17 of 261 patients.)[132]

SYNERGY AND MULTIPLE-COMBINATION BACTERICIDAL TESTING

A multiresistant isolate is resistant to all antibiotic agents from at least two of the three following classes: the beta-lactams, the aminoglycosides, or the quinolones.[1] Researchers have investigated the in vitro effects of synergy testing,

namely the activity of two antibiotic combinations against such multiresistant pathogens. Multiple-combination bactericidal testing (MCBT) is a further innovation allowing simultaneous synergy testing of three or four drug combinations.[133] Although successful combinations can be found for both multiresistant isolates of *P. aeruginosa* and *B. cepacia* complex, studies evaluating clinical effect have been lacking. A randomized double-blinded control trial enrolled 251 CF patients chronically infected with multiresistant gram-negative bacteria. Upon developing a pulmonary exacerbation, patients were randomized to receive either a 14-day course of antibiotics determined by MCBT or by conventional sensitivity testing. The time to next pulmonary exacerbation was not prolonged in the MCBT-treated group and there was no difference between the groups with respect to rate of treatment failure, changes in lung function, dyspnea score, and sputum bacterial density.[134] One possible contributing factor was the delay from initial MCBT to exacerbation. In the study, MCBT orders were based on sputum results within the 3 months before the patient's actual exacerbation. In nearly 25% of cases, MCBT-directed drug combinations were no longer bactericidal against all of the bacterial isolates recovered during the exacerbation. The study was not sufficiently powered for subgroup analysis; therefore, MCBT may have a role in a specific subset of patients and further investigation is required.

CANCER

Improved survival in CF has allowed the emergence of competing life-threatening illness such as cancer. Spurred by case reports of gastrointestinal and biliary cancers, Neglia and colleagues performed an interesting retrospective study using the registry data from the United States and Canada.[135-138] Although they found no overall increase in cancer risk in CF patients, they did find an increased risk of cancer concerning the biliary tract, small bowel, colon, liver, and pancreas. Similar results were found by Schoni in 1996 using the European registry.[139] Maisonneuve reported similar findings over 10 years but also documented increased risk of cancer in post-lung transplant patients.[140] As in the case of CFBD and CFRD, the exact etiology of this problem is not known, although patients homozygous for ΔF508 seem to be at the highest risk.[141] It is suggested that primary prevention such as smoking cessation and healthy diet choices, including antioxidants, be encouraged in CF patients. Secondary measures also should be initiated, such as occult blood screening of stool, although no evidence presently exists defining frequency and the age appropriate for initiation of testing. There is a need for the development of screening measures in this growing population.[80]

HORMONE DYSREGULATION

Aggressive nutritional programs, effective pancreatic enzyme replacement, regular exercise, and adequate blood glucose regulation have resulted in an impressive increase in the growth parameters of CF patients. Despite these interventions, a significant proportion of CF patients demonstrate poor linear growth. The 2004 Patient Registry noted that there are 16.3% of patients with stature below the 5th percentile. Often in CF children, this deficit is not corrected during puberty and patients tend to reach lower average adult heights. In addition to the obvious psychosocial impact, there has been a documented association between poor linear growth and subsequent deterioration in pulmonary function.[142,143] Although short stature in CF can occur independently of adequate weight gain, groups have investigated the role of human recombinant growth hormone (rGH) in CF patients.[144] Prepubertal children given daily rGH therapy demonstrated significantly higher height and weight Z-scores and growth velocities. A significant decrease in hospitalizations was also noted from the previous year in GH-treated children.[145] Treatment with rGH during overnight gastrostomy-tube feedings produced a significant improvement in weight and height velocity, FVC, and FEV_1 over 1 year.[146]

Schibler performed exercise testing on CF patients assigned to rGH treatment and placebo. Both $\dot{V}O_2$max and maximal workload were significantly improved after 6 months in the rGH group but unchanged in the placebo group.[147] Glucose intolerance, a theoretical concern of GH use that requires prudence, has been encountered in only two patients in the recent randomized controlled trials. Evidence indicates growth hormone provides modest benefit in prepubertal CF patients, although cost and concern over use of hormone therapy in patients without long-term data in CF has limited its use.

ISSUES FOR INFANTS AND YOUNG CHILDREN

Two issues have arisen for children with CF. Centers have recently advocated use of regular chest computed tomography scan (chest CT) every 2 years to document progression of pulmonary disease. Proponents of regular chest CT suggest that pulmonary function testing underestimates mild and moderate lung disease.[148] Presently, there is no evidence that routine chest CT improves overall outcome.[149] Additionally, a computational model developed to calculate cumulative cancer mortality from biennial chest CT radiation estimated a cumulative cancer mortality of 1% and 6.5% at ages 40 and 65 years, respectively.[150] Low radiation dose CT is being developed. Given the uncertain benefit and possible risks, more information regarding the efficacy and safety of routine chest CT is necessary before guidelines are changed.

Evidence is also accumulating regarding use of flexible bronchoscopy for organism recovery in CF patients. Baughman published the results of 28 bronchoscopies in 11 adult patients who were not improving after 10 days of antibiotics. Bronchoalveolar lavage fluid (BALF) microbiological results changed therapy in 13 of the 28 exacerbations.[151] The group proposed that bronchoalveolar lavage (BAL) was a useful diagnostic tool in CF in patients in whom empirical therapy failed. In stable adult patients, sputum collection provided equal information to bronchoscopy for characterizing the genotype and antibiotic susceptibility of chronic *P. aeruginosa* infection.[152]

Jung and colleagues evaluated oropharyngeal, sputum, and bronchoalveolar lavage samples from 38 stable CF patients. They determined the sensitivity, negative and positive predictive values, and specificity to detect *P. aeruginosa* were

35.7, 73.5, 83.3, and 96.2% for oropharyngeal cultures in nonexpectorating patients and 91.7, 94.1, 100, and 100% for sputum cultures from expectorating patients, respectively.[153]

Data specific to children with CF is sparse. In 1999, Rosenfeld and colleagues investigated difference between oropharyngeal and BALF in children with CF younger than 5 years of age. The specificity and negative predictive value of OP cultures for *P. aeruginosa* were high, whereas the sensitivity and positive predictive values are poor. They submitted that a negative oropharyngeal culture is fairly good evidence for lack of infection; however, a positive culture does not reliably indicate infection in the lower respiratory tract with *P. aeruginosa*. Specificity for *S. aureus* was lower, whereas results were similar for *H. influenza*. Further studies are justified. Presently, routine screening of pediatric patients with oropharyngeal culture is adequate; however, bronchoscopy has a place in determination of bacterial conditions in patients who cannot provide adequate sputum and in whom empirical treatment is failing.

FINAL NOTE

The CF model of cooperative clinical care and research has proved overwhelmingly effective over the last 50 years. Despite a mid-20th century median survival age of less than 10 years, presently there are as many adults as children with CF. We must sustain this progress despite scarce healthcare resources and actively encourage trainees to continue the legacy. From Dorothy Andersen to Lap-Chi Tsui, from Paul di Sant'Agnese to Leo Matthews, the motto of the venerable Montréal Canadiens' Hockey Club, taken from "In Flanders Fields" by Lt. Col. John McCrae, MD, is representative of the history and future of CF care: "*Nos bras meutris vous tendent le flambeau. A vous, toujours, de le porter bien haut.*" Translated: "To you with failing hands we throw the torch. Be yours to hold it high."

CHAPTER 61 Genetics and Disease Mechanisms

Charles R. Esther, Jr., and Margaret W. Leigh

TEACHING POINTS

- Cystic fibrosis is caused by defects in the cystic fibrosis transmembrane conductance regulator (CFTR).
- CFTR functions both as a chloride channel and as a regulator of other transporters.
- There are more than 1400 mutations in CFTR that can cause CF, but by far the most common is ΔF508.
- Genotype predicts certain aspects of CF disease severity, but other factors such as overall genetic background and the environment, play a large role in the impact of lung disease.
- The basic pathophysiologic defect in CF is altered ion transport across the membrane, which causes dehydration of extracellular fluids in most tissues affected in CF.

Our understanding of the pathophysiology of cystic fibrosis (CF) has undergone extraordinary changes over the past half century. Early studies focused on the thick, sticky mucus produced by patients with CF, reflected in the fact that CF was once known as "mucoviscidosis," a term still in use in some European countries. In the 1950s, Dr. Paul di Sant'Agnese discovered the elevated salt content in sweat from individuals with CF,[1] prompting a focus on ion permeability. Altered ion conductances in CF were shown by Dr. Quinton in ductal tissues of the sweat gland,[2] which were recognized to be essentially impermeable to chloride. Later studies in respiratory epithelia by Drs. Boucher and Knowles confirmed the decreased chloride conductance and also demonstrated an increase in sodium permeability in those with CF.[3,4] These studies and others suggested that the basic defect in CF was lack of a low-conductance, cyclic AMP (cAMP) regulated chloride channel. Surprisingly, when the gene responsible for CF was cloned in 1989 by Drs. Tsui, Collins, and Riordan, the predicted protein had characteristics more similar to a membrane transporter than the predicted channel (which are biophysically very different).[5] The gene was therefore named the cystic fibrosis transmembrane conductance regulator (CFTR), reflecting uncertainty as to whether the encoded protein acted as an ion channel or a regulator of other channels. Subsequent study of CFTR confirmed that it does function as a chloride channel, but that it also has an important role in regulating other membrane channels and transporters. The most recent studies of CF have focused on how the defects in ion transport in epithelial cells lead to the respiratory and gastrointestinal manifestations of CF, with recognition that CF epithelia have dehydration of extracellular fluids and consequent poor clearance of secretions. Our growing understanding of the pathophysiology of CF has led to novel therapeutic strategies targeted to the basic defects in ion conductances and the consequences.

CFTR GENE AND PROTEIN

Structure

The CFTR gene is located on the long arm of chromosome 7. It is a relatively large gene, with 27 exons spread over almost 250 kb of genomic DNA (Fig. 61-1A).[5] The gene is transcribed to a 6.5 kb long mRNA which can be detected in many organs affected by CF including the lung, pancreas, intestine, and sweat gland (see Fig. 61-1B). The translated CFTR protein is 1480 amino acids long. Unlike some other genes, there are few splice variants or other alternative transcripts that encode functional protein.

The CFTR protein has several structural elements that contribute to its function. The protein contains two large transmembrane domains, each of which has six hydrophobic transmembrane spanning segments (see Fig. 61-1C). Each transmembrane domain is followed by a nucleotide binding domain that contains motifs (called *Walker domains*) preserved among ATP binding proteins. CFTR also has a large hydrophilic domain between the first nucleotide binding fold and the second transmembrane domain. This region is called the *regulatory* or *R-domain*, reflecting the presence of multiple consensus phosphorylation sites that play a role in regulation of CFTR function. The C terminal end of CFTR is notable for the presence of four amino acids (DTRL) that form a consensus PDZ-binding motif.[6] The PDZ-binding motif in CFTR mediates binding with other proteins that play roles in its localization and regulation.

The pattern of two transmembrane domains each followed by a nucleotide binding fold places CFTR within a superfamily of membrane transporters called *ABC* (ATP binding cassette) *transporters*. Indeed, low resolution crystal structures suggest that the transmembrane domains of CFTR form a central pore similar to that of other ABC superfamily members.[7] CFTR differs from other ABC superfamily members both functionally (acting as an ion channel) and by the presence of the R-domain, which is unique to CFTR.

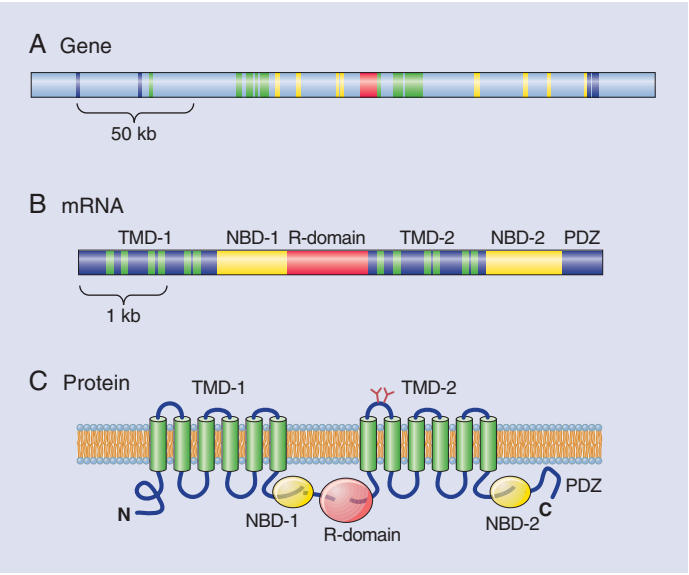

Figure 61-1 Gene, mRNA, and protein structures of CFTR. A, The CFTR gene is composed of 27 exons spanning nearly 250 kB of DNA. **B,** The CFTR mRNA is 6.5 kB long. Sequences predicted to encode the transmembrane domains (TMD), nucleotide binding folds (NBD), the regulatory domain (R-domain), and the PDZ-binding motif are shown. Each TMD is predicted to encode six transmembrane spanning segments (*green*). **C,** The primary structure of the CFTR protein is shown in orientation to the plasma membrane. The extracellular loop between the first and second transmembrane spanning regions of TMD-2 is glycosylated (*red pitchforks*). CFTR, cystic fibrosis transmembrane conductance regulator.

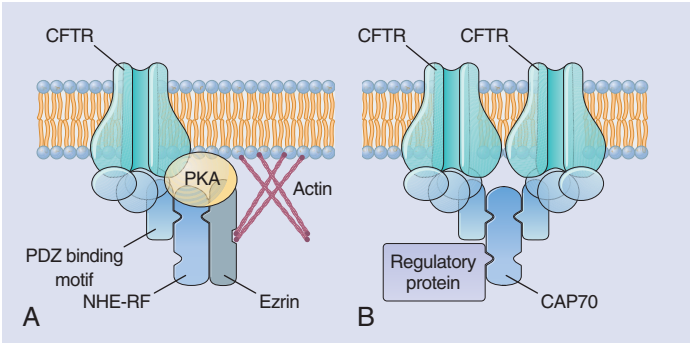

Figure 61-2 Interactions of CFTR with PDZ domain adapter proteins. A, CFTR can bind the adapter protein NHE-RF via the C terminal four amino acids (DTRL) that form a PDZ binding motif. NHE-RF interacts with ezrin which links CFTR to the actin cytoskeleton and facilitates interaction with the regulatory protein kinase A (PKA). **B,** CFTR may form dimeric structures through interaction with PDZ domain adapter proteins. In this example, the PDZ domain protein CAP70 is shown, although similar interactions have been demonstrated with other PDZ domain proteins. CFTR, cystic fibrosis transmembrane conductance regulator.

Like other transmembrane proteins, CFTR is translated and processed in the endoplasmic reticulum (ER), passes through the Golgi apparatus, then to the apical plasma membrane in epithelial cells.[8-10] CFTR undergoes its initial folding steps and core glycosylation in the ER. Folding of a large, multidomain protein such as CFTR is a complex task that requires the assistance of molecular chaperones such as Hsc70/Hsp70[11] and Hsp90.[12] These chaperone proteins interact with co-chaperones such as DnaJ homologs[13,14] and the glycoprotein binding protein calnexin[15] to form the cellular error-checking machinery that distinguishes correctly folded from incorrectly folded CFTR. This error-checking process forms an important check point in CFTR maturation. Whereas correctly folded CFTR migrates to the Golgi apparatus for further processing, misfolded CFTR is recognized as abnormal, complexed with ubiquitin, and targeted to the proteosome for degradation.[16] The maturation process is surprisingly inefficient, and as much as 75% of normal CFTR is misfolded and degraded.[17] CFTR that does successfully pass to the Golgi undergoes further modification and is then targeted to the plasma membrane in secretory vesicles. To aid this process, the N terminal end of CFTR interacts with proteins called *SNARES* (e.g., syntaxins 1a and 8),[18,19] which are part of the secretory machinery that promote targeting and fusion of secretory vesicles to the plasma membrane. CFTR at the cell surface is recovered in endosomes with a half-life of 4 to 6 hours. Some of this endosomal CFTR is recycled back to the plasma membrane and the rest is degraded.[20,21]

At the plasma membrane, CFTR is bound into a network of proteins via interaction with the multi PDZ domain adapter proteins NHE-RF/EBP-50[6] and CAP70.[22] These PDZ adapter proteins bind to the C terminal PDZ-binding motif of CFTR and act as molecular scaffolds to facilitate interactions with other PDZ domain proteins. For example, CFTR is linked to the actin cytoskeleton via the PDZ domain ezrin, and this interaction plays a significant role in targeting of CFTR to the apical plasma membrane (Fig. 61-2).[23] The PDZ adapters also bring CFTR into macromolecular complexes that involve regulatory proteins such as protein kinase A (PKA)[24] and protein kinase C (PKC).[25] There is also evidence that PDZ adapters may link CFTR to itself in a multimeric network[22] or to other biologically active proteins such as the beta-adrenergic receptor.[24] The relevance of these multimeric complexes is currently unclear, with conflicting evidence as to whether CFTR functions as a monomer or a dimer in vivo.[26]

Function

The exact functional role of CFTR remained controversial well after the cloning of the gene. Although much evidence suggested that CFTR should function as a chloride channel, all other members of the ABC transporter superfamily act as membrane transporters and not ion channels. Therefore, several investigators hypothesized that CFTR actually functioned as a channel regulator. Extensive investigation has now shown that CFTR actually has both roles: a chloride channel that regulates other channels and transporters.

ION CHANNEL

Expression of CFTR cDNA in cell systems that lack native CFTR leads to the appearance of a low conductance, cAMP-regulated chloride channel similar to the one missing in patients with CF.[27,28] Furthermore, mutations in putative pore-forming regions of CFTR lead to alterations in ion conductivity when the altered protein is expressed.[29] Perhaps most compelling, purified CFTR protein acts as a cAMP-

regulated chloride channel when reconstituted in lipid bilayers.[30] These experiments clearly demonstrate that CFTR is a cAMP-regulated chloride channel.

Under physiologic conditions, the channel formed by CFTR is highly selective for anions over cations (>10 : 1). The single channel conductance, a measure of the ability of the channel to permit passage of ions per unit time, is relatively low with a value of ~7 to 10 picosiemens (pS). CFTR conducts anions equally well in both directions (i.e., it does not rectify the current). Although generally described as a chloride channel, CFTR is capable of conducting other anions as well. The most physiologically relevant is bicarbonate, which has a conductance of about one-fourth that of chloride.

CHANNEL AND TRANSPORTER REGULATOR

In addition to its role as a chloride channel, CFTR has also been implicated in the regulation of many proteins involved in transport across the plasma membrane. These proteins include channels for sodium,[31] chloride,[32] potassium,[33] calcium,[34] and water;[35] and both the sodium/hydrogen[36,37] and chloride/bicarbonate exchangers.[38] The mechanisms and physiologic relevance of many of these interactions remain unclear, and may reflect changes in membrane potential and/or chloride flux mediated by CFTR rather than a direct regulatory interaction. Two of the more physiologically relevant and best studied regulatory interactions are discussed in more detail subsequently.

REGULATION OF THE SODIUM CHANNEL, ENaC

One of the cardinal biophysical features of CF is hyperabsorption of sodium by epithelial tissues.[39] This hyperabsorption can be blocked by the drug amiloride, indicating that it is mediated via the abundant apical membrane sodium channel called *ENa*C.[31] These observations suggest that ENaC activity is decreased in cells with active CFTR, a hypothesis that has been confirmed in studies on several cell types including frog oocytes[40] and cultured epithelial cells.[31]

The mechanisms by which CFTR mediates downregulation of ENaC are not clear. There is currently no evidence of a physical interaction between CFTR and ENaC. Several studies have suggested that changes in chloride flux or intracellular chloride concentration mediated by CFTR may be sufficient to explain the regulatory effect on ENaC.[41] In support of this hypothesis, expression of an unrelated chloride channel CLC-0 can also downregulate ENaC.[42,43] An alternative hypothesis is that the network of proteins that bind to CFTR via the C terminal PDZ domain may include regulatory elements that can influence ENaC activity. However, there is currently little experimental support for this mechanism.

REGULATION OF THE CHLORIDE CHANNEL, ORCC

Another channel regulated by CFTR is the outwardly rectifying chloride channel (ORCC), which is of historical interest because it was the initial channel identified as being abnormal in CF airway epithelia.[44,45] While detailed study clearly demonstrated that ORCC was not directly responsible for CF, other investigations showed that the presence of CFTR conferred PKC/ATP regulation on the ORCC.[32,46] The precise mechanism and the physiologic role of ORCC are unknown, although recent studies suggest that ORCC may regulate basolateral transport of chloride in epithelial cells.[47]

TRANSPORTER

The similarity of CFTR to the ABC transporter superfamily has led to speculation that the protein may serve as a transporter as well as an ion channel. Although some evidence exists that CFTR may transport certain molecules such as ATP[48] and glutathione,[49] these findings remain controversial. As noted earlier, CFTR may alter the transport properties of other molecules making a direct transport by CFTR difficult to distinguish from a regulatory interaction (see Pitfalls and Controversies box).

Regulation

CFTR is involved in highly regulated processes that control ion and water flux across the membrane. As a result, the activity of CFTR is controlled at multiple levels. The primary regulation of CFTR involves phosphorylation by various kinases, although binding and hydrolysis of ATP also plays a significant role.

cAMP/PHOSPHORYLATION

A characteristic feature of the CFTR channel is its regulation by cAMP, with increasing cAMP levels leading to increased chloride channel activity.[5] This regulation is mediated via phosphorylation of CFTR by the cAMP-responsive protein kinase A (PKA). Under normal circumstances, phosphorylation by PKA is obligatory for activation of chloride channel activity. Furthermore, as previously noted there is evidence that CFTR is structurally coupled to PKA within the plasma membrane via proteins that interact with the C terminal PDZ binding sequence.[23] Although there is still some uncertainty, it appears that nearly all of the physiologically relevant phosphorylation in mammalian cells occurs at 10 PKA sites located within the R-domain.[50] Indeed, deletion of the R-domain yields a chloride channel that is no longer dependent on PKA phosphorylation for activity.[51,52]

Other protein kinases play a role in regulation of CFTR as well. Phosphorylation by the receptor activated protein kinase C regulates CFTR-mediated chloride secretion,[53,54] and seven potential PKC phosphorylation sites are also located in this R-domain.[55] The metabolic sensor AMPK is associated with CFTR.[56]

ATP BINDING

Like all ABC transporters, CFTR contains two nucleotide binding domains that bind ATP. In most ABC transporters, the energy of ATP binding and hydrolysis is used to actively transport substances across the cell membrane. However, CFTR appears to use this energy to control chloride channel activity. The exact mechanism by which this occurs is unclear. The current working model suggests that ATP binding leads to dimerization of the two nucleotide binding folds, inducing a conformational change in CFTR that permits chloride transport (assuming appropriate phosphorylation of the R-domain).[26] ATP binding at one site is relatively stable, but ATP can be hydrolyzed at the second site, which may be involved in channel closing.[57]

Genetics of Cystic Fibrosis

CF is an autosomal recessive disorder, which means that both copies of CFTR must be mutant to manifest the disorder. Individuals who carry only one mutant copy of CFTR are called carriers and are essentially asymptomatic. A child of two carriers has a 1 in 4 chance of inheriting the mutant CFTR allele from each parent and, therefore, of having CF. CF is most common in whites of Northern European descent in whom the carrier rate is ~1 in 20, and 1 in 2500 newborns are affected.[58,59] CF occurs with much less frequency in African-American (1 in 17,000) and Asian (<1 in 100,000) populations.

Over 1400 different disease-causing mutations have been described in CFTR (http://www.genet.sickkids.on.ca/cftr/). By far the most common is a three base pair deletion called ΔF508. The mutation results in deletion of the phenylalanine residue at position 508, which is found on the exterior surface of NBD-1 in high resolution crystal structures of this domain.[60] This mutation is found in ~70% of CF chromosomes worldwide, and its presence leads to defective processing of CFTR and reduced activity of the little CFTR that reaches the cell surface. It is thought that ΔF508 mutation first occurred more than 52,000 years ago and spread through Europe in a heterogeneous time frame.[61] This spread may have been aided by heterozygote advantage (i.e., a survival benefit to CF gene carriers). Several hypotheses have been proposed to explain the heterozygote advantage, of which the best known is that CF gene carriers may be partially protected against life-threatening childhood diarrheal syndromes mediated through the CFTR chloride channel secretory pathway.[62,63] Other hypotheses include suggestions that reduced levels of CFTR protect against *Salmonella typhi* infection or bronchial asthma.[64]

In addition to ΔF508, about 15 mutations are common among whites, and account for up to 15% of the CF alleles within white populations.[65,66] Although many of these mutations occur in other ethnic groups, their frequencies may vary considerably.[59,67,68] The ΔF508 mutation occurs with less frequency in individuals of Southern European extraction (50% of chromosomes),[59,69] Ashkenazi Jewish extraction (30% of chromosomes),[70] African Americans (45% of chromosomes),[71] and Native Americans (<5% of chromosomes).[72] Perhaps the most striking example is in the Ashkenazi Jewish population, in whom the W1282X mutation accounts for 50% of the mutations in CFTR.[70] Furthermore, both Hispanic and African-American populations have distinct patterns of CFTR mutation frequencies (Table 61-1).[66,68] Regardless of ethnic group, most mutations in CFTR are rare.

The large number of mutations in CFTR leads to a bewildering number of genotypes associated with cystic fibrosis. To provide some clarity, a simple classification of five types of CFTR mutations has been proposed, with each class representing a specific mechanism regarding production and routing of CFTR protein to the plasma membrane (Fig. 61-3).[73] Class I mutations lead to no production of CFTR. These are often abnormalities in initiation of transcription (promoters), problems in splicing the mature transcript, premature truncation of the protein by a stop cordon (nonsense mutation), or frameshift mutations that result in nonsensical protein sequences. Class II mutations reflect problems in CFTR protein processing, primarily in the endoplasmic reticulum (ER), which ultimately lead to proteins being recognized as abnormal and targeted for degradation. The common ΔF508 mutation is a class II mutation. These mutations typically reflect single amino acid (missense) mutations. Class III mutations reflect altered function of the mature CFTR that has successfully transited to the plasma membrane. These mutations result from abnormalities in activating the CFTR via intracellular messengers and are often clustered in the nucleotide binding folds or the R domain. Class IV mutations also alter function of the mature CFTR, causing abnormalities in the conduction properties of the CFTR protein. These mutations are typically caused by mutations in the transmembrane spanning regions. Class V mutations result in decreased abundance of an otherwise normal CFTR protein.

In general, class I, II, and III mutations produce the most severe biophysical abnormalities, with little chloride conduction measured in cell culture systems or by nasal potential difference measurements in affected subjects.[74,75] In contrast, class IV and V mutations often preserve a degree of CFTR-mediated chloride conductance. However, these biophysical differences do not always translate into differences in an individual's phenotype.[76]

Recent advances in potential therapies have added new emphasis to understanding of the nature of CFTR mutations. Several studies have demonstrated that application of aminoglycoside antibiotics such as gentamicin can cause "read through" and permit functional expression of CFTR from certain class I stop mutations such as G542X.[77,78] Furthermore, several large-scale projects are attempting to identify compounds that enhance the ability of class II mutations (particularly ΔF508) to transit successfully through the ER. These compounds are termed "correctors" and some may soon reach clinical trials.[79] Because ΔF508 that reaches the cell surface does not exhibit wild type activity (and could therefore be classified as a class III mutation as well), the hunt is also on for "potentiators" that enhance the chloride channel properties of ΔF508 CFTR. As these potential therapies and others are developed, knowledge of the specific CFTR mutations present in an affected individual will take on greater importance.

Genotype-Phenotype Relationship

Cystic fibrosis is a monogenic disorder; it is caused by mutations in one gene, CFTR. However, its phenotypic expression is dependent on a number of factors including CFTR genotype, overall genetic background, and environmental influences. As a result, severity of any particular phenotype (lung disease, malabsorption, etc.) is related to the relative contribution of each of these factors and results in a varying degree of genotype-phenotype correlation.

CFTR GENOTYPE

The large number and variety of mutations found in CFTR led to early speculation that the CFTR genotype could be used to predict phenotypic consequences. The relationship between genotype and phenotype has been most extensively studied with the ΔF508 mutation, which was the first discovered and by far the most common. Studies on ΔF508 homozygotes

*Mutations that occur at a frequency of ≥0.1% of all mutations within a population are shown, stratified by how frequent alleles appear within the population. The order reflects relative frequency, although exact frequencies can vary considerably within subpopulations.
CFTR, cystic fibrosis transmembrane conductance regulator.
Data are a synthesis of the following studies: Watson MS, Cutting GR, Desnick RJ, et al: Cystic fibrosis population carrier screening: 2004 Revision of American College of Medical Genetics mutation panel. Genet Med 6(5):387-391, 2004; Sugarman EA, Rohlfs EM, Silverman LM, Allitto BA: CFTR mutation distribution among U.S. Hispanic and African American individuals: Evaluation in cystic fibrosis patient and carrier screening populations. Genet Med 6(5):392-399, 2004; and Schrijver I, Ramalingam S, Sankaran R, et al: Diagnostic testing by CFTR gene mutation analysis in a large group of Hispanics: Novel mutations and assessment of a population-specific mutation spectrum. J Mol Diagn 7(2):289-299, 2005.

clearly establish a link between genotype and pancreatic exocrine function; 99% of patients homozygous for ΔF508 have pancreatic exocrine insufficiency, although a few had adequate pancreatic exocrine function to prevent malabsorption in early childhood. These patients also have uniformly elevated sweat chloride values (diagnostic for CF when performed in a qualified laboratory), and more than 99% of the adult males are infertile with obstructive azoospermia attributable to congenital bilateral absence of the vas deferens (CBAVD).[80] However, lung function is quite variable within ΔF508 homozygote populations, with some individuals succumbing to lung disease in early childhood, whereas others have relatively normal lung function well into adulthood. Therefore, although the ΔF508 homozygous genotype accurately predicts some gastrointestinal, reproductive, and sweat gland phenotypes, it is a poor predictor of lung disease.

The relation between genotype and phenotype has been explored in other CF genotypes. In general, patients who are homozygous for any class I, II, or III mutation have a very high probability of pancreatic exocrine insufficiency, elevated sweat chloride, and obstructive azoospermia.[73] As a result, most class I, II, or III mutations are called "severe." In contrast, individuals with at least one type IV or V mutation are much more likely to have pancreatic sufficiency and often have lower sweat chloride values. The type IV and V mutations are therefore considered "mild." Other phenotypic consequences of CF have varying correlations to genotype. Meconium ileus and obstructive liver disease occur in ~15% to 20% and ~4% of patients with severe mutations, respectively, but are rare in those that carry a mild mutation.[81] With regard to respiratory manifestations, several studies have shown that patients homozygous for severe mutations have greater decline in lung function over time than those with at least one mild mutation.[82] However, on the individual level, these findings do not apply, and genotype cannot be used to predict severity of lung disease.

There are other variations in the CFTR gene that can influence its expression but do not sufficiently impair expres-

Figure 61-3 Genetic classes of CFTR mutations. A schematic that outlines production of functional CFTR in epithelial cells is shown on the left. CFTR DNA is transcribed in the nucleus and translated in the rough ER, the translated protein undergoes processing through the rough ER to the Golgi, and the mature CFTR gene product reaches the apical cell surface where it acts as a chloride channel, which is subject to regulation (*black arrows*). Mutations in CFTR can be classified based on their impact on this process, as shown in the schematics labeled Class I through Class V. Class I mutations result in aberrant transcription or translation of CFTR. Class II mutations result in ineffective processing of CFTR. Class III mutations result in a CFTR protein that cannot be activated by regulatory mechanisms. Class IV mutations lead to CFTR with decreased ion conductance, and Class V mutations lead to decreased production of an otherwise normal CFTR protein. A list of common (>0.1% of all CFTR mutations) mutations for each class are shown below. CFTR, cystic fibrosis transmembrane conductance regulator.

sion to cause CF. These variations are therefore referred to as polymorphisms rather than mutations, and many can be found at relatively high frequency in unaffected populations. Although polymorphisms in isolation do not cause CF, they can influence gene expression in conjunction with other CFTR mutations sufficiently to impact the CF phenotype. One well described example is the 5T/7T/9T polymorphism found in intron 8 of CFTR. Alleles with the 5T polymorphism have aberrant splicing, which results in deletion of exon 9 in most CFTR transcripts, leading to nonfunctional protein.

In an otherwise normal CFTR gene, this altered splicing has little consequence and the 5T variant can be found in the ~5% of otherwise healthy individuals.[83] However, when the 5T polymorphism occurs in conjunction with the mild mutation R117H, the result is a more severe impairment in functional CFTR expression from this allele. As a result, individuals who are heterozygous for ΔF508 and R117H with the 5T polymorphism have fairly classic manifestations of CF. In contrast, individuals heterozygous for ΔF508 and R117H in conjunction with the 7T polymorphism (which does not express the splicing defect) are often phenotypically normal or have CBAVD with no respiratory or GI disease. More than 200 polymorphisms have been described, though not all have a significant impaction CFTR expression (*http://www.genet.sickkids.on.ca/cftr/*).[81]

A growing recognition of CF as a disease entity and increased sophistication in diagnostic testing has led to identification of many patients who have mutations in both CFTR alleles but lack the classic features of pancreatic insufficiency and progressive lung disease that characterize CF. These patients often have normal or borderline sweat chloride values and mild gastrointestinal or lung disease. Such individuals have been characterized as having "atypical CF." Further complicating this issue, many men have been described who have CBAVD, mutations in CFTR, but absolutely no pancreatic or lung abnormalities. Controversy has developed over whether such individuals should be labeled as having cystic fibrosis or another term such as "CFTR related disease." In a further extension of the CFTR-deficient phenotype, the carrier state is no longer regarded as asymptomatic, as previously thought. Patients with one CFTR mutation have increased rates of pancreatitis[84] and sinusitis.[85] Therefore, it is now clear that there is a spectrum of disease related to mutations in CFTR, of which the most severe is classified as cystic fibrosis.

Characterization of the many different CFTR mutations at the molecular level has permitted examination of the rela-

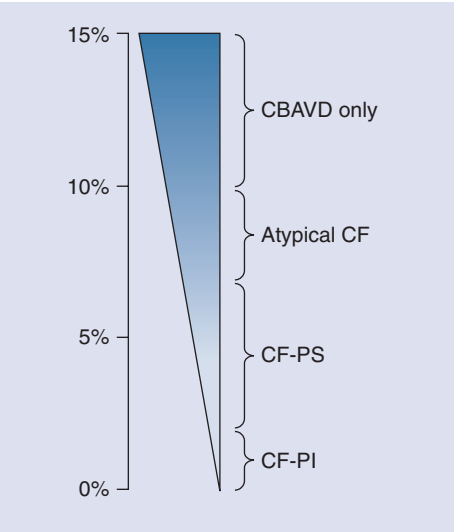

Figure 61-4 Relation between the level of expression of CFTR and clinical disease. Increasing levels of CFTR expression lead to progressively milder manifestations of CF. CBAVD, congenital bilateral absence of the vas deferens; CFTR, cystic fibrosis transmembrane conductance regulator; PI, pancreatic insufficient, PS, pancreatic sufficient.

tionship between expression of functional CFTR and the CF phenotype. Overall, there appears to be a rough correlation between the level of expression of functional CFTR and severity of illness (Fig. 61-4). Preservation of at least 10% of normal CFTR expression is generally sufficient to avoid the typical respiratory and GI manifestations of CF, although it may be insufficient to prevent CBAVD.[86] Lesser levels of expression are associated with more severe disease, with the classic features of pancreatic insufficiency and progressive respiratory decline seen when expression levels are less than 2% to 3% of normal. However, as discussed in more detail subsequently, correlations between expression of CFTR and phenotype are not exact and are influenced by other factors such as genetic background and environment.

GENETIC BACKGROUND AND MODIFIER GENES

The impacts of genetic background and the environment can be difficult to distinguish because individuals who share the same genes (e.g., siblings) often share the same environment. However, twin studies have suggested that genetic background does influence CF phenotype. Monozygotic twins, who share the same environment and 100% of their genes, have a greater concordance of disease severity than dizygotic twins, who share the same environment but only 50% of genes.[87] This finding strongly suggests that genetic factors other than CFTR play a significant role in determining CF phenotype. These data have been supplemented by results of animal studies, which have demonstrated a linkage between a region on mouse chromosome 7 and intestinal obstruction.[88] This region corresponds to human chromosome 19q13, and sibling studies have identified a locus within that region that is linked to meconium ileus.[89] The putative gene involved has been named CFM-1 although it has not yet been identified.

The recognition that genetic background can influence CF phenotype has led to significant effort to elucidate the identity of specific modifier genes. Much of this effort has focused on candidate genes which fit two criteria: (1) a biologically plausible mechanism to impact disease phenotype, and (2) presence of one or more polymorphisms within the population that can then be studied to determine linkage to phenotype.[90] Several potential candidates have been identified in small studies, including alpha$_1$-antitrypsin,[91,92] tumor necrosis factor-alpha,[93] and others. However, many initial associations are not confirmed in further investigations,[94] emphasizing the need for study of larger populations. One potential gene modifier that has been linked to CF phenotype in a larger study is MBL2. This gene encodes mannose binding lectin, a serum protein involved in innate defense.[95] Several polymorphisms in MBL2 lead to lower levels of expression, and these low-expression polymorphisms have been associated with decreased lung function in multiple studies[96] including one that included nearly 600 individuals with CF.[97]

One of the largest studies to date searching for modifier genes is the Gene Modifier Study in the United States.[98] This study enrolled more than 800 individuals all homozygous for ΔF508 (to minimize the impact of CFTR genotype) who had either mild or severe lung disease. Polymorphisms in 14 genes previously identified in smaller studies were examined for linkage to severity of lung disease. Two polymorphisms in transforming growth factor beta (TGF-β) were found to be more common in those with severe lung disease in this study, and the association was confirmed in evaluation of a separate group of 498 CF patients. No other significant associations with disease severity were found with polymorphisms in any other genes, including MBL2. Further study is ongoing to find new modifier genes and clarify the discrepancies between the various studies.

ENVIRONMENT

Environmental influences clearly play a role in the development and progression of lung disease and other manifestations in CF. This is most clearly demonstrated with the association of lower SES and poorer outcomes in CF.[99] However, specific environmental influences have proved more difficult to identify. Some studies have demonstrated a link between passive smoking and lung function,[100] although others have not.[101] Higher levels of exercise may also be associated with better lung function.[102]

Genetic Testing

The use of genetic testing has proved invaluable in the diagnosis of cystic fibrosis, particularly in clinical situations when the diagnosis is unclear with atypical pulmonary disease, normal pancreatic exocrine function, and/or nondiagnostic sweat-chloride tests. If disease-associated mutations can be defined on each allele of CFTR, the diagnosis of CF is confirmed. However, because of the large number of mutations present on CFTR, even large panels (including commercially available panels of 25 to 87 mutations) identify only 80% to 85% of all mutant CFTR chromosomes, with decreased frequency in different ethnic groups.[103] Screening for additional mutants typically adds little to the sensitivity because each novel mutation is found in a very small portion of the population.[66] Newer testing protocols that include sequencing and other methods for identifying novel mutations are now commercially available and have been reported to have

a sensitivity of 99% or greater in detecting CFTR mutations.[104] However, it is still important to recognize that even with new methods, diagnosis of CF cannot be completely ruled out on the basis of negative genetic tests because a mutation in any individual may be unique and not detectable by current assays. Furthermore, not all alterations in CFTR that can be detected with highly sensitive genetic assays are associated with disease. Therefore, genetic testing must be used with caution to avoid inappropriate inclusion or exclusion of CF as a clinical diagnosis.

POPULATION CARRIER SCREENING AND NEWBORN SCREENING

The last decade has seen a significant change in the recommendations regarding population screening. The change has been spurred in large part by the results of studies from populations that were early adopters of newborn screening for CF. The Wisconsin Cystic Fibrosis Neonatal Screening Project was a randomized, controlled trial that demonstrated that early identification of CF by newborn screening resulted in long-term improvements in nutritional parameters, although no measurable changes in lung function.[105] The data have been confirmed in other studies from the United Kingdom[106] and Australia.[107]

Based on the results of the Wisconsin study and others, a growing number of states have added neonatal CF testing to newborn screening panels. After a thorough review of the evidence, the CDC concluded in 2004 that "the magnitude of health benefits from screening for CF is sufficient that states should consider including routine newborn screening for CF."[108] Screening paradigms vary, but generally involve an initial evaluation for elevated levels of immunoreactive trypsinogen (IRT) in blood spots obtained during routine newborn screening. Newborns with elevated IRT levels are then referred to a secondary screen which involves either repeat testing of IRT from a second sample or a genetic screen for a panel of CF mutations on the original blood spot. Current screening methodologies report sensitivities of 94% to 99% but have false-positive to true-positive ratios of 9.5 to 25.[108] This is, however, in the acceptable range of tests for other diseases tested by newborn screening.

In addition to newborn screening, the American College of Obstetricians and Gynecologists and the American College of Medical Genetics issued a joint recommendation in 2001 that all women considering pregnancy be offered prenatal screening for cystic fibrosis using a genetic panel of 25 most common CFTR mutations,[109] and the genetic panel was updated in 2005.[110] If the pregnant woman is identified as a CF carrier, then the father is offered genetic testing and, if indicated, prenatal genetic testing can be performed on the fetus via amniocentesis or chorionic villus sampling.

Disease Mechanisms

CFTR has been detected in many organs including the lung, pancreas, sweat glands, liver, and colon.[5] Therefore, it is not surprising that cystic fibrosis is a multiorgan disease, with manifestations in several organ systems. It is becoming clear that much of the pathophysiology observed in CF can be linked to inadequate hydration of epithelial fluids caused by a lack of CFTR.

RESPIRATORY

Progressive obstructive airway disease leading to bronchiectasis and respiratory failure accounts for the majority of severe morbidity and mortality from CF.[111] Lung disease is known to develop after birth because the airways of infants who die with CF in the first days of life appear normal with no evidence of infection, inflammation, or significant mucus plugging.[112] Over time, the typical features of CF lung disease develop including mucus plugging of the airways, hypertrophy and hyperplasia of the secretory elements, and chronic infection, primarily with *Pseudomonas aeruginosa* and *Staphylococcus aureus*. These features generally begin in the small bronchioles and progress to the larger airways.[113] Basic pathophysiologic mechanisms that contribute to these outcomes occur at multiple levels including the airway epithelia, submucosal glands, and the response to infection and inflammation.

AIRWAY EPITHELIA

Although early studies localized CFTR predominantly to the submucosal gland,[114] more recent experiments with sensitive antibodies have clearly demonstrated that CFTR is found on the apical membrane throughout the ciliated airway epithelium, although not in alveolar cells.[115] There are also scattered cells in the airway epithelium that exhibit very high levels of CFTR, although the function of these cells is not yet understood. The role of the apically localized CFTR has been delineated by several studies on well-differentiated cultures of respiratory epithelia.[116-118] Lack of CFTR leads to a depletion of the airway surface liquid, a thin layer of fluid that lines the apical membrane of the airway epithelia.[119] The airway surface liquid is divided into two phases: an overlying mucus gel phase that sits on top of a periciliary liquid (PCL) phase that surrounds the cilia. The respiratory cilia require a sufficient depth of PCL (~7 μm) for proper function, and studies of well differentiated respiratory epithelial cultures demonstrate that healthy cells regulate apical fluid flow to maintain sufficient PCL (Fig. 61-5A). In contrast, CF respiratory epithelial cultures fail to maintain sufficient PCL, resulting in compression of cilia and a severe reduction in mucociliary transport (see Fig. 61-5B).[116]

To understand how lack of CFTR leads to depletion of the PCL, it is necessary to explore the physiologic pathways that control fluid balance in airway epithelia. The healthy airway epithelial cell generates electrochemical gradients via the sodium/potassium pump, potassium channels, and $Na^+/K^+/Cl^-$ cotransporters located on the basolateral surface of the cell (Fig. 61-6).[119] On the apical membrane, these gradients tend to favor net influx of sodium ions into the cell through the ENaC sodium channel and efflux of chloride ions out of the cell primarily through CFTR and, to a lesser extent, via calcium-activated chloride channels (CaCC). Ions can also travel through paracellular pathways to maintain electrical neutrality. Because osmotic forces favor flow of water through cellular and paracellular pathways, net influx of sodium ions leads to fluid absorption, whereas net efflux of chloride ions leads to fluid secretion. Ion transport is tightly regulated in healthy airway epithelia, balancing absorption and secretion to maintain the appropriate level of PCL. In vivo, the airway

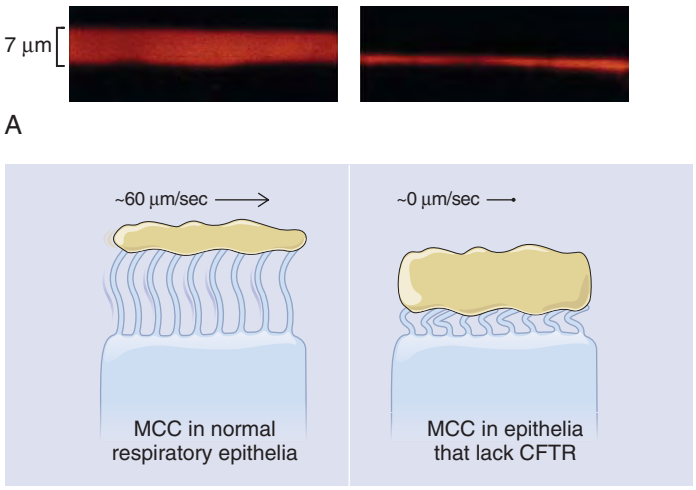

Figure 61-5 Defective airway surface liquid and mucociliary clearance in CF. A, Confocal image respiratory epithelia that express normal (*left*) or mutant (*right*) CFTR. The ASL is stained with fluorescent dye for visualization, and is notably decreased in the epithelia expressing mutant CFTR. **B,** Schematic of ciliated airway epithelial cells expressing normal (*left*) and mutant (*right*) CFTR. The normal cell has fully extended cilia and an overlying mucus layer showing typical mucociliary clearance rate of 60 μm per second (*left*). The epithelial cell with mutant CFTR has compressed cilia with increased mucus and essentially no mucociliary clearance. (**A,** courtesy of Brian Button, Ph.D., University of North Carolina at Chapel Hill.)

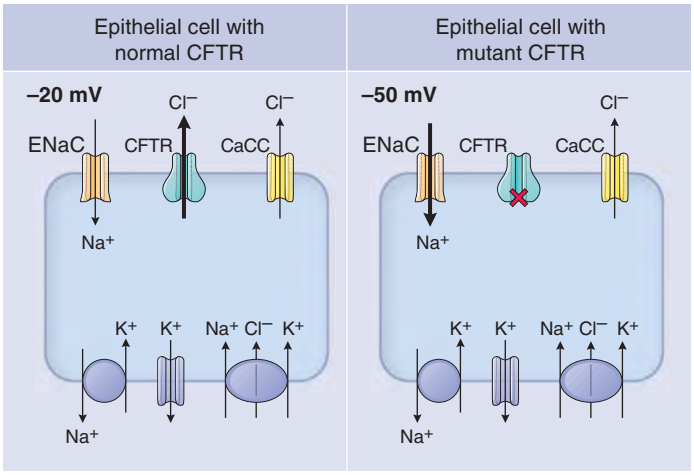

Figure 61-6 Electrochemical gradients in epithelia. Schematic of the channels and transporters responsible for regulation of ion transport in epithelial cells expressing either normal (*left*) or mutant (*right*) CFTR. In normal cells, electrochemical gradients favoring influx of sodium and efflux of chloride are generated by the actions of the basolateral sodium/potassium pump, potassium channels, and $Na^+/K^+/Cl^+$ contransporters. Chloride secretion is mediated by CFTR and, to a lesser extent, CaCC. Sodium absorption occurs through ENaC and is moderated by CFTR, and total potential difference at the apical membrane is –20 mV. Paracellular pathways for sodium and chloride (*not shown*) allow ionic balance. Cells with mutant CFTR have reduced chloride secretion and greater activity of EnaC, which increases sodium absorption. This leads to a lower potential difference of –50 mV at the apical membrane. CFTR, cystic fibrosis transmembrane conductance regulator.

epithelia is primarily absorptive, reflecting the need to absorb the bulk flow of fluid from the large surface area of the most distal airways.[120,121]

Airway epithelia that lack CFTR therefore lack the main chloride efflux pathway that leads to fluid secretion. Perhaps more significant, these cells also have upregulation of the sodium channel and therefore increased fluid absorption.[4,31] The net result is depletion of the apical fluid and hence the PCL. Depletion of the PCL results in compressed cilia and near complete loss of ciliary transport. A dehydrated mucus builds up in the airway and adheres to the epithelial surface because the normal lubricating function of the PCL is absent.[122]

The alternate chloride secretion pathway through CaCC is intact in CFTR-deficient cells, and chloride secretion through CaCC can compensate for lack of CFTR-mediated chloride secretion to some extent. These channels can be activated by the purinergic signaling pathway which involves activation of purinergic receptors by extracellular compounds such as ATP.[123] Recent evidence suggests that CaCC-mediated chloride secretion stimulated by purinergic receptors may be more active in vivo than previously believed and could account for the observation that young children with CF preserve a greater degree of mucociliary clearance than would be predicted from cell culture studies.[117] This observation is supported by promising early results from a clinical trial of an inhaled purinergic agonist.[124] However, the role of the purinergic pathway and chloride secretion through CaCC in both the pathophysiology of CF and as a treatment modality awaits confirmation from further studies.

SUBMUCOSAL GLANDS AND GOBLET CELLS

Increased mucus production is common in the CF patient, and this mucus is derived from both goblet cells and submucosal glands. Goblet cells are mucus-secreting cells that line the respiratory epithelium and typically account for ~15% of the cells. In CF, goblet cells undergo both hyperplasia (increase in cell number) and metaplasia (extension of goblet cells into the bronchioles where they do not usually occur). Similarly, submucosal glands also hypertrophy in CF. Early studies on CF focused on the abnormally thick and viscous sputum produced by patients. Although it is now understood that dehydration of extracellular fluid layers better describes the pathophysiology of CF, there are differences in mucus that may contribute to the disease phenotype. Mucus from CF patients has altered glycosylation patterns and increased sulfation.[125,126] However, these changes may reflect the presence of chronic inflammation and infection and correlate with disease severity.[127] Evaluation of mucus from cultured CF cells (presumably free from inflammation) has provided conflicting results, with increased sulfation noted in some studies but no changes in others.[128]

One of the earliest detectable abnormalities is dilation of the submucosal gland ducts in the absence of inflammation,[112] suggesting that alterations in gland secretions occur before infection and inflammation. Presumably, this dilation results from either increased gland secretion or "plugging" of the gland duct by viscous mucus secretions. Immunocytochemical studies have identified that the highest levels of CFTR expression in the lung are in the serous acini of the submucosal glands of the proximal airways (Fig. 61-7).[114]

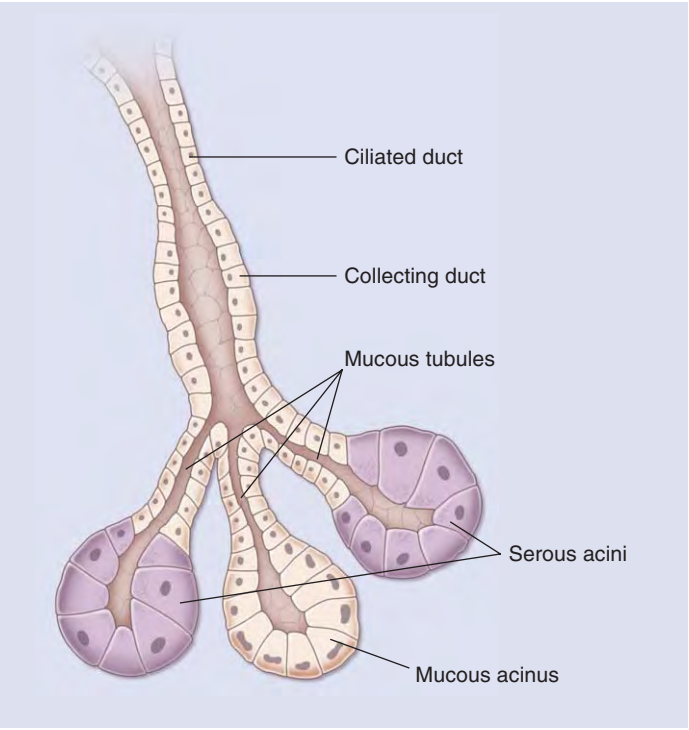

Figure 61-7 Schematic of the submucosal gland. CFTR is highly expressed in the serous acini of the gland, which aids secretion of fluid that helps flush mucus from the tubules into the collecting duct and ciliated duct. CFTR, cystic fibrosis transmembrane conductance regulator.

The serous cell secretes salt and water, and because it is located in the pole of the gland, the secreted liquid flushes mucins secreted in the mucous tubules to the gland orifice and hence to the airway surface. The electrochemical gradients that drive secretion fluid are similar to those of the airway epithelium. However, chloride secretion is mediated entirely through CFTR and is highly dependent on alteration of intracellular membrane potential by activation of basolateral membrane potassium channels. These basolateral membrane potassium channels are activated by regulatory agents such as acetylcholine that are involved in stimulation of gland secretion.[129]

Studies of gland secretions have been made possible by evolution of microanalytic techniques that permit evaluation of the secretions from a single submucosal gland. These studies demonstrate that CF gland secretions are of lower volume and higher viscosity than normal gland secretions.[130] It is currently unclear whether this represents alterations in flow from the serous cell, changes in the mucus secreted from gland goblet cells, or absorption of fluid by the glandular collecting duct or surrounding airway epithelia. Furthermore, the proximal duct of the gland contains ciliated epithelia and may experience the defects in mucociliary transport from decreases in PCL that are seen in airway epithelia. It is likely that a combination of these mechanisms accounts for the altered gland secretions seen in CF.

AIRWAY INFECTION AND INFLAMMATION

Chronic respiratory infection and elevated levels of inflammation are hallmarks of CF lung disease. The deficient secretion in airway epithelia and submucosal glands undoubtedly contributes to the infection by preventing effective clearance of bacteria out of the respiratory tract. Some studies have suggested that the salt content of the airway surface liquid is elevated in CF, which could inactivate innate defenses to bacterial infection.[131,132] However, altered ASL salt concentrations have not been demonstrated in CF patients[133] or animal models of CF.[134] There are several other factors that have been identified in CFTR-deficient respiratory epithelia that may contribute to the chronic infection and inflammation.

Patients with CF almost invariably have elevated levels of inflammatory markers such as interleukin-8,[135,136] interleukin-6, tumor necrosis factor-alpha,[137] and leukotrienes[138] in the airway. Although this is explained, in part, by the presence of chronic bacterial infection, the inflammatory response in CF is exaggerated with higher levels of proinflammatory cytokines than in non-CF patients with similar burdens of pathogens.[136] Indeed, CF epithelial cell lines produce greater amounts of IL-8 when exposed to the pathogen *Pseudomonas* than non-CF epithelia.[139] The mechanisms that underlie this greater inflammatory response are unknown. Interestingly, a transgenic mouse model that overexpresses ENaC also exhibits an increased inflammatory response,[140] suggesting that defects in ion transport may play a role in this phenomenon.

Several studies have demonstrated interactions between CF epithelia and *P. aeruginosa*, which may favor the chronic infection with this organism that occurs in most CF patients. CF epithelial cells exhibit a greater adherence to certain strains of *Pseudomonas*, which can be reduced by expression of normal CFTR.[141] CFTR may also serve as a receptor for *Pseudomonas*, permitting effective internalization and killing of this bacteria by normal, but not CF, epithelia.[142] A similar role for CFTR in the internalization of *Salmonella typhi* in intestinal epithelia has been demonstrated[143]; this may explain the high frequency of CF mutations in certain populations because internalization of *S. typhi* leads to infection and would be reduced in CFTR mutation gene carriers.[64]

Gastrointestinal

Gastrointestinal (GI) manifestations are common in CF, and pancreatic insufficiency is a nearly universal feature of the most severely affected patients.[80] In general, the pathophysiology in the GI tract is similar to that of the airway: dehydration of secretions due to lack of chloride secretion leading to build-up of thick, inspissated secretions.

PANCREAS

CFTR can be readily detected in the pancreas and has been localized to the apical membrane of the intralobular pancreatic duct.[144] The pancreas is one of the few organs in CF that is often affected at birth, with obstruction of the pancreatic duct and ductules with inspissated secretions. In fact, the eventual development of cystic changes and fibrosis in the pancreas are actually responsible for the name of the disease, which is more fully rendered as cystic fibrosis of the pancreas.[113] In addition to the blocked pancreatic ducts, the fluid secreted from the CF pancreas is not as alkaline as in healthy individuals.

The pathophysiology of pancreatic dysfunction in CF is in many ways similar to that of airway epithelia. As in the

airway, normal CFTR permits net secretion of fluid into the extracellular space based on gradients established by the sodium/potassium pump, $Na^+/K^+/Cl^-$ transporter, and potassium channels. However, a major difference between the pancreas and airway epithelia is that the predominant secreted anion is bicarbonate rather than chloride. CFTR is involved in bicarbonate secretion via two mechanisms. First, the apical surface of the pancreatic duct contains a chloride/bicarbonate anion exchanger that transports chloride secreted by CFTR into the cell in exchange for bicarbonate, leading to a net transport of bicarbonate.[38] More recent evidence suggests that CFTR itself transports significant quantities of bicarbonate under certain circumstances.[145]

Lack of CFTR leads to decreased secretion of an inadequately alkalinized fluid, dehydration of secretions, and eventual blockage of the pancreatic ducts in most patients.[80] Digestive enzymes released by the pancreas remain in the ducts, leading to inadequate digestion of intestinal nutrients and eventual destruction of the pancreatic structures causing the pathognomonic cystic and fibrotic changes. Over time, the destructive influence of the pancreatic enzymes can affect the pancreatic islet cells, leading to reduced ability to secrete insulin and CF-related diabetes,[146] which is associated with more severe pulmonary disease.[147]

INTESTINES

CFTR is found in the apical membrane throughout the small and large intestines, and is localized predominantly to the crypt cells. As with other epithelia, the fundamental defect in the CF intestine is the inability to secrete chloride ions via a cAMP-regulated mechanism. The electrochemical gradients that drive chloride secretion are similar to those in airway epithelia, but like the submucosal gland, the intestine lacks the alternative chloride efflux pathway through CaCC. In another similarity to respiratory epithelia, CFTR in the intestine appears to downregulate the activity of the sodium channel ENaC.[148] The biophysical defect of altered chloride secretion is present in colonic epithelia and can be measured in rectal biopsies using specialized equipment. Such measurements can be used to establish a diagnosis of CF, and measures of residual chloride current correlate well with phenotypic manifestations of disease.[149]

Lack of CFTR in the intestine leads to dehydration of fecal contents and intestinal obstruction. Intestinal mucus secretion is also enhanced in CF, although the mechanism is not clear. In the newborn, the thick fecal contents can block the terminal small bowel, leading to meconium ileus, a pathology that is found almost exclusively in CF. Similar pathophysiology is thought to contribute to the distal intestinal obstructive syndrome (DIOS) seen frequently in older individuals—once called "meconium ileus equivalent."

Recent evidence suggests that the CF intestine may experience enhanced inflammation and bacterial overgrowth similar to that of the airway. Increased inflammatory markers have been detected in the intestines of both CFTR-deficient mice[150] and humans.[151-153] Furthermore, evaluation of CFTR-deficient mice detected a 40-fold overgrowth of intestinal bacteria relative to controls.[154] The potential contribution of intestinal inflammation and infection to the malabsorption phenotype of CF is intriguing, but remains to be explored.

LIVER

CFTR can be detected in the biliary ducts and is thought to mediate chloride and fluid secretion. In many patients with CF, the biliary ducts are obstructed with thick secretions. As a consequence of this obstruction, a subset of CF patients develop hepatobiliary disease of varying severity ranging from asymptomatic elevation of liver enzymes to multilobular cirrhosis and portal hypertension. The factors that predispose certain patients to liver disease but leave others unaffected are currently unknown, but are under investigation.

Reproductive Tract

With few exceptions, CF males are sterile with obstructive azoospermia. The anatomic defect is absence, atrophy, or obstruction of the vas deferens as well as the tail and body of the epididymis and can be detected at birth in many infants.[155] The pathophysiologic basis for these changes is unclear. One proposed mechanism for atrophy of the vas deferens and epididymis is prenatal failure of the CF epididymis epithelium to secrete ions and water that dilate the lumens of these structures. However, a study of 12 to 18 week (gestational age) aborted CF fetuses found structurally normal vas deferens, although with some mucus accumulation in the lumen.[156] Alternatively, CFTR itself may be important for maturation of the epididymis.

Females also have decreased fertility. CFTR is expressed in the uterine epithelium, and expression in this region appears to be menstrual cycle dependent.[157] Cervical mucus in CF women is thickened. Typically, cervical submucosal glands and the endocervical canal are dilated and obstructed by mucus plugs. This viscous cervical mucus impedes sperm migration, leading to decreased fertility. Another potential mechanism is altered salt and water secretion by the oviduct epithelium. The resulting dehydration of oviduct fluid may impair migration of sperm and eggs through the oviduct.

Sweat Gland

The sweat gland is a complex structure with an acinar region that secretes an isotonic liquid and a ductal region that is functionally designed to absorb salt but not water.[158] The net effect is to deposit a dilute watery solution on the skin surface for evaporative water loss and cooling. The physiology of secretion from the acinar region is similar to that of other cells: electrochemical gradients favor secretion of chloride through the apical membrane; sodium and water follow. Both CaCC and CFTR chloride channels are present in the acinus, and these cells exhibit a secretory response to both acetylcholine (which stimulates increased intracellular calcium that activates CaCC) and, to a lesser extent, beta agonists (which stimulate increased intracellular cAMP that activates CFTR). As expected, the CFTR-mediated secretion is absent in patients with CF,[159] but total sweat volume is relatively well preserved owing to the remaining secretion through CaCC.

The sweat duct expresses significant quantities of CFTR, but differs from all previously discussed tissues of the respiratory and gastrointestinal tract in that it selectively absorbs salt but not water from the lumen (Fig. 61-8). This can be accomplished because the tight junctions of the sweat duct are not leaky as they are in other tissues, and they create a barrier to passage of ions or water through paracellular routes.

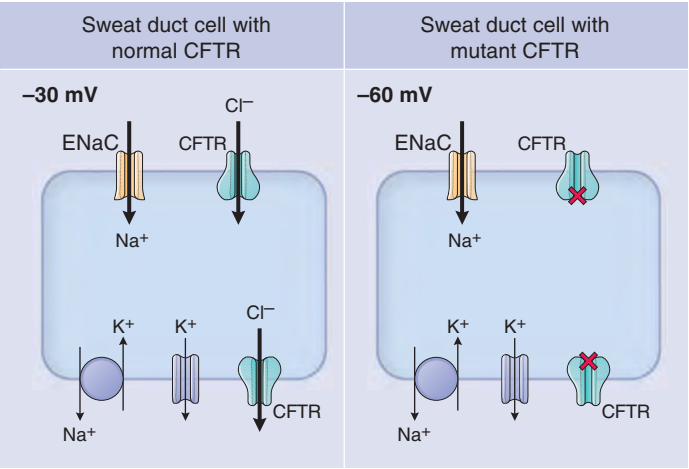

Figure 61-8 Electrochemical gradients in the sweat duct. Schematic of the sweat gland collecting duct expressing normal (*left*) or mutant (*right*) CFTR. In the normal sweat duct, the sodium/potassium pump and potassium channels generate an electrochemical gradient that favors absorption of sodium through ENaC. Chloride follows due to electrochemical forces. The lack of chloride transport in the sweat duct with mutant CFTR prevents absorption of both sodium and chloride and results in the abnormal elevations of salt in the sweat of patients with CF. CFTR, cystic fibrosis transmembrane conductance regulator.

Sodium is absorbed through ENaC in the apical membrane and is exported from the cell via a basolaterally located sodium/potassium pump. Because ductal cells lack the $Na^+/K^+/Cl^-$ cotransporters found in respiratory and gastrointestinal epithelia, there is no driving force for chloride secretion. Therefore, the active removal of sodium ions from the lumen and intracellular regions of the cell creates an electrochemical driving force for transcellular passage of chloride out of the lumen through both apical and basolateral CFTR channels. There may be an additional contribution from active absorption of chloride through the chloride/bicarbonate exchanger. In the absence of functional CFTR, chloride can no longer be absorbed from the sweat duct lumen. In addition, unlike other cell types, absence of functional CFTR leads to a *decrease* in ENaC activity, further reducing the absorption of salt from the lumen.[160] The result is a sweat content that is increased in sodium and chloride compared to that in healthy individuals.

Under usual circumstances, the increase in salt content of sweat has little physiologic consequence. However, under conditions of severe heat stress, individuals with CF are at risk for dehydration owing to excessive loss of salt and water in the sweat. Dehydration in CF infants was observed by Dr. Paul di Sant' Agnese during a heat wave in New York in the 1950s, and served as the initial recognition that sweat content may be abnormal in CF.[1] His astute observation eventually led to the development of the sweat chloride test, which continues to serve as the main diagnostic procedure for CF.

SUMMARY

Over the past half century, study of CF has elucidated significant insights into the basic physiology of epithelia and the pathophysiology of disease. More importantly, a better understanding of the genetics and disease mechanisms of CF has led to important clinical initiatives such as newborn screening programs and clinical trials of new therapeutic agents aimed at addressing basic cellular defects. Further study will no doubt elicit more scientific breakthroughs that can be translated into longer, higher quality lives for those who have CF.

PITFALLS AND CONTROVERSIES

CFTR is a member of the ABC family of membrane transporters, suggesting that it may have a transport function as well as acting as an ion channel. An ABC transporter uses energy from hydrolysis of ATP to pump a substance across the plasma membrane; in contrast, a channel serves as a pore through which substances pass due to their electrochemical gradients. Early studies suggested that CFTR may transport ATP across the plasma membrane, where it could act on purinergic receptors to regulate epithelial physiology.[48] Others have proposed that CFTR transports glutathione, which would suggest that the airways of patients with CF may have decreased tolerance to the oxidative damage normally mitigated by extracellular glutathione.[49] These findings remain controversial and not all laboratories demonstrate physiologically relevant transport activities with CFTR. Furthermore, the regulatory actions of CFTR make it difficult to distinguish a transport activity of CFTR from that of an interacting protein.

CHAPTER 62 Respiratory Manifestations

Harm A. W. M. Tiddens and Margaret Rosenfeld

TEACHING POINTS

- Structural lung damage is due primarily to a vicious cycle of bacterial infection and the host inflammatory response.
- Structural damage begins early in life, generally in the peripheral airways.
- Most structural lung damage is irreversible (what is lost is lost).
- Cystic fibrosis (CF) lung disease is the sum of the present and the past.
- Lung function measurements are relatively insensitive to structural abnormalities.
- CF care is center care.
- Cross infection of microorganisms between patients should be prevented.

Cystic fibrosis, affecting all races, is well known as the most common life-shortening inherited disease in whites. Although lung disease is still the cause of death in >80% of CF patients, survival has improved dramatically around the world over the past 3 decades: in the United States median survival increased from 14 years in 1969 to 36.8 years in 2005.

The marked improvement in CF quality of life and survival is due to improvements in nutritional management, the increasing provision of care through multidisciplinary specialized CF care centers, more aggressive use of antibiotics, and new therapeutics such as inhaled antibiotics and mucolytic agents. The adoption of newborn screening for CF by a growing number of regions is likely to add to this improving picture, as are collaborative quality improvement projects and the active investigation of many new drugs now in the CF "research pipeline."

PATHOPHYSIOLOGY OF CF LUNG DISEASE

Since the identification and cloning of the cystic fibrosis transmembrane conductance regulator (CFTR) gene in 1989,[1] great progress has been made in elucidating the pathophysiologic cascade responsible for CF lung disease. However, controversies and questions remain in our understanding of how defective or absent CFTR function promotes the chronic endobronchial infection and vigorous neutrophilic inflammation that cause the progressive structural airway damage of CF lung disease (Fig. 62-1).

The ciliated respiratory epithelium of the airways is lined with airway surface liquid (ASL), which consists of two layers, a periciliary liquid layer adjacent to the epithelial surface in which the cilia beat, and an overlying mucus layer that can be propelled by the cilia. In the normal lung, the periciliary liquid layer height and volume are tightly regulated to provide for optimal mucociliary clearance, a critical primary innate airway defense. Maintenance of an adequate periciliary liquid layer enables normal ciliary function and lubricates the high molecular weight mucins in the gel layer, whose properties are altered by water content, ion concentrations, and pH.

In the CF lung, the first step in the pathophysiologic cascade is abnormal regulation of periciliary liquid volume and possibly of ionic content caused by absent or defective CFTR function (Fig. 62-2).[2,3] Decreased periciliary liquid volume reduces mucociliary clearance by hindering ciliary beat and promoting interactions between gel layer mucins with cell-surface mucins that inhibit particle clearance.[4] Altered viscosity and regulation of submucosal gland secretion may further impair host defense. Reduced mucociliary clearance may overwhelm innate antimicrobial peptides and promote the initial endobronchial infection in CF as well as the chronic infection.

The link between the abnormal composition and mechanical properties of airway secretions in the CF lung and its propensity for chronic endobronchial bacterial infection is incompletely understood. CFTR has been proposed to be a receptor for *Pseudomonas aeruginosa* internalization.[5] Reduced *P. aeruginosa* binding to mutant CFTR could result in decreased ability of the CF lung to clear this organism, and allow for initiation of endobronchial infection. In addition, CF epithelial cells in vitro appear to have decreased sialylation of apical receptors, which may promote adherence of *P. aeruginosa* to the CF airway[6]; the in vivo relevance of this observation is unknown.

Because CFTR is expressed primarily in the airways, with particularly high expression in submucosal glands, CF lung disease is localized primarily to the airways and submucosal glands. The alveoli and interstitium are spared until the late stages of the disease. The lungs in CF patients appear histologically normal at birth.[7,8] However, endobronchial bacterial infection and the accompanying vigorous neutrophilic inflammatory response begin in infancy, often in the first several months of life.[9] Lower airway inflammation can be seen in bronchoalveolar lavage (BAL) fluid from which bacterial pathogens are simultaneously isolated or not.[10] Although inflammation in the apparent absence of infection may be due, at least in part, to regional heterogeneity of infection,

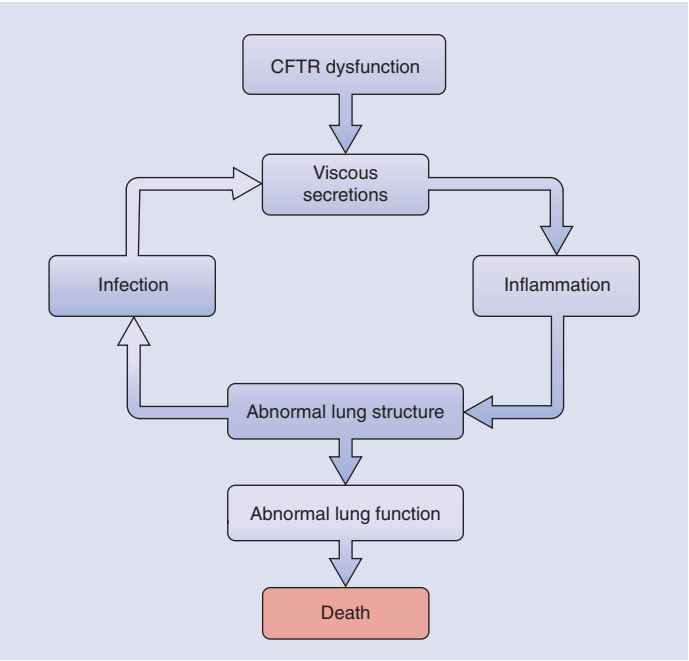

Figure 62-1 This general scheme shows the pathway from abnormalities in the CFTR protein to damage of lung tissue, which leads to impaired lung function and premature death in many patients. Note that abnormalities of lung structure are present before abnormalities in lung function are detected.

debate continues as to whether the CF respiratory epithelium may be intrinsically proinflammatory.[11] In addition, the role of viral infections in promoting airway inflammation is incompletely understood.

Neutrophils are the primary culprit in the pathogenesis of CF lung disease, releasing massive amounts of elastase and other proteases that overwhelm local host defenses including α_1-antitrypsin and secretory leukocyte protease inhibitor (SLPI) and inflicting structural airway damage.[12] This damage further impairs mucociliary transport and facilitates the attachment and growth of bacteria, particularly *Pseudomonas aeruginosa*, thus reinforcing the vicious cycle.[13-15] Dying neutrophils release large amounts of DNA that increase the viscosity of the endobronchial secretions, further reducing mucociliary clearance and promoting further bacterial infection. Interleukin-8 (IL-8), produced by epithelial cells, macrophages, and neutrophils, appears to be the critical neutrophil chemoattractant in the CF airway.[16] IL-1β, tumor necrosis factor-α, neutrophil elastase, and leukotriene B_4 also play important roles in heightening and maintaining neutrophil influx.

Chronic infection and inflammation result in airway wall thickening and plugging of bronchioles with purulent secretions, a process that appears to begin in the peripheral airways. As the disease progresses, airways become irreversibly dilated and bronchiectatic. Airway damage can display striking regional heterogeneity, with regions of advanced bronchiectasis adjacent to regions of relatively normal lung (Fig. 62-3). With advanced bronchiectasis, the lung parenchyma can become atelectatic or infected, impairing gas exchange. Chronic hypoxia may lead to pulmonary hypertension. Hypertrophy of the bronchial circulation may lead to recurrent hemoptysis.

CLINICAL PRESENTATION OF CF LUNG DISEASE

The clinical manifestations of CF lung disease are highly variable in onset, rate of progression, and severity. Within the first 6 months of life many infants develop cough, tachypnea or wheeze, often triggered or worsened by intercurrent viral respiratory infections.[17] Cough, while intermittent early in the course of the disease, eventually becomes a prominent, daily symptom, generally accompanied by expectoration of sputum beginning in early school age. CF lung disease is characterized by intermittent, recurrent episodes of increased cough and sputum production, often accompanied by a decline in pulmonary function and systemic symptoms such as anorexia and fatigue, termed a *pulmonary exacerbation.*[18] These episodes require more intensive antibiotic therapy, including intravenous therapy, if the response to oral or inhaled antibiotics is inadequate or the exacerbation is severe. Recurrent sinusitis is nearly universal and is a major source of symptoms in some patients; nasal polyposis is also a frequent finding. As disease severity progresses, patients develop progressive exercise intolerance and are at increased risk for sleep-disordered breathing. Recurrent hemoptysis may develop. As lung disease becomes severe, the burden of the daily medical regimen increases—as does the frequency of hospitalizations and intravenous antibiotics. Patients with advanced lung disease may require supplemental oxygen, particularly with sleep. Lung transplantation may be considered in patients with end-stage lung disease to potentially improve survival and quality of life. In the United States, there are about 150 lung transplantations and about 420 deaths in CF patients annually.[19]

CF RESPIRATORY MICROBIOLOGY

Early Pathogens

CF-related lung disease is characterized by a unique set of bacterial pathogens that are acquired in an age-dependent fashion (Fig. 62-4).[19] At a very early stage *Staphylococcus aureus* and *Haemophilus influenzae* are the most frequently isolated organisms. *P. aeruginosa*, the most significant pathogen in CF lung disease, is also frequently acquired in the first several years of life. In a prospective study of 40 infants from the time of diagnosis through 3 years, sequential specimens from oropharyngeal swabs and BAL fluid yielded cultures positive for *P. aeruginosa* in one third of patients by two years, and combined microbiological and serologic evidence of exposure was seen in 97.5% of patients by 3 years.[20]

The ascertainment of initial *P. aeruginosa* respiratory tract infection in CF is difficult because of the limitations of current techniques. Children younger than about 6 years of age can rarely expectorate sputum for culture. Oropharyngeal cultures are widely used as a surrogate for lower airway cultures in these patients, but have poor sensitivity and positive predictive value for lower airway *P. aeruginosa* infection.[9,21] BAL, while sampling the lower respiratory tract, is invasive and may produce false-negative results owing to regional heterogeneity of infection[22] and dilution. Measurement of serum antibodies against *P. aeruginosa* may be used to identify *P. aeruginosa* infection at an early stage.[17,23] Initially

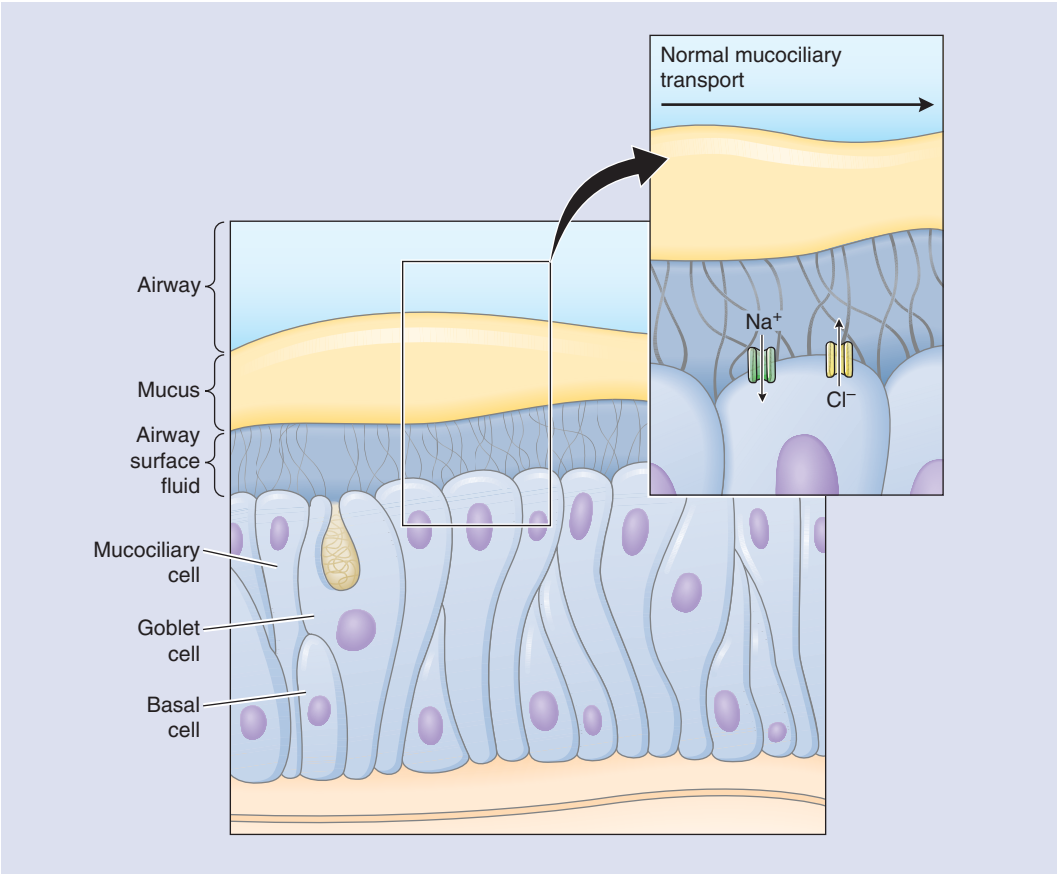

Figure 62-2 Mucociliary transport in the healthy lung: A fluid layer is maintained through a balance of chloride secretion through the CFTR channel and sodium absorption. This fluid layer covers the surface of airway epithelial cells and supports a thin mucus layer produced by mucosal secretory glands. The mucus layer is transported by respiratory cilia from the lower airways to the central airways. A defective chloride channel leads to depletion of the fluid layer and an impaired mucociliary transport. (With permission from Ratjen F: N Engl J Med 354:291-293, 2006.)

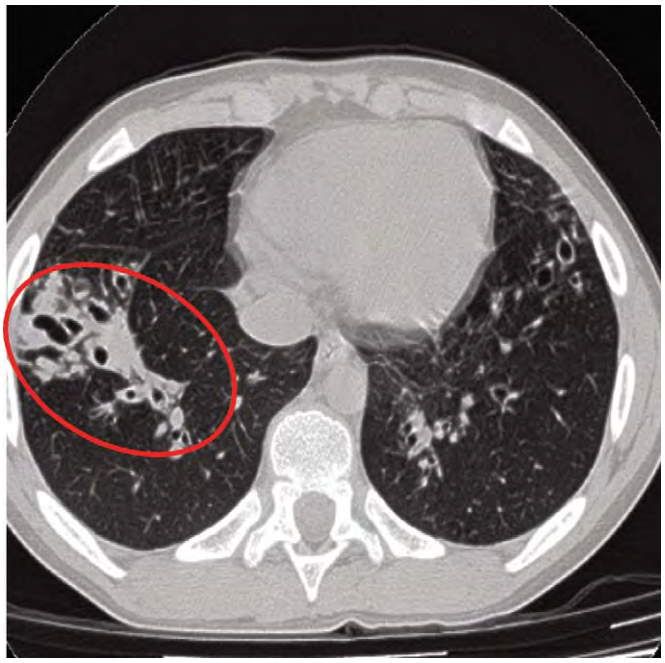

Figure 62-3 This high resolution CT image clearly shows the heterogeneity of cystic fibrosis lung disease. An area of localized end-stage lung disease (*red ellipse*) can be seen next to areas that are apparently normal.

P. aeruginosa is nonmucoid and highly antibiotic sensitive in most patients.[20] There is a window of opportunity for suppression and possible eradication of initial nonmucoid *P. aeruginosa*.[24,25] Because chronic *P. aeruginosa* infection is associated with more morbidity and a worse prognosis,[17,26-28] aggressive early *P. aeruginosa* eradication regimens have been adopted at most CF care centers. When infection persists, *P. aeruginosa* changes to a mucoid phenotype that cannot be eradicated with current treatment options.

Late Pathogens

With progression of the lung disease, antibiotic treatment in general becomes more intensive. As a result, resistant pathogens such as *Burkholderia cepacia* complex, *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, methicillin-resistant *S. aureus*, *Aspergillus fumigatus*, and nontuberculous mycobacteria are progressively selected.[4] The prevalence of *B. cepacia* complex varies considerably between centers.[23] Epidemic strains have been described. Some genomic species of *B. cepacia* complex are associated with the *B. cepacia* syndrome, characterized by high fever, bacteremia, and rapid progression to severe necrotizing pneumonia and high risk of death.[29] Cohort studies have not demonstrated an association between isolation of *S. maltophilia* or *A. xylosoxidans*

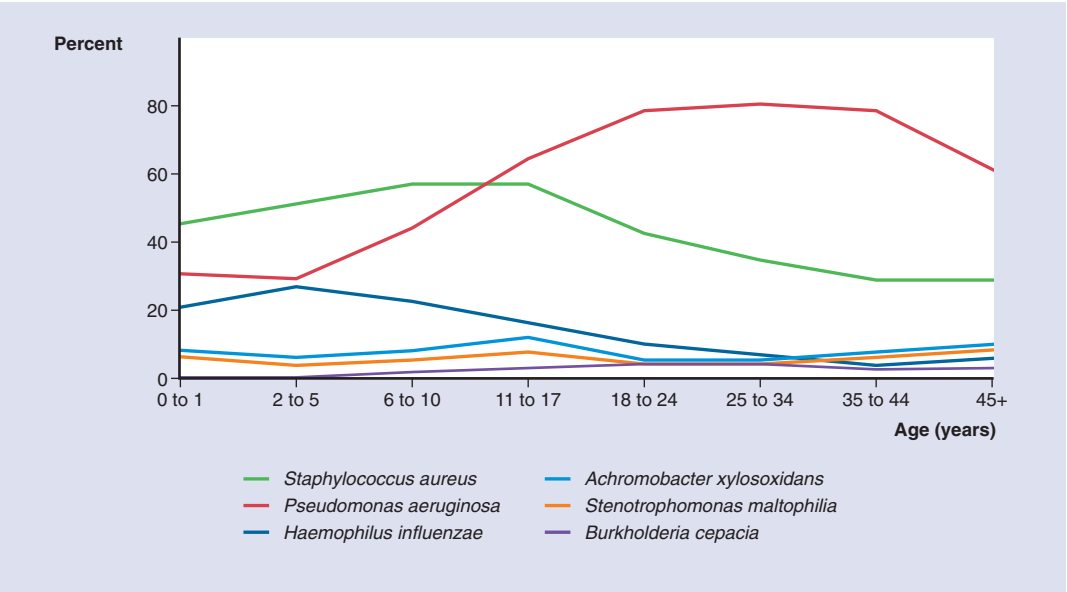

Figure 62-4 Age-specific prevalence of airway infections in patients with cystic fibrosis. Organisms reported to the U.S. Cystic Fibrosis Patient Registry, 2001. Overall percentage of patients (all ages) who had at least one respiratory tract culture (sputum, bronchoscopy, oropharyngeal, or nasal) performed in 2001 that was positive for the following organisms: *Pseudomonas aeruginosa* (*red line*), 58.7%; *Staphylococcus aureus* (*green line*), 48.0%; *Haemophilus influenzae* (*dark blue line*), 15.9%; *Stenotrophomonas maltophilia* (*orange line*), 8.4%; *Achromobacter xylosoxidans* (*light blue line*), 4.4%; *Burkholderia cepacia* (*purple line*), 3.1%. (From the Cystic Fibrosis Foundation.)

from respiratory cultures and decline in lung function.[30,31] However, in individual patients these microorganisms may contribute to the progression of lung disease.

The prevalence of *A. fumigatus* in respiratory cultures varies from 2% to 57%.[32-35] There is emerging evidence that *A. fumigatus* contributes to structural lung damage,[36] although no consensus exists to routinely treat this organism.

Some CF patients develop a specific allergic immunologic response to *A. fumigatus*, termed allergic bronchopulmonary aspergillosis (ABPA).[32,34,35] The diagnosis of ABPA is difficult in CF because many of the diagnostic criteria overlap with common manifestations of CF. The U.S. CF Foundation recently adopted a standard set of diagnostic criteria for ABPA (Box 62-1),[37] and recommended routine annual screening for ABPA through assessment of serum IgE. ABPA should be considered in the setting of an acute or subacute clinical deterioration not responsive to appropriate antibiotic therapy.

Nontuberculous mycobacteria (NTM) are environmental organisms found in soil and dust, and can be isolated from the sputum of CF patients utilizing culture techniques that inhibit overgrowth by *P. aeruginosa*. In a large, multicenter study, the overall prevalence of NTM in a pediatric and adult CF population was estimated to be 13%.[38,39] Risk factors for NTM colonization included older age and better-preserved lung function.[38,39] Allergic bronchopulmonary aspergillosis and systemic steroids also appear to be risk factors.[40] Approximately 20% of CF patients from whom NTM is cultured meet ATS microbiological criteria for NTM infection as opposed to colonization. Diagnostic criteria for NTM infection in CF include: multiple positive respiratory cultures for NTM; clinical or lung function deterioration not responsive to conventional antibiotic therapy; and CT findings of peripheral nodules of "tree in bud" appearance and/or cavitating disease.[41] Individuals with NTM infection require aggressive antimycobacterial therapy, typically with three antibiotics and often for prolonged periods. Relapse is common.

BOX 62-1 Criteria for the Diagnosis of Allergic Bronchopulmonary Aspergillosis (ABPA)

Classic criteria
- Clinical deterioration
- Immediate positive skin test or positive RAST
- IgE > 1000 kU/L
- *Aspergillus fumigatus*–positive precipitins or presence of anti–*A. fumigatus* IgG
- Altered chest radiograph

Consensus of the Cystic Fibrosis Foundation for the diagnosis of ABPA. (From Stevens DA, Moss RB, Kurup VP, et al: Allergic bronchopulmonary aspergillosis in cystic fibrosis—state of the art: Cystic Fibrosis Foundation Consensus Conference. Clin Infect Dis 37 Suppl 3:S225-S264, 2003.)

ORGANIZATION OF CF CARE

One of the major advances in CF care over the past several decades has been the development of specialized CF care centers throughout Europe, Australia, the United States, Canada, and parts of South America. The regular monitoring

and aggressive treatment that can be provided by these centers has been associated with improved outcomes.[42,43] At these centers, CF care is provided by an experienced multidisciplinary team that includes pulmonologists, nurses, social workers, nutritionists, and respiratory therapists. Other providers involved in CF center care may include a gastroenterologist, endocrinologist, otorhinolaryngologist, microbiologist, pharmacist, radiologist, and psychologist. The microbiology laboratory affiliated with each CF center is specialized in the analysis of CF respiratory specimens. Centers generally maintain a patient database for clinical care, quality improvement projects, and to identify potentially eligible research subjects for clinical trials. With the increasing life span of CF patients, separate adult care centers have now been established, to which patients transition generally between 16 and 21 years of age.

Although most *Pseudomonas aeruginosa* isolates are environmentally acquired, cross infection in the hospital is a serious risk. Outbreaks of epidemic strains of highly virulent, multidrug-resistant *P. aeruginosa* and several *Burkholderia* species have caused fatalities and rapid decline in lung function at a number of CF centers around the world.[44,45] Thus, strict infection-control policies must be maintained at centers caring for CF patients.[46,47] Infection-control policies and cohort segregation seem to be effective to reduce the spread of epidemic strains.[45] One of the most important issues is implementation of proper hand cleaning procedures and cough hygiene for all members of the CF team and for the patients.

Some clinics segregate cohorts of patients by bacterial strain. This makes the organization of the clinic complex and it does not exclude cross infection of newly acquired but undetected strains or viruses within a cohort. Other clinics have the policy of minimizing or preventing contact between patients. Clearly, these infection control policies have an important emotional impact on the lives of CF patients. Despite these negative effects, the majority of patients are in favor of infection control measures to reduce the risks of cross infection.[45]

MONITORING OF LUNG DISEASE

A standardized approach to the monitoring of CF lung disease is critical to effective treatment. Through serial respiratory cultures, lung function tests, and imaging studies, disease progression is assessed at multiple levels of the pathophysiologic cascade (Fig. 62-5). This monitoring process should ideally start at diagnosis, so that abnormalities can be detected and treated early, potentially before they become irreversible. However, monitoring is particularly challenging in infants and young children. Symptoms lag behind structural damage. Children younger than about 6 years of age generally cannot expectorate sputum for culture. Lung function tests are difficult to perform in the youngest children and are insensitive to localized or early damage.[56,57] However, infant lung function tests have shown that airway function is diminished soon after diagnosis and does not catch up during infancy and early childhood.[61,62] Imaging techniques such as CT scans are currently the most sensitive method with which to detect early structural changes, but they also carry inherent risks.

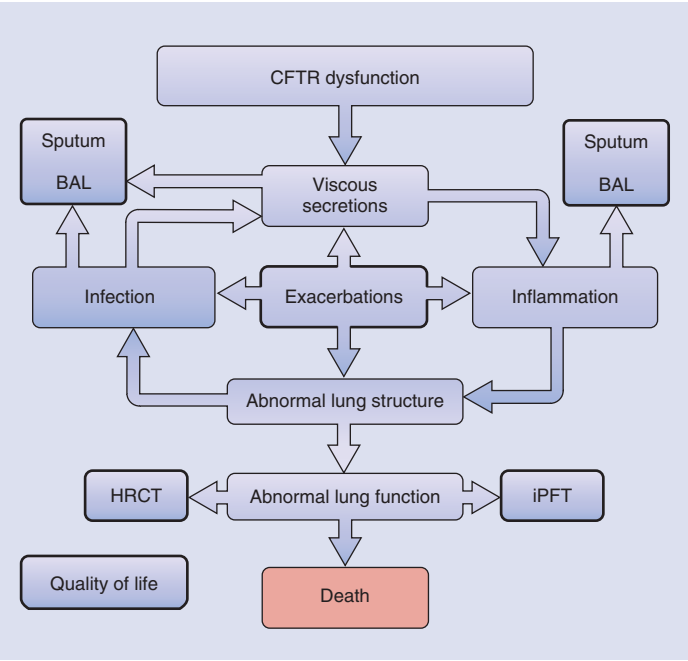

Figure 62-5 Methods to monitor cystic-fibrosis-related lung disease for clinical management. BAL, bronchoalveolar lavage; CFTR, cystic fibrosis transmembrane conductance regulator; HRCT, high-resolution computed tomography; iPFT, infant pulmonary function tests.

LUNG MICROBIOLOGY

Regular monitoring of respiratory tract cultures is needed to guide antibiotic treatment. In patients able to spontaneously expectorate, sputum serves as an adequate proxy for lower airway secretions. In pre-expectorating children, oropharyngeal cultures are often used to screen for the presence of *P. aeruginosa* and other pathogens. These cultures have good specificity but low sensitivity for lower airway *P. aeruginosa*.[48] Hence, a negative oropharyngeal culture makes lower airway infection with *P. aeruginosa* less likely, but a positive culture is not sufficient to establish the diagnosis of lower airway *P. aeruginosa* infection. Endolaryngeal suction and cough plates[49] are alternative methods for obtaining upper respiratory tract cultures but their diagnostic accuracy for lower airway organisms is unknown. Sputum induction with 6% to 7% hypertonic saline has been safely used in adults and older children with CF, but is generally not successful in children younger than 8 years of age.[50] BAL, while allowing direct sampling of lower airway secretions, is an invasive procedure that cannot be repeated frequently. Hence, as a method to detect early *P. aeruginosa* infection, it is of limited use. A diagnostic bronchoscopy should be considered in non-expectorating patients with newly acquired auscultatory findings and/or symptoms that persist despite antibiotic treatment.

LUNG FUNCTION

Lung function has been considered the standard for monitoring the pulmonary condition of CF patients for decades. Spirometry repeated at each outpatient visit is valuable to identify trends, detect acute changes in lung function, and monitor response to therapy (Fig. 62-6). From 6 years of age, most children are able to perform a flow-volume maneuver

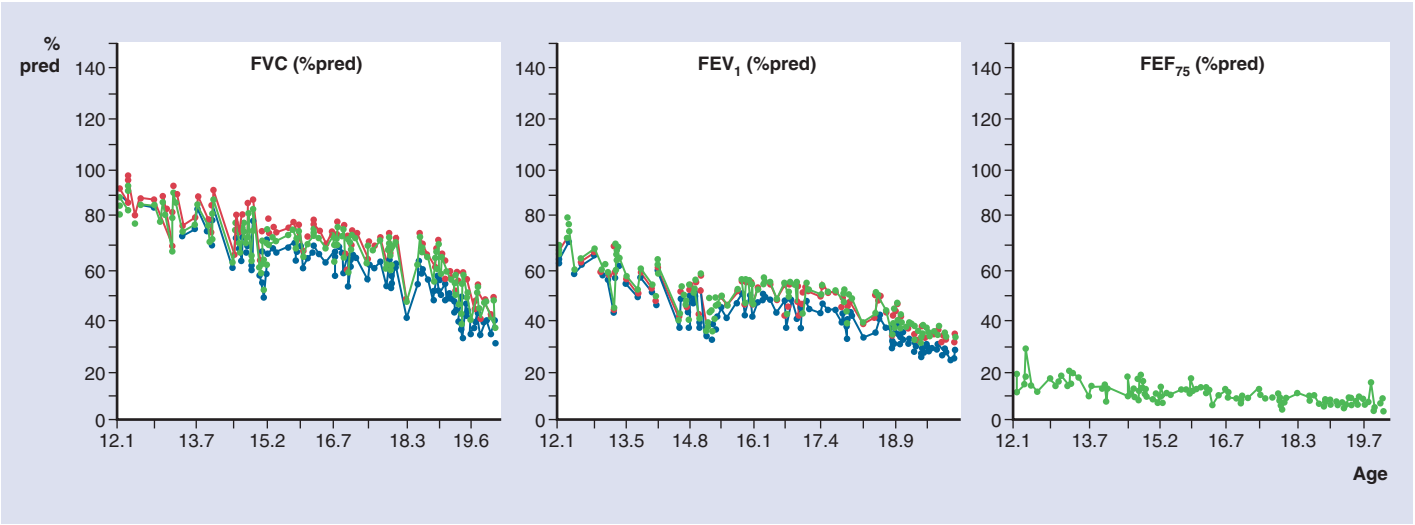

Figure 62-6 Longitudinal plot of FVC, FEV_1 and FEF_{75}% predicted versus age of a cystic fibrosis patient who progressed to end stage lung disease for three commonly used sets of reference equations.[182-184] At the age of 12 years the FEF_{75}% predicted is substantially and consistently reduced, whereas FVC is still in the lower normal range and FEV_1 is in the intermediate range. These curves are indicative of early and irreversible abnormalities in the peripheral airways that precede more central airway changes. In addition, note the negative trend of the FVC, FEV_1 curves that reflect progressive deterioration of the lungs. Also note the more frequent data points (clinic visits) and dips in the curves related to pulmonary exacerbations that required extra antibiotic treatment. FEF, forced expiratory flow; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

in a reproducible fashion. At that age, dynamic flow-volume parameters such as FVC and FEV_1 are mostly in the normal range. The first changes that can be observed in lung function are reduced peripheral flows such as the FEF_{25-75}, FEF_{50}, and FEF_{75} (Fig. 62-7).[51] These peripheral flows are more variable than FEV_1 and FVC because they are influenced by a large number of small airways.[52,53] The importance of peripheral airway involvement in CF was supported by cross-sectional data from the European Epidemiologic Registry of Cystic Fibrosis, which showed that the FEF_{25-75} is the first lung function parameter to decline with age and parallels the decline in FEV_1 and FVC in patients with or without a history of *P. aeruginosa* isolation.[51] Many CF patients show bronchodilator responsiveness of FEV_1 and the peripheral flows. This finding of airway hyperreactivity in a CF patient does not necessarily equal the diagnosis of asthma. Such improved flows can be explained by smooth muscle relaxation in combination with thickening of the airway walls.

Routine monitoring of lung function would ideally begin in infancy. Unfortunately, lung function measurements in children younger than 5 to 6 years of age remain problematic. In infants younger than 3 years of age, adult-type spirometry and lung volume measurements can now be obtained,[54,55] but they require sedation, expensive specialized equipment and training, and are time consuming.[56,57] In children 3 to 6 years of age, too old for sedated infant lung function testing yet too young to cooperate with spirometry, the best method for monitoring airway obstruction is not established. Specific airway resistance measured with a body plethysmograph may be most sensitive to early changes in CF but again requires specialized equipment and training.[58] Spirometry can be successfully performed by the majority of preschool children using modified acceptability criteria,[59,60] but the sensitivity of these measurements to early CF lung disease is not known. For these reasons, lung function measurements in young children are not done routinely in most CF centers.

Repeated lung function testing in young children with CF shows persistent decreased flows.[61,62] Hence, airway function is diminished soon after diagnosis in infants with CF and does not catch up during infancy and early childhood. More recently, gas washout techniques have been used in CF to determine the homogeneity of ventilation distribution. Substantial inhomogeneity was observed in the majority of young children with CF even in the presence of normal lung function as judged by spirometry.[63,64] Multiple-breath inert gas washout was considered of greater value than spirometry to detect early cystic fibrosis lung disease . Although gas washout techniques appear promising for the detection and monitoring of early CF lung disease, currently no standardized, com-

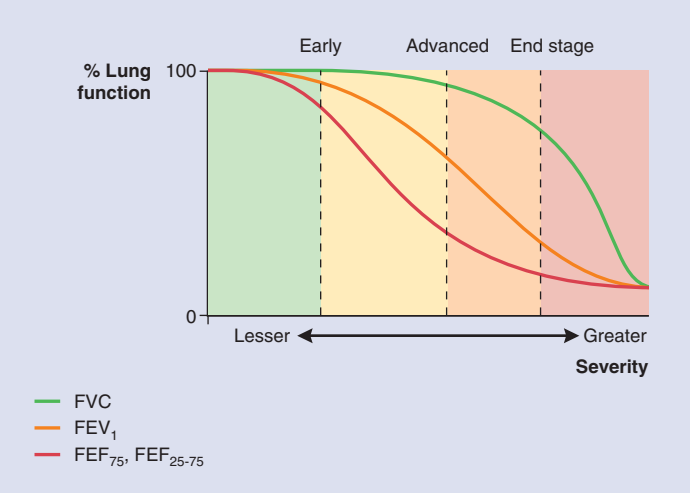

Figure 62-7 This theoretical plot shows the relation between various lung function parameters on the vertical axis and disease severity on the horizontal axis. (Based on Tiddens HAWM: Detecting early structural lung damage in cystic fibrosis. Pediatr Pulmonol Suppl 34:228-231, 2002.)

mercially available device exists with which to perform these measurements.

In the late 1980s, lung function parameters such as the FEV_1 and FVC were sensitive parameters to monitor CF-related lung disease because the annual loss in lung function was high.[65] With improved therapy, the rate of decline in lung function has steadily improved in many centers and now approaches 1% per year for FEV_1 in many cohorts.[36,66] This low annual rate of decline in lung function combined with the variability of flow volume parameters implies that lung function has become a relatively insensitive tool to monitor CF lung disease.

For clinical management it is important to realize that there can be a considerable discrepancy between lung function and structure (Fig. 62-8), the most striking being structural damage in lungs of patients with normal lung function. Such patients can have mild, moderate, and even severe structural lung disease. About one third of the patients with an FEV_1 above 85% in a Dutch cohort followed longitudinally showed substantial damage on the CT scan.[36] With disease progression, eventually structural lung changes will result in functional abnormalities.

Lung function testing has the major advantage that it is readily available, relatively inexpensive, and that it does not require radiation. It will remain an important tool as long as one realizes that it does not give the complete picture of lung abnormalities.

LUNG STRUCTURE

The result of the vicious circle of infection, inflammation, and viscous pulmonary secretions is structural lung damage. The most sensitive technique to monitor structural changes in CF is chest CT.[67] In patients 6 years and older it has been estimated that CT is about 10 times as sensitive as lung function parameters for detecting progression of CF lung disease.[68] On chest radiographs, it is often not possible to identify the nature of increased markings. Furthermore, chest radiographs are relatively insensitive for detecting important structural changes such as bronchiectasis. The identification of structural abnormalities on CT is, in general, straightforward and often the nature of the structural abnormality can be readily identified. The two CT techniques that can be used for the evaluation of CF lung disease are high-resolution CT (HRCT)

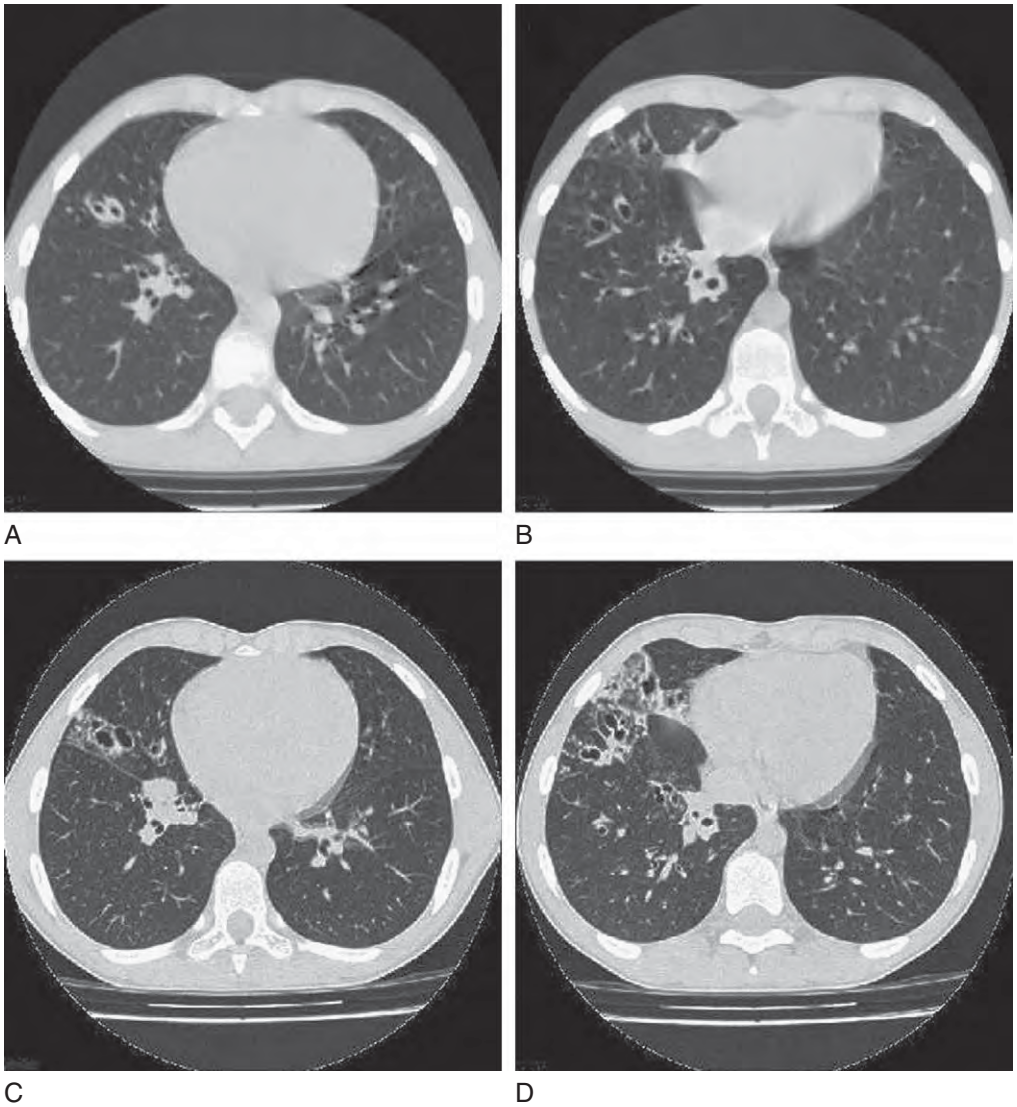

Figure 62-8 Patient with cystic fibrosis with improvement of lung function but deterioration of lung structure. The top panels (**A** and **B**) show high-resolution computed tomography (HRCT) scan in a patient of 10 years of age. Lung function (% predicted) is as follows: forced expiratory volume in 1 second (FEV_1) of 86, forced vital capacity (FVC) of 93, forced mid-expiratory flow (FEF_{25-75}) of 80, and FEV_1/FVC of 80. The lower panels (**C** and **D**) show HRCT images at 13 years of age. Lung function (% predicted) at time of CT was: FEV_1 96, FVC 91, FEF_{25-75} 105, and FEV_1/FVC 90. Note the inhomogeneity of the lung abnormalities. (Reprinted with permission from de Jong PA, Nakano Y, Lequin MH, et al: Progressive damage on high-resolution computed tomography despite stable lung function in CF. Eur Respir J 23:93-97, 2004.)

and volumetric, or spiral, CT. HRCT uses thin sections (<2 mm) obtained at intervals through the lungs, which limits the radiation exposure of the patient.[62] A volumetric CT images the whole lung and is considered the optimal technique for longitudinal evaluation and for quantitative analysis such as the airway wall thickness. Furthermore, a volumetric CT is faster than HRCT but it exposes the patient to more radiation. The most striking structural abnormality in the CF lung is bronchiectasis, which is an irreversible change that can be observed early in life (Fig. 62-9). In longitudinal studies that followed the pulmonary status of CF patients with computed tomography (CT), bronchiectasis was generally irreversible (Fig. 62-10).[68] The lungs of CF patients with end-stage lung disease contain a large number of bronchiectatic airways, reflecting the sum of structural damage that occurred in previous years. Bronchiectatic airways are reservoirs of large quantities of bacteria, inflammatory mediators, and DNA released from the nuclei of decomposed neutrophils. The presence of bronchiectasis is likely to result in damage to adjacent healthy areas of the lung. In patients with

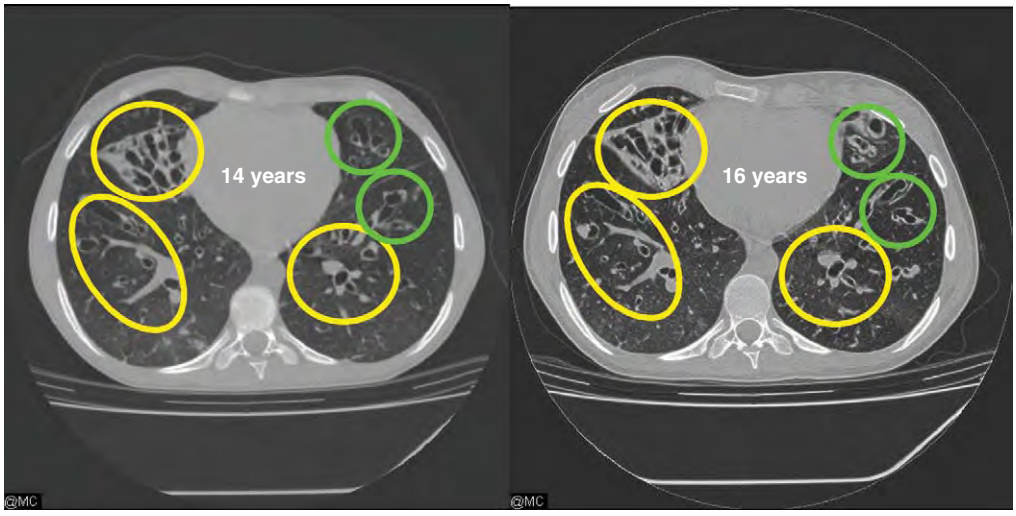

Figure 62-9 These CT scans are of a girl with cystic fibrosis (ΔF508, ΔF508 mutation) and advanced lung disease who was 14 years old when the first CT was made and 16 when the second CT was made. FEV_1 and FVC were 53% and 56% at time of first CT and 58% and 74% at time of second CT. Note that most of the bronchiectatic airways in the *yellow circles* visible on the 1st CT are still present on the 2nd CT. The areas enclosed by the *green circles* have progressed slightly. FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

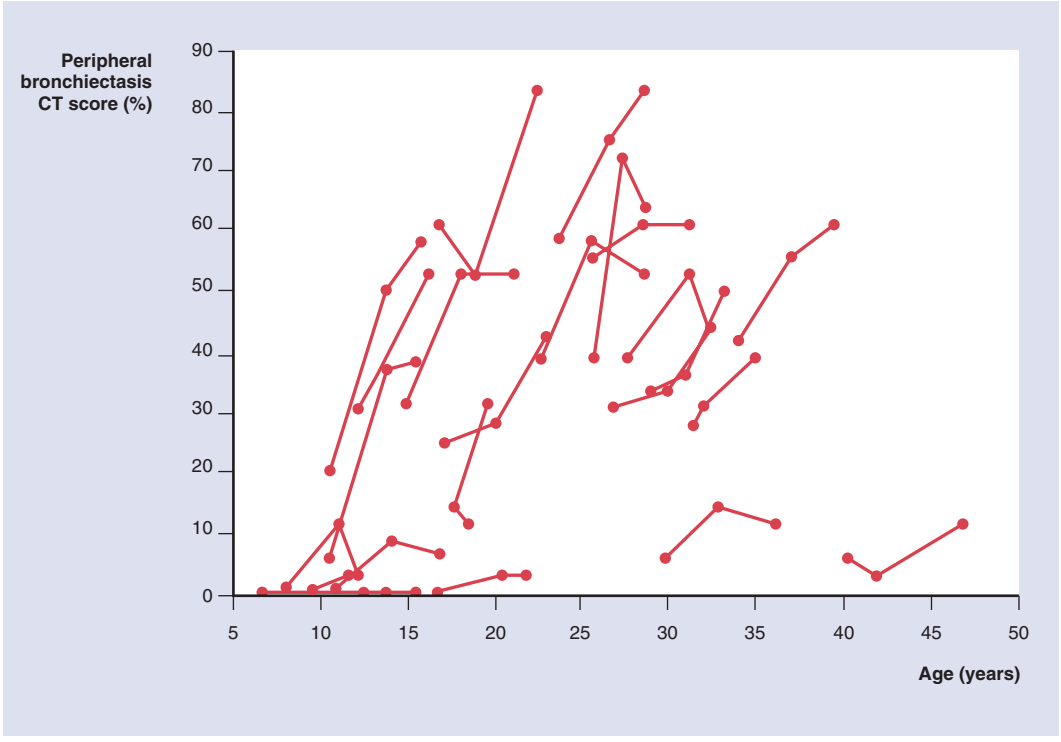

Figure 62-10 Changes in the peripheral bronchiectasis CT score over 6 years in 24 patients who had three CT evaluations. Most of the 24 patients had a stable FEV_1 over the 6 years, whereas the peripheral bronchiectasis CT score showed the expected disease progression. FEV_1, forced expiratory volume in 1 second. (Reprinted from de Jong PA, Lindblad A, Rubin L, et al: Progression of lung disease on computed tomography and pulmonary function tests in children and adults with cystic fibrosis. Thorax 61:80-85, 2006.)

chronic obstructive pulmonary disease (COPD), the presence of bronchiectasis correlates with quality of life. It is likely the same is true for CF.

Another important structural change in CF detectable by CT is airway wall thickening. This thickening is present early in the disease process and more severe in the peripheral airways. In lung tissue obtained from CF patients undergoing pneumectomy for lung transplantation, airways were up to threefold thicker relative to airways of smokers undergoing lobectomy for a lung tumor. Importantly, in both groups of patients but particularly in CF, the inflammatory process and geometric changes were more severe in the peripheral than in the central airways.[14] Indeed, airway wall thickening in CF patients with end-stage lung disease is as severe as in asthma patients who died from acute status asthmaticus.[69] In other pulmonary diseases such as COPD and asthma, airway wall thickening is proportional to the severity of the airway inflammation.[70] Clearly, airway wall thickening is an important feature of lung disease in CF.

Thickened central airways can be identified on CT scans. Thickening of peripheral airways smaller than 1 mm cannot be directly identified. However, on expiratory scans, trapped air can be observed as darkened areas (Fig. 62-11). Because of airway wall thickening and mucus impaction, small airways close at a volume above residual volume. Airway wall thickening and areas of trapped air can be observed early in the disease process and seem to be reproducible over time, suggesting irreversibility of the structural changes causing the defects.[71,72]

CT studies reveal that the lung pathology in CF is inhomogeneous. Normal areas can be adjacent to areas with end-stage lung disease (see Figs. 62-3 and 62-8). Although CT is a sensitive technique to identify structural lung abnormalities and to monitor disease progression, it must be used judiciously because of radiation exposure and expense. The cancer risks associated with radiation exposure are cumulative, so lifelong exposure should be limited to the technical minimum. The radiation exposure for each study should be minimized by utilizing settings adapted to the size of the child. The number of lifelong examinations should be monitored and minimized. In a number of CF centers, a CT scan is performed every second or third year to monitor disease progression.[68] The radiation burden of this strategy is considered to be acceptable.[73] It is likely that the radiation dose used for chest CT can be further reduced in the near future and that magnetic resonance imaging will, at some point, allow further reduction of the number of CT scans.

Because many children show considerable structural abnormalities by the age of 4 to 5 years, it seems to be appropriate to perform the first CT scan at an earlier age. This can be done under sedation using the controlled ventilation technique.[74] With this technique the radiation dose can be reduced and the development of atelectasis can be avoided. Alternatively, in slightly older children with modern scanners, a CT scan of the lung can be made during spontaneous respiration. To reduce the radiation dose, some investigators have reduced the number of images to 4 to 6 at predefined anatomic positions.[74] This approach could be important

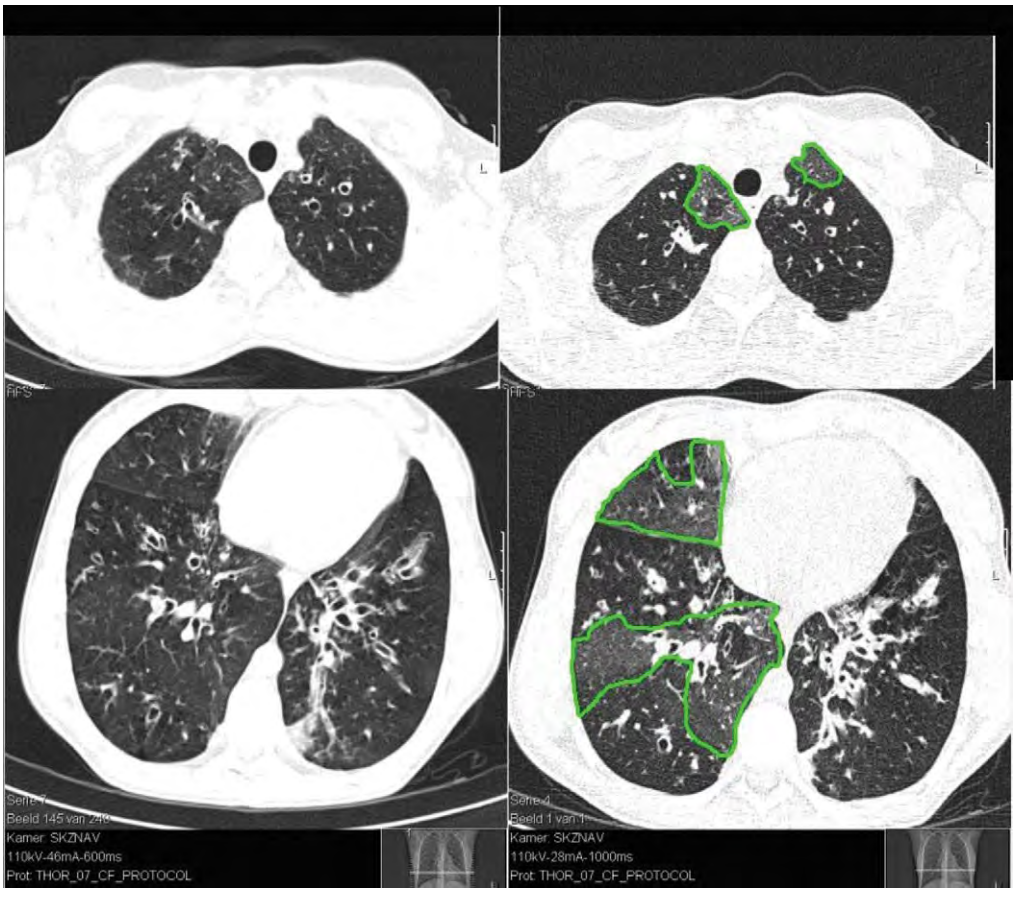

Figure 62-11 The left two images are selected from a volumetric chest CT examination in inspiration. The two images on the right are taken at identical levels after exhalation. The areas encircled in *green* show an increased density relative to the inflation images. Most of the other areas show near identical density indicating trapped air. Note in addition a barrel-shaped chest. The large anterior posterior diameter is larger relative to the side-to-side diameter.

especially for young children who are known to be more sensitive to radiation. A disadvantage of this approach is that it substantially reduces the sensitivity of CT to detect localized structural abnormalities.[73] In young children substantial abnormalities can be observed, such as thickened airway walls, narrowed airway lumens, bronchiectasis, and air trapping.[71]

Modern imaging techniques such as CT can play an important role in estimating the severity of CF lung disease starting at an early stage of the disease. Unfortunately its use is limited by radiation exposure. Newer tools such as MRI can hopefully be developed to visualize relevant structural changes with sufficient precision.

TREATMENT OF CF LUNG DISEASE

The primary aim of therapy is to preserve the normal architecture of the lung and to prevent any damage from occurring. This is important because most structural lung damage, such as bronchiectasis, is irreversible and cannot be restored. Because chronic airway inflammation and infection start in infancy, treatment should ideally start at that age. Unfortunately, many CF therapies have not been tested in infants and young children, so their safety and efficacy in this age range is unknown. Treatment must be lifelong, and ensuring lifelong adherence to the often burdensome treatment regimen is the major challenge of the CF team and the patient.

Therapy can be directed at various levels of the disease process (see Fig. 62-1). Some of these therapies are in active clinical use, whereas others are in development. Gene therapy is the most rational form of therapy; unfortunately, it is also the most challenging.[75-77] In the field of gene therapy an increased understanding of vector biology and host interaction has led to the development of novel strategies to enhance the efficiency and selectivity of gene delivery to the lung. Although significant challenges remain, there is now a realistic prospect of a clinically effective treatment in the next 10 years. For today's treatment, it is key to keep in mind that gene therapy will not be able to reverse structural abnormalities such as bronchiectasis. Hence, even if at some point a cure for the basic defect in CF becomes available, a patient with bronchiectasis will remain a bronchiectasis patient for life.

The next level of therapies is directed toward restoring normal tonicity and ion content of airway surface liquid and improving impaired mucociliary clearance. Potentiator and corrector therapies aimed at partially restoring CFTR function are in the drug discovery pipeline—as are therapies aimed at decreasing sodium absorption through the epithelial sodium channel (ENaC) or increasing chloride efflux through alternate chloride channels. Recombinant human DNase is a mainstay of CF therapies, and hypertonic saline is coming into more widespread use.

At the next level, chronic airway infection and inflammation are major challenges. Fortunately, major steps forward have been made in the understanding of antibiotic treatment strategies in CF. In contrast anti-inflammatory treatment is largely unexplored territory. Only a few studies have been performed on the effect of anti-inflammatory treatment on relevant end points. The various therapeutic modalities will be addressed subsequently.

Antibiotics

Antibiotic treatment in CF is prescribed for four general indications: to prevent the infection by a certain microorganism; to eradicate a microorganism at an early stage of an infection; to suppress the growth of a microorganism that is chronically present in the airways; or to treat a pulmonary exacerbation.

The antibiotics can be administered orally, by inhalation, or intravenously. The oral route offers the advantages of ease of administration and systemic absorption, allowing the drug to reach poorly ventilated areas of the lung that may not be reached by the inhaled route. However, the oral route also introduces some disadvantages, the most important of which is the unpredictable gastrointestinal absorption of some drugs in CF and interaction with food.[78] A second disadvantage is that the maximal dose is often limited by gastrointestinal side effects. When tissue levels are below the minimal inhibitory concentration (MIC), resistance is more likely to occur. Exposure of the GI tract to the antibiotic changes the composition of gut flora and may induce antibiotic resistance in intestinal organisms. In addition, adherence to oral antibiotic regimens may be challenging for drugs that require exact timing in relation to meals or, in young children, for drugs that have an unpleasant taste. Many patients develop symptoms such as diarrhea and growth of *Candida*.

Although more time-consuming than oral administration, inhalation of antibiotics allows delivery of high concentrations to the site of infection with minimal systemic absorption. When antibiotics are nebulized, a filter on the expiration port of the nebulizer is needed to prevent contamination of the environment by the exhaled antibiotic. An inhaled antibiotic should be delivered with the nebulizer and compressor with which use of the drug has been approved. An alternative nebulizer should be used only when approved by the regulatory agencies after proper registration studies.

Patients with CF frequently require intravenous (IV) antibiotics for treatment of pulmonary exacerbations, which are episodic increases in respiratory signs and symptoms characterized by increased cough, increased sputum production, poor appetite, reduced exercise tolerance, and a decline in lung function parameters.[79] The doses of antibiotics that can be given through the IV route are in general much higher compared to the oral route.

In patients requiring frequent courses of IV antibiotics, placement of a totally implantable venous access device (TIVAD) should be considered. Up to one third of the total population of adult CF patients has a TIVAD at some time in their lives.[80] The average lifetime of a TIVAD ranges from 440 to 1429 days.[80-83] TIVAD-related complications occur in 1 in 1065 to 2059 catheter days and in up to one third of the patients with a TIVAD, and can range from minor to severe (Table 62-1).[80] The most common complication is thrombosis—either surrounding the catheter or adherent to the vein.

Prophylactic Antibiotics

The effect of prophylactic treatment has primarily been investigated for anti-staphylococcal treatment early in life in a limited number of randomized controlled studies.[105] Anti-

Table 62-1
Complications of Totally Implantable Venous Access Device

Variables	Number of Complications	Catheter Use Complications/Days
Thrombosis	0.185/1000 catheter days	1/5405
Infection	0.119/1000 catheter days	1/ 8403
Mechanical problem	0.079/1000 catheter days	1/12658
Superior vena cava syndrome	0.026/1000 catheter days	1/38461
Air embolism	0.013/1000 catheter days	1/76923
Pneumothorax	3.4% of catheter placements	—

staphylococcal antibiotic treatment leads to fewer children having isolates of *Staphylococcus aureus*, when commenced early in infancy and continued up to 6 years of age. Whether this strategy leads to improved outcome is unclear. In addition, whether long-term anti-staphylococcal prophylactic treatment leads to increased acquisition of *P. aeruginosa* infection is still a matter of debate. It has been suggested that anti-staphylococcal treatment from diagnosis up to the age of 3 years is effective and safe.[105]

P. AERUGINOSA, FIRST INFECTION

Initial *P. aeruginosa* isolates are generally nonmucoid, highly susceptible to antibiotics, and present at low density.[84] These features suggest a "window of opportunity" for early intervention with antipseudomonal antibiotics in an attempt to delay or prevent chronic *P. aeruginosa* infection. Over time, the distinct microenvironment in the CF airways allows selection of *P. aeruginosa* uniquely adapted for chronic, persistent infection. These organisms are mucoid, become increasingly antibiotic-resistant, are present at high density, and are virtually impossible to eradicate. Chronic *P. aeruginosa* infection is clearly associated with poorer clinical outcomes among CF patients.[28,85-88] Thus, early eradication regimens have gained widespread acceptance. Clinical trials have demonstrated a clear microbiologic treatment effect of antipseudomonal therapy at the time of early *P. aeruginosa* infection,[24,25,89,90] but there has been minimal evaluation of clinical outcomes or emergence of resistant *P. aeruginosa* or new pathogens associated with aggressive early intervention.

The ideal regimen for eradication needs to be further established. In studies of limited size, it has been shown that nebulization of 300 mg tobramycin for inhalation twice daily was highly effective in eradicating *P. aeruginosa*.[25] Alternatively nebulization of 80 mg tobramycin twice daily for 1 year or 3 weeks or 3 months of oral ciprofloxacin combined with nebulized colistin seems to be effective as well.[24,89,91]

P. AERUGINOSA, CHRONIC INFECTION

Nebulized antibiotics have become the cornerstone of treatment of chronic *P. aeruginosa* infection. Intermittent maintenance therapy with 300 mg tobramycin for inhalation twice daily for patients with chronic *Pseudomonas* infection has been shown to be an efficacious and safe strategy to improve lung function, reduce exacerbation rate, and improve quality of life.[92-94] Importantly, this strategy does not seem to induce major resistance problems.[95] An increase in fungal organisms (*Candida albicans* and *Aspergillus* species) during prolonged intermittent treatment with tobramycin for inhalation was observed. The improvement in FEV_1 during tobramycin for inhalation treatment was slightly less for patients where *Aspergillus* was present in their sputum.[20] Tobramycin inhalation is labeled to be nebulized by a Pari LC Plus nebulizer combined with a Pulmo Aide or comparable compressor.

Colistin is another nebulized antibiotic that is frequently prescribed for maintenance therapy against *Pseudomonas*.[91] Limited comparative data suggest that colistin is less effective than tobramycin for inhalation in preserving lung function of patients chronically infected with *P. aeruginosa*.[96,97]

The effectiveness of long-term maintenance therapy with colistin in relation to a specific aerosol delivery system has been less well documented.[98,99] Because of the lack of proper registration studies, colistin is not registered for nebulization in CF in many countries. Technically colistin can be nebulized using a Pari LC star or Hudson updraft II.[100] There have been reports of airflow obstruction and chest tightness with colistin inhalation both in adults and children.[101,102] Symptoms can be reduced by inhaling a bronchodilator prior to the colistin inhalation.

EXACERBATIONS

Clinically, CF lung disease is characterized by episodic increases in respiratory symptoms such as cough and sputum production, often accompanied by systemic symptoms such as weight loss, anorexia, and fatigue.[18] Pulmonary exacerbations are changes in respiratory signs and symptoms from the patient's baseline necessitating treatment. Although pulmonary exacerbations are a prominent feature of CF lung disease, no standardized definition exists, so the presence of an exacerbation remains essentially a clinical diagnosis. Table 62-2 shows the odds ratio for the association of clinical characteristics with the presence of a pulmonary exacerbation in a large cohort of CF-patients.[79] Treatment of a pulmonary exacerbation generally includes antibiotics and increased airway clearance. Antibiotics are generally chosen based on the antimicrobial susceptibility pattern of isolates from a recent respiratory culture.

Patients chronically infected with *P. aeruginosa* with a mild pulmonary exacerbation may be treated with a course of oral ciprofloxacin. It possesses excellent bactericidal activity against *P. aeruginosa* and may be additive when used in combination with aminoglycosides such as tobramycin for inhalation. In addition, it has an excellent oral absorption and

Table 62-2
Odds Ratio for Association of Clinical Characteristics with the Presence of a Pulmonary Exacerbation*

Characteristics	Odds Ratio
PATIENT HISTORY	
Increased cough	24.5
Increased sputum production or chest congestion	24.5

bioavailability in airway secretions. Early clinical studies of ciprofloxacin monotherapy in adults with CF experiencing pulmonary exacerbations demonstrated improved pulmonary function in some cases comparable with intravenous antibiotics.[103] Emergence of *P. aeruginosa* and *S. aureus* resistant to ciprofloxacin and other quinolones is a concern and is associated with monotherapy for more than 3 to 4 weeks.

More severe pulmonary exacerbations in chronically *P. aeruginosa*–infected patients are generally treated with a combination of an aminoglycoside and a beta-lactam antibiotic to achieve synergistic antibacterial activity.[104] Once-daily aminoglycoside dosing appears to provide equivalent efficacy and safety in CF patients compared to three times daily dosing, and even decreased risk of nephrotoxicity in young children.[105] Because CF patients have more rapid clearance of many antibiotics, particularly aminoglycosides,[106] drug levels must be carefully monitored. It must be emphasized that antibiotic therapy for a pulmonary exacerbation in patients chronically infected with *P. aeruginosa* decreases the endobronchial burden of *P. aeruginosa* but cannot completely eradicate the organism. Unfortunately, there is a poor correlation, if any, between the choice of antibiotic based on antimicrobial susceptibility patterns and clinical response.[107,108] The value of susceptibility testing in the selection process for antibiotics is, therefore, not clear but currently our best option.

The effect of treatment can be evaluated using serial lung function testing, oxygen saturation profile, weight gain, sputum volume, and feeling of well-being by the patient. The aim of therapy is to recover the lung function to the personal best in the year before the admission. Typically, patients are treated with intravenous antibiotics for 2 to 3 weeks, which in the majority of patients is the time after which a plateau in improvement in lung function is observed.[109] In patients failing to respond to appropriate antibiotics, additional pathogens such as nontuberculous mycobacteria should be considered, screening should be undertaken for allergic bronchopulmonary aspergillosis, and complications such as atelectasis or pneumothorax should be evaluated.

With increasing use of long intravenous catheters coupled with greater availability of drug delivery services, greater numbers of CF patients are treated with intravenous antibiotics at home. A few small studies have compared the efficacy of treating exacerbations at home versus treatment by hospitalization, with conflicting results.[110,111] However, most studies have found significant cost savings and important psychosocial benefits for the patients and the family when treated at home.[112] Of course, careful patient selection is of prime importance.

Improving Mucociliary Clearance

Mucociliary clearance is severely impaired in CF owing to abnormal tonicity and composition of the epithelial lining fluid and the presence of large quantities of free DNA. Therapeutic options to improve mucociliary clearance are airway clearance techniques and various inhaled therapies.

AIRWAY CLEARANCE TECHNIQUES

Airway clearance techniques aimed at augmenting clearance of viscous lower airway secretions is a cornerstone of CF care at all ages. A range of techniques is employed, including passive techniques requiring the assistance of a second individual (manual percussion, postural drainage, autogenic drainage) and active and passive techniques providing patients more autonomy (positive expiratory pressure [PEP] mask, Flutter, Acapella, and high frequency chest wall oscillating vests). Although airway clearance techniques have been demonstrated in small studies to have short-term effects on increasing mucus transport and lung function,[113] there is surprisingly little evidence from randomized controlled trials regarding longer-term clinical efficacy.[114-116] Furthermore, it is unclear which technique is most effective because well-designed comparative studies are lacking.[115-117] Therefore, the selection of the most appropriate technique can be determined primarily by the preference of the patient. Clearly, the patient is most likely to adhere to a technique that fits best in his or her daily life. In general, patients prefer self-administered airway clearance techniques. A small pilot study demonstrated equivalent short-term efficacy of high frequency chest wall oscillation and conventional percussion with postural drainage,[118] but published larger controlled studies are lacking. Physical exercise is thought to be an effective form of physiotherapy that may be equally effective as other physiotherapy techniques.

RhDNase

Bronchiectatic airways in lungs of CF patients are reservoirs of large quantities of bacteria, inflammatory mediators, and DNA released from the nuclei of decomposed neutrophils. Bronchoalveolar lavage fluid from CF infants has increased free elastase, elevated neutrophil counts, and interleukin-8 levels and elevated DNA concentrations.[9] DNA levels are 3 to 5 times higher than in subjects without CF and tend to be higher in older patients. Recombinant human RhDNase I

(RhDNase) improves mucociliary clearance by hydrolyzing extracellular DNA present in elevated levels in lower airway secretions.[119] Large multicenter placebo-controlled trials have shown that maintenance treatment with nebulized RhDNase delivered by Pulmo-Aide or Portaneb compressor and Hudson T-Updraft II or Sidestream nebulizer improves lung function, and reduces the exacerbation rate.[120,121] In a large-scale 2-year placebo-controlled study in children between 6 and 10 years of age with well-preserved lung function (mean FEV_1 96% predicted and mean FEF_{25-75}, 85% predicted), FEV_1 improved by 3% and FEF_{25-75} by 8% compared to placebo. This study was the first to demonstrate the importance of the peripheral airways in CF.

RhDNase should be delivered to the patient with a jet-nebulizer as used in these studies. There are indications that administration of RhDNase by a compressor-nebulizer combination that delivers a high output rate and low medium particle size is more effective.[122] However, this should be further investigated in well-designed studies of sufficient size. RhDNase should not be mixed in the nebulizer with any other drugs. As many patients nebulize RhDNase before physiotherapy as followed by physiotherapy.[123] However, there are studies that suggest that nebulization of RhDNase followed by physiotherapy improves efficacy.[124,125] The optimal relation between inhalation of RhDNase and physiotherapy should be discussed with each patient.

Bronchoscopic instillation of RhDNase has been advocated for the treatment of lobar atelectasis that persists after intravenous antibiotics and physiotherapy.[126,127] Persistent atelectasis is associated with a poorer prognosis and, thus, every attempt should be made to reverse the atelectasis. Direct instillation of 2.5 mg RhDNase in 10 mL normal saline has effectively been used to mobilize large quantities of mucopurulent secretions from the obstructed bronchus and to expand the atelectatic lobe.[126,127]

Hypertonic Saline

Through osmotic forces, hypertonic saline may increase the volume of airway surface liquid, restore mucus clearance, and improve lung function. In patients with cystic fibrosis, inhalation of hypertonic saline produced a sustained acceleration of mucus clearance and improved lung function. This treatment may protect the lung from insults that reduce mucus clearance and produce lung disease.[128-130] In addition, it has been shown in a large randomized controlled study of 48 weeks' duration that nebulization twice daily of 4 mL NaCl 7% after inhalation of a bronchodilator resulted in a moderate improvement of lung function (FVC, and FEV1) and in a reduced exacerbation rate.[131] Importantly, this effect was in addition to the effect of RhDNase, which was used by 36% of study subjects. In a cross-over study, it was shown that hypertonic saline was inferior to RhDNase in terms of improving lung function.[132] The nebulizer system used in this trial was a Pari Proneb Turbo compressor and PariLC plus nebulizer.

Other Mucolytics

In some countries mucolytics such as *N*-acetylcysteine are still used on a large scale. The effectiveness in relation to a specific delivery system of inhaled *N*-acetylcysteine for CF patients has not been investigated in sufficiently large trials with relevant end points.[133] Hence, at present there is no evidence supporting the use of mucolytics such as *N*-acetylcysteine in cystic fibrosis. Other mucolytics, such as mannitol and heparin, are in development to be used in CF.[134,135]

Anti-inflammatory Therapy

Airway disease in CF is characterized by a continuous cycle of chronic infection and inflammation dominated by a neutrophilic infiltrate. This inflammation, which starts early in life, is characterized by the increased production of proinflammatory cytokines in the airways.[9,21,136] The relation between the abnormal CFTR gene product and the development of inflammation and progression of lung disease in CF is not fully understood.[137] The exaggerated immune response is the rationale for treatment with anti-inflammatory agents. However, it is unclear how far the inflammatory response can be dampened without progressing toward serious infection. The most important trials to date with anti-inflammatory agents were done with orally administered drugs such as prednisone, ibuprofen, and azithromycin.[138-140] Interestingly, treatment with these drugs improved lung function in CF. However, oral treatment with prednisone was associated with severe side effects. Oral treatment with ibuprofen is effective at slowing decline in lung function but is considered to be burdensome by some patients because blood levels need to be monitored regularly and consistent timing of doses is required. Short term (6-month) studies with azithromycin showed improvement in lung function and a decline in the rate of pulmonary exacerbations.[140] It is not clear whether the observed improvements are primarily the result of anti-inflammatory, antibiotic, or of a more systemic effect. However, in general, it is thought that long-term data are needed to determine the safety and effectiveness of azithromycin when used chronically for more than 6 months. The use of azithromycin is associated with a substantial increase in resistance to *Staphylococcus aureus* and *Haemophilus influenzae*.[141] Inhalation of corticosteroids is a popular alternative for anti-inflammatory therapy in CF.[123] Unfortunately, there is no evidence to support the widespread prescription of inhaled corticosteroids because conclusive long-term studies on the efficacy of inhaled corticosteroids are lacking.[142] A recent large-scale study demonstrated that in most CF patients receiving maintenance inhaled corticosteroids, this medication could be withdrawn without significant changes in lung function or exacerbation rate.[143]

Clearly, inhaled corticosteroids should be prescribed in patients who suffer from asthma-like symptoms, although the diagnosis of asthma is difficult to make in CF. When treatment of inhaled corticosteroids is indicated, this can best be prescribed by pressurized metered dose inhaler (pMDI)–spacer or with a breath actuated pMDI. Most available dry powder inhalers (DPIs) used for inhaled corticosteroids show flow dependency of aerosol characteristics for inspiratory flows between 30 and 60 L/minute. Many CF patients are not able to generate inspiratory flows of 60 L/minute or higher.[144] Suboptimal flows not only reduce the output of drug from the DPI but also increase particle size. This is

not desirable because larger particles have a low probability of reaching the peripheral airways, where most pathology is localized in CF. When inhaled corticosteroids are prescribed, they should be inhaled after chest physiotherapy to limit impaction in the central airways and avoid immediate clearance from the lungs by the clearance techniques. After inhalation, the patient should rinse his/her mouth to reduce the risk of oral candidiasis. New anti-inflammatory drugs are being tested in clinical trials and might open this therapeutic area.

Bronchodilators

Many CF patients are routinely treated with bronchodilators.[123] However, similar to inhaled corticosteroids, there is very little evidence to support this widespread use.[145] Some studies have shown that lung function of CF patients improves after inhalation of bronchodilators.[146] Furthermore, it has been suggested in a limited study that the daily use of salbutamol reduces the number of exacerbations and the decline in lung function.[147] However, some CF patients experience a paradoxical drop in lung function after inhalation of bronchodilators.[148,149] This might be caused by a reduced stability of central airways during a forced expiration.[150] Furthermore, the use of β_2-sympathomimetics increases the metabolic rate.[151,152] Based on the limited data on the effectiveness of bronchodilators on relevant end points and their possible negative effects in CF, it seems wise to restrict their use.[145] Bronchodilators can be used for those patients who show substantial reversibility of airflow obstruction after inhalation of bronchodilators and who report relief of symptoms after inhalation. In addition, bronchodilators are used prior to the inhalation of drugs such as colistin and hypertonic saline that are known to cause bronchial obstruction. This kind of obstruction can be the result of bronchial smooth muscle shortening but also of inflammatory changes of the airway wall. For CF patients who need bronchodilators, it makes sense to prescribe long-acting β_2-sympathomimetics.[153] The delivery device of first choice is a pMDI-spacer or a breath-actuated pMDI for reasons discussed earlier.

MANAGING THE THERAPEUTIC PACKAGE

Fortunately, many new treatment modalities are currently in development. With new treatments, however, comes the need to make future choices between modalities. Ideally these decisions would be based on the results of comparative studies, but it is unlikely that such studies will be conducted because of their considerable expense. Nonetheless, new therapies cannot be endlessly added to the existing therapeutic package. The more complicated and time-consuming daily therapies are for a CF patient, the more likely it is that adherence will decrease and mistakes will be made . The total therapeutic package of a CF patient should be critically evaluated at least annually. The aim should be to select a therapeutic package that is acceptable for the patient and that will obtain a maximal short- and long-term effect. The selection of drugs in this package should first of all be based on evidence-based medicine. Fortunately, the number of high quality studies of sufficient sample size and correct design is

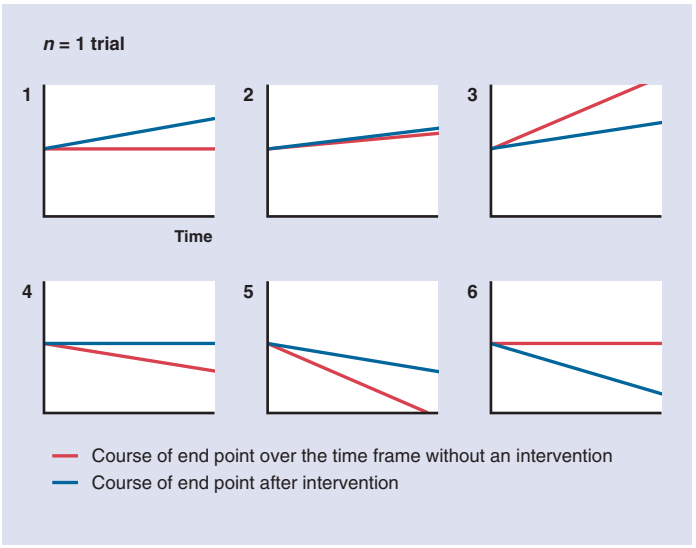

Figure 62-12 The *red line* represents the natural course of an end point (such as lung function) over the time frame of a hypothetical intervention. The *blue line* represents the course of the end point after the hypothetical intervention. In reality, the natural course of the disease for an individual patient over the time frame of the intervention is unknown. In panels 1, 2, and 3 the clinician might have concluded that there was a positive response to the intervention, whereas in panels 4, 5, and 6 the response would have been interpreted as poor or even negative. In reality, the response in panels 1, 4, and 5 is positive, whereas for panels 2, 3, and 6 the response is poor or even negative.

on the rise.[154,155] Some physicians use the $n = 1$ study to determine the effect of a new treatment modality in a single patient. The usefulness of this approach is limited because it can only be used when the natural course of the disease is known for the observational period. Unfortunately, for CF this will seldom be the case because the natural course of disease is highly variable (Fig. 62-12).

CF therapies are time-consuming. The most time-consuming treatments are nebulized medications. A patient treated with daily nebulization of RhDNase, and twice-daily tobramycin for inhalation is spending up to 60 minutes a day on nebulizer therapy. The use of these systems should, therefore, be restricted to drugs with proven efficacy. Regular maintenance of nebulizer devices and critical evaluation of the technical skills of the patients is crucial to optimize efficacy, to reduce the risks of aerosol therapy, and to avoid waste of patient time and resources. For each drug and each administration, the time relation between inhalation of the drug and physiotherapy should be reviewed with the patient on a regular basis.[123]

ADVANCED LUNG DISEASE

CF patients generally slowly progress to more advanced lung disease (see Fig. 62-6). Lungs of such patients are highly abnormal (Fig. 62-13). The damage that can be observed represents the sum of lifelong chronic infection and inflammation and of recurrent exacerbations. Most of the structural abnormalities that can be observed on the CT scan of such patients are irreversible. The clinical condition of such patients is in general characterized by increased work of breathing, expectoration of large quantities of sputum, weight

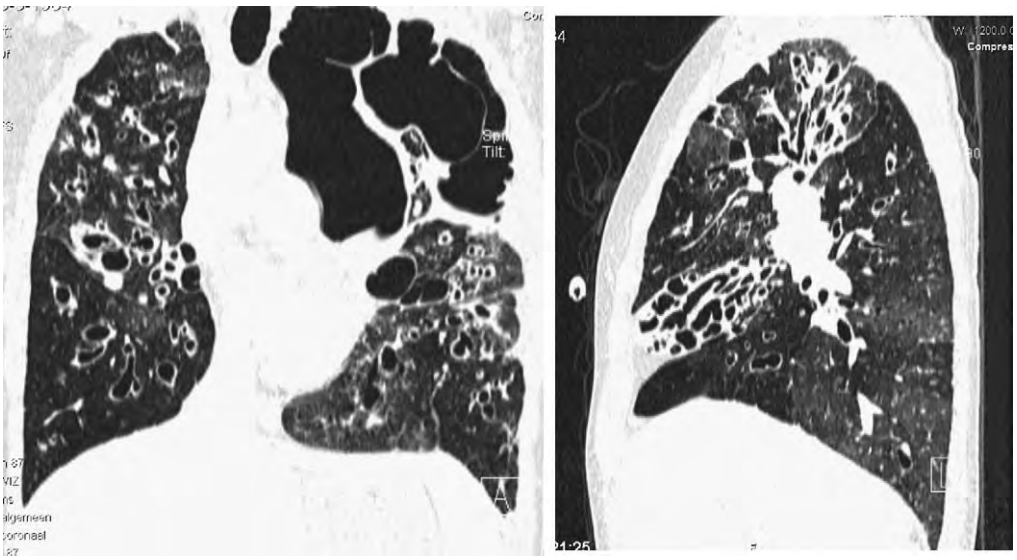

Figure 62-13 End-stage lung disease in a 23-year-old patient. Hardly any normal tissue is available. Note the large bullae in the left upper lobe. Note the extensive areas with bronchiectasis. In the right lower lobe, dark areas are visible compressing the rest of the left lung. These areas are hypoperfused and contain trapped air.

loss, and reduced exercise tolerance. These patients are at increased risk of complications such as hemoptysis and pneumothorax. Therapy in these patients becomes more intensive because any worsening of the pulmonary condition leads to noticeable reduction in ability to conduct activities of daily living.

Hemoptysis

Hemoptysis is defined as expectoration of blood in sputum. Mild hemoptysis, characterized by blood-tinged sputum, is not uncommon when infection and inflammation in a patient becomes more severe, and generally responds to antibiotics. In a large retrospective observational cohort study it was estimated that the annual incidence of hemoptysis was 0.87% and occurred in 4.1% of patients overall. Moderate or massive hemoptysis was more prevalent in older patients with a mean age of around 24 years.[156] In addition, it was more prevalent in patients with a FEV_1 below 40% predicted. Other principal risk factors associated with an increased occurrence of moderate to severe hemoptysis included the presence of *S. aureus* in sputum cultures, and diabetes. Following moderate to severe hemoptysis there is an increased morbidity and an increased 2-year mortality rate. Most cases of hemoptysis can be handled conservatively.[156] In the case of massive life-threatening hemoptysis, bronchial artery embolization should be considered. This procedure has a high success rate for short-term control of bleeding. However, more than one half of the patients require repeated embolization during long-term follow-up.[157]

Pneumothorax

Pneumothorax is a serious complication in CF patients. Spontaneous pneumothorax is a complication that is reported commonly in older patients with CF. In a large retrospective observational cohort study it was estimated that the annual incidence was in the order of 0.64% and in 3.4% of patients overall. Pneumothorax was more prevalent in older patients with a mean age of 21.9 years. In addition, it was more prevalent in patients with severe pulmonary impairment. Almost 75% of pneumothoraces occurred in patients with FEV_1 of below 40% predicted. Other risk factors that were associated with an increased occurrence of pneumothorax were the presence of *P. aeruginosa*, *Burkholderia cepacia*, or *Aspergillus*, enteral tube feeding, pancreatic insufficiency, allergic bronchopulmonary aspergillosis, and massive hemoptysis. Following pneumothorax, there is an increased morbidity and an increased 2-year mortality rate.[158]

MANAGEMENT OF ADVANCED LUNG DISEASE

Oxygen

Hypoxia during sleep and exercise may occur in CF patients with more advanced lung disease. These patients are likely to have reduced exercise tolerance, poor sleep quality, reduced quality of life, and eventually may develop pulmonary hypertension. It seems logical to treat these patients with oxygen therapy. Unfortunately, only a few studies have evaluated the effectiveness of various forms of oxygen therapy.[159,160] Only one randomized controlled trial evaluated the effect of nocturnal oxygen therapy on clinical end points.[161] The authors concluded that nocturnal oxygen treatment in CF did not appear to affect mortality rates, frequency of hospitalizations, or the progression of disease. However, school and work attendance was maintained in the oxygen group but deteriorated in the placebo group. They recommended that oxygen use should be instituted only after the development of symptoms of hypoxia.

There is no clear-cut definition of hypoxia in CF.[159] It is well recognized that patients with a resting awake SaO_2 below 93% have significant nocturnal desaturation. However, one third of patients with a SaO_2 above 93% became hypoxic at night.[162] One of the definitions used to define sleep hypoxia is when a nocturnal SaO_2 is observed below 93% for more than 25% of the study time. Other studies have selected a mean SaO_2 of below 95%. Exercise-induced arterial hypoxia

in children has been defined as a fall in SaO_2 during exercise of 4% or over from baseline. Hypoxia is reported to occur more frequently during sleep than with exercise, suggesting that for screening purposes a nocturnal SaO_2 profile might be appropriate. Because of this lack of randomized controlled trials, the indication for oxygen therapy is somewhat arbitrary. In the American consensus guideline it is recommended that night-time oxygen therapy is indicated for adults when SaO_2 is below 88% to 90% for 10% or more of the time and oxygen during exercise if SaO_2 falls below 88% to 90% during exercise.[158] There is evidence of modest enhancement of exercise capacity and duration with oxygen supplementation, especially in individuals with more advanced lung disease.[160,163] In a meta-analysis it was concluded by the authors that oxygen therapy should be reserved for those individuals with objective evidence of hypoxemia, either at rest while awake or during either exercise or sleep.[160] Short-term oxygen therapy during sleep and exercise improves oxygenation but is associated with modest and probably clinically inconsequential hypercapnia. Attention to blood gas analysis is warranted in individuals with advanced lung disease and chronic hypercapnia.

The introduction of oxygen therapy suggests a decline in the pulmonary condition of the patient and adds substantially to the daily therapeutic burden. Introduction of oxygen should ideally be done when the patient is motivated and convinced of the potential benefit of such therapy. Clearly, introducing oxygen therapy in the home situation requires quite some organization (Box 62-2). When the initial flow to the patient is below 0.3 L/minute oxygen can be delivered by cylinders. For higher flows an oxygen concentrator is preferred with back-up portable cylinders for breakdowns and for ambulatory use.[164] Many countries have guidelines for home oxygen programs. Flying and holidays at high altitudes expose a CF patient to a reduced inspired oxygen pressure. For a patient with severely impaired lung function this can result in a reduced oxygen saturation and increased work of breathing. From the literature, it is not clear when in-flight oxygen is required or when a holiday at high altitude should be discouraged.[165] Some authors suggest testing the patient with a 20-minute inhalation of a test-mixture of 15% oxygen and nitrogen.[166-168] Others suggest that preflight spirometric tests are a better predictor of desaturation during flight than the preflight hypoxic challenge.[169] If oxygen is required it is important that arrangements with the airline are made well in advance.

BOX 62-2 Requirements for Home Oxygen Therapy in CF

Instruction and support:
- Adequate training and written instructions on safe use of oxygen in home environment
- Round-the-clock technical and medical support in place

Equipment:
- Oxygen cylinders that can be used for flow rates ≤0.3 L/minute
- Oxygen concentrators are usually preferred for flow rates of ≥0.3 L/minute
- Back-up lightweight cylinders for breakdown and ambulatory use
- Humidification system for flows ≥1 L/minute for nasal comfort
- Appropriately-sized soft twin prong nasal cannulas
- In case of use of wheelchair consider cylinder fitting

Based on Balfour-Lynn IM, Primhak RA, Shaw BN: Home oxygen for children: Who, how and when? Thorax 60(1):76-81, 2005.

Physiotherapy of Advanced Lung Disease

Many patients with advanced lung disease have difficulty keeping up with physiotherapy. When the daily production of sputum exceeds the capacity of the patient to expectorate, the patient will deteriorate. It is important to consider that such an imbalance might be developing in a deteriorating patient, and to consider more aggressive support by a physiotherapist or a change in airway clearance technique. If a patient requires intubation and mechanical ventilation for reversible respiratory failure, regular bronchoscopic sessions should be considered to eliminate amounts of sputum comparable to that which the patient was mobilizing before intubation.

Noninvasive Ventilation

For patients with chronic respiratory failure, noninvasive positive pressure ventilation should be considered as supportive therapy. It was shown in patients with daytime hypercapnia ($PaCO_2 > 6$ kPa [45 mm Hg]) and/or symptoms of nocturnal hypoventilation that noninvasive positive pressure ventilation was effective to reduce the work of breathing and in improving gas exchange.[170,171] Because introduction of this therapy requires some time for patient training, it should be considered before the occurrence of acute respiratory failure in patients screened for lung transplantation. For patients who develop acute respiratory failure, invasive mechanical ventilation should be seriously considered because about one half of the patients survive such an intervention.[172] It has been suggested that for CF patients listed for lung transplantation, those requiring short-term mechanical ventilation for respiratory failure have outcomes similar to those who do not require invasive ventilatory support before lung transplantation.[173]

Lung Transplantation

Lung transplantation is a viable option for the treatment of end-stage lung disease in CF.[174] Although models capable of clearly predicting short-term survival in CF are lacking,[175,176] referral criteria have been established and are shown in Box 62-3. Survival of CF patients after transplantation is similar to that of recipients with other pulmonary diseases. Approximately one half of the patients are still alive 4 years after transplantation.[177,178] In most countries there are long waiting lists for a lung transplant owing to the relative shortage of donor lungs. In other countries, about one half of the CF patients listed for transplant actually die waiting for donor organs.[179] In Austria and Belgium with "presumed-consent" donor legislation, rates of heart and lung donation are at least

BOX 62-3 Lung Transplant Referral Criteria

Progressive pulmonary function impairment manifest by $FEV_1 \leq 30\%$ predicted, severe hypoxemia, and hypercarbia

Rapid fall in FEV_1 despite optimal medical management; resting arterial blood gas analysis while breathing room air showing a $PaCO_2$ of >50 mm Hg or a PaO_2 of <55 mm Hg

Increasing functional impairment, evidenced by increasing frequency and duration of hospital treatment for pulmonary exacerbation, and increasing cachexia

Major life-threatening pulmonary complications, such as recurrent massive hemoptysis

Increasing antibiotic resistance of bacteria infecting the lung

Data based on Yankaskas JR, Mallory GB Jr: Lung transplantation in cystic fibrosis: Consensus conference statement. Chest 113(1):217-226, 1998; Glanville AR, Estenne M: Indications, patient selection and timing of referral for lung transplantation. Eur Respir J 22(5):845-852, 2003.

twice as high compared to similar countries with an "explicit consent" legislation. Hence, the waiting times in these countries are lower.[180]

The leading causes of morbidity after lung transplantation for cystic fibrosis are pulmonary bacterial infection and opportunistic infections. Bronchiolitis obliterans develops in more than one half of lung transplant recipients who survive for more than 3 years and is the major cause of death in the late post-transplantation period.[178]

CONCLUSIONS

CF lung inflammation is early, sustained, and severe.[181] The same is true for lung damage. The peripheral airways are involved early in the disease process. Most lung damage is irreversible. The lung condition should be monitored by frequent microbiological sampling, lung function testing, and by lung imaging. Patients should be examined frequently to detect and treat progression of disease at an early stage. Hence, early treatment is focused on prevention. Treatment of more advanced lung disease is focused on maintaining the condition of the lung at the most optimal level and halting disease progression.

CHAPTER 63 Other Clinical Manifestations

Philip Robinson

TEACHING POINTS

- Cystic fibrosis (CF) is a multisystem condition.
- 90% of persons with CF have pancreatic insufficiency requiring treatment.
- CF may produce clinical symptoms in many body systems including the gastrointestinal tract, hepatobiliary tract, the reproductive system, endocrine system, and cardiac system, as well as the lung.
- Complications from some of these manifestations such as diabetes may have direct influences on patient survival.

PANCREATIC EXOCRINE INSUFFICIENCY

Pathophysiology

Exocrine pancreatic insufficiency occurs to a sufficient degree to produce clinical malabsorption in approximately 90% of patients with cystic fibrosis (CF).[1]

While the exocrine insufficiency results in inefficient digestion and absorption of all three of the major food groups, Fletcher noted over 60 years ago that "of the 3 important ferments normally present in the secretion of the pancreas it would seem that particularly in children the lipase steapsin is the one most liable to show variations in its functional activity as the result of disease of the pancreas."[2]

In patients with pancreatic insufficiency, the pancreas is shrunken and shows marked fibrosis, fatty replacement, and cyst formation.[3,4] Stenosis and atresia of large pancreatic ducts have been reported but, in general, pancreatic lesions are caused by obstruction of small ducts by inspissated secretions. Imrie and others have shown that this obstruction commences in utero, resulting in periductal inflammation, fibrosis, and loss of exocrine function.[3,5,6] Hypoplasia and eventually necrosis of ductal and centroacinar cells, together with inspissated secretions, block pancreatic ductules and can cause atrophy of the lining epithelium.[4,7]

Pancreatic function status is genetically determined by specific CF mutations. Patients carrying one or two mild mutations are almost always pancreatic sufficient. Among patients homozygous for the common ΔF508 mutation, 99% will be pancreatic insufficient. Mutations associated with pancreatic sufficiency are generally class IV or V CF transmembrane conductance regulator (CFTR) defects and include R117H, R334W, R347P, A455E, and P574H.

An International Cystic Fibrosis Genotype-Phenotype Consortium in 1993 examined Δ508 homozygotes and seven of the most common 508 compound heterozygotes (G542X, R552X, N1303K, W1282X, 1717-1G-A, 612 + 1GT, R117H). All 19 patients with the R117H/Δ508 genotype had pancreatic sufficiency, whereas all the matched Δ508 homozygotes had pancreatic insufficiency. Walkowiak and associates[8] correlated exocrine pancreatic function assessed by fecal elastase-1 to 15 different mutations in 394 patients with CF and found again that patients carrying two severe mutations developed pancreatic insufficiency, whereas those who carried at least one mild mutation were generally pancreatic sufficient. The presence of one mild mutation did not, however, exclude pancreatic insufficiency.

Clinical Manifestations

Clinical evidence of exocrine pancreatic insufficiency occurs with loss of over 95% of exocrine output and results in malabsorption of fats and proteins and, to a lesser extent, carbohydrates. Steatorrhea and azotorrhea can be pronounced. Clinically, this malabsorption may manifest as poor or absent weight gain, abdominal distention, deficiency of subcutaneous fat and muscle tissue, frequent loose bulky, foul-smelling, greasy stools, and rectal prolapse.

Pancreatic Function Testing

Exocrine pancreatic function can be assessed by either direct or indirect tests. Direct tests include the gold standard, the secretin-cholecystokinin test, which has high sensitivity and specificity; however, the test has major disadvantages for use in pediatric populations, being expensive, uncomfortable, and poorly standardized in children.[9,10]

Indirect tests are used more widely in clinical practice, as they are generally less invasive, relatively cheap to perform, and less time consuming. Three main categories of indirect tests can be described as follows[11]:

1. Measurement of pancreatic enzymes in the serum (amylase, isoamylase, lipase, trypsinogen, elastase[12-14]) or stool (chymotrypsin, lipase and elastase[15-17])
2. Assessment of the absorption of markers that are hydrolyzed from conjugates by pancreatic enzymes and subsequently appear in urine or serum: pancreolauryl or NBT-PABA test[18-20]

3. Analysis of undigested and unabsorbed food components in feces—fecal fat excretion, fecal fat concentration, steatocrit, acid steatocrit[21-23]—or the analysis of oxidation products of digested and absorbed fat in expired air[24-26]

Assessment of serum enzymes contributes to assessment of exocrine pancreatic function with poor quantitative precision about residual function, while measurement of fecal enzymes provides a more sensitive assessment. Tests from the remaining two categories rely on the biological effect of pancreatic enzymes—digestion and absorption. Tests of fecal fat excretion may be influenced by other factors not related to pancreatic enzyme function such as gastric acid hypersecretion and loss of bile salts, as well as the presence of other conditions such as celiac disease. In CF patients, the correlation between the fecal fat excretion and the secretin-cholecystokinin test is less than that between the fecal elastase-1 concentration and the secretin-cholecystokinin test.[27]

Fecal elastase-1 has been shown to be a more sensitive test of exocrine pancreatic function than fecal chymotrypsin, fecal lipase, or breath test in CF.[27,28]

Although the test has the highest sensitivity of the indirect tests, the practical value of the measurement of fecal elastase-1 concentration in the assessment of mild pancreatic dysfunction is limited; however, it may have a role in assessing declining pancreatic enzyme function, as may occur over the first year in some infants diagnosed on newborn screening.[28]

The fecal elastase-1 test is unable to differentiate between primary exocrine pancreatic dysfunction and exocrine pancreatic dysfunction secondary to intestinal villous atrophy and has been shown to be abnormal in conditions including celiac disease as well as during acute episodes of diarrhea.[29]

While measurement of serum immunoreactive trypsinogen (IRT) is widely used in newborn screening programs for CF, the use of the test in the assessment of pancreatic function is limited. IRT in pancreatic-insufficient infants falls sharply in the first 2 years of life, so that over 95% of patients have subnormal values by the age of 7 years.[13] Under the age of 7 years, IRT has low sensitivity in differentiating between pancreatic-sufficient and pancreatic-insufficient infants.[30]

Several tests of pancreatic function involve the oral administration of a measurable tracer bound to a peptide specifically cleaved by one of the pancreatic enzymes. The synthetic peptide *n*-benzoyl-*l*-tyrosyl-*p*-aminobenzoic acid (bentiromide) is cleaved by chymotrypsin. The liberated *p*-aminobenzoic acid (PABA) is absorbed and excreted in the urine. Accordingly, PABA recovery reflects intraluminal chymotrypsin activity.[18] The sensitivity and specificity of the test can be improved by measuring PABA in plasma 90 minutes after the administration of a large dose of bentiromide or by the administration of a test meal that stimulates enzyme secretion.[31,32]

For practical clinical purposes, the relevance of exocrine pancreatic dysfunction is manifested as steatorrhea, and the measurement of daily fecal fat excretion over a period of 72 hours is the accepted standard procedure. Collected stool can be assayed for fecal fat content by several techniques, including gravimetric analysis, near-infrared analysis, and the generally "standard" but time-consuming technique of chemical analysis.[33,34]

In infants under 6 months of age, including those recently diagnosed by newborn screening programs, the coefficient of fat absorption is approximately 85% and increases with age such that above the age of 4 years the coefficient of fat absorption should exceed 95%.

Several breath tests dependent on the digestion of a substrate have been developed and may offer a useful, albeit expensive, alternative for assessment of fat digestion and absorption. The mixed triglyceride breath test is very sensitive for assessing severe excorine pancreatic deficiency and is a direct assessment of the presence of pancreatic lipase.[35,36]

An alternative breath test uses cholesteryl octanoate, which is hydrolyzed by cholesterol esterase, a process that requires the presence of pancreatic lipase and bile salts. This test has the advantage that cholesteryl octanoate is not hydrolyzed by preduodenal lipase and has been postulated to be an effective assessment for exocrine pancreatic function in young children in whom preduodenal lipase is more active.[11,37,38]

Nutrition

An adequate nutritional status is a key factor for a long-term survival in CF patients.[39] Studies have shown a positive effect of nutrition intervention on anthropometric measurements and pulmonary function.[40,41] Supplemental gastrostomy feedings were shown to be associated with significant improvements in weight and height percentiles for age,[40] increase in percent of body fat and fat-free mass, sustained growth, and stabilization in pulmonary function status.[39-41]

Edema and Hypoproteinemia

As newborn screening for CF is increasingly being introduced in major treatment centers, clinical presentations of CF secondary to prolonged lack of specific treatment are becoming increasingly uncommon. In areas where newborn screening is, however, not established, the presentation of patients with clinical consequences of pancreatic insufficiency may still occur. Secondary to proteolytic enzyme deficiency and malabsorption, infants with underrecognized pancreatic insufficiency may present with edema secondary to hypoproteinemia secondary to protein calorie malnutrition.[42,43]

CF patients may develop severe protein-calorie malnutrition and edema, often as the presenting manifestation of their disease, and particularly in areas without access to newborn screening.[44] Features may include hypoalbuminemia, hepatomegaly, elevation of liver enzyme values, anemia, and a characteristic dermatitis secondary to deficiencies of protein, zinc, and essential fatty acids.[45] A false-negative sweat test result may occur in the presence of edema, probably secondary to a low sweat secretory rate.[37] Infants with this syndrome need intensive nutritional therapy, including adequate calories, essential fatty acids, protein, zinc, and vitamins, along with pancreatic enzyme supplementation. A prolonged course of parenteral nutrition or enteral supplementation often is required.

Vitamins and Trace Metals

FAT-SOLUBLE VITAMINS

Deficiencies of fat-soluble vitamins A, D, E, and K have been repeatedly demonstrated in individuals with CF, particularly

in those with pancreatic insufficiency.[46-48] Fat-soluble vitamin deficiency has been reported to occur in infants as young as 2 months, and thus determination of such vitamin levels and supplementation with such vitamins is often necessary in infants diagnosed by newborn screening programs.[46,47]

Contributing factors that may lead to such a deficiency include suboptimal intake, malabsorption due to inadequate pancreatic enzyme levels either endogenous or as a result of insufficient replacement enzyme therapy, liver disease, bowel resection, and increased consumption.[49-53] Fat-soluble vitamin deficiencies in CF have been shown to be associated with poorer clinical status.[54]

VITAMIN A

Vitamin A is an essential nutrient for epithelial cell maintenance and repair. Dietary vitamin A (retinol or retinol esters) is found in eggs, fish, and dairy products. Both beta- and alpha-carotene can act as precursors for the synthesis of vitamin A and are postulated to function as antioxidants, inhibiting the oxidation of membrane lipids during infection. Deficiency of vitamin A may cause night blindness, conjunctiva and corneal xeroses, dry thickened skin, and abnormalities of bronchial mucosal epithelialization.[55] Vitamin A deficiency in individuals with CF appears to be multifactorial. Low retinol levels have been observed during periods of infection and inflammation.[56]

Assessment should therefore be performed during periods of clinical stability, rather than during acute exacerbation of lung function. Low levels may also be a consequence of low levels of retinol binding protein, which is responsible for transporting vitamin A from the liver to peripheral tissues. In addition, zinc deficiency may result in low vitamin A levels, as zinc is required for the release of vitamin A and retinol binding protein from liver stores.[54]

VITAMIN E

Vitamin E acts as an antioxidant protecting against oxidation of polyunsaturated fatty acids, particularly in lipoproteins and cellular membranes. Vitamin E deficiency is common in individuals with CF, and significant clinical sequelae of vitamin E deficiency have been reported, including hemolytic anemia in infants and ataxia and neuromuscular degeneration or compromised cognitive function in older patients.[57,58]

VITAMIN K

Clinical deficiency of vitamin K is considered to be uncommon in CF; however, Durie[59] has shown that frequent antibiotic treatment can result in a reduction in vitamin K levels by reducing the intestinal microflora capable of producing vitamin K. Subclinical deficiencies have been shown in more than 80% of pancreatic-insufficient children and in all patients with significant liver disease.[60-61]

Water-Soluble Vitamins

In the absence of other mitigating factors, significant deficiencies of water-soluble vitamins have generally been thought to be uncommon in CF.[47] In a study of children with CF who presented with angular stomatitis, over 80% were found to have biochemical evidence of B-group vitamin deficiency.[62] Regular vitamin B_{12} supplementation is required if the terminal ileum has been resected as a result of meconium ileus at birth.[63]

Trace Metals and Salts

Individuals with CF are at risk of increased sweat losses of sodium and chloride, particularly with exercise or exposure to high temperatures. CF infants are particularly at risk of salt depletion due to low levels of sodium in breast milk and substitutes. Sodium chloride deficiency is characterized by hyponatremia, decreased serum osmolarity, decreased appetite, nausea, vomiting, muscle cramps, fatigue, poor concentration, and headaches.[64] Additional sodium supplementation may be needed by infants, as requirements are increased during rapid growth and, due to their relative large body surface area, during periods of illness. During these periods, regular dietary intake decreases and is replaced by oral fluid supplements or enteral tube feeds, which have a low sodium content. This is also applicable in adults before undertaking additional strenuous work or physical activity, and when holidaying or living in hot or humid conditions.

Iron and Zinc

Iron deficiency is common in individuals with CF and may be related to multiple factors including inadequate dietary intake, malabsorption, chronic infection, blood loss, and excessive losses in sputum.[65] Severe zinc deficiency is less common, although there is evidence to suggest that milder zinc deficiency is widespread and associated with fat malabsorption.[66]

Zinc deficiency may have implications on vitamin A status as zinc has been shown to participate in the absorption, mobilization, transport, and metabolism of vitamin A, most likely through its involvement in protein synthesis and cellular enzyme functions.[67] Plasma levels of copper and ceruloplasmin may be elevated, reflecting ceruloplasmin's role as an acute phase reactant.[68]

Symptomatic hypomagnesemia has been reported in patients treated with repeated courses of intravenous aminoglycosides and manifesting as paresthesias, weakness, tremulousness, and muscle cramps.[68,69]

Monitoring

Levels of both iron and zinc should be periodically monitored in individuals with CF, and a trial of supplementation given if necessary, as low levels of either can contribute to suboptimal growth.[48]

Essential Fatty Acids

The essential fatty acid (EFA) status of individuals with CF is variable, ranging from normal to highly disturbed compositions. In general, individuals who are pancreatic sufficient have normal or less-disturbed fatty acid compositions (in plasma phospholipids, cholesteryl esters, triglycerides, nonesterified fatty acids, and erythrocyte lipids) than do individuals who are pancreatic insufficient.[70] Biochemically, EFA deficiency is common in CF; however, unless routinely screened for, it is often not detected as it rarely presents with clinical signs and symptoms.

Pancreatic Enzyme Therapy

Pancreatic enzyme replacement therapy is introduced once clinical evidence of pancreatic insufficiency is confirmed. Due to the progressive nature of CF, individuals who are pancreatic sufficient at diagnosis require periodic assessment of pancreatic function. This can be inferred by knowledge of their genotype and class of their *CFTR* mutation.

Most pancreatic enzyme replacement guidelines[71] recommend using a dietary fat–based dosage to link consumption of grams of fat to units of lipase in the capsules or body weight as a basis and then individualizing the dose based on assessments of efficacy. It is recommended that when commencing pancreatic enzyme replacement therapy (PERT), the minimum dose in the recommended range is used.[71]

Redistribution of pancreatic enzyme capsules over the day, based on the fat content of the foods consumed, has been shown to lead to a significant improvement in the coefficient of fat absorption and hence absorbed energy.[72] Fat-based dosing may assist individuals with CF in achieving the high-energy, high-fat diet recommended by helping to improve patient knowledge of food composition. Patient knowledge, particularly of fat, has been shown to be poor.[73]

Minimum effective doses are recommended in order to decrease the risk of fibrosing colonopathy, which continues to be found in association with "enzyme overdosing."[74] An upper limit of 10,000 IU lipase/kg body weight/day has been recommended to reduce the risk of fibrosing colonopathy. An audit of use of PERT in patients attending CF centers in the United Kingdom (1999-2000) demonstrated that patients on preparations containing 10,000 or 25,000 IU lipase per capsule commonly exceeded recommendation.[75] Further, they reported that use of high-strength PERT increased the risk of overdosing, with two thirds of patients in this group exceeding recommendations compared with one third in the standard-strength preparation group.

Patients with exocrine pancreatic insufficiency require long-term replacement therapy with pancreatic enzyme supplements. Although originally available as powdered pancreatic extracts, most, if not all, pancreatic extracts are prepared today as enteric-coated microsphere or microtablet preparations. The introduction of enteric-coated preparations has increased significantly the efficiency of these enzymes, which work maximally at an alkaline pH and thus, unprotected, would be exposed to significant degradation in their passage through the stomach. In infancy, the capsules containing the microspheres can be opened and administered in a soft non-alkaline food such as applesauce. In infants, enzyme dosing can be based on food intake, starting with 2000 to 4000 lipase units/120 mL formula or per breastfeeding.[76] Beyond infancy, weight-based dosing is more practical. It should begin with 1000 lipase units/kg per meal for children younger than 4 years and 500 lipase units/kg for those older than 4 years.[76] Enzyme dosage expressed as lipase units/kg per meal should be decreased in older patients because they tend to ingest less fat per kilogram of body weight. Usually, half the standard dose is given with snacks. There is great interindividual variation in response to enzymes, so a range of dosages is recommended, based on stool pattern and weight gain. Dosages greater than 2500 lipase units/kg per meal or 10,000 lipase units/kg per day should be used with caution and only if they are documented to be effective by 3-day fecal fat measure. After initiation of enzyme therapy, there should be almost immediate reduction in stool frequency and degree of steatorrhea, improvement in abdominal symptoms, and decrease in appetite. Most patients are able to achieve a coefficient of fat absorption greater than 85%.

Variations in enzyme requirements and patient response may be related to endogenous enzyme output, type of diet, microsphere size, gastric emptying time of microspheres, postprandial duodenal pH, and bile salt concentration.[77] Failure of enzyme release secondary to a low postprandial duodenal pH is probably the major factor leading to inefficient enzyme function.[78] In patients who have persistent steatorrhea (>10% fecal fat loss) despite apparently adequate enzyme dosage, addition of an acid-reducing agent may lead to significant enhancement of fat absorption.[79-82]

Some patients on high-dose enzyme therapy have ongoing abdominal symptoms unrelated to exocrine pancreatic deficiency.[83] In such cases, 72-hour fecal fat measure and evaluation for concurrent gastrointestinal disorders (lactose malabsorption, giardiasis, bacterial overgrowth, celiac disease, Crohn disease) are indicated. The development of constipation in a patient who is taking enzymes may be an indication for increased enzymes. A misguided reduction in enzyme dosage in this situation may precipitate an episode of distal intestinal obstruction syndrome (DIOS).

The most significant complication of pancreatic enzymes is fibrosing colonopathy, a condition associated with the use of high daily doses of enzyme. This diagnosis should be considered in patients who have symptoms of obstruction, bloody diarrhea, chylous ascites, or the combination of abdominal pain with ongoing diarrhea or poor weight gain.[84] Patients at highest risk are those who are younger than 12 years, have taken more than 6000 lipase units/kg per meal for longer than 6 months, or have a history of gastrointestinal surgery or complications.[74,85] Most cases involve the ascending colon, but pancolonic involvement can occur.[84] A barium enema is the most reliable diagnostic measure. Colonic shortening, focal or extensive narrowing, and a lack of distensibility are highly suggestive. Diagnosis is confirmed by biopsy. Bowel wall thickening, which may be a precursor of stricture formation, may be detected by ultrasonography. Most cases of fibrosing colonopathy require hemicolectomy.[86]

NUTRITIONAL MANAGEMENT

The principal aim of nutritional management in CF is the prevention of undernutrition secondary to energy imbalance. This requires both prevention and early interventive treatment, taking into account each individual's energy needs and nutritional status. Intervention is indicated whether nutritional imbalance is a result of either increased resting energy expenditure or decreased nutritional status, and should be instituted sufficiently early enough to prevent inadequate weight gain or a measurable decline in lung function. Comprehensive assessments of body composition, dietary intake, and biochemical markers should be routinely conducted in order to detect deterioration early.

A consensus document on the nutritional assessment and management in CF by Ramsey and associates[87] introduced the concept of anticipatory guidance by specialist CF dieti-

tians. In the review, five response categories for the provision of nutritional support were identified:

1. Routine management of all patients: high energy, high fat, high salt, nutritional education, and dietary counseling; and PERT and vitamin-mineral supplementation for those with pancreatic insufficiency
2. Anticipatory guidance of patients at risk of developing energy imbalance, but who are maintaining adequate nutritional status: energy dense dietary education, close monitoring of dietary intake, and behavioral management counseling
3. Supportive intervention for patients with decreased weight velocity and/or slightly compromised nutritional status: anticipatory guidance plus oral supplements, such as fortified milk drinks and desserts and glucose polymers
4. Rehabilitative care for patients whose nutritional status is compromised: overnight supplementation via an enteral tube
5. Resuscitative and palliative care for patients whose nutritional status is significantly compromised: 24-hour continuous enteral tube feeds and/or total parenteral nutrition, particularly in those awaiting organ transplantation

PANCREATITIS

Approximately 20% of pancreatic-sufficient patients are at risk of developing symptoms of recurrent, acute pancreatitis or chronic pancreatitis.[48] It is postulated that hyperconcentration of pancreatic secretions leads to obstruction of the pancreatic ducts, initiating autodigestion of the pancreas by pancreatic proteolytic enzymes.[88] Patients may present with severe abdominal pain, vomiting, and mid epigastric tenderness. Elevated levels of serum and urinary amylase and serum lipase are present. Increased echogenicity of the pancreas may be seen on ultrasonography.[89] Pancreatic-sufficient patients who develop pancreatitis should be closely monitored for progression to pancreatic insufficiency.

Repeated episodes may occur in patients over several years. Early reports of this occurrence frequently identified individuals as having a mutation on a single copy of the *CFTR* gene but could not rule out the possibility of a second rare mutation. When other hereditary forms of pancreatitis were excluded, however, sequencing analysis of *CFTR* confirmed that increased risk of pancreatitis requires two *CFTR* mutations (or a *5T* allele).[90] Adults who present with pancreatitis and who are found to have two *CFTR* mutations were initially thought to represent a "single-organ" manifestation of CF. Further research, however, has shown that many of these individuals do have extrapancreatic pathology, which may include abnormal sweat test results, congenital bilateral absence of the vas deferens (CBAVD), sinusitis, and chronic bronchial infection.[91]

PANCREATIC ENDOCRINE DEFICIENCY

Islet Cell Pathology

Early pancreatic changes in CF include inspissation of viscid secretions, ductal dilatation, and acinar fibrosis progressing to acinar atrophy, which in combination with fatty cell infiltration characterizes the adult CF pancreas. CF-related diabetes (CFRD) develops in individuals with CF as a consequence of this pancreatic pathology. Islet tissue in ribbon-like strands has been reported in subjects with CFRD. Preservation of islet number is observed in nondiabetic CF subjects; however, a reduction in beta-cell numbers in subjects with CFRD has been reported. Islets from subjects with CFRD show a significant reduction in surface area of insulin-staining cells compared with nondiabetic CF subjects.

Clinical Features

CFRD occurs in about 10% to 15% of all people with CF and increases with age, with a median age of onset of between 18 and 21 years. Lanng and associates[92] found that after 10 years of age, there was an increase in CFRD of 5% per year, with 24% of patients having CFRD by 20 years of age. CFRD generally occurs earlier in females, which is thought to reflect their earlier onset of puberty and the associated increase in insulin resistance that occurs. The incidence of CFRD is also higher in those with CF liver disease.[93]

Diagnosis

Relatively few patients with CFRD are identified by symptoms and diagnostic blood glucose levels. A standardized oral glucose tolerance test (OGTT), interpreted according to accepted international criteria (World Health Organization [WHO], 1999), might be the only means to diagnose diabetes mellitus or impaired glucose tolerance in CF (Table 63-1). Unlike classic type 1 diabetes mellitus, the onset of CFRD is usually insidious, and while many patients may be asymptomatic at diagnosis, a decline in lung function may precede the diagnosis (Table 63-2). Additional difficulty in making the diagnosis may arise as a patient's current clinical status or treatment may alter the glycemic status. A patient who has overt diabetes during an infective exacerbation may develop normal glucose tolerance weeks or months later.[94] Isolated

Table 63-1
Suggested Action on the Results of Routine Oral Glucose Tolerance Test (OGTT)

Possible action on results of screening OGTT	
Normal glucose tolerance (NGT)	Repeat OGTT in 1 year.
Impaired oral glucose tolerance (IGT)	Repeat OGTT in 1 year or sooner if clinical parameters worsen, e.g., lung function, unexplained weight loss.
Diabetic glucose tolerance (cystic fibrosis–related diabetes mellitus [CFRD]) in person who is asymptomatic	Arrange home blood glucose monitoring for 2 weeks with a food/activity diary; if normal, repeat the OGTT within 6 months.

From Management of Cystic Fibrosis Related Diabetes Mellitus: Report of the UK Cystic Fibrosis Trust Diabetes Working Group. Cystic Fibrosis Trust, June 2004.

Table 63-2
Classification of Clinical Categories of Cystic Fibrosis–Related Diabetes Mellitus (CFRD)

Stage of Disease	Premeal Sugar Levels	Postmeal Sugar Levels	Symptoms	Microvascular Complication Risk	Treatment
Reactive hypoglycemia	Normal	Low	Hypoglycemia	Unknown—likely to be very low	
Impaired glucose tolerance	Normal	Intermittently raised	None or weight loss or clinical decline	Unknown—likely to be low	Consider insulin or tablets with meals
CFRD without fasting hyperglycemia	Normal	Mostly raised	None or thirst, polyuria, weight loss, or clinical decline	Unknown—likely to be related to duration, control, and risk factors	Insulin or tablets with meals
CFRD with fasting hyperglycemia	Mostly raised	Mostly raised	Thirst, polyuria, weight loss, or clinical decline	Unknown—likely to be related to duration, control, and risk factors	Insulin or tablets with meals

From Management of Cystic Fibrosis Related Diabetes Mellitus: Report of the UK Cystic Fibrosis Trust Diabetes Working Group. Cystic Fibrosis Trust, June 2004.

random fasting or 2-hour postprandial plasma glucose, glycosylated hemoglobin, and first-phase insulin response to glucagon stimulation, or combinations are not thought to be sufficiently reliable as diagnostic tools in establishing CFRD. Some studies have shown that a normal Hb_{A1c} can be found in up to 70% of patients in whom diabetes is confirmed on an OGTT.

Management

Extensive reviews of CFRD management have been published and are beyond the scope of this chapter. The 2004 guidelines from the UK Cystic Fibrosis Trust Diabetes Working Group summarized its recommendations to include the following (see also Table 63-3):

1. Treatment should be aimed at correcting symptoms of hyperglycemia and maintaining adequate nutrition, growth, and respiratory function and should be initiated in patients with a diabetic OGTT and/or regular hyperglycemia.
2. Treatment should also be considered in the presence of an impaired OGTT when there is associated weight loss or deteriorating clinical condition or with hyperglycemia.
3. Insulin remains the preferred treatment, although oral tablets may be used in some patients initially or where there are practical issues with taking insulin. Regular blood glucose monitoring is an essential part of therapy.
4. A diet advised by a dietitian with CF experience will be high in energy and high in fat and include well-planned use of refined carbohydrates. The insulin dosage should be adjusted to the diet rather than the diet adjusted to the insulin.[95]

Long-term microvascular complications occur in CFRD, including retinopathy, nephropathy, and neuropathy. In a study of 311 patients with CF, microvascular complications were identified in 10% of patients with CFRD with duration of diabetes mellitus of 1 to 7 years.[96] Similar studies have reported incidences of up to 20% to 30%.[97] All patients with CFRD should have annual screening to identify any such complications.[95]

Table 63-3
Management of Cystic Fibrosis–Related Diabetes Mellitus

Energy	Individualized 120% to 150% or normal depending on nutritional state
Fat	40% of total energy
Refined sugars	Allow throughout the day
Carbohydrate	45% to 50% of total energy
Dietary fiber	Encouraged in the well nourished, but in poorly nourished patients may compromise energy intake
Protein	200% of reference nutrient intake (RNI)
Salt	Increased requirement
Snacks	Ad libitum

HEPATOBILIARY DISEASE

Liver Pathology

Liver disease, although included in the initial description of CF, accounts for a small percentage of morbidity of the disease. Advances in the management of the pulmonary complications of CF may result in an increasing prevalence of a number of hepatic and biliary abnormalities, which may, therefore, become more important in the long-term management of CF patients. While liver involvement in CF was first described over 50 years ago, the increased survival into adulthood of many CF patients has been associated with an increase in clinically relevant liver dysfunction.[98]

Symptomatic liver disease is still considered uncommon and the cause of death in less than 2% of patients, but typical bilary cirrhosis has been reported in up to 50% of postmortem studies and in approximately 25% of adults.[6,99,100]

The characteristic lesion seen in CF is focal bilary fibrosis with inflammatory cell infiltration, bile duct proliferation, and patchy accumulation of eosinophilic material. The CFTR has been located in the apical membrane of intrahepatic bile duct cells, and the resultant abnormalities in chloride transport are believed to be responsible for the failure to adequately hydrate the canalicular-produced bile, resulting in increased bile viscosity. There is evidence that the increased

bile viscosity is due, in part, also to an increased production of mucus by the intrahepatic biliary epithelial cells.[101]

Prolonged Neonatal Jaundice

Neonates with CF may present with prolonged obstructive jaundice, presumably secondary to obstruction of extrahepatic bile ducts by thick bile along with intrahepatic bile stasis (inspissated bile syndrome).[102] In most cases, liver histology shows features compatible with bile obstruction. The liver is usually enlarged and firm. Approximately 50% of cases occur in association with meconium ileus or delayed passage of meconium. The prognosis for patients with neonatal cholestasis is generally good, although elevated bilirubin values may persist for up to 7 months and early-onset liver failure or cirrhosis may develop.[102] In some patients, the biliary obstruction can be relieved by intraoperative irrigation of the biliary tree with saline and *N*-acetylcysteine.[103]

Cirrhosis and Portal Hypertension

Most patients with CF develop mild liver abnormalities including slightly elevated liver biochemical tests, hepatosteatosis, and focal areas of portal tract disease (biliary plugging with eosinophilic material, bile duct proliferation, and cholangitis). Only a small proportion of CF patients, most of whom have classic CF, develop CF-related liver disease (CFLD) with multilobular cirrhosis leading to portal hypertension and hypersplenism. The median age at diagnosis of CFLD is 9 to 10 years, and most cases of CFLD are diagnosed by mid adolescence. Because the ability of the liver to synthesize proteins, metabolize toxins, and secrete bile tends to remain intact for many years and even decades, most complications of CFLD are attributable to the consequences of portal hypertension. A number of putative modifier genes of CFLD have been reported, but, in a recent study of a larger number of patients with severe CFLD, only two candidate genes (the *Z* allele for α_1-antitrypsin deficiency and polymorphisms of transforming growth factor [TGF]-β1 with increased expression) were shown to be statistically associated with CFLD.

Gallbladder

Approximately 25% of CF patients have a nonfunctioning gallbladder, with anatomic abnormalities present in approximately 33% of patients with CF.[104,105]

A variety of abnormalities may occur including nonvisualization of the gallbladder on oral or intravenous cholecystography, cholecystitis, and radiolucent gallstones, with an increasing incidence with age. In one postmortem study, gallstones were found in 24% of adult patients with CF. A more recent study in children with CF found anomalies of the gallbladder, including absence or microgallbladder or stones, in 24% of 48 patients studied.[106-110]

The high incidence of gallstones, which are almost universally radiolucent, has been related to biliary stasis, increased bile viscosity, and abnormalities of bile salt metabolism.[110] Analysis of gallstones removed from CF patients has shown that they are mainly composed of calcium, bilirubinate, and proteinaceous material.[111] Most CF patients with gallbladder abnormalities are asymptomatic. In a large series, only 24 (3.6%) of 670 patients developed symptomatic disease.[109] All but one of these patients had exocrine pancreatic deficiency and all but one was older than 12 years. In patients with typical biliary colic, cholecystectomy leads to total cessation of symptoms, whereas in patients with atypical symptoms the results of cholecystectomy are often equivocal. Laparoscopic cholecystectomy under continuous epidural anesthesia is preferred, especially in patients with severe pulmonary disease.[112]

GASTROESOPHAGEAL REFLUX

Gastroesophageal reflux (GER) is multifactorial in origin in patients with CF. While significant lung disease may predispose to increased GER due to the generated negative intrathoracic pressures, reflux is not infrequently seen in patients with well-preserved lung function. Other contributing factors that may predispose to GER include the use of pharmacologic agents known to reduce the tone of the lower esophageal sphincter, including salbutamol and aminophylline, and head-down positions during physiotherapy.[113,114]

GER has been documented in approximately 80% of unselected patients with CF younger than 5 years and 75% of symptomatic patients older than 4 years.[115,116] There is evidence that, particularly in young infants, chest physiotherapy can induce episodes of reflux, particularly in the head-down position; however, other investigators have failed to confirm these findings.[117,118] Presenting symptoms include upper abdominal pain, epigastric or substernal burning, vomiting, hematemesis, dysphagia, failure to thrive, or pulmonary disease that does not respond to usual therapy.[116,119] Esophageal strictures secondary to chronic esophagitis have been reported.[120]

Infants with reflux and/or secondary esophagitis may present with irritability, vomiting, regurgitation, poor oral intake, and growth failure. The diagnosis is suspected clinically and then confirmed by prolonged intraesophageal pH monitoring, upper gastrointestinal endoscopy, and esophageal biopsy. An upper gastrointestinal series may be necessary to exclude an anatomic lesion.

Treatment must be tailored to the individual patient, but may include frequent small meals, positioning, antacids, H_2 blockers, or proton pump inhibitors. Most centers would recommend, particularly in young infants, the avoidance of head-down tilting during chest physiotherapy despite the apparent conflicting evidence.[117,118]

The prokinetic agent cisapride, which increases the tone of the lower esophageal sphincter and which had been shown to be effective in young CF patients with GER, is now not generally available because of its potential effect on the cardiac QT interval.[115] When medical management fails, a Nissen fundoplication may be indicated, although published experience with surgical correction of reflux in CF is sparse.

PEPTIC ULCER DISEASE

CF patients have been shown to have acid hypersecretion on pentagastrin testing, and with the additional lack of pancreatic bicarbonate secretion, it is not surprising that there is an increased risk of peptic ulcer disease.[121] This combination will produce a duodenal pH significantly more acidic than

that of non-CF individuals, with second part duodenal pH recordings of between 5.5 and 6.5 compared with pH levels of about 7.0 in non-CF individuals.[78]

In an often-quoted series of 146 CF cases, 8% of patients showed peptic ulcerations involving the stomach and duodenum at postmortem; however, at least part of these lesions are now believed to be terminal events. In addition, many of the symptoms attributed to peptic ulcer disease, such as epigastric pain, nausea, or anorexia, may be attributable to reflux rather than to peptic ulcer disease.

The combination of gastric hypersecretion and diminished pancreatic bicarbonate secretion and the resultant hyperacidic duodenal pH has direct influence on the efficiency of pancreatic enzyme therapy, as a pH above 5.8 is required for dissolution of the enteric coating. In addition, the contained pancreatic enzymes are irreversibly destroyed by exposure to a pH of below 4.0. Manipulation of the duodenal pH by acid-modifying agents has been shown to not only improve GI symptoms but also directly improve pancreatic enzyme efficiency and fat absorption.[78,79]

The causative role of *H. pylori* in gastroduodenal disease in the CF population remains largely unknown. The overall seroprevalence of *H. pylori* in patients with CF has been described in earlier studies as similar to that in non-CF control subjects[122]; however, other investigators have failed to confirm this relationship.[123] Przyklenk and colleagues[122] recently showed cross-reactivity between solid-phase *H. pylori* antigens and anti-*Pseudomonas* antibodies occurring in patients with CF, which means that serologic detection of *H. pylori* infection may be overrepresented in CF populations.

DISTAL INTESTINAL OBSTRUCTION SYNDROME

DIOS, previously called "meconium ileus equivalent," refers to episodes of abdominal pain due to partial or compete intestinal obstruction with abnormally viscid mucofeculent material in the terminal ileum or the ascending colon. It is caused by the impaction of mucofeculent material in the distal ileum, cecum, and proximal colon and increases in frequency with increasing age. It is estimated to occur in some 2% of patients younger than 5 years, increasing to 27% of patients over the age of 30 years. Some 7% to 15% of patients beyond the neonatal period are believed to have experienced episodes of DIOS.[124,125] While much more common in pancreatic-insufficient patients, there have been several reports of its occurring in patients with pancreatic sufficiency.[126,127] Contributing factors include abnormal intestinal mucins, undigested food residues, prolonged intestinal transit time, low dietary fiber content, bowel dilation, and abnormal intestinal electrolyte and water transport. Clinical manifestations include crampy lower abdominal pain, distention, vomiting, anorexia, abdominal tenderness, and palpable masses in the right lower quadrant. Episodes may occur within a normal stooling pattern, even during symptomatic periods. There may be progression to complete obstruction, volvulus, or intussusception. Patients may have isolated episodes with long symptom-free periods or chronic symptoms with intermittent exacerbations. The differential diagnosis includes intussusception, volvulus, appendicitis, esophagitis, peptic ulcer disease, gallbladder disease, pancreatitis, and other non–CF-related conditions. Most cases of DIOS will be suspected on the basis of the history and physical findings. Abdominal radiographs show dilated small bowel loops with a bubbly, granular appearance in the area of the ileum and cecum consistent with retained stool.[128]

When significant impaction is present, without complete obstruction, the treatment of choice is the administration of a balanced intestinal lavage solution (GoLYTELY) orally or by nasogastric tube.[129] Effective therapy may take 4 to 6 hours. The end point of therapy is determined by passage of stool, resolution of symptoms, and disappearance of a previously palpated right lower quadrant mass. If there is complete obstruction or peritoneal irritation, surgical intervention is indicated.[130]

Intussusception

Intussusception is estimated to be up to 10 times more common in those with CF than in the general population, with a risk of around 1%.[131] The true incidence may be unknown because some cases, particularly ileoileal intussusceptions, have been reported to reduce spontaneously.[132] There is a bimodal distribution for intussusception in CF and a male preponderance as reported for non-CF cases. After intussusception of infancy, a second peak occurs in CF at around 10 years of age. Cases occurring in older children and adults have also been reported.[133,134] In older patients, lead points such as polypoid lesions have been identified. In addition, intussusception may complicate DIOS, whereby a tenacious fecal bolus adheres to the mucosa and acts as a lead point[134] (Fig. 63-1). The appendix, often enlarged and distended secondary to inspissated mucofeculent contents, may also act as a lead point in producing intussusception in CF.[135]

Patients usually present with the acute onset of intermittent crampy abdominal pain, often accompanied by vomiting. Other manifestations include a palpable abdominal mass, rectal bleeding, and decreased or absent bowel movements. Atypical or chronic symptoms occur in 25% of patients with intussusception.[131] Most episodes are ileocolic, but ileoileal,

Figure 63-1 Transverse ultrasound image of intussusception in left flank demonstrating typical "target" sign.

Figure 63-2 Air enema reduction of intussusception. The intussusception is present in the region of the hepatic flexure.

ileocecal, colocolic, and even appendiceal locations have been reported.[136] The diagnosis is usually confirmed by contrast enema, but in some cases is made only at laparotomy. Hydrostatic reduction may be successful, but most cases require surgical correction[131,132] (Fig. 63-2).

APPENDICEAL DISEASE

In patients with CF, there are typical histologic findings in the appendix.[137] The number of goblet cells is increased, and they are often markedly distended with mucus secretions. The crypts are dilated and appear wider, and at times deeper, because of distention of the lumen by accumulated secretions. Eosinophilic casts of the crypts may extrude into the lumen of the appendix. Inspissated secretions may extrude through the orifice of the appendix to form a local cecal mass. There is little or no cellular infiltration, and the muscularis layer is not affected. The diagnosis of CF has been suggested by the histologic appearance of an appendix removed from some patients with acute or recurrent/chronic abdominal pain.[138,139] An asymptomatic right lower quadrant mass secondary to mucoid impaction of the appendix has been described as a presenting manifestation of CF.[140] The reported incidence of acute appendicitis in patients with CF is only 1% to 2%, compared with a rate of 7% in the general population.[141] This may be accounted for by the long-term use of antibiotics in many patients with CF. Patients with CF who have acute appendicitis may present with classic symptoms, but the diagnosis is often delayed because of an atypical or a subacute presentation and confusion with DIOS.[141,142] At laparotomy, a high percentage of patients show appendiceal perforation and periappendiceal abscess formation.[143]

Clinically, CF patients with acute appendicitis have right lower quadrant pain, nausea, and anorexia. Fever and change in stool frequency may or may not be present. The initial diagnosis is usually DIOS. Abdominal ultrasound and gallium scans generally are not helpful in establishing a diagnosis.[141]

A contrast enema may be helpful if it shows extrinsic cecal compression or appendiceal filling. However, failure to visualize (fill) the appendix before or after evacuation of contrast material cannot be used as a sign of appendicitis in patients with CF.[144] Failure of visualization is most often related to mucus plugging of the appendiceal lumen. The possibility of an appendiceal abscess should be considered when a patient with CF presents with pain, a mass, or drainage from the right flank; prolonged fever; a limp; or failure of suspected DIOS to respond to appropriate therapy.[145] In patients with DIOS, abdominal radiographs usually show extensive stool accumulation and the white blood cell count is normal or only mildly elevated. Abdominal computed tomography may be a useful diagnostic tool. Treatment usually involves surgical drainage and intravenous antibiotics followed by an elective appendectomy.

MECONIUM ABNORMALITIES

Meconium Ileus

Meconium ileus, in which intraluminal intestinal obstruction is secondary to inspissation of tenacious meconium in the terminal ileum, occurs in approximately 18% of newborns with CF.[146] With rare exception, almost all full-term infants with meconium ileus eventually have a confirmed diagnosis of CF. There is a strong familial trend for the occurrence of meconium ileus, with a recurrence rate of 29% to 39% in subsequent CF-affected siblings.[147] There is evidence that meconium ileus is, in part, genetically determined. There is a decreased risk in patients who carry R117H, A455E, or other mild mutations that confer pancreatic sufficiency, and an increased risk in patients who carry certain severe mutations or modifier genes that have an impact on the CF alleles.[148]

Affected infants present within the first 48 hours of life with abdominal distention, bilious vomiting, and failure to pass meconium. There may be a maternal history of polyhydramnios. Approximately 50% of cases are complicated by volvulus, atresia, perforation, ischemic necrosis, meconium peritonitis, or pseudocyst formation.[149,150] The diagnosis of meconium ileus is supported by abdominal radiography that shows distended loops of bowel, usually without air-fluid levels, and a granular ground-glass appearance in the area of the terminal ileum, indicating the mixture of air bubbles with meconium (soap-bubble sign). Contrast enema shows an unused microcolon (Fig. 63-3). In the presence of meconium peritonitis, there may be flecks of intraperitoneal calcium throughout the abdomen. The presence of abdominal calcification, is usually associated with non-CF causes of meconium peritonitis; conversely, the absence of calcification favors CF as the cause of meconium peritonitis.[151]

The diagnosis of meconium ileus and meconium peritonitis can be made prenatally by ultrasonography. In several cases, the obstruction has been relieved by intrauterine amniography with urografin.[152] In the absence of complications,

Figure 63-3 Small-caliber colon with filling defects throughout the colon and rectum, largest one in the ascending colon causing obstruction and proximal small bowel dilatation. The contrast could not be passed beyond the distal ascending colon. These features are in favor of meconium ileus.

up to 50% of cases can be treated successfully by the administration of hyperosmolar (Gastrografin) or iso-osmolar contrast enemas under fluoroscopic control.[150] During this therapy, the patient's fluid and electrolyte status must be monitored closely to prevent hypovolemia. Repeated attempts to evacuate meconium may be required. If the patient's condition remains stable without change in abdominal findings, therapeutic enemas can be repeated over several days. The procedure may be complicated by intestinal perforation in up to 15% of cases.[153]

Patients who have complications of meconium ileus or do not respond to nonoperative therapy require surgical intervention. In some instances, the inspissated meconium can be cleared by intraoperative irrigation with acetylcysteine, hyperosmolar contrast, or saline.[154,155] If irrigation is unsuccessful or if there are complications, patients are managed by resection of the involved bowel followed by primary anastomosis or a temporary double-barrel (side-by-side) enterostomy. After surgery, patients will require a period of total parenteral nutrition followed by intensive enteral nutritional support. In patients with a history of meconium ileus, there is earlier acquisition of *P. aeruginosa*. Although previously shown from an unscreened population that at ages 8 and 13 years pulmonary function was similar in patients with and without meconium ileus,[156] a more recent study from a screened population has shown that although there were no differences between those patients born with meconium ileus and those detected by newborn screening with regard to height, weight, incidence of liver function abnormalities, frequency of hospitalization, and airway microbiological colonization, patients born with meconium ileus had a significantly lower FEV_1 and FVC as well as a lower Shwachman chest radiograph score.[156,157] Long-term survival among males and females with meconium ileus is similar to that of females without meconium ileus but significantly shorter than that of males without meconium ileus.[156,157]

Meconium Plug Syndrome

First described in 1956, meconium plug syndrome (MPS) describes a condition occurring in very young infants who present with transient large bowel obstruction relieved by the passage of meconium plugs. Although initially considered a distinct condition in its own right, MPS has since been reported as a presenting feature of Hirschsprung disease or CF.[158] There also appears to be some overlap with small left colon syndrome (SLCS), a condition reported in infants of diabetic mothers (IDDM) in whom contrast enema shows a narrow left colon.[159] In one series, MPS occurred in 12 of 87 newborns (14%) with CF in the absence of meconium ileus, and in another series, 43% of newborns who presented with MPS eventually had a diagnosis of CF made.[158,160] It is likely that MPS and meconium ileus represent gradations of the same underlying abnormality, differing only in degree of severity and site of obstruction. In general, MPS is a benign condition usually relieved following anal stimulation, administration of enemas, or a diagnostic contrast enema. The success of nonoperative treatment is probably a result of the lower site and significantly easier removal of the obstructing meconium in infants with MPS compared with those with meconium ileus.

RECTAL PROLAPSE

Rectal prolapse in CF was much more common in the years immediately following Andersen's original description of CF in 1938 than it is currently, due in a large degree to improved nutrition and more efficient pancreatic enzyme therapy. The introduction of newborn screening programs for CF has also significantly reduced the incidence of rectal prolapse. In unscreened populations, rectal prolapse occurs in approximately 20% of patients with CF, usually between 6 months and 3 years of age, and may precede the diagnosis of CF.[161]

The prolapse may involve only the mucosa (mucosal prolapse) or all layers of the rectum (complete prolapse or procidentia). Predisposing factors in CF include increased intra-abdominal pressure secondary to chronic coughing, diarrhea, malnutrition, and pelvic floor weakness. The treatment of rectal prolapse is mainly conservative and includes optimization of pancreatic enzyme therapy, high-fiber diet, and improved nutrition. Surgical intervention may be required for recurrent rectal prolapse refractory to conservative measures; however, in CF, this is rarely required. A simpler, less invasive, approach for refractory cases may be perirectal injection with a sclerosing agent.[162]

MISCELLANEOUS AND ASSOCIATED INTESTINAL ABNORMALITIES

Cancer

Twenty years ago, Abdul-Karim and associates[163] described a CF patient with cancer, an adult with an extrahepatic biliary tract cancer. Since that initial report and as more CF patients reach adulthood, additional reports have described CF patients with adenocarcinomas of the pancreas,[164-166] ileum,[167,168] and bowel,[169] as well as leukemia[170] and neuroblastoma.[171]

In 1993, Sheldon and colleagues[172] conducted the first cohort study of the association of CF with malignancy and observed a possible association of CF with adenocarcinoma of the pancreas and of the terminal ileum, but only a single case was observed in each organ. In 1995, data from the CF databases of North America and Europe were interrogated for cases of cancer, and an overall increase in the number of digestive tract cancers was observed.[173] Subsequently, cases of colon cancer[174] and embryonal carcinoma of the testis[175] in CF patients have been reported. In a review from the U.S. CF database in 2003 describing over 28,000 CF patients with a total of 202,999 person-years of observation between 1990 and 1999, 75 cancers were observed in nontransplanted CF patients. Of these, 69.7 would have been expected. Twenty-three digestive tract tumors were observed, with some five expected. More cancers than expected were observed of the small bowel, colon, and biliary tract but not of the stomach or rectum.[176]

Celiac Disease

Gluten sensitivity leading to small bowel villous atrophy, as in celiac disease, may be present in CF; however, evidence does not support the previously held belief of an increased risk of celiac disease in patients with CF.[177] Lloyd-Still suggested that the incidence of celiac disease is in fact closer to 10 times less frequent in the CF population than the general population.[178]

Clostridium difficile Infection

Patients with CF have a high rate of C. *difficile* carriage compared with normal children, most likely the result of more widespread use of broad-spectrum antibiotics. Infection may extend from asymptomatic carriage to severe disease such as pseudomembranous colitis with complications including toxic enterocolitis or megacolon. It is unclear whether subclinical infections contribute to malabsorption in patients with CF by causing direct mucosal damage or whether patients with CF develop acquired tolerance to C. *difficile* toxin.[48]

Crohn Disease

In patients with CF, there is evidence of increased small intestinal permeability, probably because of the leakage of large molecules (disaccharides) through paracellular pathways. This increased intestinal permeability is probably related to underlying pancreatic dysfunction. The passive transcellular uptake of small molecules is preserved. Orocecal transit time has been shown to be prolonged in both children and adults with CF.

Crohn disease is another multigenic disease that is said to occur with increased frequency in CF. In a study of over 11,000 CF patients, Lloyd-Still[178] found that there were 28 patients with inflammatory bowel disease including 25 with Crohn disease and 3 with ulcerative colitis. These figures suggest an overall increased prevalence rate of inflammatory bowel disease in CF of 7 times that of controls, with Crohn disease being 17 times more prevalent in CF patients than in controls.

Genetic mapping studies have isolated an important susceptibility gene (*NOD2*) as well as a number of Crohn susceptibility loci on chromosomes 1, 5, 6, 12, 14, 16, and 19.[179] As with celiac disease, it has been postulated that Crohn disease may become manifest in a genetically susceptible individual as a result of one or more second "hits." Aberrant immunologic interactions with gut microflora, pathogenic bacteria, or bacterial antigens are all hypothesized as examples of second hits. It is possible that CF disease increases susceptibility to Crohn disease through an unknown CF-related intestinal mechanism. Possibilities include increased intestinal permeability and inflammation, alterations in the intraluminal environment resulting from maldigestion, the presence of bacteria in the small intestine, or changes in gut microflora.[48]

Intestinal Permeability, Transit Time, and Absorption

In general, small intestine biopsy samples from patients with CF show normal histology; however, there may be a thick mucus cover over the brush border membrane.[180] CFTR expression in the intestinal epithelium is relatively high and is highest in the duodenum. Through the small intestine, CFTR expression decreases steadily and is lowest in the colon. CFTR is uniformly high in the crypts, suggesting that all cell types—goblet cells, Paneth cells, and undifferentiated epithelial cells—express similar levels of CFTR. CFTR expression decreases toward the tips of the villi, and only a weak signal is detected on the top one third of the villi.[180] While absorption of metabolically inert saccharides such as xylose and mannitol have been shown to be absorbed at a normal rate in CF patients, other disaccharides have been shown to be taken up at a faster rate by CF small intestinal mucosa. In addition, Mack and associates[181] were able to show a direct relationship between intestinal lactulose permeability and the degree of exocrine pancreatic dysfunction. Enzyme-depleted small intestinal villi are present in some patients. This may be a result of impaired maturation secondary to nutritional deficiencies or failure of enterocytes to increase their brush border enzymes secondary to impaired absorption of nutrients.[180]

CARDIOVASCULAR COMPLICATIONS

Evaluation of Cardiac Status

Cor pulmonale secondary to chronic hypoxemia is a common complication in CF patients with advanced pulmonary disease and remains a significant cause of morbidity and mortality. In addition, a number of other cardiovascular complications have been documented.

Physical Examination

The early clinical recognition of cor pulmonale may be difficult in patients with CF.[182] Tachypnea, tachycardia, and hepatomegaly are common secondary to underlying pulmonary disease. However, an enlarged tender liver is often an early clue to right ventricular failure.[183] An accentuated second heart sound in the pulmonic area may be a helpful sign but is often blunted by an anterior chest wall deformity

and air trapping. Patients may develop a tricuspid insufficiency murmur, either during or shortly after the onset of cardiac enlargement. Peripheral edema is not a common finding and, when present, appears late in the clinical course. In patients with heart failure, weight loss is as common as weight gain.[183]

Laboratory Findings

The degree of hypoxemia and pulmonary artery pressure are closely correlated. A PaO_2 below 50 mm Hg and PCO_2 above 45 mm Hg are consistently associated with severe cor pulmonale.[184,185] Hypoalbuminemia secondary to expansion of plasma volume may be a helpful early clue to right ventricular failure.[186]

Chest Radiography

Estimation of heart size may be difficult to determine on plain chest radiography because of severe air trapping. In general, there is poor correlation between echocardiographic findings and cardiothoracic ratio.[187] Cardiomegaly may be obvious only in patients with overt right heart failure. There may be enlargement of the main pulmonary arteries, but this is often obscured by significant hilar lymphadenopathy and surrounding parenchymal disease.

Electrocardiogram

Electrocardiographic recording may document right ventricular hypertrophy, right atrial hypertrophy, or right-axis deviation in patients with CF; however, these changes are generally nonspecific and the electrocardiogram (ECG) is usually normal in CF patients with right ventricular enlargement.[188] Significant evidence of right ventricular hypertrophy may be difficult to detect due to chest hyperinflation and abnormal positioning of the heart relative to the chest wall. Several authors do not believe the ECG to be a reliable indicator of right ventricular disease in CF.[182,189]

Echocardiogram

Studies using two-dimensional imaging of the right ventricle in CF have given conflicting results, with some studies showing increased right ventricular dimensions that correlate with a patient's clinical score, whereas others have reported normal right ventricular dimensions in patients with severe lung disease.[187,190,191]

Right ventricular free wall thickness has been used as a marker of right ventricular dysfunction and has been found to be increased in patients with CF, possibly reflecting underlying pulmonary hypertension.[187,192]

Radionuclide Scans

Radionuclide angiography has demonstrated reductions in both right and left ventricular ejection fractions. Reduction in right ventricular ejection fraction has been shown to parallel disease severity with Burghuber and associates[193] demonstrating an inverse linear correlation between right ventricular ejection fraction and afterload, as assessed by mean pulmonary artery pressure and pulmonary vascular resistance.

Cor Pulmonale

The combination of alveolar hypoventilation, chronic hypoxemia, and pulmonary vasoconstriction will result in up to 70% of patients eventually developing pulmonary hypertension and hypertrophy of the right ventricle (cor pulmonale).[194] A clear relationship has been demonstrated between the degree of hypoxemia and pulmonary artery pressure. Echocardiography is the most sensitive noninvasive technique for the early recognition and monitoring of cor pulmonale.[194] For practical purposes, cor pulmonale is assumed to be present when one or more of the following is present: right ventricular hypertrophy on ECG, PaO_2 less than 50 mm Hg, signs of heart failure, radiographic evidence of enlarged pulmonary arteries, and forced vital capacity greater than 60% predicted. After the onset of right-sided failure, most patients are significantly disabled and mean survival is 8 months (range, 1 to 63 months).[183] The presence of pulmonary hypertension has been cited as one of the referral criteria for transplantation in CF patients.[195]

ENDOCRINE AND METABOLIC COMPLICATIONS

Thyroid Gland

The demonstration of expression of CFTR in the thyroid epithelium has raised the possibility of an intrinsic abnormality in thyroid glandular cells and the possibility that changes in the metabolic activation of thyroid follicular cells lead to alterations in colloid secretion. CFTR protein has been described in approximately two thirds of thyroid follicles, but only 16% of follicular cells were positive per follicle, suggesting phase-specific expression of CFTR. Several roles for the function of CFTR in thyroid epithelium have been postulated, including promoting iodide secretion into the thyroid follicles or regulation of electrolyte and fluid transport.[196]

Thyroid function impairment has been sporadically described in CF and ascribed to iodine overload or selenium deficiency.[197] Volta and colleagues[198] evaluated thyroid function in CF in 17 young adult CF patients and 18 age-matched controls and found normal serum levels of TSH, free T_3, and free T_4 in the CF group. Within the CF group thyroid function did not vary in relation to C-reactive protein serum levels, respiratory function, or clinical condition as described by the Shwachman score.

RENAL ABNORMALITIES

Several studies have identified the presence of CFTR in the kidney, and its mRNA has been detected in all nephron segments by reverse transcription–polymerase chain reaction (PCR).[199] CFTR has been demonstrated in the proximal tubule, thin limbs of Henle's loop and luminal membrane of the distal tubule, cortical collecting ducts, and the inner medullary collecting ducts by immunocytochemistry.[200] CFTR has also been detected in the proximal and distal tubules and in cortical and inner medullary collecting ducts.[201] Despite this high expression of CFTR, patients do not show major renal dysfunction, but it is known that the renal excretion of some drugs, particularly antibiotics, and the renal capacity to concentrate and dilute urine are deficient.[199]

Nephrolithiasis has been shown to be increased in CF patients. Chidekel and Dolan[202] found a cumulative incidence of 5.7% in a group of 140 patients. The majority of patients had calcium oxalate stones. An additional 4% of patients showed calcium oxalate crystaluria. All patients had pancreatic insufficiency in keeping with the description of hyperoxaluria in other groups of patients with gastrointestinal diseases and associated fat malabsorption.[202]

Increased renal clearance and subsequent lower serum concentrations of a number of antibiotics, including aminoglycosides, beta-lactam antibiotics, and quinolonones, have been reported. It is believed that the increased clearance is due to impaired tubular reabsorption secondary to alterations in the renal tubular ion-transport mechanism.[203]

ELECTROLYTE ABNORMALITIES

Metabolic Alkalosis

Increased electrolyte loss in the sweat over a prolonged period of time may lead to electrolyte depletion and chronic metabolic alkalosis. Contributory factors include increased gastrointestinal losses, acute intercurrent illness, thermal stress, and limited electrolyte intake. While standard infant feeding recommendations satisfy electrolyte requirements for growth of non-CF infants, they are inadequate to compensate for the increased electrolyte losses present in infants with CF.[204]

Sodium losses of up to 80 mEq and chloride losses of up to 100 mEq have been reported in infants in situations of profuse sweating.[205] Such complications are more frequent in arid climates.[206] Patients often present with anorexia, irritability, vomiting, and failure to thrive, usually in the absence of dehydration or cardiovascular instability. Laboratory abnormalities include elevation of blood pH and P_{CO_2}, bicarbonate and base excess, and low serum concentrations of sodium, chloride, and potassium. Urinary excretion of sodium and chloride is markedly decreased as a result of secondary hyperaldosteronism.[207] Preventive measures include avoidance of thermal stress and provision of adequate salt in the diet. This can be accomplished by adding $^1/_4$ teaspoon table salt (23 mEq sodium) to each liter of infant formula or liberal amounts of salt to solid foods. Treatment consists of the replacement of calculated fluid and electrolyte losses.

FEMALE REPRODUCTIVE TRACT

Genital Abnormalities

Excess cytoplasmic and extracellular cervical mucus is present in patients with CF in the absence of inflammation or other obvious contributory factors. This is a consistent finding in newborns, and although it decreases in frequency, it remains a common finding throughout infancy and childhood.[208] The submucosal glands, uterine cavity, and cervical os may also be filled with mucin-rich material. In one third of adult patients, multicystic ovaries and reduced uterine size are demonstrated on ultrasonography, especially in patients with amenorrhea or irregular menstrual cycles.[209] The histologic appearance of the endometrium, fallopian tubes, and ovaries is otherwise normal.[208]

Analysis of cervical mucus reveals that it is scanty and dehydrated, usually containing less than 80% water.[210] This is below the minimum critical water level of 93% to 95% believed to be essential for sperm migration.[211] Moreover, the typical mid cycle increase in water content and the accompanying thinning of cervical mucus that occur in normal subjects are not seen in patients with CF. This may result in the formation of a tenacious mucus plug in the os that impedes sperm penetration. The electrolyte pattern of the cervical mucus is noncyclic; the average sodium concentration in the dry residue is only one tenth of normal during the critical mid cycle period.[210]

Male Infertility

The majority of men (>95%) with CF have associated congenital bilateral absence of the vas deferens. This abnormality is directly associated with the genetic mutation in the CFTR-regulated gene as the encoded cyclic adenosine monophosphate–regulated chloride channel abnormalities influence the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two thirds of the epididymis. The anomalies associated with the latter include absent or atrophic seminal vesicles, ejaculatory ducts, and the body and tail of the epididymis in addition to the absence of the vas deferens. Rare case reports of fertile men with CF mutations and mild symptoms of CF have been reported; however, most patients present with azospermia and infertility.[212]

While absence of the vas deferens is not amenable to surgical correction, the advent of assisted reproductive techniques (ARTs) has permitted sperm harvesting from either the epididymis or the testes in combination with oocytes retrieved from the female partner, thus allowing men with CF to be biological parents. The techniques for aspirating sperm include microsurgical epididymal sperm aspiration (MESA), percutaneous epididymal sperm aspiration (PESA), and testicular sperm aspiration (TSA). MESA yields the most sperm and therefore is the preferred method. Aspirated sperm are cultured directly with retrieved oocytes from the female partner in an in vitro fertilization (IVF) system, or an individual sperm is injected directly into the oocyte. This latter technique, referred to as intracytoplasmic sperm injection (ICSI), yields a greater pregnancy rate in the CF setting than does standard IVF.[213]

Hubert and associates[214] reported that of 19 couples undergoing IVF/ICSI because of congenital absences of the vas, 12 (62%) achieved a pregnancy, including 2 ectopic pregnancies, 2 spontaneous abortions, 1 termination of pregnancy for polymalformed twins, and 11 single deliveries in nine couples. Similar results were given in the report by Phillipson and colleagues,[215] in which fresh and cryopreserved sperm were used for ICSI. Of 29 cycles with fresh spermatozoa, a fertilization rate of 76% of oocytes injected and a 17% embryo implantation rate occurred. Twenty-four cycles in which cryopreserved spermatozoa were used resulted in an oocyte fertilization rate of 69% and an embryo implantation rate of 20%. Eighteen clinical pregnancies occurred with 14 live births without congenital anomaly. Multiple pregnancies are a frequent occurrence with this technique.

Female Fertility

CFTR is found in large quantities on the cervix and, although anatomically normal, histologically the columna epithelium is distorted by mucus-filled balloon or signet ring cells. The expression of CFTR is believed to be hormonally mediated; in health, the water content of cervical mucus varies during the menstrual cycle, peaking at ovulation when 93% to 95% hydration allows the passage of sperm through the cervical canal, but these cyclic changes in hydration are not seen in patients with CF and the mucus retains increased tenacity throughout the cycle. Endocervical polyps and mucus plugs have been reported to arise either de novo or triggered by hormonal contraception, and the cervical os and canal may become blocked with mucus plugs, which are thought to be one cause of infertility in patients with CF.[208,210,216,217]

The endometrium and fallopian tubes contain some CFTR but are reportedly normal. The ovaries do not express CFTR, but although they develop normally in children, abnormalities are seen in adolescents and adults with redundant follicular cysts and reduced number of follicles noted from both ultrasound and postmortem studies. Patients with CF who are undernourished may show a delay in pubertal growth spurt by 12 to 14 months. Menarche, which usually occurs around the age of 13 for females without CF, has been reported at between 14.2 and 14.9 years in patients with CF.[218-221]

It has been postulated that menarche is triggered by the achievement of a critical body composition of approximately 17% body fat, which corresponds to approximately the 10th percentile of weight for height.[218] Studies have shown that girls with CF are shorter and lighter than normative data for healthy females but that the height, weight, and percentage fat of menarchal girls with CF are the same as for younger menarchal girls without CF. Menarchal delay is correlated to the severity of malnutrition, and multiple stepwise regression has shown weight to be the most significant determinant of menarchal delay. It has been noted, however, that up to 20% of young women with CF may menstruate without reaching the critical 17% body fat composition, which suggests that when critical body composition is not reached in time, other unspecified factors may become influential.

Pituitary Gonadal Axis

Luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone, progesterone, and estrogen have all been measured in large groups of females with CF from the prepubertal to adult age groups. In women, FSH changes follow the same changes with age as in non-CF individuals but at lower levels and result in a delay of approximately 2 years before pubertal levels are reached. Progesterone and estrogen peaks are delayed 2 years. The mechanism of such delay is unknown; however, because infusion of gonadotropin-releasing hormone shows normal or near normal LH and FSH responses, primary pituitary failure appears to be unlikely. CFTR has been identified in the hypothalamus and is postulated to influence the release of GnRH, which may explain the pubertal delay in healthy well-nourished CF individuals.

Menstruation

Once established, the majority of young women with CF develop normal or near normal menstrual cycles,[209] although menstrual problems are frequent. Stead and associates[209] studied 45 female patients with CF aged 15 to 40 years and found that 40 of the 45 patients had commenced menstruation. Of those who had commenced menstruation, 50% were regular, while a further 28% had irregular or missed periods. Only 22% of the group had secondary amenorrhea. Pulmonary function showed considerable overlap between the groups, but all amenorrheic patients had an FVC of less than 55% predicted.

Female Reproduction

Thirty years ago, the first report of fertility in female patients with CF quoted an incidence of less than 20%; however, this is almost certainly an underestimation at this present stage due to the improved overall health of adult females with CF in the 21st century.[210] Because the reproductive tract is normal in most women with CF, those with acceptable weight and lung function would be expected to develop into sexually mature adults who should ovulate and menstruate normally. There appears to be little evidence that fertility is reduced in healthy women with CF except by the mechanical barrier of the cervical mucus plug, a barrier that can be reduced by the administration of contraceptive hormone preparations. Early reports of pregnancies occurring in women with CF occurred in the early 1960s. These early reports, however, were associated with high complication rates and deterioration of maternal health both during and after pregnancy. In a large review of more recent pregnancy outcomes, Kent and Farquharson[211] found a spontaneous abortion rate of 4.6% across 15 separate studies. While 14% of pregnancies were terminated, 82% of pregnancies progressed beyond 20 weeks' gestation, with 24% resulting in premature delivery. Of these, 11.6% of cases were due to maternal complications of CF and 88% were due to spontaneous natural labor.[222]

Pancreatic insufficiency, poor prepregnancy body weight, and poor maternal weight gain were initially considered markers of disease severity associated with a poor outcome during pregnancy. More recently, the number and proportion of mothers with pancreatic insufficiency having a successful pregnancy are increasing, and as nutritional care improves, pancreatic status has become a less significant variable, although recent studies still confirm a better prognosis for patients with pancreatic insufficiency.[222]

The development of diabetes with a diagnosis before pregnancy or during pregnancy confers a worse prognosis to both the mother and the infant.[223,224]

Maternal mortality has been estimated to approach 10% at 6 months after delivery and 14% at 2 years after delivery, and patients with a prepregnancy FVC of less than 60% predicted have an elevated rate of premature delivery and an associated high rate of maternal mortality.

Long-term Outcome for the Mother

Fiel and FitzSimmons[223] used the 1990 North American Cystic Fibrosis Database to examine pregnant women with CF and compared their outcomes to controls matched for

age, lung function, and weight percentile. Two hundred fifty-eight women who had live births were compared with 889 controls, and no differences were found between cases and controls in rates of decline of FEV_1 or in the frequency of complications, including hemoptysis, pneumothorax, and infective exacerbations during pregnancy, or during the subsequent 2 years. Pregnancy was therefore not an independent risk factor for survival but an end point that was equal in both cases and controls while worse for those with poor lung function, low body weight, or diabetes in both groups.

HEMATOLOGIC ABNORMALITIES

Iron deficiency anemia has been reported in 33% to 66% of patients with CF.[225,226] In a study of 71 adult CF patients, Pond[226] found functional iron deficiency (transferrin saturation <16%) in 62% of patients. Hemoglobin concentration and mean cell volume were lower in iron-deficient patients, in whom there was a nonsignificant trend for lower serum ferritin. Ten iron-deficient patients were anemic. There were no significant differences between iron-deficient and normal-iron patients in intake of calories, protein, iron, and vitamin C as determined by dietary records. Dietary iron deficiency was not thought to be an important factor in functional iron deficiency in adult CF patients. Impairment of absorption by exogenous pancreatic enzyme supplements has been postulated as a possible cause of iron deficiency in CF patients; however, Pond's study suggests this is unlikely as enzyme intake was the same in the two groups. Chronic inflammation is likely to be the primary cause of functional iron deficiency in adult CF patients. Thrombocytopenia in patients with CF is almost always related to hypersplenism secondary to cirrhosis and portal hypertension.

OCULAR COMPLICATIONS

Ocular abnormalities in CF include visual field defects, venous engorgement, tortuosity, hyperemia and blurring of the optic nerve head, abnormal pupillary responses, and decreased contrast sensitivity.[227,228] Examination of the ocular surface shows an increase in fluorescein staining and clinical blepharitis, as well as decreased Schirmer testing and tear lysozyme. Conjunctival epithelial cell morphology is normal.[229] Adolescents and young adults with vitamin A deficiency may manifest conjunctival xerosis and night blindness (decreased dark adaptation).[53,230] In patients with hyperglycemia, there is evidence of breakdown of the blood-retina barrier; this is considered to represent a functional abnormality that is a precursor to diabetic microangiopathy.[213] Proliferative diabetic retinopathy with blurred vision, neovascularization, vitreous hemorrhages, and cataract formation has been reported in CF patients with long-standing CFRD.[232]

SALIVARY GLANDS

In patients with CF, there are characteristic histologic abnormalities of the salivary glands. In the submaxillary glands, there are dilated mucus acini and ductules filled with inspissated mucus secretions. In the labial mucus glands, there are dilated ducts with inspissated mucus, atrophy and cyst-like dilation of acini, and metaplasia of the ductile epithelium. While enlargement of the submaxillary glands has been observed in a large proportion of patients, parotid gland enlargement is rare.[233,234]

Studies of flow and constituent composition of the various salivary glands have yielded conflicting data, probably related to differences in methods of salivary gland stimulation and saliva collection. Shori and Asking[235] examined the effects of parasympathetic and sympathetic autonomic nerve stimulation on these glands using a rat model and demonstrated the existence of three separate nerve pathways through which secretion of protein could be evoked from serous and mucous exocrine cells. These pathways allow the secretion of proteins from the intracellular compartments in a constitutive, intermediate, or regulated manner. The primary aspects of the secretory profile, including concentration and the degree of hydration of secreted material, differ greatly between the pathways, are cell type specific, and presumably are a direct consequence of controlled changes in the levels of second messengers induced on stimulation of these cells. Previously published reports suggested that only the β-adrenergic–regulated pathway was affected in CF, and as a result, differences between the pathways in their secretory profiles have been postulated to possibly influence the development of lung disease through disparate disturbances in the secretion of protein and fluid from serous and mucous cells of the submucosal glands lining the bronchiolar tree in humans.

SKIN MANIFESTATIONS

Several reports have described infants displaying generalized erythematous rashes at diagnosis. In these infants, the rash typically begins as erythematous papules in the nappy area, which may then spread, to become generalized and confluent with well-demarcated erythematous, scaly papules covering most of the body. Papules and desquamation occur on palms and soles. This spectrum of symptoms has been attributed to kwashiorkor secondary to pancreatic insufficiency and malabsorption, and is believed to be due possibly to free radical damage to mitochondria and lipid membranes in the skin, due in part to multiple nutritional deficiencies including zinc and essential fatty acids. Zinc replacement and correction of pancreatic insufficiency are associated with clearing of the rash.[236-238]

In patients receiving treatment, the commonest skin manifestations are erythematous or purpuric reactions secondary to medication use, particularly antibiotics. Photosensitivity to quinolone antibiotics is common and has been estimated to develop in up to 50% of adult patients taking ciprofloxacin.[239]

MUSCULOSKELETAL ABNORMALITIES

Over the past two decades, reduced bone mineral density has been recognized in both adult and pediatric CF patients. Gibbens and associates[240] found reduced bone mineral density in 57 patients with CF with a mean age of 12 years. Similar findings were reported by Hendersen and Madsen,[241] who examined 62 patients (mean age, 10.7 years.) and found a mean *Z* score for bone mineral density (BMD) of –1.03 at the lumbar spine and –0.71 at the femoral neck. Additional studies have also shown reduced BMD in adults with CF. Haworth and colleagues[242] found mean BMD *Z* scores of

–1.21 (lumbar spine) and –1.25 (femoral neck) when measured using dual-energy x-ray absorptiometry (DEXA) techniques. Body mass index, percent predicted FEV_1, and physical activity were all positively related to the mean BMD score.

Osteoporosis may manifest as asymptomatic bone loss identified on imaging studies, evidence of asymptomatic bony fractures such as anterior wedge compression of vertebral bodies, or clinically evident fractures, commonly involving ribs.[243] Osteoporosis in CF is generally multifactorial in origin. Identified risk factors for the development of osteoporosis include malabsorption of vitamin D and calcium, low body weight, decreased physical activity, hypogonadism, respiratory acidosis and the osteolytic action of circulating cytokines, amenorrhea, glucocorticoid use, diabetes, chronic infection, and delayed puberty.[244] Osteoporosis may also occur as in association with lung transplantation.[245] In addition to nutritional support, pancreatic enzyme replacement, management of hypogonadism, adequate exercise and avoidance of corticosteroids, and calcium and vitamin D supplements may be useful in preventing bone loss in CF. The use of bisphosphonates, well established in the treatment of osteoporosis in postmenopausal women, is not yet well established in CF. In addition, Haworth and associates[246] reported that in a group of CF adults, the administration of the intravenous bisphosphonate pamidronate was associated with severe bone pain following injection. An increase in circulating cytokines has been postulated as an explanation for this side effect. In a 6-month placebo-controlled study of 31 patients with CF (15 in active treatment), Haworth and associates[246] found that the 3 times monthly administration of pamidronate increased BMD in the lumbar spine and in the hip but decreased BMD in the distal forearm. Bone pain was the most common adverse event, occurring in 11 of 15 participants not receiving corticosteroids. There was no significant difference in survival between the actively treated and placebo groups, although this may have been due in part to short-term follow-up and small sample size.[247]

Digital Clubbing

The well-known clubbing of fingers and toes that occur in CF, as well as other diseases of the chest, has been considered to be a form of hypertrophic pulmonary osteoarthropathy (HPOA).[248] Nakamura found digital clubbing in 75 of 100 (75%) of a group of 100 patients with CF (43 males, 57 females; mean age, 15.7 years). The degree of clubbing was inversely correlated with PaO_2, FEV_1, and FEF_{25-75}. Clubbing was positively correlated with right ventricular hypertrophy and the slope of phase 3 of single-breath nitrogen washout. There was no significant correlation between the degree of clubbing and age, total lung capacity, $PaCO_2$, or a history of liver disease.[249]

HPOA is the most common form of arthropathy in CF. Although its etiology remains obscure, progressive lung suppuration and declining pulmonary function are implicated. The presence of long bone pain and joint swelling that may be aggravated by pulmonary exacerbations in a clubbed patient are the main clinical criteria for diagnosing HPOA. HPOA occurs in 5% to 15% of patients with CF, usually in those over 12 years of age and with advanced suppurative lung disease. By the time radiographic changes such as periostitis appear, HPOA is usually relatively advanced. Bone scintigraphy has been reported as a sensitive method for detecting HPOA, although there is no absolute standard. The features of the delayed phase of the radionuclide bone scan include the appearance of a diffuse, symmetric tracer accumulation in the diaphyses and metaphyses of tubular long bones along their cortical margins, creating a distinctive "parallel track" sign. Radiographs of involved areas may remain normal for several months after positive features are apparent on the delayed bone scan.

HPOA manifests as bilateral painful swelling of the distal third of affected bones, usually the long bones of both upper and lower limbs. Smaller limb bones such as metacarpals and metatarsals are less commonly involved. There may be arthralgia, stiffness, joint swelling, and effusion. In severe cases, involvement of ribs, clavicles, scapulae, pelvis, and malar bones has been reported. Pathologically, there is edematous thickening of the periosteum, inflammatory periostitis, and subperiosteal new bone formation. Synovial biopsy shows cellular infiltration, hyperplasia of synovial cells, and fibrosis. The arthropathy is usually chronic, with intermittent exacerbations at times of pulmonary exacerbations. Management involves optimization of the pulmonary care and treatment of chest exacerbations aggressively. Nonsteroidal anti-inflammatory medication may relieve the discomfort but does not reverse the disease.

Arthritis

Approximately 20% of adult patients with CF have been reported with arthropathy, but the incidence in pediatric populations is less well defined. There is a clear association between age and the presence of musculoskeletal problems, and this probably relates to declining pulmonary function.

Episodic Arthritis

Episodic arthritis (EA) first described by Newman and Ansell in 1979[250] does not appear to be as closely associated with diminished pulmonary function or age as HPOA. While progression to persistent erosive changes has been reported, this appears uncommon.[251] Bone scans show the presence of synovitis, with an appearance distinctly different from that of HPOA. The arthritis may be associated with fever and skin lesions usually located distally on the legs.[252] Neither HPOA nor episodic arthritis has been linked to any particular HLA type.[253]

Back Pain and Spinal Deformity

Mechanical back disorders have received less attention than other musculoskeletal complications of CF. A review from our large pediatric specialist clinic in Melbourne, Australia, found that 25% of adolescents older than 15 years had kyphosis (R. J. Massie, personal communication, 2006) An association with advancing age, female sex, poor lung function, and worse clinical score was evident. None of the kyphoses was considered serious enough to contribute to reductions in pulmonary function. Osteoporosis and crush fractures are a potential cause for serious mechanical back disorders in children and adolescents with CF.

CHAPTER 64 Congenital Malformations of the Lungs and Airways

Jean-Martin Laberge and Pramod Puligandla*

TEACHING POINTS

- The classification of congenital lung lesions is the subject of controversy.
- There are multiple reports of "hybrid" congenital lung lesions, with overlapping features of congenital cystic adenomatoid malformation (CCAM)/congenital pulmonary airway malformation (CPAM), sequestration, and bronchial atresia.
- Echogenic lung lesions may regress or disappear prenatally. Postnatal chest radiograph may appear normal, but computed tomography scan is necessary to confirm true disappearance.
- CCAM/CPAM type 4 may be indistinguishable from type 1 pleuropulmonary blastoma, a malignant tumor.
- Congenital cystic lung lesions should be excised even when asymptomatic.
- Many theories exist to explain lung malformations; recently attention has turned to signaling proteins and growth factors implicated in lung development (Shh, FGF 7 and 10, lgl-1, and retinoic acid, among others).

Congenital anomalies account for one third of infant deaths and are one of the leading causes of death in this age group in most developed countries.[1,2] Congenital malformations of the respiratory system now rank second, behind those of the cardiovascular system, as a cause of infant mortality. With a rate of 0.25 death per 1000 live births, they have surpassed those of the nervous system (0.23 per 1000) in the past decade in the United States.[3] This is mostly due to increased selective termination for the latter.[1] Eighty percent of infant deaths from respiratory system malformations are caused by lung hypoplasia or "dysplasia."[2,3] However, congenital malformations of the lungs and airways include a wide spectrum of developmental anomalies, some of which remain asymptomatic and are discovered incidentally on imaging studies. Their frequency has been reported to range from 7.5% to 18.7% of all congenital malformations,[4,5] but their exact overall incidence is difficult to ascertain. They may be part of more complex syndromes and are often associated with other congenital anomalies, particularly those involving the heart and great vessels. Bohin and Field[6] have divided malformations of the respiratory system into those affecting the upper and the lower airway. Among the former, laryngeal and tracheal defects are the most common, with a reported incidence of 1 in 10,000 to 1 in 50,000 births for laryngeal malformations[7]; however, it is doubtful that this includes all cases of mild laryngomalacia, especially since Callahan estimates the incidence of primary tracheomalacia, which is less common, at 1 in 1445.[8] Furthermore, the incidence jumps if one adds the tracheoesophageal fistulas and tracheomalacia usually accompanying esophageal atresia, which has an incidence around 1 in 4000.[6] Among lower respiratory tract anomalies, one can include (1) anomalies of the chest wall and diaphragm, the most common being congenital diaphragmatic hernia with an incidence around 1 in 3000 live births; (2) pulmonary hypoplasia, which is the most common single abnormality found at autopsy, reported in 15% to 20% of early neonatal deaths, but its exact incidence is difficult to find since it is usually secondary to other conditions; and (3) finally, abnormalities of lung development, which are often described as "rare."[6] Among these, cystic lung lesions are the most common, with an incidence quoted at 4 to 6 per 10,000,[9] but the original article gave an estimate of 4.2 "bronchogenic cysts" per 10,000 hospital admissions.[10] This same 1952 paper quotes an incidence of congenital cystic lung disease discovered on routine chest radiographs in asymptomatic young adults of 5 per 100,000 population. Further difficulties arise with these estimates since many of the cystic lesions in the early series may have been acquired[9]; on the other hand, some lesions may remain asymptomatic and undetected. The incidence just cited can be compared with the incidence reported for congenital cystic adenomatoid malformation (CCAM), reported to occur in 1 in 10,000 to 1 in 25,000 births (see later); this malformation is the most common of the ones involving lung development and comprises about 25% of the congenital parenchymal malformations.[11] Yet, others quote an incidence of pulmonary sequestration at 0.15% to 1.7% in the general population, without providing a reference.[12] Stocker[13] found 13 cases of extralobar sequestrations in a series of 47,000 autopsies performed on stillborn and liveborn infants. Considering that most patients with sequestration do not die, it is unlikely that the incidence could be higher than 1 in 4000 births. Finally, an overall incidence of congenital lung malformations of 2.2%

*The authors with to acknowledge the significant contribution of Dr. Barry S. Clements, who authored this chapter in the previous edition. Some of the text and many figures and references from his chapter were used in the current edition.

is quoted by some authors, but the original article likely refers to the incidence of congenital malformations in relation to acquired lung diseases.[14] In conclusion, congenital parenchymal lung malformations are not so rare, but their exact incidence is elusive.

PATHOGENESIS

Many theories have been proposed to explain the various respiratory tract malformations encountered. Older theories have focused on mechanical and vascular aspects of lung growth; examples are Pryce's vascular traction theory[15] and the accessory bud theory to explain pulmonary sequestration[16,17] and the vascular insufficiency[18] and vascular maldevelopment theories[19] that try to explain all abnormal lung development. Authors have looked at molecular markers of lung development, implicating a dysregulation in branching morphogenesis and/or in cellular proliferation.[20-22] Animal models are providing new information. In the Adriamycin-induced esophageal atresia rat model, various forms of communicating bronchopulmonary foregut malformations can be seen, including tracheal atresia with a right esophageal lung and absent left lung.[23] Signaling proteins associated with lung development and their receptors are also being studied; these include growth factors such as Sonic Hedgehog (Shh), fibroblast growth factors (FGF) 7 and 10, lung growth ligand-1 (lgl-1), and transcription factors such as Hox genes, Gli genes, and thyroid transcription factor-1 (TTF-1).[24] Some of these are responsible for early lung development (FGF-10), lung branching (Shh), and alveolar development (lgl-1). Vitamin A (retinoic acid) and its receptors also play an important role. A multitude of studies using various knock-out models in mice have shed some light on the roles of these factors and their receptors on airway and lung development, and a few reports attempt to establish a correlation in fetuses or neonates with lung malformations.[20,24-33] The reader is referred to an excellent recent review by Groenman and colleagues.[24]

The various theories on normal and abnormal early foregut embryology were recently reviewed by Kluth and Fiegel, who also analyze results from the Adriamycin rat model.[34] Further lung development is described in Chapter 3. Some important principles that help to understand the various malformations encountered are worth repeating here:

1. Bronchial branching to terminal bronchiole is complete 16 weeks after conception.[35] An insult affecting lung development in the 8th week of intrauterine life will result in an entirely different lesion than if the same insult occurred in the 20th week, when bronchial branching is complete.
2. Pulmonary vascular development is similar to the pattern of bronchial branching but occurs slightly later.[36]
3. Alveolar development follows the formation of the respiratory bronchioles, and later the saccules, after the 24th week of gestational age, and continues after birth for some years.[35,37-39]
4. At any stage during pulmonary development, the rate of growth of individual component tissues, namely the airway, alveoli, arteries, veins, and lymphatics, may not be uniform.[35]
5. In the early stages, the tips of the dividing bronchial buds are supplied by primitive bronchial arteries arising from the dorsal aorta near the celiac axis. The extrapulmonary part of these arteries disappears during the 6th week of gestation and the definitive bronchial arteries arising from the aorta develop between the 9th and 12th weeks; their capillary bed is limited to the bronchial wall. Persistence of a primitive bronchial artery explains the infradiaphragmatic origin of the systemic artery supplying some lung sequestrations.[18] Parallel to this, the pulmonary arteries develop and supply lung units starting at the level of respiratory bronchioles. Their proximal part results from angiogenesis (branching from preexisting vessels), while their distal part, in future alveolar regions, forms concurrently by vasculogenesis (blood lakes that form within the mesenchyme and transform into vessels); the two then fuse together, likely in the second trimester of gestation.[40] Of note, all intrapulmonary structures, including bronchi, drain to the pulmonary veins, with connections established as early as 54 days of gestation, much before pulmonary artery supply develops.[40]

The relationship between embryology and pathology is further discussed as we describe individual malformations.

CLASSIFICATION

In the past, many classifications of congenital lung malformations have been proposed, although none has gained universal acceptance. These have been based on anatomic localization, histopathologic type, pathogenesis, or extent of lung involvement. In general, lesions involving the lung unit as a whole, or the trachea and the major bronchi, are simply and easily defined, whereas lesions involving the lung parenchyma tend to be more complex, and it is here where consensus on terminology is lacking. In 1966, the American College of Chest Physicians in their catalogue of congenital lung lesions[41] abandoned any attempt at a formal classification and merely produced an inventory of the different malformations. When Landing produced his review on the subject in 1979,[42] he was forced to use the same format. In 1987, Clements introduced the malinosculation concept, also dubbed the "wheel" theory or classification[43] (Fig. 64-1). Achiron recently suggested a new classification based on Clements' work and two-dimensional and Doppler findings on prenatal ultrasound.[44] Because the term *malinosculation* had not gained wide acceptance, Achiron proposed the term *dysplasia*, meaning "abnormal tissue formation." Although semantically correct, this term would likely lead to more confusion for clinicians, who already use it in the context of bronchopulmonary dysplasia, alveolar capillary dysplasia, and other less common entities.[45] Sebire[45] questions the clinical usefulness of introducing five more categories of "fetal lung dysplasia" to encompass virtually all developmental respiratory tract anomalies. Bush[46] has also proposed a new nomenclature that appears oversimplified and without clinical usefulness, with the term *congenital thoracic malformation* encompassing most of the congenital lung malformations that will be discussed later.

The confusion resulting from attempts to classify complex and overlapping anomalies is best exemplified in the group of parenchymal lesions. CCAM of the lung was classified into three types by Stocker in 1977,[47] who subsequently revised the classification into five types[48] (Table 64-1). He later

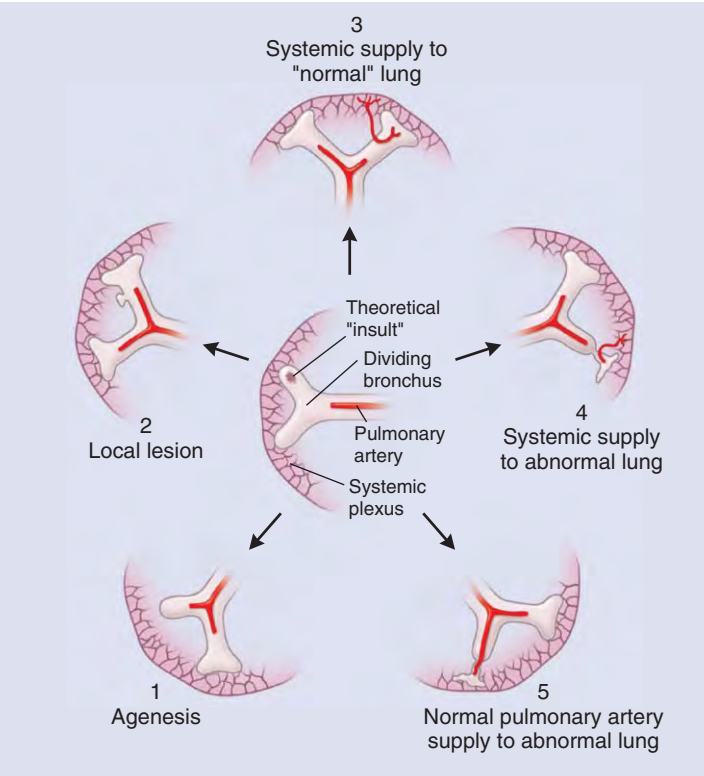

Figure 64-1 Abnormal lung development. The range of possible outcomes following an insult to the developing lung bud *(center)* is simplistically displayed here as the spokes of a wheel.

changed the catchy name "congenital cystic adenomatoid malformation" to "congenital pulmonary airway malformation" (CPAM)[49] because most types are not adenomatoid and only three types are cystic. In recent years, many hybrid lesions have been described, mostly having features of both sequestration and CCAM/CPAM.[50-60] Furthermore, prominent pathologists disagree on the definition and nomenclature, which has changed over time.[47-49] For example, Stocker[49] believes that intrapulmonary bronchogenic cysts and other congenital unilocular lung cysts are type 1 CCAM, whereas others disagree.[51] Other pathologists caution that the new Stocker type 4 has features that overlap with type I pleuropulmonary blastoma (PPB) so much so that they recommend approaching these lesions in infants as malignant until proved otherwise.[61,62] Langston believes that the five types of CPAM represent different malformations with varying etiologies and proposes a new classification.[51]

Back in 1974, Buntain[63] suggested that all congenital lung lesions be considered as one clinical group. Because the purpose of this chapter is to provide clinically useful information for pediatric specialists dealing with patients with respiratory tract malformations, we describe these malformations using the terms generally used, highlighting some of the controversies and overlapping features as we go. Most important, clinicians should use descriptive terms (such as the presence and size of cysts, the presence of a systemic arterial connection) instead of trying to assign a pathologic diagnosis based on imaging alone.

AIRWAY MALFORMATIONS

Larynx

LARYNGOMALACIA

Laryngomalacia is the most common congenital anomaly found in the upper airway. Fortunately, most cases are mild, readily diagnosed clinically, and generally require no more management than parental reassurance. Strictly speaking, it is not a true malformation but represents a delay in the maturation of the supporting structures of the larynx. This causes the larynx to be more collapsible than normal during inspiration, resulting in inspiratory stridor (the most notable symptom associated with this condition), which varies with the inspiratory force at the time. This stridor is usually first noticed in the early neonatal period, with most patients

Table 64-1
Stocker's Classification of CCAM/CPAM

Type/Synonym	0/Acinar Dysplasia or Agenesis	1/Large Cyst or Predominant Cyst	2/Medium Cyst	3/Small Cyst or Solid or Adenomatoid	4/Peripheral Cyst
Approximate frequency (%)	1-3	>65	20-25	8	2-4
Cyst size (maximum, cm)	0.5	10.0	2.5	0.2	7
Microscopic appearance	Ciliated Bronchial-like structures lined by pseudostratified tall columnar epithelium with goblet cells	Multilocular, large cysts Broad fibrous septa Mucogenic cells Ciliated Pseudostratified tall columnar epithelium	Small, uniform cysts Irregular proliferation of ectatic structures resembling bronchioles	Solid, bulky lesion Irregular curving channels and small air spaces lined by cuboidal epithelium	Multilocular, large cysts lined by flattened alveolar lining cells
Muscular wall thickness (μm) of cysts	100-500	100-300	50-100	0-50	25-100
Mucus cells	Present in all cases	Present (33% of cases)	Absent	Absent	Absent
Cartilage	Present in all cases	Present (5%-10% of cases)	Absent	Absent	Rare
Skeletal muscle	Absent	Absent	Present (5% of cases)	Absent	Absent

having presented by 6 weeks of age, although some patients appear not to have significant symptoms until a few months of age, when the stridor may be made apparent for the first time following an intercurrent upper respiratory tract infection. In some cases laryngomalacia is due to short arytenoepiglottic folds, to the flaccidity of an omega-shaped epiglottis, or to collapsing arytenoids.[64] Laryngomalacia may also be acquired, as seen in some neonates and infants with Pierre Robin sequence who have upper airway obstruction and must generate high negative pressures during inspiration.[65] The stridor is generally more prominent during crying, feeding, and respiratory tract infections. A sudden, sharp inspiratory effort often results in a loud, high-pitched inspiratory "whoop," which may alarm the parents. Some patients have stridor at rest, and in 10%, a minor expiratory component may occasionally be present as well. Significant airway obstruction in laryngomalacia is unusual, although occasionally patients with severe forms may become quite distressed, particularly during intercurrent respiratory tract infections, requiring in-hospital care and, rarely, ventilatory support. Other potentially serious complications include pulmonary hypertension and cor pulmonale, failure to thrive, and impaired intellectual development secondary to episodes of hypoxia and hypercapnia.[49] Laryngomalacia is associated with multiple congenital anomalies or neurologic compromise in 20% of cases.[66] A familial form has also been described.[67] The diagnosis in most cases should be based on clinical history and physical examination, but flexible laryngoscopy is essential in neonates or infants with associated malformations or conditions such as prematurity, prolonged intubation, or failed extubation. When considering investigating these patients, it should also always be borne in mind that laryngomalacia often coexists with other laryngotracheal malformations (such as tracheomalacia and esophageal atresia) and cardiovascular malformations. In such patients, the flexible endoscopy is often completed by rigid bronchoscopy performed under general anesthesia.

Laryngomalacia in mild cases is a benign, self-limiting condition. Symptoms usually resolve within the first 12 to 18 months and almost always by 2 years of age. However, strong reassurance and ongoing support are often needed to allay parental anxiety. Patients who exhibit significant sleep disturbance, as evidenced on polysomnography, may benefit from administration of positive airway pressure through a closely applied face mask during sleep. However, this form of treatment can be fraught with difficulties and is often not well tolerated, in which case surgical intervention, either epiglottoplasty, epiglottopexy, release of the arytenoepiglottic folds, or rarely tracheostomy, may need to be considered. This is particularly true in cases with severe, potentially life-threatening airway obstruction, or when symptoms are sufficiently severe to interfere with normal growth and development.[64,68] Although it is generally accepted that patients who have had laryngomalacia in infancy show no ill effects clinically once their symptoms have subsided, some follow-up studies of these patients have demonstrated abnormalities of inspiratory flow on pulmonary function testing in late childhood.[69]

LARYNGEAL ATRESIA, WEBS, AND STENOSIS

Laryngeal atresia is a life-threatening malformation. The lesion results from failure of recanalization of the epithelial septum, which forms around 6 weeks of gestation and separates the developing esophagus from the tracheal bud. At 10 weeks, the epithelial membrane is ready to open again into the now-developing primitive laryngeal aditus. Despite the complete lack of communication with the airway, distal lung development and general fetal growth are usually unaffected, although fetal ascites may develop.[70] In the past, affected babies would often die at birth or have severe neurologic sequelae because of the failure to establish an airway. In recent years, routine prenatal ultrasound examinations have allowed the diagnosis to be made before birth, resulting in a higher survival. On ultrasound, the lungs appear more echogenic and enlarged, causing eversion of the diaphragms; a distended trachea can also be observed. Magnetic resonance imaging confirms the increased fluid content of the lung, with a hyperintense signal on T2-weighed images (Fig. 64-2). Near term, the fetus is delivered using the EXIT procedure (EX-utero Intrapartum Treatment), which is a cesarean section done under deep maternal general anesthesia to provide uterine relaxation.[71,72] The fetal head and neck are exposed and the airway is secured, usually by tracheostomy, while oxygenation is maintained through the placenta. Prognosis has greatly improved with prenatal diagnosis and proper perinatal management, although it may also be affected by the presence of associated defects.[73] Furthermore, subsequent laryngeal function in survivors is usually abnormal, often requiring surgical reconstruction at a later date, particularly to assist with speech.[64] Tracheomalacia and abnormal function of the hyperplastic lungs are also common and often require prolonged ventilator support.

The prognosis is better with *laryngeal webs*, which can present with openings of varying sizes. Of these, 75% are glottic, with the rest supraglottic or subglottic in location. They are usually situated anteriorly, with a posterior concave glottic opening. Complete webs present like atresias, whereas partial webs present with stridor and a hoarse or weak cry and may cause varying degrees of respiratory difficulty depending on the degree of obstruction. Partial webs may also present as a difficult to intubate neonate who is placed under general anesthesia for repair of another malformation such as esophageal atresia. Intubation with a smaller tube may be successful but a stenosis may later develop. The diagnosis of laryngeal webs is confirmed at endoscopy and treatment is excision or laser ablation, although some smaller subglottic webs may respond to dilation.[64,74]

The most common anomalies associated with laryngeal atresia and webs are those of the VACTERL association (*V*ertebral, *A*nal, *C*ardiac, *T*racheo-*E*sophageal, *R*enal, *L*imb).[75] Others include syndromes such as Fraser, Di George, and velocardiofacial (both related to 22q11 deletion) and partial trisomy 9; families with an autosomal dominant inheritance pattern have also been described.[49,70,76,77]

The congenital form of *subglottic stenosis*, similar to laryngeal web and atresia, results from defective recanalization of the larynx, although in subglottic stenosis the defect occurs at the level of, and usually involves, the cricoid cartilage, approximately 2 to 3 mm below the glottis. The most common presenting symptom is stridor, which is worsened by increased respiratory effort and upper respiratory tract infection. In fact, in milder forms the stridor may only be noticed during intercurrent upper respiratory tract infections and be mis-

A

labeled as croup. Therefore, recurrent "croup" in infancy should always raise the possibility of a fixed upper airway narrowing such as subglottic stenosis, particularly when the course of the illness and response to treatment are atypical. High-voltage radiographs of the upper airway may help with the diagnosis, and both anteroposterior and lateral views should be requested because the narrowing is often maximal in the anteroposterior direction. Flexible endoscopy is useful for initial assessment. Bronchoscopy is the definitive diagnostic tool and is usually necessary to exclude other causes of narrowing in this region, particularly subglottic hemangioma. This lesion may be differentiated clinically from congenital subglottic stenosis in that the history is usually of worsening symptoms with growth of the hemangioma. On plain radiographs, the outline of hemangiomas is generally more ragged and may show a typical unilateral shouldering. Acquired subglottic stenosis is much more common than the congenital form. The diagnosis of the former is supported by a history of laryngeal trauma, the most common of which would be endotracheal intubation. This is particularly true when intubation is prolonged, as in the premature neonate. Treatment is the same for both types. Because the subglottic narrowing generally improves with laryngeal growth, a conservative approach using supportive care, particularly during intermittent episodes of "croup," should be the goal in all patients. Surgery should be reserved for patients who fail to cope with this conservative management, and a cricoid split is often the first line surgical treatment.[78] Treatment options include the cricoid split procedure, laryngotracheoplasty, tracheal resection and anastomosis, and tracheostomy for patients who have lesions that are not amenable to resection or reconstructive procedures. Most tracheostomized patients can be successfully decannulated within 2 to 3 years, although stridor and varying degrees of breathing difficulties may persist for many years.

LARYNGEAL CYSTS

These are usually supraglottic and generally present in the neonatal period (although possibly much later) with hoarse or muffled voice or even aphonia, stridor, and respiratory difficulty.[79,80] A lateral neck radiograph may show a rounded supraglottic swelling, and at laryngoscopy, a bluish fluid-filled cyst is found, usually in the epiglottic folds. Aspiration can relieve acute symptoms, but resection is ultimately necessary to prevent recurrence.[81]

LARYNGOTRACHEOESOPHAGEAL CLEFTS

A cleft larynx occurs in approximately 1 in 10,000 to 20,000 live births and comprises less than 1% of all laryngeal anomalies.[82] Male patients are affected more commonly than are female patients. Familial occurrences have been reported, as well as associations with various syndromes, including G syndrome and Pallister-Hall syndrome.[83,84] Association with other laryngotracheoesophageal anomalies, particularly esophageal atresia and tracheoesophageal fistula, is high. Pulmonary hypoplasia also occurs from the unchecked egress of

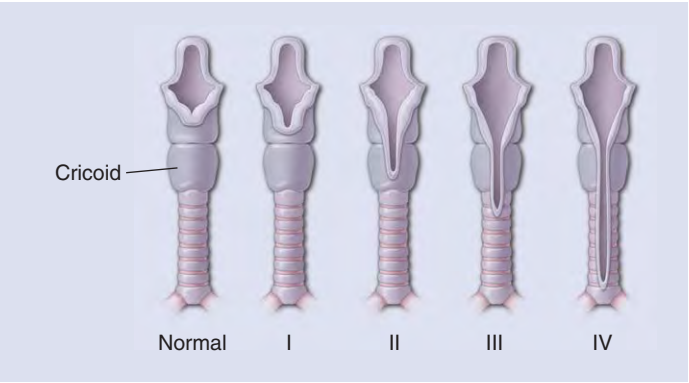

Figure 64-3 Classification of laryngeal and laryngotracheoesophageal clefts. (Redrawn from Dubois JJ, et al: Current management of laryngeal and laryngotracheoesophageal clefts. J Pediatr Surg 25:855-860, 1990.)

pulmonary fluid through a large cleft in fetal life. The clefts are classified into four types according to their severity, from type 1, the most common (50%), which is a simple laryngeal cleft, to type 4, which extends down to the carina and may involve one or both mainstem bronchi[82] (Fig. 64-3). Embryologically, a laryngeal cleft arises from abnormal separation of the trachea from the foregut, which occurs between 25 and 35 days of embryonic life. At the same time, the cricoid cartilage develops as two lateral centers of chondrification from the sixth branchial arch at the origin of the lung bud from the esophagus. Dorsal fusion of the cricoid plate is complete by day 50 to 54 and laryngeal muscular development ensues. The range of abnormalities seen results from defects in cricoid chondrification or fusion (types 1 and 2) or failure of septation of the primitive foregut (types 3 and 4). A multitude of signaling proteins are involved in this process of partition as reviewed by Groenman.[24] Among others, TTF-1 and Shh knock-out mice have demonstrated tracheoesophageal septum defects.[85,86]

These clefts create an abnormal communication between the esophagus and the larynx and trachea, thus increasing the likelihood of repeated aspiration of saliva and milk into the airway. This results in coughing, choking, respiratory distress, and recurrent pneumonia. Type 1 clefts may be asymptomatic, whereas type 2 clefts can cause problems of varying severity, making diagnosis difficult and often delayed. Increased salivation, stridor, and a low soundless cry are said to be characteristic symptoms that would point to the diagnosis of a cleft. However, this triad is rare, and more often stridor is absent and the cry is harsh. Therefore, in any neonate or infant who develops respiratory difficulties associated with feeding, the presence of a laryngotracheoesophageal cleft should be considered. The differential diagnosis also includes choanal atresia, esophageal atresia with or without tracheoesophageal fistula, pure tracheoesophageal fistula, laryngoesophageal dysmotility syndromes (functional or neurologic), esophageal compression (such as with a vascular ring), and gastroesophageal reflux. A contrast swallow and esophagogram (see later under pure tracheoesophageal fistula) is usually done in those neonates who are suspected of aspiration, but it rarely demonstrates the cleft clearly. In neonates who are intubated because of respiratory distress, posterior displacement of the endotracheal tube on radiographs suggests the diagnosis (Fig. 64-4A). The cleft is easily missed on direct laryngoscopy done for intubation.[87] Rigid bronchoscopy is necessary to make the diagnosis and to define the extent of the lesion. Endoscopic surgical correction for minor lesions is possible; however, many type 1 defects may not require correction, particularly if complicating factors such as gastroesophageal reflux are absent or can be controlled. Timing of surgery for type 2, 3, and 4 lesions depends largely on the overall condition of the child at diagnosis. If the child's respiratory and nutritional status are stable, early repair should be considered. If not, staged repair incorporating tracheostomy initially (with or without gastrostomy and fundoplication or gastric division), followed by definitive repair when the child is stable, may be best. Type 4 clefts require special tracheostomy tubes for postoperative stenting. They can be repaired through an anterior transtracheal approach or a lateral approach; cardiopulmonary bypass or extracorporeal membrane oxygenation are often required.[88,89] Overall survival with improved techniques and aggressive treatment is 70% but is significantly less for patients with extensive type 4 defects, significant prematurity, and severe associated anomalies. Complications following surgical repair are common and include wound breakdown and tracheoesophageal fistula formation, continuing aspiration and swallowing difficulties, gastroesophageal reflux, tracheobronchomalacia, and chronic respiratory problems.[88-90]

Trachea

TRACHEAL ATRESIA AND AGENESIS

Much like esophageal atresia (see later), various types of tracheal atresia have been described, ranging from complete pulmonary agenesis to segmental atresia with an intervening fibrous cord.[91,92] When no esophageal communication exists, the lungs are distended with fluid as discussed with laryngeal atresia; prenatal imaging, however, will fail to identify a distended trachea. In other cases the lungs appear normal although lobulation defects may occur.[92] Again, this spectrum of anomalies has been described in animal models studying the effects of various growth and transcription factors.[24] Tracheal atresia is commonly observed with anomalies of the VACTERL association, as well as gastrointestinal, genitourinary, and central nervous system anomalies.[93,94] This malformation is usually lethal. Neonates with short-segment atresia of the cervical trachea may be saved by an EXIT procedure with tracheostomy if the diagnosis is established before birth (see Fig. 64-2) or if a cleft or fistula allows temporary ventilation through a tube placed in the esophagus.[73] Even if neonatal survival can be achieved, long-term management is fraught with complications.[91]

ESOPHAGEAL ATRESIA AND RELATED TRACHEOESOPHAGEAL MALFORMATIONS

Laryngotracheoesophageal cleft, tracheal atresia, and esophageal atresia are all malformations related to defective septation of the primitive foregut. The latter is the most common, with an incidence of 1 in 3000 to 5000 live births. In 80% of cases, the esophageal atresia is accompanied by a fistula between the lower trachea or carina and distal esophagus (Fig. 64-5). The diagnosis is easily made, and the well-established management can be found in standard pediatric surgi-

Figure 64-4 Complete laryngotracheoesophageal cleft in a premature baby with high imperforate anus. The child was breathing spontaneously until surgery for colostomy. Intubation by the anesthesiologist under direct laryngoscopy was uneventful. **A,** Postoperative radiograph, showing a very abnormal position of the endotracheal tube. **B,** Lateral radiograph, showing the posterior displacement of the endotracheal tube overlying the nasogastric tube. A complete cleft was suspected and confirmed by rigid bronchoscopy.

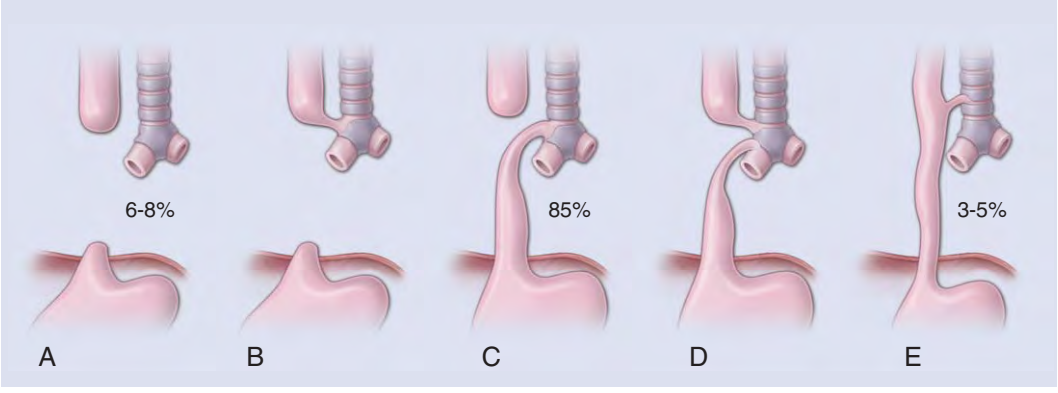

Figure 64-5 Types and incidence of the main esophageal atresia and tracheoesophageal fistulas: **A,** esophageal atresia without fistula, **B,** upper esophageal fistula with distal atresia, **C,** most common type with upper pouch atresia and distal fistula, **D,** proximal and distal esophageal fistulas, and **E,** H-type tracheoesophageal fistula.

cal textbooks.[95-97] The prognosis is excellent unless severe anomalies or extreme prematurity are associated.[98-101] For the purpose of this chapter, we address issues more likely to come to the attention of pediatric respiratory specialists.

Early postoperative complications include esophageal anastomotic stenosis (≈10%), recurrence of the tracheoesophageal fistula (3% to 8%), and gastroesophageal reflux, which is seen in nearly all patients to some degree.[97,102,103] Tracheomalacia is also common and is thought to be related to abnormally shaped tracheal cartilages and a widened pars membranacea,[104,105] especially at the level of the upper esophageal pouch. The differential diagnosis between these four entities can be very difficult to establish when the infant has coughing and choking spells with feedings in the postoperative period. A lateral fluoroscopy of the chest may demonstrate a localized tracheal collapse during expiration when severe tracheomalacia is present. A contrast study is usually done next to assess the swallowing mechanism and the anastomotic patency; some discrepancy is always expected between the dilated upper esophageal pouch and the narrow

distal esophagus. Sometimes this study will start with the injection of contrast medium through a small nasoesophageal tube placed at the level of the anastomosis; a recurrent fistula will be easier to delineate and any contrast in the trachea will not be confused with material aspirated from the pharynx. If a significant stricture is discovered, with delay of passage through the anastomosis, dilation can be performed under fluoroscopy. Even without a significant stricture, the normal distention of the upper pouch during swallowing may compress the trachea because of the associated tracheomalacia, to the point of near-total tracheal occlusion (Fig. 64-6). Tracheal collapse can also occur during forced expiration such as crying. Such infants who present with "blue spells" or "dying spells" are treated with aortopexy; by suturing the aortic arch to the undersurface of the sternum, the anterior wall of the trachea is brought forward, preventing the posterior wall from occluding the lumen during feeding or crying.[106-108] A rigid bronchoscopy is necessary to confirm the severity of the tracheomalacia and exclude the possibility of a recurrent fistula or a missed laryngotracheoesophageal cleft.[87] The tracheomalacia is best appreciated with the patient breathing spontaneously, because positive airway pressure will tend to keep the trachea open. In most cases, the collapse is localized and amenable to treatment by aortopexy (Fig. 64-7); diffuse tracheomalacia is more difficult to treat and requires tracheal, and sometimes bronchial, stenting.[109] Tracheomalacia tends to improve with time, but aortopexy is more effective and less risky than prolonged intubation or tracheostomy for patients with dying spells. In most cases, however, a "barking cough" typical of esophageal atresia patients will be the only symptom of tracheomalacia and this tends to improve over time (see discussion of tracheomalacia later). Despite this, Chetcuti and associates[110] have found that 40% of adults still had the typical barking cough of tracheomalacia. Other late postoperative sequelae after esophageal atresia repair are an increased frequency of respiratory infections, possibly related to impaired mucus clearance from absent or dysfunctional ciliated cells,[111] as well as asthma-like symptoms, whether related to tracheomalacia or reactive airway disease. In the study by Chetcuti and associates, these symptoms were present in 24% of patients.[110] Gastroesophageal reflux often persists and contributes to recurrent respiratory problems. Vaccinations against *Haemophilus influenzae* and respiratory syncytial virus are recommended after esophageal atresia repair. Chest wall deformities may also occur, usually in patients who have required repeated thoracotomies for complications (anastomotic dehiscence, recurrent tracheoesophageal fistula [TEF]) or who have hemivertebrae or other vertebral anomalies, which are commonly seen as part of the VACTERL association.

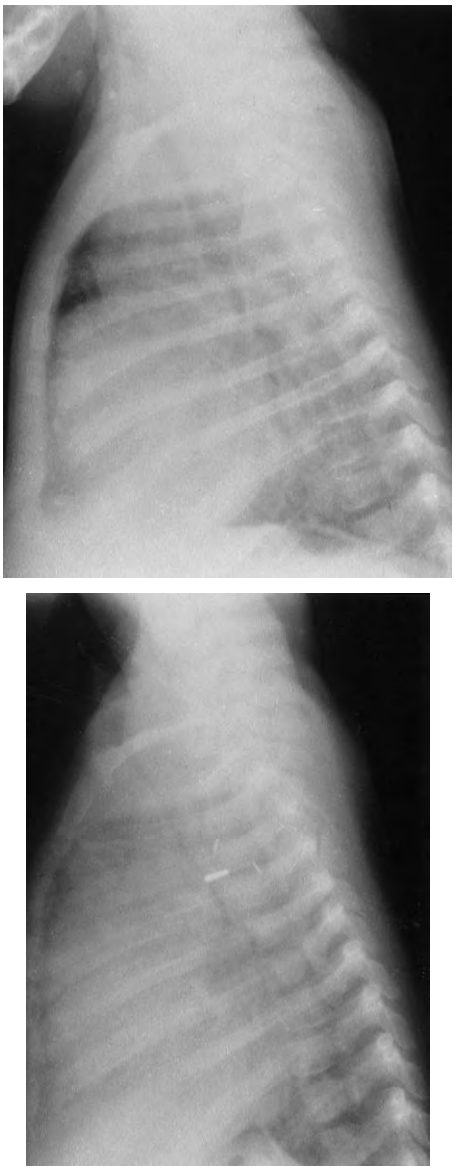

Figure 64-6 Tracheomalacia. Lateral chest radiographs show the abnormally marked collapse of the trachea during expiration *(lower)* compared with normal tracheal diameter during inspiration *(upper)*, which is characteristic of tracheomalacia.

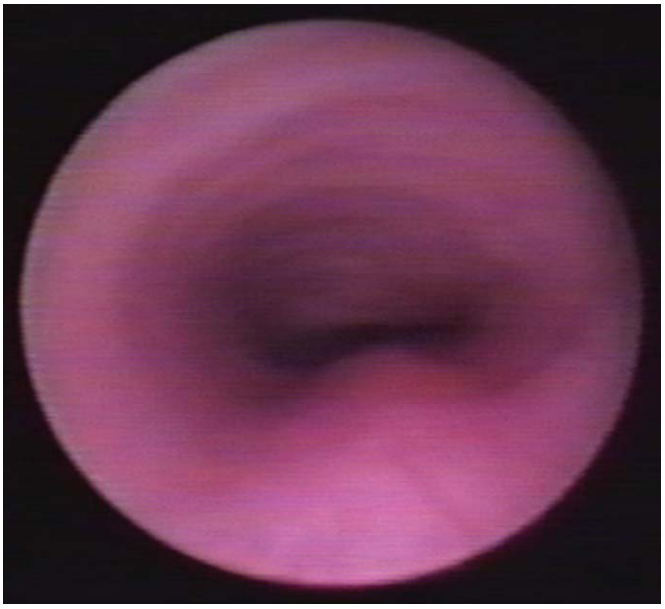
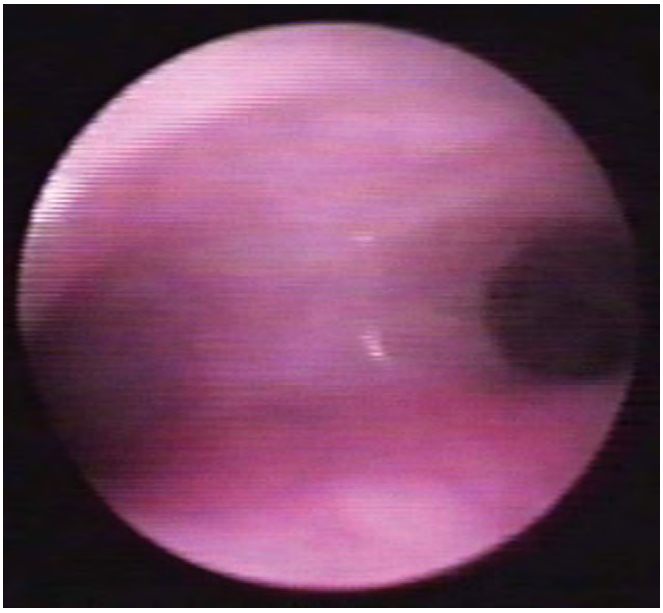
An *isolated tracheoesophageal fistula* is the third most common form of esophageal malformation, seen in about 5%. The symptoms are recurrent coughing and choking, especially during feedings. The diagnosis is often delayed, resulting in recurrent pneumonia.[112,113] A distended abdomen with air-filled loops may also be noted. When the diagnosis is suspected, fluoroscopy is performed in the prone position with contrast injection through a nasoesophageal tube starting in the mid-esophagus and gradually moving up.[114] False-negative studies may occur. Rigid bronchoscopy is essential to confirm the diagnosis and it facilitates the operation. The fistula, usually located in the lower cervical area, is cannulated during bronchoscopy to facilitate intraoperative identification and minimize the amount of dissection, thereby decreasing the risk of recurrent laryngeal nerve injury.[112,113,115] Simple ligation and division of the fistula through a cervical approach give excellent results with few long-term complications.[116] Attempts at endoscopic occlusion of the fistula with glue, laser, or other means is associated with a high recurrence rate and do not appear warranted in H-type fistulas that can be divided through a cervical approach. These techniques may have their place in the management of recurrent TEF.[117] About 10% of H-fistulas are too low to be divided through a cervical approach and require thoracotomy or thoracoscopy.[118]

TRACHEOMALACIA

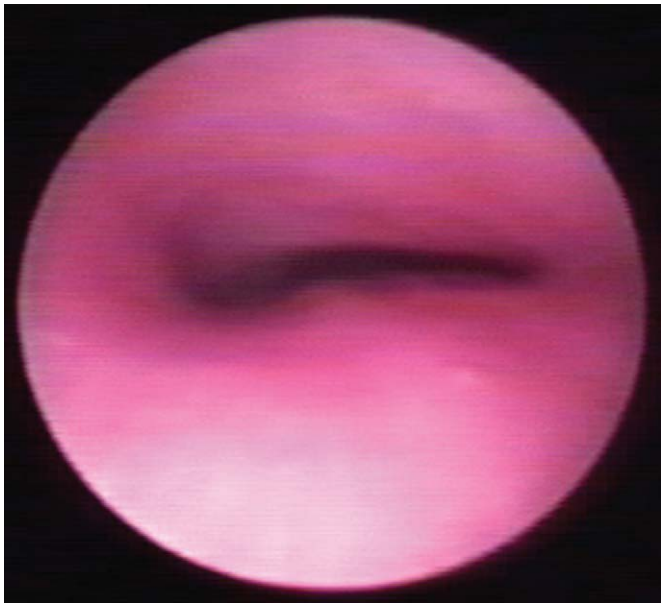
Tracheomalacia can be primary or secondary and may be localized or generalized. Primary tracheomalacia is usually



A



C



B

Figure 64-7 Rigid tracheoscopy on a patient with severe tracheomalacia and desaturations with oral feedings after esophageal atresia repair (type C). **A,** Normal proximal trachea with segmental collapse seen distally. **B,** Severe collapse, corresponding to the level of the aortic arch anteriorly and the esophageal pouch posteriorly. **C,** Distal trachea and mainstem bronchi show minimal collapse. Aortopexy resolved the symptoms.

considered uncommon, but Callahan[8] cites an incidence of 1 in 1445 children based on a small series of patients. When it occurs, it usually takes the form of an abnormal softness of the cartilage, or a shortening of the cartilage rings with a correspondingly large pars membranacea.[64,119] The Williams-Campbell syndrome is a rare and severe familial form of generalized tracheobronchomalacia in which there is marked reduction or absence of cartilage throughout the tracheobronchial airway.[120] However, the deficiency may be more severe in the cartilage distal to the main segmental bronchi.[121] Primary tracheomalacia has been found in association with Down syndrome, trisomy 9, DiGeorge syndrome (22q11 deletion), diastrophic dwarfism, absence of the pectoralis muscle (Poland syndrome), congenital absence of the thumbs, pectus excavatum, Ehlers-Danlos syndrome, Hurler and Hunter syndromes (mucopolysaccharidoses types I and II), and some congenital heart defects.[8] Most commonly, though, tracheomalacia occurs as a localized abnormality secondary to extrinsic compression such as from a vascular ring or mediastinal cyst.[122] It is also found in virtually all patients with esophageal atresia as discussed earlier and can be secondary to prolonged intubation, tracheostomy, and severe tracheobronchitis.

Clinical symptoms usually appear in early infancy and include a harsh loud vibratory cough (the "barking cough" typical of patients after esophageal atresia repair), rattly chest, dyspnea, wheeze, and possibly stridor. The cough and rattly chest are caused by impaired clearance of normal mucous secretions past the abnormal tracheal segment. Collapse of this malacic segment as a result of increased intrathoracic pressure during expiration causes narrowing of the airway lumen, airway obstruction, and expiratory stridor. The stridor may be both inspiratory and expiratory if laryngomalacia coexists.[64] This effect is exaggerated by increased respi-

ratory effort, such as during crying, feeding, and coughing, or during an intercurrent upper or lower respiratory infection, leading rapidly to dyspnea and severe respiratory distress. As the distress increases, inspiratory difficulty may be noted as well. In its severest form, acute severe obstructive episodes with cyanosis ("dying spells," as discussed earlier) may be seen. These require immediate treatment with oxygen and positive-pressure ventilation, although on occasion this can prove surprisingly difficult to achieve until the abnormal segment is bypassed with an endotracheal tube. Because wheezing is a common symptom in these patients, many are mistakenly treated for asthma for long periods. It is now believed that the incidence of asthma is not higher in patients with tracheomalacia than in the rest of the population, so this diagnosis should always be reconsidered in these patients when they show no convincing response to an adequate trial of bronchodilators. Other symptoms include the "bagpipe sign," a sibilant expiratory note persisting after the end of visible expiration.[123] Marked changes in airway caliber of the malacic segment may be detected on lateral inspiratory and expiratory chest radiographs[124] (see Fig. 64-6). This is particularly the case in short-segment malacia, in which the difference between the abnormal segment and the remaining normal trachea is readily discernible. When a large segment or the whole of the trachea is involved, it can be difficult to determine whether the degree of airway caliber change is abnormal, since there is a wide range of "normal" variation. This is particularly true in young infants, where the change in caliber may be as high as 50% during conditions of increased respiratory load such as during respiratory infections.[125] Rigid bronchoscopy affords direct visualization of the malacic area, as discussed earlier. When there is a well-defined, localized area of tracheomalacia in patients without esophageal atresia, an extrinsic lesion compressing the trachea should always be considered. At bronchoscopy, if the abnormal area is seen to pulsate vigorously, a vascular malformation should be suspected. If the pulsation is noted across the anterior wall of the trachea, an "anomalous" innominate artery is the most likely cause. Classically, this diagnosis is confirmed simply by elevating the tip of the bronchoscope, thereby compressing the pulsating mass while palpating the right radial artery for changes in flow and pressure. Most authors now consider that this anterior compression is caused by a normal innominate artery, whose origin is more to the left in infants[64,126]; localized tracheomalacia is the problem rather than an abnormal vessel.[107] Pulsations on the posterior tracheal wall usually suggest the presence of a vascular ring, which may be complete (double aortic arch and right aortic arch variants) or incomplete (retroesophageal right subclavian artery and left pulmonary artery sling).[127] Nonpulsatile lesions compressing the airway include bronchogenic cysts, cystic and solid mediastinal tumors, and enlarged lymph nodes. With all lesions compressing the trachea, computed tomography or magnetic resonance imaging is usually necessary to define the anatomy before surgery.[128,129] In patients with tracheomalacia from an extrinsic compression, the offending lesion usually should be addressed surgically. Occasionally, even after removal of the lesion or division of a vascular ring, the localized malacic segment continues to cause significant symptoms and requires treatment as discussed under the esophageal atresia section. Most patients with isolated tracheomalacia can be managed conservatively, with physiotherapy to improve clearance of trapped secretions, together with antibiotics for recurrent infections. With increasing age, airway function gradually improves as the tracheal diameter increases and the abnormal area stiffens. However, it may be many months or even years before symptoms have resolved. In neonates or young infants with significant ongoing obstructive problems from diffuse tracheomalacia, a period of continuous positive airway pressure can be used to "splint" the airway open until tracheal wall rigidity improves, which takes an average of 22 months. This positive pressure may be administered through a facemask, nasopharyngeal tube, or endotracheal tube. This treatment may be associated with feeding difficulties, delayed speech and language, and potential developmental delay.[130]

Patients with severe obstructive problems refractory to conservative measures have a significant morbidity and mortality risk. Because this may be as high as 80% in some cases, surgical treatment should be offered. Patients with dying spells are part of this group. Other indications for surgery include recurrent pneumonia, inability to extubate, and feeding difficulties with failure to thrive.[108,131] Tracheostomy, with or without continuous positive airway pressure, is one option,[64] although problems may persist when the end of the tracheostomy tube does not extend beyond the malacic segment. Aortopexy is generally effective for localized tracheomalacia.[131-133] Endoscopic stenting has been associated with severe complications such as perforation and arterial fistulization, making it less appealing than aortopexy for localized tracheomalacia. However, it has provided a life-saving option for patients with severe diffuse tracheomalacia.[109,134] The more generalized form of the disorder, Williams-Campbell syndrome, is associated with severe obstruction and recurrent infection progressing to bronchiectasis.[120] Other than physiotherapy and antibiotic treatment, no definitive therapy is available for this disorder; lung transplantation is an option but proximal airway malacia can lead to failure.[135]

TRACHEAL STENOSIS

Fixed narrowing of the trachea may be intrinsic or associated with an external compression. The former can be seen as a less severe form of tracheal atresia in which a narrow patent segment of trachea is present instead of a fibrous cord, while the latter shares common features with localized tracheomalacia. Congenital intrinsic tracheal stenosis is usually associated with complete cartilaginous tracheal rings. A number of forms have been recognized. Wolman described two types.[136] The first is a short narrowed segment with a trachea of normal caliber above and below; the second involves a tracheal lumen that narrows progressively as it descends toward the carina in a carrot-shape or "rat-tail" trachea. Stenosis is often seen in the segment of trachea distal to the origin of a tracheal bronchus (see later), with the narrowing characteristically extending to the carina, whereas the left and right main bronchi are usually normal in diameter (Fig. 64-8). More than 80% of patients with complete tracheal rings have associated anomalies, most frequently cardiovascular (the left pulmonary artery sling syndrome being the most common).[137] Down syndrome, chondrodystrophies such as Ellis–van Creveld syndrome, and congenital stippled epiphyses have also been associated with various forms of tracheal steno-

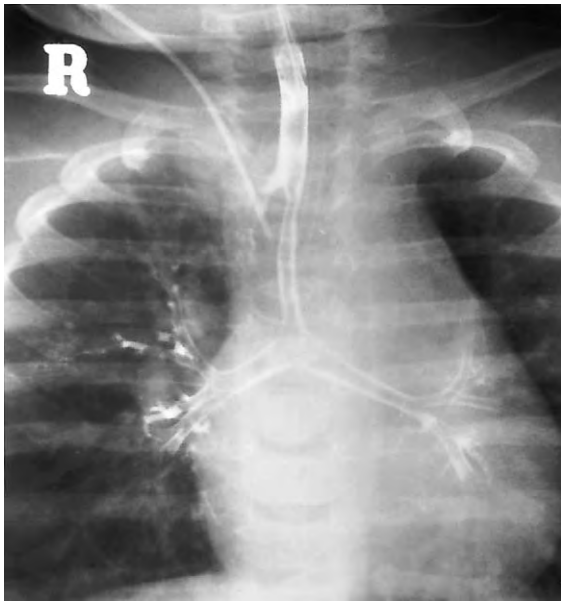


Figure 64-8 Tracheal bronchus with distal tracheal stenosis. A well-recognized configuration of this anomaly is demonstrated in this bronchogram from a 13-month-old girl with a history of bidirectional wheeze and stridor worsening with infection. It shows the tracheal bronchus (invariably right-sided) arising from the intrathoracic trachea, the subsequent portion of trachea stenosed to the carina, normal caliber left and right main bronchi and beyond, and absence of the normal right upper lobe bronchial branch.

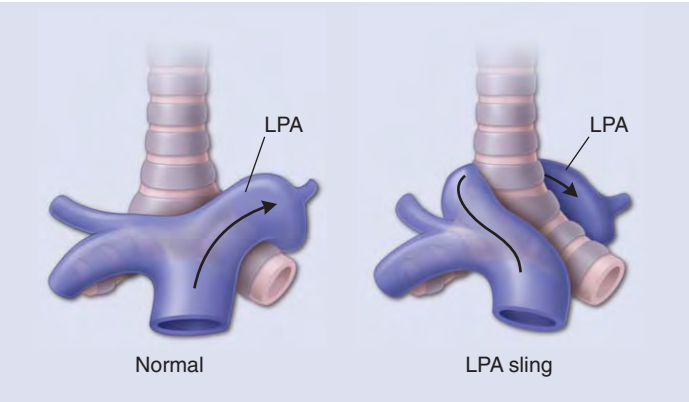

Figure 64-9 Left pulmonary artery (LPA) sling. Diagram showing the normal and abnormal configuration where the left pulmonary artery curls around the right side of the carina before progressing between the trachea and the esophagus to supply the left lung.

sis.[138] Other rare causes of short segment stenosis include tracheal webs (found usually just above the carina), tracheal cysts, and sequestered esophageal tissue in the trachea (which is much less common than the reciprocal, that is, tracheal remnants sequestered in the esophageal wall leading to esophageal stenosis).[139] Characteristically, patients with tracheal stenosis localized to the extrathoracic portion of the trachea present with stridor, which is usually more prominent during inspiration. Patients with intrathoracic stenosis generally present with wheeze or mixed wheeze and stridor, which is predominantly expiratory. In both instances, when the stenosis is severe and fixed, the added noises may be prominent in both inspiration and expiration. A wet-sounding biphasic breathing pattern that transiently clears with coughing is referred to as "washing-machine breathing" by Rutter.[137] Additional factors, such as associated structural weaknesses in the airway adjacent to the stenosis and the increased pressures this airway is subjected to in the presence of narrowing, also influence the sounds produced during respiration. When the narrowing is severe, breath sounds may be accompanied by significant respiratory distress, whereas in mild cases they may be noticeable only when respiratory load is increased, as with exercise or infection. Penetrated radiographs of the airway may identify a narrowed segment, although CT or MRI is necessary to define the extent of the lesion and to search for an extrinsic cause.[140] Bronchoscopy may also be helpful to plan treatment. Respiratory function tests show evidence of fixed obstruction with characteristic flattening of the inspiratory and expiratory portions of the flow-volume loop.

Management is difficult. In some patients the stenosis improves with tracheal growth, and conservative symptomatic treatment and support should be the recommended approach when possible.[141] Results of dilation techniques and laser resection of the intraluminal narrowing have been disappointing, with subsequent recurrence of the stenosis the rule. Endoscopic stenting has been used in some centers.[142,143] This should be avoided when there is an associated vascular ring or sling because of the risk of erosion with arterial fistulization.[137] Surgical options include resection and primary anastomosis for short segment stenosis and the tracheal slide technique for longer narrowings.[144,145] Tissue engineering will undoubtedly provide a useful alternative for tracheal reconstruction in the future.[146,147]

The *left pulmonary artery sling syndrome* is a particularly well-described cause of tracheal stenosis.[127] In this condition, the left pulmonary artery passes initially to the right in front of the carina. It then curls posteriorly over the origin of the right main bronchus before crossing to the left hemithorax between the esophagus and trachea (Fig. 64-9). This looping of the aberrant vessel around the carina usually has a strangling effect, resulting in variable degrees of compression and localized narrowing. The compressed area may be malacic or, in some cases, associated with severe annular constriction of the trachea. This may either be localized to this area or, more commonly, involve the length of the trachea (and possibly major bronchi) in a carrot-shape configuration. When this configuration is present, the tracheal cartilages are characteristically abnormal in that they are increased in number (both in the trachea and major bronchi) and that they take the form of complete annular cartilage, so-called napkin ring cartilages. Although these patients usually present in the first few days of life with severe respiratory distress characterized by inspiratory and expiratory difficulty, some infants surprisingly do not develop significant respiratory difficulties until a few weeks or even several months of age despite an exceedingly narrow trachea. The chest radiograph reveals apparently normal lungs, although the carina and a variable portion of the trachea are not identifiable. Diagnosis is best made on magnetic resonance angiogram, which is complemented by CT scan or bronchoscopy if necessary.[148] Long segment tracheal stenosis is difficult to repair, and often fatal; a localized narrowing may be improved by reimplantation of the left pulmonary artery, but a fixed associated intrinsic stenosis or

localized malacia may persist and should be addressed at the same setting. This may be accomplished with either stenting (for severe malacia) or resection/tracheoplasty as discussed earlier for complete cartilage rings.

TRACHEAL DIVERTICULUM

This is an extremely rare anomaly, usually arising from the right posterolateral surface of the trachea, that may give rise to symptoms only late in adult life when it becomes infected. Because of this, it has been suggested that it may be an acquired rather than a congenital lesion, but a few reports of congenital diverticula exist.[149,150] Some consider this malformation as a blind-ending tracheal bud, i.e., the lesser form of an accessory tracheal bronchus.[151,152]

TRACHEOBRONCHOMEGALY (MOUNIER-KUHN SYNDROME)

This condition is characterized by marked dilation of the trachea and major bronchi, probably as a result of abnormal development of elastic and muscular tissues in the airways.[153] Most patients present in adult life but cases have been reported in children as young as 18 months.[154] It is often associated with other congenital defects of the ribs and lung topography.[155] The finding of this condition coexisting with Ehlers-Danlos syndrome and cutis laxa supports the possibility of an underlying connective tissue abnormality. A familial occurrence suggesting an autosomal recessive inheritance has also been described.[49] Reduced efficiency of airway mucociliary clearance and inefficient cough found in this condition eventually lead to recurrent infection and the development of bronchiectasis, although many of these patients may remain asymptomatic until late adulthood.[156] Marked dilation of the trachea is obvious on the plain radiograph, with the tracheal shadow often being as wide as the vertebral bodies. Physiotherapy and aggressive treatment of infection may retard the development of bronchiectasis.

Mainstem and Lobar Bronchi

TOPOGRAPHIC ANOMALIES

Topographic anomalies of the whole lung such as situs inversus and left mirror image and right mirror image lung (bilateral left or bilateral right lung) have been shown to correlate in almost all instances with topographic anomalies of atrial arrangement (situs inversus, left isomerism, and right isomerism, respectively), and with abdominal aorta and vena caval relationships.[157] Several growth and transcription factors important in early lung development have recently been implicated in right-left asymmetry development in animal models.[24,158-160] Clinically, five types of polysplenia/asplenia syndromes have been described in association with bronchial isomerism (bilateral left or bilateral right lung), some in boys only, some in girls only, some in both sexes equally.[161] Intestinal malrotation and liver isomerism are common in several of the types, including the Ivemark asplenia syndrome.[49,161]

Isolated lobar or segmental topographic bronchial anomalies are now often recognized, although most cause no symptoms and are diagnosed incidentally or at autopsy. Tracheal bronchus, abnormal segmental bronchial branching, supernumerary segmental or lobar bronchi, and bridging bronchi are the most common abnormalities found. Bronchial branching anomalies are also found in the scimitar syndrome, which almost always affects the right side only (see later).

Tracheal Bronchus. Tracheal bronchus always occurs on the right, as do 80% of all bronchial topographic anomalies.[162] It is also known as a pre-eparterial bronchus and often called a "pig-bronchus" because of its normal occurrence in swine.[152,163] The incidence of a tracheal bronchus has been reported from 0.001% to 2%, the latter in a large series of *symptomatic* patients younger than 5 years undergoing bronchoscopy.[152,164] It may be associated with trisomy 21 and other malformations.[152] The abnormal bronchus usually arises from the midthoracic trachea and supplies either:

1. The apical segment of the right upper lobe (with the normal right upper lobe bronchus supplying the rest of the lobe), or
2. An accessory segment within the upper lobe, or
3. An accessory segment completely separate from the upper lobe, or
4. The whole right upper lobe (in which case the normal right upper lobe branch is absent [see Fig. 64-8]).[151]

Structural abnormalities such as stenosis and malacia may be found in these bronchi, although the lung segment supplied by this bronchus is usually normal or at least initially so. Poor drainage of this segment often leads to recurrent infection and bronchiectasis in later life. The bronchus itself is more commonly the site of bronchial adenoma, carcinoma, or bronchogenic cysts. Patients usually present with signs and symptoms of persisting right upper lobe infection or tracheal stenosis. The diagnosis is usually made at bronchoscopy or on imaging studies. Management is directed at improving drainage of the affected segment with physiotherapy and controlling infection with antibiotics. If the segment becomes bronchiectatic and problems persist despite conservative treatment, resection may be necessary. Symptoms caused by any associated tracheal stenosis usually improve with tracheal growth, although if the stenosis is severe, they may prove particularly troublesome and difficult to manage until growth occurs.

Bridging Bronchus. A bridging bronchus is an anomalous bronchial branch arising from the left mainstem bronchus and crossing the mediastinum to enter the right lower lobe. In the first two cases reported, the right lung was bilobed and areas of stenosis in the tracheobronchial tree were present.[165,166] Both children died of recurrent infection in early infancy, but there are recent reports of successful repair.[167] An interesting theory was proposed by Wells and colleagues[168] to explain the anatomy found in patients with a left pulmonary artery sling and a tracheal bronchus supplying the right upper lobe. According to the level of origin of the tracheal bronchus, this would be the normal level of the carina, and the bronchi supplying the right middle and lower lobes would be bridging branches originating from the left main bronchus.

MORPHOLOGIC ABNORMALITIES

Bronchomalacia. Bronchomalacia is most commonly found in association with tracheomalacia, and the symptoms, diagnosis, and treatment of these combined lesions are discussed in the section on tracheomalacia. It is defined as an abnormal weakness in the airway wall and is found more commonly in premature neonates and patients with Down syndrome,

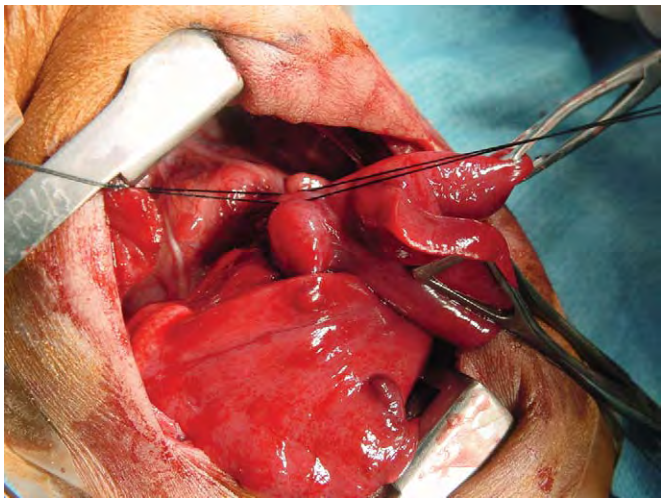
although it may occur in full-term infants. As with tracheomalacia, spontaneous improvement with age is the rule and only patients with significant respiratory problems require treatment in the meantime. Isolated segments of bronchomalacia are rare and occur most commonly as a result of extrinsic compression. A generalized severe form of bronchomalacia with absence or marked deficiency of airway cartilage, known as Williams-Campbell syndrome, is described in the section on tracheomalacia. Bronchomalacia associated with defective cartilage development has also been implicated in the pathophysiology of congenital lobar emphysema (see later).

Bronchial Stenosis. Congenital isolated stricture of a bronchus occurs predominantly in mainstem or first-generation bronchi and predisposes to recurrent and chronic infection in the area distal to the narrowing as a result of impaired drainage of secretions. Secondary narrowing is far more common and is usually caused by compression by mediastinal cysts, tumors, and vascular anomalies.[42] Apart from infection, these patients may present with a recurrent wheeze that does not respond to bronchodilators. The diagnosis is made on CT scan or MRI or at bronchoscopy. Surgical resection of the stenosed area usually is precluded by inaccessibility and the small size of the lesion. Chronic infection and bronchiectasis distal to the stenosis usually necessitate resection of the affected lung segment or lobe.

Bronchial Atresia. In bronchial atresia, a lobar or segmental bronchus ends blindly, either with an atretic membrane or in a blind pouch, with a short gap to the distal continuation of the airway to that particular lobe or segment. This entity also overlaps with congenital lobar emphysema (CLE) which is discussed later.[169] Older reports of isolated bronchial atresia focus on the predominance of left upper lobe, right middle, and right upper lobe lesions with radiologic and pathologic similarity to CLE.[49,51,170,171] Older patients are often asymptomatic, with the hyperinflated lobe discovered incidentally on chest radiograph. Ventilation of the segment is thought to occur through the pores of Kohn, which favors inspiration rather than expiration, resulting in gas trapping. The only physical finding may be decreased breath sounds over the affected area. When a major bronchus is atretic, the affected distal lobe may be significantly hyperinflated, causing compression of surrounding healthy lung and shift of the mediastinum to the opposite side. In such patients, symptoms of reduced exercise tolerance and possibly wheeze and shortness of breath may be prominent. CT is commonly used to confirm the diagnosis. Surgical excision is indicated when overdistention of the affected lung segment or lobe leads to compromise of surrounding normal lung (as in congenital lobar emphysema) and significant symptoms. Mainstem bronchial atresia is much more serious; a single report describes two fetuses who became hydropic and died, one despite an attempt at fetal intervention.[172]

In recent years, the increasing use of prenatal ultrasound has changed the concept of isolated bronchial atresia.[51] Echogenic lung lesions, with and without cystic changes, are now being discovered in the fetus and resected soon after birth (Fig. 64-10). Many of the lesions previously described as CCAM and intralobar sequestration have been found in association with bronchial atresia, often involving the lower lobes.[51,173,174] These authors now see bronchial atresia as the underlying cause of many congenital lung malformations. This is discussed further in the section on lung malformations.

A



B

Figure 64-10 Prenatal diagnosis of a hybrid lung lesion (bronchial atresia and sequestration). Prenatal ultrasound examination was compatible with a large, mostly echogenic left lung CCAM/CPAM causing severe mediastinal shift and polyhydramnios but no hydrops. **A,** Fetal MRI at 25 weeks' gestation. This coronal (but slightly oblique) T2-weighted view shows the very bright enlarged left upper lobe herniating into the right chest. Only a small rim of normal right lung was seen, and none on the left. Flattening of the left diaphragm was observed on sagittal views (not shown). The fetus was closely monitored with serial ultrasonograns and lung hypoplasia was feared. After 32 weeks of gestation, the mass started regressing and the mediastinal shift improved. At birth, the infant had minimal respiratory symptoms but gradually became more tachypneic, leading to an operation on the second day of life. **B,** At operation, part of the upper lobe was nonaerated. This segment, which was separated from the rest of the upper lobe by a pseudo-fissure, was fed by an aberrant systemic artery (held by silk sutures) from the aorta. There was no bronchus at all to the upper lobe. At pathology a diagnosis of bronchial atresia was made, with dilated distal bronchi filled with mucus, without features of CCAM/CPAM; the systemic artery to the apical segment was confirmed.

Bronchiectasis. Bronchiectasis is not a congenital malformation as such, but develops in several congenital and familial conditions. The most common is cystic fibrosis; others include the immotile cilia syndrome (called Kartagener syndrome

when associated with situs inversus) and several immunodeficiency states (IgG, IgA, alpha$_1$-antitrypsin, neutrophil, complement).[49] In Williams-Campbell syndrome, discussed under tracheomalacia, bronchiectasis may occur early in infancy.

Bronchogenic Cysts. Bronchogenic cysts are part of the spectrum of foregut duplications. They account for approximately 5% of mediastinal masses in infants and children; this percentage is higher in adults. Some are diagnosed incidentally at thoracotomy or at autopsy,[175] which indicates that they may be more common than is normally appreciated. They are solitary, unilocular cystic structures that contain fluid or mucus. They are usually 1 to 3 cm in diameter but may reach up to 10 cm in older patients.[51] Most commonly located in the mediastinum near the tracheal bifurcation, they may be found from the suprasternal area to below the diaphragm, and even within the pleura and subcutaneously.[51,176,177] Some pathologists consider intrapulmonary bronchogenic cysts as instances of type 1 CPAM (see later),[49] but other pathologists disagree.[51] Although it is generally recognized that they do not communicate with the tracheobronchial tree,[51] some series report that such communications are frequent.[178] In at least 20% of the cases the cyst is totally separated from the bronchopulmonary tree, lying subpleurally in the mediastinum or occasionally attached to other structures such as the esophagus or the pericardium.[179] Bronchogenic cysts have been described in association with other congenital lung anomalies such as sequestration.[50] The cyst is thin walled, lined with ciliated respiratory epithelium and mucus glands, and surrounded by smooth muscle and fibrous tissue. The presence of cartilage in the wall is used to differentiate bronchogenic cysts from esophageal duplications, although overlap exists and both can simply be considered as foregut duplications.[179] Foregut duplication cysts may rarely communicate with an abdominal duplication or with the spinal canal; the latter are called neurenteric cysts and are usually associated with hemivertebrae or other vertebral defects[179,180] (Fig. 64-11). The classic embryologic explanation for bronchogenic cysts is that the developing bronchus is disrupted at a particular stage and a fragment of bronchial tissue separates to form the bronchial cyst. The eventual location and histologic features of the cyst depend primarily on the time of the disruption. The recent review of foregut duplications by Azzie and Beasley[179] mentions that altered expression of the *Shh* gene by the notochord could affect the *Shh-Gli* signalling pathway and lead to some of these malformations.

Bronchogenic cysts are found in five major locations within the thorax, according to a classic review[181]:

1. The right paratracheal region (corresponding to the usual site of origin of the tracheal bronchus), 19%
2. The carinal region (where they are most likely to cause symptoms by airway compression), 51.5%
3. The hilar region (where the cyst is located on or near a mainstem or lobar bronchus and is often latent), 8.6%
4. Paraesophageal region (usually low near the cardia and may compress the esophagus), 13.8%
5. Other locations such as pericardial, retrosternal, and paravertebral, 6.9%

A very small number, which would more likely correspond to the histology of esophageal duplications rather than bronchogenic cysts, communicate with the spinal canal or through the diaphragm as mentioned earlier. However, some thoracic foregut duplications may be associated with a separate abdominal duplication.[179] Clinical findings are diverse, depending on the location of the cyst. Proximal tracheal compression can cause stridor and respiratory distress. Compression at the carinal area leads to cough, wheezing, dyspnea, atelectasis, overinflation of one or both lungs, or recurrent infections. Compression of a smaller bronchial branch may cause localized signs with recurrent infections and hyperinflation or atelectasis of the distal lung parenchyma. The cyst itself can become infected (usually by contamination through a tracheobronchial communication), leading to acute distention and exacerbation of compressive symptoms. Hemoptysis can also occur. Dysphagia is a symptom of esophageal compression. Many cysts are asymptomatic and may be diagnosed incidentally on chest radiographs or other imaging modalities performed for other reasons.[182,183] In recent years, bronchogenic cysts have also been diagnosed prenatally by ultrasonography, sometimes resulting in congenital lobar overinflation.[182,184,185] On chest radiography, they appear as rounded space-occupying lesions projecting from the mediastinum, often displacing and compressing the lower trachea and bronchus adjacent to the cyst (Fig. 64-12). A barium swallow may demonstrate esophageal compression or a lesion separating the trachea and esophagus. CT is the most often used modality for identifying, localizing, and defining the cystic mediastinal lesion, although MRI has become more popular in recent years because of the risks of postradiation malignancy.[186] The mucoid content is sometimes so thick

Figure 64-11 Neurenteric cyst. The presence of a cleft vertebral anomaly underlying a rounded mass indenting the upper trachea and deviating to the right, as seen in this chest radiograph, is characteristic of a neurenteric cyst.

that a bronchogenic cyst may be misinterpreted as a solid mass on CT because of its elevated density. On MRI, however, the lesion will appear bright on T2-weighted images as for other fluid-containing structures (Fig. 64-13). For neurenteric cysts, MRI provides the best imaging of all components of the malformation. Drawbacks in its use are that children usually require sedation or even general anesthesia for the procedure, and it is less useful than CT for the evaluation of the bronchial tree. Bronchoscopy is seldom necessary but may demonstrate compression and displacement of the airway. Bronchography has been abandoned in favor of CT and MRI. Surgical excision is indicated in all cases of foregut duplications because of their propensity to produce complications and a higher rate of intraoperative complications. Resection can be accomplished by a thoracoscopic approach in most cases.[182]

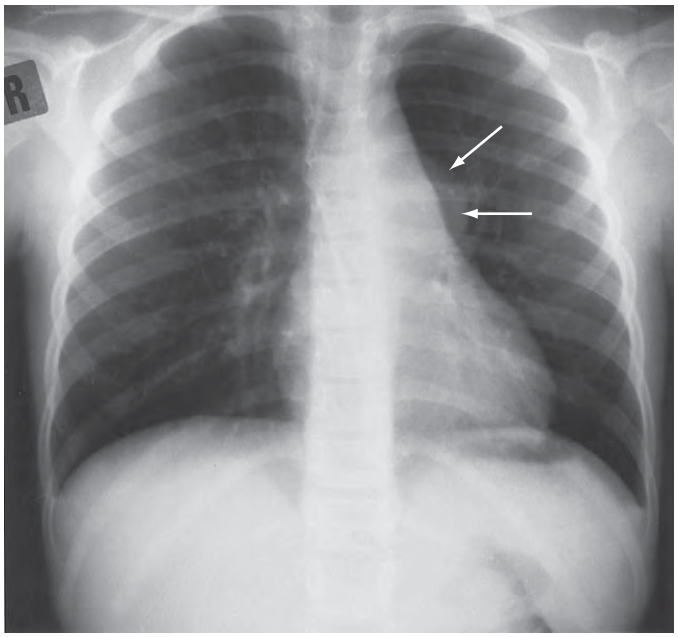


Figure 64-12 Bronchogenic cyst. The typically rounded hilar mass *(arrows)*, seen on this chest radiograph indenting the left main bronchus and lower trachea while deviating the trachea to the right, was confirmed at surgery to be a bronchogenic cyst.

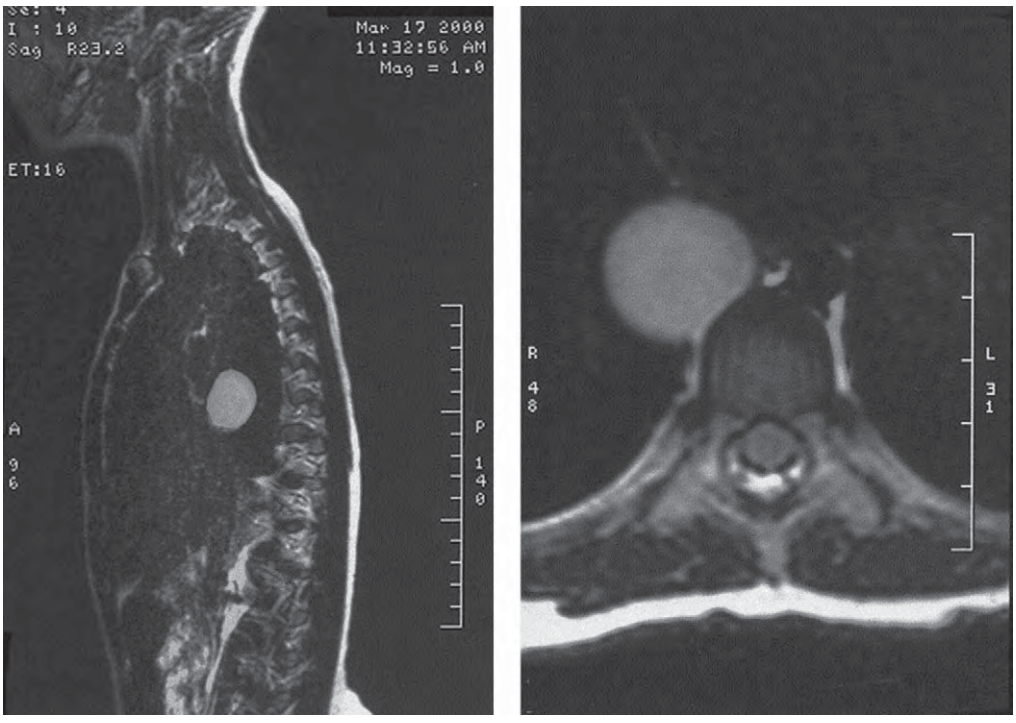
Other Mediastinal Cysts. Enteric duplication cysts have already been discussed; pericardial cysts, benign cystic teratomas, dermoid cysts, thymic cysts, and mediastinal meningoceles should be included in the differential diagnosis of bronchogenic cysts.

Bronchobiliary/Tracheobiliary Fistula. This is a rare anomaly usually presenting early in infancy because of symptoms produced by the intense inflammatory effect of bile secretions in the bronchial tree. Fewer than 30 cases have been described. A tract connects the biliary tree to the lower

PITFALLS IN AIRWAY MALFORMATIONS

- A laryngotracheoesophageal cleft is often missed on direct laryngoscopy and flexible endoscopy; rigid bronchoscopy is required.
- A pure "H-type" tracheoesophageal fistula is easily missed on routine contrast swallow; a tube contrast esophagogram yields better results but rigid tracheoscopy remains the best diagnostic test.
- The extent and severity of tracheomalacia is best appreciated with rigid tracheoscopy under general anesthesia with the patient breathing spontaneously; lateral chest fluoroscopy can be a useful initial investigation.



A B

Figure 64-13 A 6-year-old girl had been operated on and followed since birth for a low lumbar lipomeningocele. An asymptomatic foregut duplication cyst was incidentally detected on these T2-weighted magnetic resonance images done to evaluate for a tethered cord (**A,** sagittal view; **B,** axial view). She underwent an uncomplicated thoracoscopic resection. (From Laberge J-M, Puligandla P, Flageole H: Asymptomatic congenital lung malformations. Semin Pediatr Surg 14:16-33, 2005.)

trachea, carina, or one of the main bronchi, nearly always on the right near the carina.[187,188] Yellow or green bile-stained sputum associated with cough, atelectasis, and infection forms a distinctive clinical picture in infancy. Early surgery is recommended before extensive autolytic damage occurs.[189] The embryologic origin of the lesion remains obscure.[151] Associated anomalies are uncommon but have included esophageal atresia with tracheoesophageal fistula, biliary atresia, and right congenital diaphragmatic hernia.[190-192]

LUNG MALFORMATIONS

Lung Unit as a Whole

PULMONARY AGENESIS

Bilateral agenesis is exceedingly rare and may occur in association with anencephaly.[193] It has been observed in mice deficient in FGF10 or its receptor.[26,194] The role of retinoic acid in lung development was recognized as early as 1949[195] and was recently reviewed[31]; mice deficient in its receptor show a variety of developmental defects such as agenesis of the left lung and pulmonary hypoplasia.

Unilateral agenesis is found in 1 in 10,000 to 20,000 autopsies.[196] The agenesis affects both lungs with equal frequency, with a slight female preponderance of 1.3 : 1.[49] Lobar agenesis is rarer than complete absence of one lung and, when it occurs, usually affects the right upper and middle lobes together. Long-term survival with unilateral lung agenesis is possible in the absence of associated severe anomalies, which include anencephaly and cardiovascular, gastrointestinal, skeletal and urogenital malformations.[178,197-201] Absence of one lung has been described with esophageal atresia and other VACTERL anomalies.[202-204]

Neonatal respiratory distress is common. Chest radiographs show a marked mediastinal shift with herniation of the contralateral lung across the mediastinum. The absence of the carina or, more commonly, a blind-ending bronchus (sometimes termed "aplasia" instead of "agenesis," where there would be no carina or bronchial stump) may be appreciated on a penetrated film or a CT scan with reconstruction (Fig. 64-14). Echocardiography and angiography show absence of the pulmonary artery, and it is always necessary to exclude other associated cardiovascular lesions. There is also agenesis of both sympathetic and parasympathetic plexuses, generally with a lack of parietal pleura.[151] Mortality is said to be higher with right lung agenesis, possibly because of the smaller size of the left lung but also because of a higher incidence of cardiovascular anomalies with right lung absence.[199] A higher risk of vascular compression of the trachea with right lung agenesis has also been implicated.[205] The differential diagnosis includes total atelectasis caused by bronchial obstruction, unilateral emphysema with compression or collapse of the contralateral lung, or severe pulmonary hypoplasia.

With more routine prenatal ultrasound screening, the diagnosis may be made before birth, although the enlarged unilateral lung may be mistaken for an abnormal lung (such as seen with CPAM/CCAM; see later) with mediastinal shift and severe compression of the presumed normal lung (which is in fact absent). Careful repeat imaging, including fetal MRI, should be done to avoid the catastrophic consequences of an EXIT resection of this presumed abnormally enlarged lung, which would in fact be the infant's one and only lung.[206]

Patients presenting late usually have readily detectable flattening and reduced movement of the chest wall on the affected side, with reduced air entry on auscultation, although this often sounds surprisingly better than expected. There may be some breathlessness on exertion and the chest wall deformity may be quite pronounced, with an associated secondary scoliosis. On the chest radiograph, there is considerable mediastinal shift and the involved hemithorax is small, with narrowed intercostal spaces.

Management is initially limited to supportive treatment (including oxygen if necessary), correcting associated malfor-

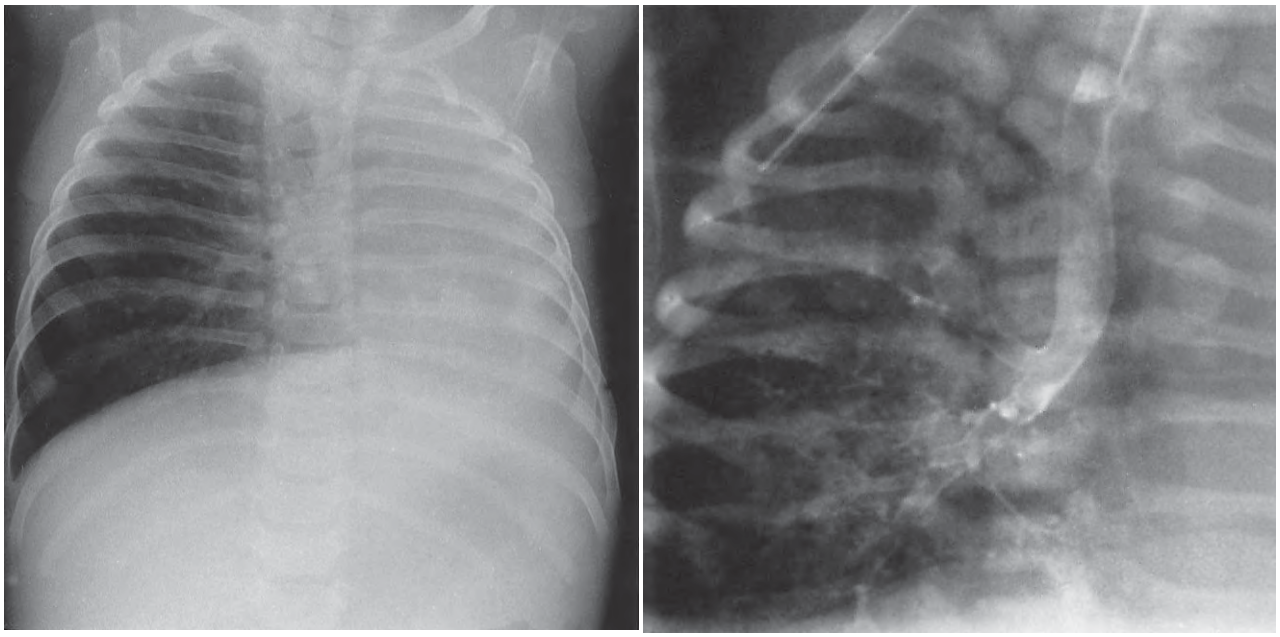


Figure 64-14 Left lung agenesis. Agenesis of the left lung with absence of the carina and left bronchial stump confirmed on tracheobronchogram. Note the associated vertebral anomaly, a common association with major airway abnormalities. Advanced imaging techniques such as CT scan have largely replaced bronchography.

mations, and the prevention and treatment of respiratory infections. In some cases tracheal stenosis or vascular compression may coexist and require treatment.[205,207,208] Imaging techniques combined with rigid bronchoscopy allow a precise diagnosis to be made.[209] Pulmonary hypertension is a complication that requires particular care and attention. It is more common in these patients simply because a normal blood volume must flow through a reduced pulmonary vascular bed. The presence of hypoxia (which is a potent pulmonary vasoconstrictor) or a cardiac left-to-right shunt (which further increases the flow through the already reduced pulmonary vascular bed) will compound this effect and is likely to accelerate the progression of the pulmonary hypertension to irreversible pulmonary vascular disease. Because of the severe mediastinal shift, some patients develop a progressive deterioration similar to the postpneumonectomy syndrome and may improve with the insertion of a tissue expander in the ipsilateral chest.[208]

PULMONARY HYPOPLASIA

Pulmonary hypoplasia is usually defined as a lung weight more than 2 standard deviations below the normal for age (or gestational age), or in terms of lung weight–to–body weight ratio, the normal being 0.222 ± 0.002 for term and near-term infants.[197] Because postnatal events such as pulmonary edema and pneumonia may affect lung weight, the radial alveolar count[210] and the mean terminal bronchiole density[211] are other methods to assess the adequacy of lung development. Alveolar counting and lung volume measurements have also been used.[212,213]

Pulmonary hypoplasia is almost always accompanied by hypoplasia of the corresponding pulmonary vessel. This follows obviously from the second rule of lung embryogenesis, in which the vasculature follows the bronchial development.[214] Hypoplasia as an isolated phenomenon is rare; a familial form has been described.[215] More commonly, pulmonary hypoplasia is associated with conditions that interfere with lung growth; Box 64-1 lists some of these.[49,151,216,217] Severe oligohydramnios (whether from prolonged rupture of membranes or urinary tract malformation) is the most frequent cause of pulmonary hypoplasia. Initially thought by some to be a primary phenomenon as part of the Potter syndrome, its reversibility has been demonstrated experimentally.[218,219] Furthermore, while chest wall compression by the uterus was classically thought to explain the lung hypoplasia, measurements of amniotic fluid pressures in the remaining pockets have shown pressures to be lower than normal.[220,221] In experimental studies, it was also found that severe oligohydramnios increased spinal flexion, causing compression of abdominal contents, elevation of the diaphragm and lung compression.[222] Lower amniotic fluid pressures combined with elevation of the diaphragm causes more lung fluid to egress through the larynx; a decrease of alveolar distention by lung fluid results in pulmonary hypoplasia, as demonstrated experimentally by Moessinger and colleagues.[223] The same mechanism explains the pulmonary hypoplasia that can be seen with large tracheoesophageal fistulas and complete laryngotracheoesophageal clefts; in these cases the pulmonary fluid escapes through the defect, resulting in the loss of the 1 to 2 cm H_2O gradient normally maintained by the larynx.[224]

BOX 64-1 Most Common Causes of Pulmonary Hypoplasia

Conditions Leading to an Egress of Lung Fluid

Severe oligohydramnios (from premature rupture of membranes, bilateral renal agenesis, or urinary tract obstruction). Compression of the thoracic cage and abdominal contents by the uterus and limitation of breathing movements may also play a role.
Laryngotracheoesophageal cleft
Large tracheoesophageal fistula

Space-Occupying Lesions

Congenital diaphragmatic hernia, eventration
Lung malformations (CCAM, sequestration, others)
Thoracic tumors
Pleural effusion, chylothorax
Abdominal conditions pressing on the diaphragm (massive ascites, cysts, and tumors)

Thoracic Cage Anomalies

Jeune syndrome (asphyxiating thoracic dystrophy)
Achondroplasia, others
Scoliosis

Conditions Preventing Normal Fetal Breathing Movements

Anencephaly
Phrenic nerve agenesis
Other syndromes and conditions affecting the central nervous system

Miscellaneous Conditions, Where the Mechanism of Lung Hypoplasia Is Unclear or Multifactorial

Giant omphalocele
Chromosomal anomalies, including trisomy 13, 18, and 21.

With space-occupying lesions such as congenital diaphragmatic hernia (discussed in more detail later), the hypoplasia is more severe on the ipsilateral side, although the contralateral side is also affected, to a lesser degree, because of the fetus' mobile mediastinum. Sometimes the hypoplasia is part of an intrinsic developmental problem, such as seen with the abnormally formed right lung in the scimitar syndrome (see later).

Clinically, patients with pulmonary hypoplasia may present in early infancy with respiratory distress ranging from mild to severe, depending on the degree of hypoplasia. Commonly, it is the associated anomalies that draw the attention. In severe bilateral hypoplasia the thoracic cage is obviously reduced in size and characteristically bell shaped, with the base of the chest widening at diaphragmatic level to a normal-sized abdomen. The patient is tachypneic, with restricted chest wall movement, and in respiratory distress. Less severe degrees of hypoplasia—unilateral or bilateral—may present later with persistent tachypnea or disproportionate shortness of breath with exercise. Occasionally, the abnormality is coin-

cidentally noticed on examination or chest radiograph when the patient presents with an intercurrent infection. In unilateral hypoplasia, the chest cage appears asymmetric, with diminished air entry and chest expansion on the side of the lesion together with mediastinal shift to that side. The chest radiograph confirms mediastinal deviation and a lung that often appears hyperlucent. Isotope scanning usually reveals a greater impairment of perfusion than ventilation on the side of the lesion. In right-sided hypoplasia, it may be important to establish the pattern of vasculature because of the common association with scimitar syndrome (see later). In the absence of associated lesions, unilateral pulmonary hypoplasia is compatible with normal growth, development, and survival. Long-term complications include reduced exercise tolerance, recurrent infections and sometimes a worsening chest deformity with scoliosis.

PULMONARY HYPERPLASIA

Pulmonary hyperplasia is the growth of lung parenchyma beyond its normal control. It is always a secondary phenomenon, usually in response to airway obstruction in utero.[51] Diffusely enlarged lungs are seen with laryngeal and tracheal atresia as discussed earlier, and can be reproduced experimentally with fetal tracheal occlusion.[223-225] More localized areas of lung hyperplasia will be discussed in the next section.

Parenchymal Malformations

This is where most of the controversies lie regarding pathogenesis and classification of congenital lung lesions. For the purpose of this chapter we will use the terms currently employed in clinical practice, recognizing that they are changing and that overlap exists between some of these malformations. Box 64-2 shows a pathologic classification recently proposed by Langston. This can be contrasted with the more "old-fashioned" or clinically oriented approach used here.

CONGENITAL LOBAR EMPHYSEMA

Congenital lobar emphysema (CLE) is used to describe a distended, hyperlucent lobe on plain radiographs, most often the left upper lobe, followed by the right middle and the right upper lobes.[151,226] The term *emphysema* is often considered a misnomer because it implies parenchymal destruction to pathologists, but it is consistent with the meaning of its Greek root "inflation." Pathologically, a distinction is made between a *polyalveolar lobe*, in which the number of alveoli is greatly increased, and *congenital lobar overinflation* (CLO), in which the alveoli are markedly distended but normal in number. CLO is thought to be caused by a partial bronchial obstruction creating a ball-valve effect. This obstruction may be intrinsic (bronchomalacia) or less commonly extrinsic (vascular, bronchogenic cyst), but in many instances an exact cause cannot be determined.[49,227,228] The pathogenesis of a polyalveolar lobe remains uncertain but transient bronchial obstruction in utero has been suggested.[229]

CLE is rarely detected prenatally.[229,230] It appears as an echogenic homogeneous lung mass that may regress before birth.[229,231] The typical postnatal presentation is progressive tachypnea with lobar hyperinflation, mediastinal shift, and sometimes contralateral atelectasis. Occasionally, it is difficult to determine whether the contralateral collapse is the primary phenomenon or if it is secondary to the CLE; identifying a collapsed ipsilateral lobe is helpful. Initial postnatal films may show fluid retention, as seen in Figure 64-15, although the pathologic diagnosis was different in that case; as the fluid clears the lobe gradually becomes hyperinflated. When this leads to respiratory distress, lobectomy is indicated. Positive pressure ventilation will only worsen the hyperinflation. High-frequency oscillating ventilation may be useful as a temporary preoperative measure. The diagnosis is based on the clinical course and plain radiographs. Because extrinsic lesions are uncommon, the limited benefits of CT scan should be weighed against the potential risks of respira-

BOX 64-2 Langston's Classification of Congenital Lung Malformations

Bronchopulmonary Malformation

- Bronchogenic cyst (noncommunicating bronchopulmonary foregut malformation)
- Bronchial atresia
  - Isolated
  - With systemic arterial/venous connection (intralobar sequestration)
  - With connection to gastrointestinal tract (intralobar sequestration/complex or communicating bronchopulmonary foregut malformation)
  - Systemic arterial connection to normal lung
- Cystic adenomatoid malformation, large cyst type (Stocker type 1)
  - Isolated
  - With systemic arterial/venous connection (hybrid lesion/intralobar sequestration)
- Cystic adenomatoid malformation, small cyst type (Stocker type 2)
  - Isolated
  - With systemic arterial/venous connection (hybrid lesion/intralobar sequestration)
- Extralobar sequestration
  - Without connection to gastrointestinal tract (with/without CAM, small cyst type)
  - With connection to gastrointestinal tract (complex/communicating bronchopulmonary foregut malformation)

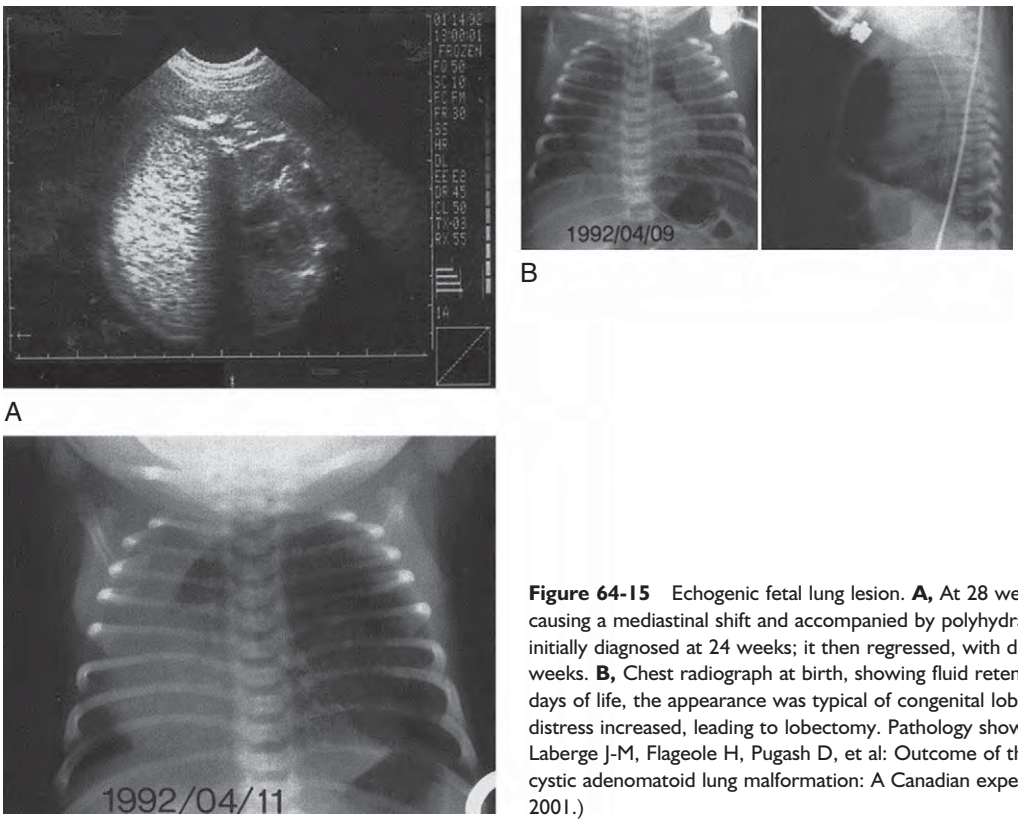
Pulmonary Hyperplasia and Related Lesions

- Laryngeal atresia
- Solid or adenomatoid form of cystic adenomatoid malformation (Stocker type 3)
- Polyalveolar lobe

Congenital Lobar Overinflation

Other Cystic Lesions

- Lymphatic/lymphangiomatous cysts
- Enteric cysts
- Mesothelial cysts
- Simple parenchymal cysts
- Low-grade cystic pleuropulmonary blastoma



A B C

Figure 64-15 Echogenic fetal lung lesion. **A,** At 28 weeks' gestation, hyperechogenic mass causing a mediastinal shift and accompanied by polyhydramnios and mild ascites. The lesion was initially diagnosed at 24 weeks; it then regressed, with disappearance of the ascites at 31 weeks. **B,** Chest radiograph at birth, showing fluid retention in the left upper lobe. **C,** At 2 days of life, the appearance was typical of congenital lobar emphysema and the respiratory distress increased, leading to lobectomy. Pathology showed a CCAM/CPAM type 2. (From Laberge J-M, Flageole H, Pugash D, et al: Outcome of the prenatally diagnosed congenital cystic adenomatoid lung malformation: A Canadian experience. Fetal Diagn Ther 16:178-186, 2001.)

tory deterioration. The same holds true about rigid bronchoscopy. Lobectomy is performed via a thoracotomy because the involved lobe does not collapse, making a thoracoscopic approach difficult. When CLE is discovered in an asymptomatic patient, treatment is usually conservative because the lesion may regress.

In neonates, the lesion should be distinguished from pulmonary interstitial emphysema, which is secondary to barotrauma in small premature infants. Most cases of lobar emphysema discovered beyond the neonatal period are acquired, often after bronchiolitis, and tend to resolve spontaneously.[232]

CONGENITAL CYSTIC ADENOMATOID MALFORMATION (CONGENITAL PULMONARY AIRWAY MALFORMATION)

CCAM is considered a hamartomatous lesion of the bronchial tree by some, whereas others favor a localized arrest in the development of the fetal bronchial tree as the etiology.[49,183,227,228] Recent evidence points toward an arrest in lung development.[233] Ch'in and Tang[234] first distinguished this entity from other types of congenital cystic lung disease in 1949. These lesions were initially classified into three types by Stocker,[47] who later added two more variants, types 0 and 4 (Fig. 64-16; see also Table 64-1).[48] Because some types are not cystic and only one type has the adenomatoid appearance, the term *congenital pulmonary airway malformation* (CPAM) was recently proposed.[49] The malformation is usually limited to a lobe, with 10% involving a whole lung or being bilateral. There is no clear predilection between upper and lower lobes, or between right and left involvement. Once considered a rare defect, an increase in the rate of detection and reporting of this lesion appeared with the introduction of routine prenatal ultrasound examination. The incidence of CCAM/CPAM has been estimated at 1 per 25,000 to 35,000 pregnancies in one study,[235] while another reports a population prevalence of 9 per 100,000 total births.[236] The International Pleuropulmonary Blastoma Registry based in St. Paul, Minnesota, has obtained incidences of congenital lung cysts varying from 1 per 8300 to 1 per 18,500 from Australian, Canadian, and New York State congenital malformations registries (J. R. Priest, personal communication). For the purposes of prenatal diagnosis and management, the lesions are better classified as macrocystic or microcystic because Stocker's classification was not meant for mid-gestation fetuses and cannot be based on cyst size alone.[235,237,238]

Type 1 CCAM/CPAM is generally considered the most frequent, comprising more than half of cases.[49] Traditionally, it presented in early infancy with respiratory distress, or later in life, and even in adulthood, with recurrent infection[239,240] (Fig. 64-17). Less common forms of presentation include pneumothorax, hemoptysis, and bronchioloalveolar carcinoma, which is thought to arise from the mucigenic epithelium.[183,240-243] In recent years, it has been diagnosed prenatally in many instances.[235] Although the prognosis is generally favorable, some cysts may become so large in the fetus as to cause fetal hydrops or pulmonary hypoplasia and lead to fetal or neonatal death; thus fetal treatment, usually in the form of a thoracoamniotic shunt, is indicated in selected cases[55,235,244] (Fig. 64-18). Many large fetal thoracic masses are also accompanied by polyhydramnios, presumably secondary to the mediastinal shift impairing the swallowing of amniotic fluid; this may result in premature labor and delivery, leading to further morbidity or mortality. Therefore, amnioreduction is

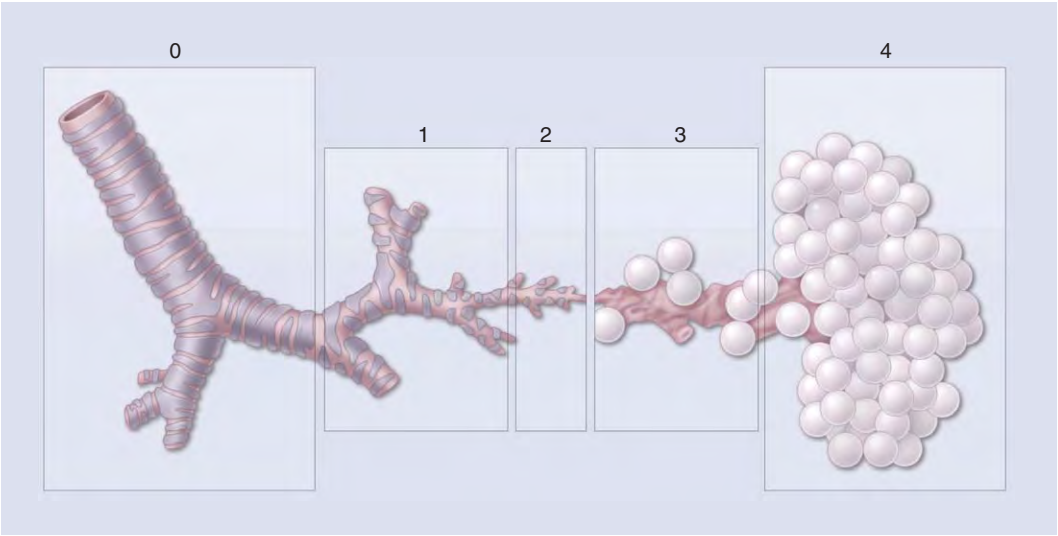


Figure 64-16 Stocker's classification of congenital cystic adenomatoid malformation, now called congenital pulmonary airway malformation. (From Gilbert-Barness E: Respiratory system. In Potter's Pathology of the Fetus and Infant. St. Louis, Mosby, 1997, pp 741-769.)

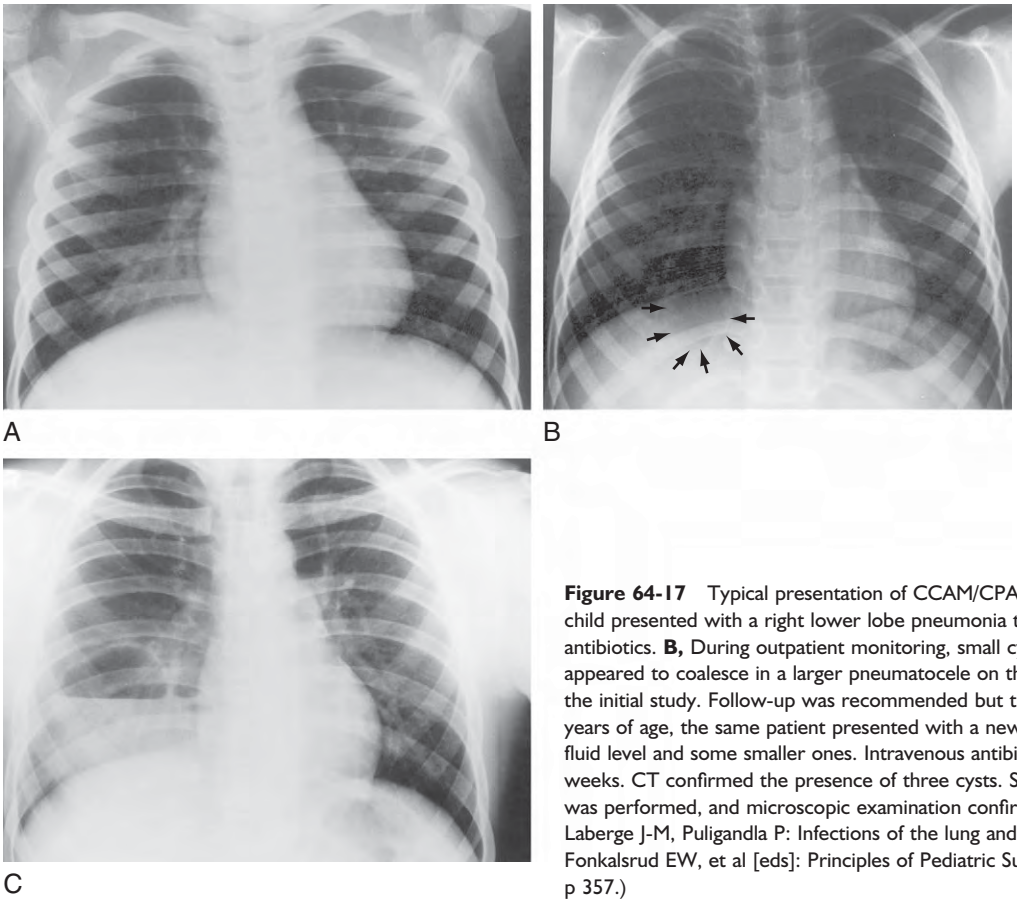

Figure 64-17 Typical presentation of CCAM/CPAM in the older child. **A,** A 5-year-old child presented with a right lower lobe pneumonia that responded to intravenous antibiotics. **B,** During outpatient monitoring, small cysts were noted 6 weeks later and appeared to coalesce in a larger pneumatocele on this radiograph, taken 11 weeks after the initial study. Follow-up was recommended but the family did not comply. **C,** At 14 years of age, the same patient presented with a new episode of infection with a large air-fluid level and some smaller ones. Intravenous antibiotics were required for more than 2 weeks. CT confirmed the presence of three cysts. Six weeks later, a right lower lobectomy was performed, and microscopic examination confirmed a type 1 CCAM/CPAM. (From Laberge J-M, Puligandla P: Infections of the lung and airway. In O'Neill JA, Grosfeld JL, Fonkalsrud EW, et al [eds]: Principles of Pediatric Surgery, 2nd ed. St. Louis, Mosby, 2004, p 357.)

another form of prenatal intervention that is beneficial in certain cases.

Postnatally, the diagnosis is suspected on plain radiographs, which demonstrate one or more air-filled cystic areas. In a neonate with respiratory distress, a "babygram" is useful to exclude a congenital diaphragmatic hernia; no other investigation is necessary before surgery. In less symptomatic patients, the diagnosis is confirmed with CT scan. The differential diagnosis includes pneumatoceles following pneumonia, pulmonary interstitial emphysema, simple lung cysts, bronchogenic cysts that may have eroded into and communicate with a bronchus, and cystic pleuropulmonary blastoma.[51,61,183] This tumor will be discussed further later. Unless there has been a prior chest radiograph showing lung cysts, the differ-

Figure 64-18 Fetal shunt for CCAM. A macrocystic CCAM was diagnosed at 18 weeks' gestation. It was initially observed but at 21 weeks signs of hydrops appeared, necessitating cyst decompression. **A,** Longitudinal section showing the large cyst surrounded by several smaller ones. The head is on the left; notice the anterior placenta (P), which prevented initial placement of a thoracoamniotic shunt. After 8 weeks of twice-a-week needle thoracentesis, polyhydramnios helped to stretch the uterus and move the placenta away, allowing placement of the shunt. **B,** The baby was born after induced vaginal delivery at term with the shunt in place, with minimal respiratory distress. **C,** The chest radiograph shows the cystic disease on the right with marked mediastinal shift. A right lower lobectomy was performed the same night; microscopic examination showed a type I CCAM/CPAM. The postoperative course and long-term follow-up were uneventful.

entiation between a suprainfected CCAM/CPAM and post-pneumonia pneumatoceles (typically staphylococcal) requires a period of observation; the latter should regress within a period of months (see Fig. 64-17).

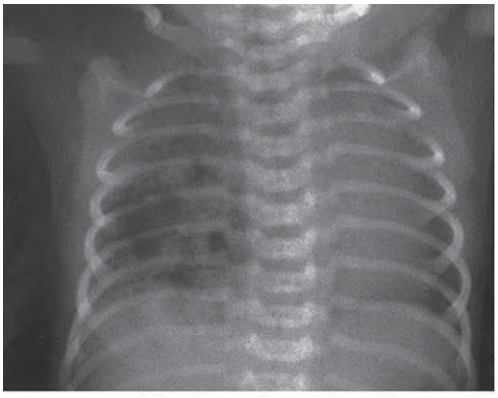
Type 2 CCAM/CPAM was initially described mostly in autopsy series, often in association with other malformations, and was considered to have a poor prognosis.[47,49] However, many cases of cystic lung lesions now diagnosed prenatally turn out to be type 2 malformations without associated anomalies and an excellent prognosis[183,235] (Fig. 64-19). Langston[51] believes that this pattern of maldevelopment is secondary to airway obstruction during development and, as such, should be considered as part of a malformation sequence rather than a separate entity. Indeed, bronchial atresia has been identified in many instances, and may have been overlooked in others.[51,173,174] Furthermore, the type 2 histology is identified in 40% to 50% of extralobar sequestration, a malformation where there is no bronchial connection[227,245]; if the "bronchial atresia sequence" theory was correct, it is unclear why we do not see the same maldevelopment in *all* cases of extralobar sequestration.

Type 3 CCAM/CPAM is the adenomatoid variant. It is less common, more often involves a whole lung, and has a poorer prognosis compared with types 1 and 2. Some pathologists consider this as simple lung hyperplasia, as seen with airway obstruction such as laryngeal atresia; they imply that the immature-appearing tissue is due to the fact that these lesions were most often found in preterm fetuses and stillborns.[51] However, airway obstruction is not identified in most cases, and the lesion has been described in surviving term neonates and infants.[235,238,239]

Type 4 CCAM/CPAM is a recent addition to Stocker's classification. Because of its large cysts, most cases were previously considered as type 1. Immunohistochemistry studies have demonstrated an acinar-alveolar type of epithelium, in contrast with the bronchiolar type found in types 1 to 3.[233] Other than the usual presentation with respiratory distress or pneumonia, perhaps the type 4 is more notable for the frequent occurrence of spontaneous pneumothorax. A major difficulty with this type is its differentiation from cystic pleuropulmonary blastoma, both from the clinical presentation and the histologic appearance.[61,62,246] This tumor is discussed in more detail further.[247,248]

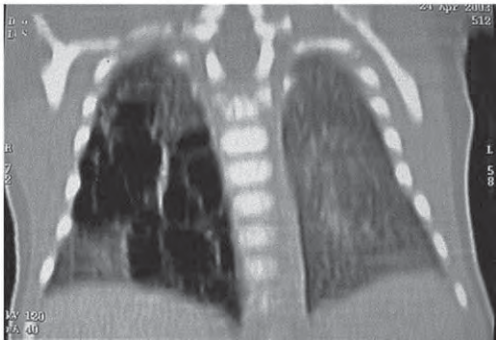
Type 0 CCAM/CPAM is rare and of interest mostly to pathologists. It is generally lethal and is associated with cardiovascular anomalies and dermal hypoplasia.[49]

The pathogenesis of CCAM has been the subject of controversy. Langston[51] believes that the five types may repre-



A

B



C

Figure 64-19 A fetus was diagnosed with a large mixed solid/cystic lung lesion filling 80% of the thoracic cavity at 19 weeks' gestation. Despite severe mediastinal shift and inversion of the diaphragm, hydrops did not develop and the lesion gradually regressed after 24 weeks' gestation. The baby was asymptomatic at birth. **A,** Chest radiograph at birth showed multiple lucencies in the right lung with mediastinal shift. **B,** Given the initial size of the lesion, CT scan was performed earlier than usual, at 3 weeks of age. Multiple cysts are seen in the right lower lobe. **C,** This reconstructed CT image demonstrates the cysts involving most of the lower lobe, reaching up to the apex of the thorax. Although the baby remained asymptomatic, the fear of sudden enlargement with respiratory distress led to an early elective lobectomy at 5 weeks of age. She was discharged 4 days after surgery. Microscopic examination was consistent with a type 2 CCAM/CPAM. (From Laberge J-M, Puligandla P, Flageole H: Asymptomatic congenital lung malformations. Semin Pediatr Surg 14:16-33, 2005.)

sent different malformations with varying etiologies. Other studies support the notion that dysregulation in the branching morphogenesis of the lung is associated with the development of abnormal lung tissue, in both CCAM and sequestration.[20] A dysregulation of lung maturation is also suggested by the increased cell proliferation seen in CCAM.[21,22]

Several areas of controversy exist in the management of CCAM/CPAM. Patients who are *symptomatic* require surgery, but the surgical approach and extent of surgery are debated. Some authors have advocated segmental resection, but this often results in incomplete resection, persistent pneumothorax, and the need for completion lobectomy.[9,249-254] Many surgeons and pathologists agree that lobectomy is safer, in part because the limit between CCAM and normal parenchyma is impossible to determine grossly.[48,50,55,60,255-258] The impossibility to distinguish type 4 CCAM from type I PPB and the development of malignancy years after a segmentectomy lends further support to this recommendation.[61,246,259] Several studies have demonstrated compensatory lung growth after a pulmonary lobectomy in infancy, with normal pulmonary function tests in follow-up.[260-264] Interestingly, dell'Agnola and colleagues[265] performed intraoperative measurement of pulmonary function in infants with asymptomatic CCAM and demonstrated significant improvement after resection of the affected lobe. Hence, segmentectomy should be reserved for patients with bilobar or bilateral disease. Lobectomy by thoracoscopy has been advocated in some centers. Albanese[266] has reported a series of 14 consecutive thoracoscopic lobectomies in patients with asymptomatic congenital lung lesions without any complication and a mean postoperative stay of 38 hours. These excellent results may not be generalizable and the technique may not apply to neonates with respiratory compromise or older children who have had recurrent infections. A limited lateral thoracotomy is safe, well tolerated in children, and compatible with lengths of stay of 3 to 5 days in most cases.

The management of *asymptomatic* patients is more controversial.[183] While a few authors recommend simple observation, the majority favor surgical resection, mostly because of the risk of infection, which increases the surgical complication rate and can be lethal.[60,228,265,267-269] Other risks include pneumothorax, hemoptysis, and malignancy.[183,270] Some of these complications occur in adulthood, making long-term follow-up nearly impossible. Of note, the risk of malignancy in congenital lung cysts appears to be greater when there is associated childhood neoplasia or dysplasia in the patient or family.[271] The presence of cystic renal lesions in children with lung cysts particularly heralds the risk of pulmonary malignancy.[272,273]

PULMONARY SEQUESTRATION

Pulmonary sequestration is generally thought to result from an abnormal accessory tracheobronchial bud arising from the foregut.[49,228] Intralobar sequestration (ILS) and extralobar sequestration (ELS) types are recognized, based on whether the visceral pleura is shared with the adjacent normal lobe or not. ELS is sometimes referred to as a "Rokitansky lobe" in old texts.[11,151] Typically, the lung tissue in sequestrations does not have a connection to the normal tracheobronchial tree and is supplied by an anomalous systemic artery, but many variants exist.[49,50,228] Most ILSs are located in the lower lobes; most ELSs are found posteromedially in the left lower chest but can occur within the diaphragm, below it, or rarely in other locations.[52,274,275]

Extralobar sequestrations situated in the lower chest receive their blood supply through one or several branches of

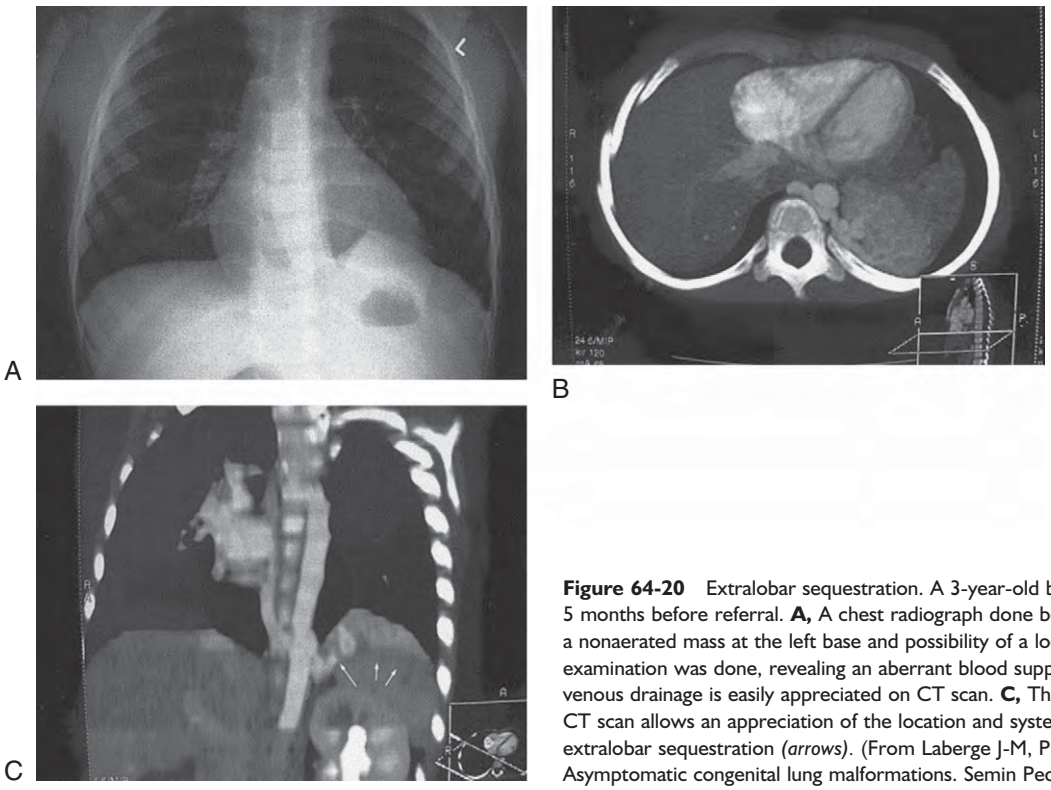


Figure 64-20 Extralobar sequestration. A 3-year-old boy was diagnosed with pneumonia 5 months before referral. **A,** A chest radiograph done because of persistent cough showed a nonaerated mass at the left base and possibility of a localized eventration. An ultrasound examination was done, revealing an aberrant blood supply to the mass. **B,** The aberrant venous drainage is easily appreciated on CT scan. **C,** This reconstructed image from the CT scan allows an appreciation of the location and systemic arterial supply of this extralobar sequestration *(arrows)*. (From Laberge J-M, Puligandla P, Flageole H: Asymptomatic congenital lung malformations. Semin Pediatr Surg 14:16-33, 2005.)

the thoracic or abdominal aorta (Fig. 64-20) and, rarely, from a branch of the pulmonary artery. The venous drainage is usually through the systemic circulation, although 20% are drained partially or completely by the pulmonary veins.[49,276] Other systemic arterial origins may be encountered, especially with ELS in unusual locations.[51,275] There is a 3 : 1 male predominance.[13,277]

Although some authors state that only 10% of patients with ELS are asymptomatic,[49] these malformations are often discovered because of an associated congenital diaphragmatic defect, which was present in over 40% of cases in a large review.[276] Many recognize that ELS may remain asymptomatic through life.[183,228,277] Uncommon complications from isolated ELS include respiratory distress, symptomatic shunting with right heart failure, and infection, which is rare unless the sequestration is connected to the esophagus through a patent bronchus (see in discussion on communicating bronchopulmonary foregut malformation later). There are rare reports of hemothorax, torsion, and malignancy.[183] Antenatal complications will be discussed later.

Extralobar sequestrations usually present as a solid nonaerated, pyramid-shaped, or ovoid mass found on chest radiography, with nearly 80% occurring above the left diaphragm. Less frequently, the lesion may be cystic; the presence of air usually signifies an esophageal connection. Ultrasound with Doppler, CT scan with intravenous contrast infusion, and MRI can all be useful in demonstrating the systemic arterial supply (see Fig. 64-20), making diagnostic arteriography obsolete.[52]

Microscopically, the lesion may consist of nonaerated pulmonary parenchyma with dilated bronchioles, alveolar ducts, and alveoli. It is now recognized that in about half of the cases the histology is similar to type 2 CCAM, while 15 years ago this finding was the subject of case reports.[11,49,51,227,278] Prominent subpleural lymphatic channels reminiscent of congenital pulmonary lymphangiectasis may be seen in up to one third of cases.[13] The coexistence of type 2 CCAM features within ELS lends further support to the theory that the former would be a pattern of maldevelopment secondary to obstruction rather than a separate entity. However, it does not answer all questions, as mentioned previously in the CCAM section.

Some sequestrations have been shown to completely and spontaneously involute[279-282]; therefore, small asymptomatic lesions without significant shunting may be observed.[183] Others have proposed embolization,[283] simple ligation of the aberrant artery,[284] and thoracoscopic resection.[266,285] Neuroblastoma has to be considered in the differential diagnosis of ELS, whether intrathoracic or subdiaphragmatic. However, because these tumors may also regress spontaneously when discovered in neonates and young infants,[286,287] close observation may be preferable to biopsy or excision even if a precise diagnosis cannot be confirmed.

Intralobar sequestrations are usually situated in the lower lobes. They also have a systemic blood supply, with more than one branch in 15% of cases, as in ELSs.[276] In contrast, however, the venous drainage is usually through the inferior pulmonary vein and rarely systemic. Only 15% are associated with other anomalies compared to 50% or more of ELSs.[276] Although some authors think that most ILSs are acquired lesions formed through repeated episodes of pneumonia,[49] the majority of those dealing with children recognize their congenital nature in this age group.[50,51,59] Even though sequestrations should not have a normal bronchial connection, the lesions are usually aerated, presumably from the adjacent normal segments through the pores of Kohn. Ventilation is inefficient, resulting in the trapping of air, mucus, and bacteria and leading to recurrent infection, which is the usual

mode of presentation. The development of cysts is common, and pneumothorax, congestive heart failure, and hemoptysis have also been described.[183,288]

Recurrent infection and/or persistent consolidation or cystic changes of basal segments on chest radiograph should raise the suspicion of ILS. CT scan is most often used to confirm the diagnosis, but ultrasound with Doppler and MRI can also play a role. Resection is indicated in all cases,[11] although embolization alone or prior to surgery has been proposed.[43] Particular attention is required to avoid bleeding complications from the systemic arterial supply.

PRENATAL DIAGNOSIS AND MANAGEMENT OF CONGENITAL LUNG LESIONS

As discussed earlier, the precise differentiation between the various congenital lung lesions may be difficult even after microscopic analysis by experienced pathologists. It is therefore not surprising that an exact diagnosis is difficult to achieve in a second trimester fetus. Too often, obstetricians or radiologists try to make a diagnosis of a precise type of CCAM/CPAM based on the ultrasound size of lung cysts and make prognostic implications based on this.[183] The emerging consensus is that imaging findings should simply be described, without attempting to make a pathologic diagnosis. Adzick, in 1985,[238] first made the distinction between macrocystic and microcystic (hyperechoic) lung lesions on prenatal sonograms. This is frequently interpreted as CCAM but can be found in sequestration and other lung malformations or may represent a transient finding in normal babies.[58,60,235,236,289,290]

With the increasing number of obstetrical ultrasounds performed and the improving quality of these examinations, congenital lung malformations are diagnosed more frequently before birth. They appear as hyperechoic or cystic or mixed lesions within the chest (or abdomen for some sequestrations) that may displace the heart and mediastinum and occupy most of the thoracic cavity. Doppler interrogation may reveal a systemic arterial supply from the thoracic or abdominal aorta. This generally confirms a diagnosis of sequestration, although mixed lesions can occur, as discussed earlier. While some congenital lung malformations may give rise to serious complications in utero, such as polyhydramnios with premature labor or hydrops with fetal demise, most remain stable or show evidence of regression.[55,58,235,236,249,291]

In a small percentage of cases, fetal intervention may be warranted. The mere presence of a large mass causing mediastinal shift, even diaphragmatic eversion, is not an indication for treatment (see Fig. 64-10). However, the size of the mass and its rate of growth may help to predict which fetus is at risk for developing signs of hydrops, which is an indication for intervention. The CCAM volume ratio (CVR) was developed as a means to tailor the frequency of repeat sonograms to the risk of developing hydrops.[292] Maternal betamethasone administration may decrease the rate of growth of the lesion and prevent complications.[293,294] Figure 64-21 illustrates the algorithm followed in several centers for monitoring such fetuses. This mentions CCAM (or CPAM) as the main diagnosis because it is the most frequent, but a final diagnosis cannot be established until postnatal imaging, followed by surgical resection if the lesion persists. Extralobar sequestrations may occasionally produce massive pleural effusions (possibly from obstructed lymphatic or venous return), which also can lead to hydrops and pulmonary hypoplasia.[13] This is amenable to fetal intervention through thoracentesis, pleuroamniotic shunting or laser ablation of the feeding artery.[295] Fortunately, prenatal intervention is not required in the majority of cases, but having detected a lesion before birth ensures proper postnatal follow-up. For asymptomatic neonates who have a normal or near-normal chest radiograph, a CT scan is necessary to evaluate the presence or absence of a lesion. Sometimes an echogenic lung "lesion" in utero regresses in the third trimester and the CT scan (usually done after a few weeks of age to allow any retained lung fluid to be evacuated) is completely normal. Such instances are presumed to be secondary to a transient bronchial obstruction or plugging in utero. Most often, however, the lesion will be visible on postnatal CT scan. Any congenital cystic lung lesion should be removed electively at 3 to 6 months of age, mainly because of the risks of infection and the impossibility of differentiating these from type I pleuropulmonary blastoma.[183]

PLEUROPULMONARY BLASTOMA

Pleuropulmonary blastoma (PPB) is a rare intrathoracic neoplasm of early childhood with an unfavorable outcome. It is discussed here because of its overlapping features with congenital cystic lung lesions and its recent description in fetuses and neonates. The term was defined in 1988[296] and regroups tumors previously described as pulmonary rhabdomyosarcomas, cystic mesenchymal hamartomas, blastomas, and other types of undifferentiated sarcomas.[247] PPB has been classified into three groups based upon the gross characteristics of the tumor: type I, purely cystic; type II, intermediate cystic/solid; and type III, predominantly solid. Evidence, based on patient age at diagnosis, as well as recurrence with more advanced type, would suggest that type I tumors may evolve into the more malignant type II and III if undiagnosed or inadequately treated.[62,247,297] PPB, a mesenchymal childhood neoplasm, is very different from adult-type pulmonary blastoma which has malignant mesenchymal and epithelial tissue. Adult pulmonary blastoma has not been associated with congenital lung cysts. PPB commonly presents with symptoms that are mistaken for a lower respiratory tract infection. The cystic types can also present with pneumothorax. The tumor is usually located at the periphery of the lung, but it may also be located in extrapulmonary locations, such as the mediastinum, diaphragm, and/or pleura. Common metastatic sites for PPB include the brain, bone, and liver. Lymph nodes, pancreas, kidneys, and adrenal glands are rarely involved.[62,298] The diagnosis is made by histopathology. Despite aggressive treatment protocols, the prognosis for patients with PPB is not good, with 5-year survival rates of 83% for type 1 and 42% for types 2 and 3.[62,247,297] Furthermore, it appears that type II and III lesions have a tendency to recur, even at remote or contralateral sites, despite presumed complete primary resection.

PPB has frequently been described in association with cystic lung disease including bronchogenic cysts, CCAM/CPAM, and air-filled cysts.[183,299-301] It is not known whether the tumor can develop in preexisting benign cystic lung disease or whether the cysts in these cases are type I PPB from the outset.[61,62] The latter opinion has been favored recently, espe-

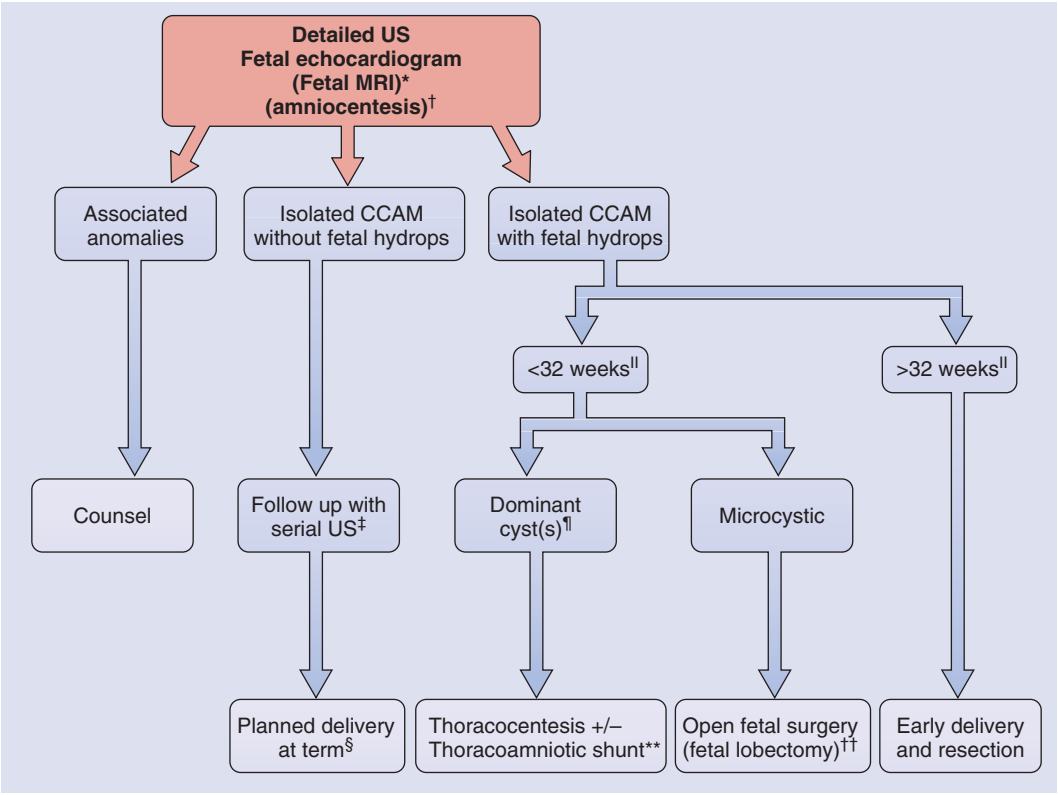

Figure 64-21 Prenatal management of congenital lung lesions.

*Magnetic resonance imaging (MRI) is not done routinely but can be useful to eliminate other diagnoses if repeat ultrasonography (US) performed by an experienced sonographer leaves any doubt.

†Chromosomal anomalies are rare in isolated CCAM.

‡Serial US should be weekly initially, since rapid growth can be observed between 18 and 24 weeks. This is increased to twice weekly if CCAM volume ratio (CVR) is greater than 1.6.[292] If the lesion is stable after 2 to 3 weeks, surveillance can decrease to every two weeks, and every month after 26 to 28 weeks if the lesion has regressed and mediastinal shift is absent. CVR is a useful parameter to follow in assessment of CCAM and for prognostic purposes. CVRs greater than 1.6 on presenation in microcystic CCAM are predictive of evolution of hydrops. CVR tends to increase until 25 to 26 weeks, after which regression is observed.

§In cases in which the lesion has regressed and lung hypoplasia and respiratory distress are not of concern, we allow spontaneous vaginal delivery.

‖Maternal betamethasone administration may be considered in an effort to arrest CCAM growth and reverse hydrops.[293,294] Some advocate early delivery of a hydropic fetus after 28 weeks and postnatal (or intrapartum, i.e., EXIT) resection, but the mortality in such cases is very high. Discussion with a fetal treatment center is warranted.

¶In cases of macrocystic CCAM, multiple cysts often communicate, allowing thoracentesis or thoracoamniotic shunt to provide adequate decompression.

**In cases of macrocystic CCAM, at the first sign of hydrops (skin edema, mild ascites, or pleural effusion), aspiration of the cyst can be done to relieve the pressure. An associated significant pleural effusion can also be drained. Because of rapid reaccumulation, cyst aspirations should be done twice weekly and, preferably, a thoracoamniotic shunt can be placed (Rocket KCH catheter, Rocket Medical, Herts, England; introducer from De Ellis or Storz [Bausch and Lomb, San Dimas, Calif]). Repeat thoracentesis may be useful when an anterior placenta or difficult fetal positioning makes shunting more hazardous.

††A 50% long-term survival rate (11 of 22 patients) has been reported for fetal lobectomy for microcystic CCAM with hydrops.

(Modified from Adzick NS, Kitano Y: Fetal surgery for lung lesions, congenital diaphragmatic hernia and sacrococcygeal teratoma. Semin Pediatr Surg 12:154–167, 2003.)

cially because it has been identified in fetuses and neonates.[248,302] Being an uncommon tumor, PPB is rarely considered in the differential diagnosis of cystic lung disease in children. Subtle findings in support of a preoperative diagnosis of PPB include the presence of peripherally based lung cysts (Fig. 64-22) and multifocal and/or bilateral cystic disease. A history of neoplasia, hyperplasia, or dysplasia, and particularly of cystic renal lesions, in the patient, sibling, or close relative should also raise suspicion of PPB since such an association is found in approximately 25% of patients as reported in the International Registry[271,272] (www.ppbregistry.org). The difficulty in making a diagnosis of PPB based on imaging alone has led many authors to propose prophylactic removal of all congenital cystic lung lesions, even if asymptomatic.[183,302,303] The surgical procedure of choice for PPB is lobectomy because the limit between the lesion and normal parenchyma may be difficult to determine grossly. Furthermore, the subsequent development of cystic lung

Figure 64-22 Pleuropulmonary blastoma. A 3-year-old child presented with a 2-month history of low-grade fever and cough. The examination was normal except for decreased breath sounds in the left lower chest. **A,** Posteroanterior chest radiograph demonstrating a large hyperlucency in the lower left hemithorax with some subsegmental collapse in the upper lobe. **B,** Computed tomography scan of the chest confirmed the presence of a multicystic air-filled lesion in the left hemithorax. One large and several smaller cysts were identified on coronal reconstruction films that appeared to compress the left upper lobe. The left lower lobe was superimposed upon these cystic lesions. Neither calcification nor air-fluid levels were observed within the cysts. At thoracoscopy, the large cystic lesion was attached to the left lower lobe by only a small band of tissue. A margin of normal lung tissue was removed en bloc with the specimen, which was placed in an endo-bag. A diagnosis of type I pleuropulmonary blastoma was made on microscopic examination, and the case was submitted to the registry (www.ppbregistry.org). (From Al-Backer N, Puligandla PS, Su W, Anselmo M, Laberge J-M: Type I pleuropulmonary blastoma in a 3-year-old male with a cystic lung mass. J Pediatr Surg 41:E13-E15, 2006.)

lesions after histologic confirmation of PPB should be treated by resection whenever feasible, because these lesions invariably demonstrate malignant features. Even with a resected lesion, the diagnosis of type I PPB is not always easy to make, and this tumor may be confused with a type 4 CCAM/CPAM.[61,62] Adjuvant chemotherapy is indicated for PPB.

HYBRID AND RARE LESIONS

As previously mentioned, there are multiple reports describing single lesions that fulfill the criteria for CCAM and ILS or ELS, coexisting lesions in different lobes, and lesions typical of one entity on imaging but corresponding to another pathologically[50-60,174,183] (see Fig. 64-15).

Any time a congenital lung lesion is approached surgically, the surgeon should be aware of the possibility of an aberrant arterial supply, even if this is not demonstrated by advanced imaging techniques. The possibility of separate coexisting lesions should also be considered[50] (see Fig. 64-10). These unusual combinations are being recognized more frequently and they may help to uncover the pathogenesis of congenital lung malformations.[56] For example, the coexistence of bronchogenic cysts in close proximity to ELSs allows speculation as to a common etiology, hence the regroupment under the term "bronchopulmonary foregut malformations."[13,304]

Communicating Bronchopulmonary Foregut Malformations. Gerle introduced the term *congenital* bronchopulmonary foregut malformation to describe cases of sequestrations that communicate with the upper digestive tract, usually the esophagus.[305] Other authors have since used this to include a variety of malformations such as sequestrations and bronchogenic cysts.[304] For the sake of clarity, we agree with Srikanth and colleagues to use the term *communicating bronchopulmonary foregut malformation* to describe a segment, lobe, or whole lung that communicates with the digestive tract.[16] One could recognize a *forme fruste,* where there is only a nonpatent fibrous attachment, but most often the malformation presents as either an accessory lobe or lung attached to the esophagus (Fig. 64-23), or a normal lobe or lung with an esophageal instead of a bronchial connection. Interestingly, in the Adriamycin-induced rat model of esophageal atresia, 30% of the fetuses with esophageal atresia and tracheoesophageal fistula exhibit a communicating bronchopulmonary foregut malformation that consists of either an accessory lung attached to the lower esophagus via a patent bronchus, an anomalous bronchus originating from the lower esophagus and communicating with the lower left lung, or tracheal atresia with a right esophageal lung and absent left lung. This suggests that communicating bronchopulmonary foregut malformation, and esophageal atresia and tracheoesophageal fistula, may be part of a common spectrum of abnormalities caused by defective budding, differentiation, and separation of the primitive foregut.[23,306] This fits well with the proposed classification and embryogenesis suggested more than a decade ago.[16]

Scimitar Syndrome. This syndrome takes its name from the presence of an anomalous pulmonary venous drainage, typically of the right lung, which gives a scimitar-shaped shadow on chest radiographs (Fig. 64-24). Many other anomalies are associated with this syndrome, including right lung hypoplasia, hypoplastic right pulmonary arteries, systemic arterial supply to the right lung (partial or total), and congenital heart disease.[307] Two forms of the scimitar syndrome exist: a severe infantile form that presents with tachypnea, heart failure, and failure to thrive and a milder pediatric/adult form where symptoms may be totally absent. Cardiac catheterization is necessary to establish a diagnosis and identify the scimitar vein, which usually traverses anterior to the hilum of the lung and connects to the inferior vena cava below the diaphragm. This vein provides drainage of the whole lung in two thirds of cases; in the other patients there is a normally connected superior pulmonary vein.[307] Coil embolization of the systemic arterial supply of the lung for infantile forms, if possible, allows time for growth and reversal of cardiac insufficiency.[308] Corrective surgery, through either rerouting of the anomalous pulmonary venous drainage to the left atrium or resection of the lung drained by the scimitar vein, may then be delayed until 1 year of age.[307] In the latter case, total pneumonectomy may be required due to the abnormal lobulation of the lung often observed with this syndrome. Surgical intervention for pediatric or adult patients is debated, especially if asymptomatic.[309]

Figure 64-23 Communicating bronchopulmonary foregut malformation. This neonate presented with cyanosis and respiratory distress with feeding. A barium swallow showed an accessory "trachea" originating from the distal third of the esophagus which divided into right and left "main bronchi," each then subdividing to supply an extralobar and an intralobar sequestration on each side. (From Bratu I, Di Lorenzo M, Chen MF, et al, The multiple facets of pulmonary sequestration. J Pediatr Surg 36:784-790, 2001.)

OTHER PARENCHYMAL MALFORMATIONS

Simple lung cysts are included in the differential diagnosis of cystic lung lesions. Some of these may actually be intrapulmonary bronchogenic cysts or unilocular variants of CCAM/CPAM. From the clinical point of view, simple lung cysts have to be distinguished from postinfectious pneumatoceles as discussed earlier. Any localized cystic lung lesion that appears congenital and is confirmed on CT scan or MRI should be excised because of the potential risks of infection, erosion into an adjacent bronchus, pneumothorax and the inability to distinguish it from the type I pleuropulmonary blastoma.

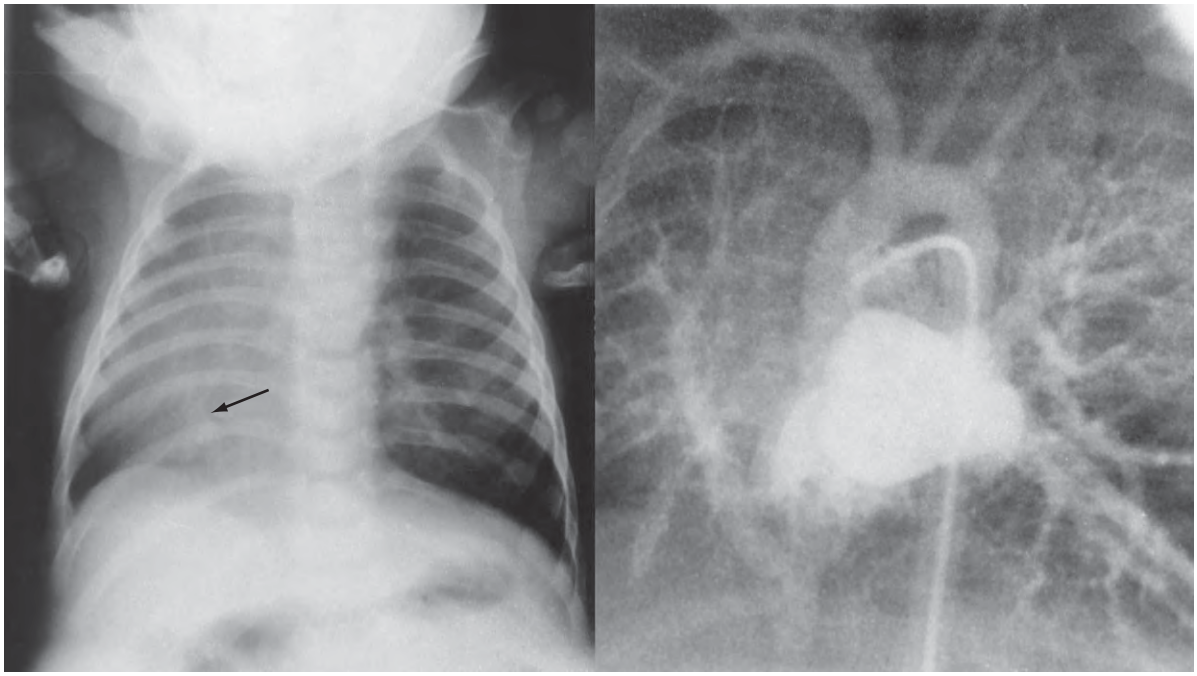

Figure 64-24 Scimitar syndrome. Chest radiograph *(left)* demonstrating the scimitar-shaped shadow *(arrow)* that represents the anomalous vein and gives the syndrome its name. Angiography *(right)* subsequently confirmed this shadow to be the scimitar vein draining the right lung anomalously to the inferior vena cava.

Once the lesion is excised, the pathologist can usually determine its exact nature.

Multiple peripheral "cysts" may occur in patients with Down syndrome or congenital heart disease or as a result of pulmonary infarction.[49,227,310] These are subpleural air collections, lined with alveolar cells, which communicate with alveolar ducts and bronchioles. Resection is not indicated. Pulmonary interstitial emphysema, usually a result of barotrauma, may also result in large air-filled spaces that may be confused with lung cysts.

Apical blebs are often considered in the same category as peripheral lung cysts. They are typically seen in tall thin adolescents and young adults who present with spontaneous pneumothorax. The cysts are most often located at the apex of the lung, but can sometimes be found in the superior segment of the lower lobes.[311] According to Stocker,[49] these cysts resemble those seen in patients with Down syndrome. Whether these are congenital, appear during postnatal lung growth, or during the adolescent growth spurt remains unclear.[310]

ABNORMAL PARENCHYMAL SHAPE OR LOCATION

Variations in lung fissures and septation may occur without alteration of the underlying bronchial pattern.[151] Fissures may be incomplete or completely absent, and extra fissures are found in about 20% of the population, most commonly those defining the "dorsal lobe" (superior segment of either lower lobe) or the "cardiac lobe" (medial basal segment of the right lower lobe).[151] The *azygous lobe* results from a septum impressed on the lung by an aberrant azygos vein in the apical portion of the right upper lobe. It is not a true accessory segment or lobe. It can be detected radiologically in 0.1% to 0.4% of the population.[151]

A *horseshoe lung* has been described, analogous to a horseshoe kidney; the lungs are fused in the midline behind the heart.[312] This connection, which may be separated by visceral pleura, usually occurs behind the esophagus but anterior to the descending aorta. The bronchial and vascular connections to the isthmus usually arise from the right mainstem bronchus and right pulmonary artery, respectively. The diagnosis is best made through computed tomography but bronchography may be more useful in delineating the tracheobronchial anatomy.[312] This anomaly has a strong association with the scimitar syndrome, which has been shown to occur in 80% of cases,[313] as well as the VACTERL association.[309,314] Complications of this anomaly include pulmonary hypertension, and the development of recurrent pulmonary infection that may require resection.

Cervical Herniation. Lung herniation is congenital in 15% to 20% of cases.[315] One third occurs in the cervical region. Some consider cervical herniation of the lung in neonates a normal variant, but it has been reported in association with iniencephalus and syndromes such as Klippel-Feil and cri du chat (trisomy 13); an autosomal dominant familial occurrence has been described.[49,316] It is thought to result from congenital absence of the endothoracic fascia in the cervical thoracic outlet region. This unusual abnormality presents in the neonatal period as bilateral supraclavicular masses that increase in size with crying. Most patients are asymptomatic but chronic cough, dysphagia, and neck pain have been described.[317] Nerve compression has been described in acquired hernias in adults.[315] Surgery, involving the closure of the defect and the reinforcement of the surrounding structures, is only indicated in symptomatic patients. Diaphragmatic and intercostal herniation also occur, but the majority are acquired after trauma or surgery.[318]

Pulmonary Vascular Malformations

Abnormalities of the pulmonary arteries or veins associated with congenital heart disease are not considered to be primary anomalies of lung development and are not discussed here; nor do we discuss the hypoplastic vascular bed associated with pulmonary hypoplasia (see discussion on congenital diaphragmatic hernia).

ARTERIOVENOUS MALFORMATIONS

Pulmonary arteriovenous malformations are most commonly found at the capillary or arteriolar level but may occur more proximally (Figs. 64-25 and 64-26). Some of these may occur

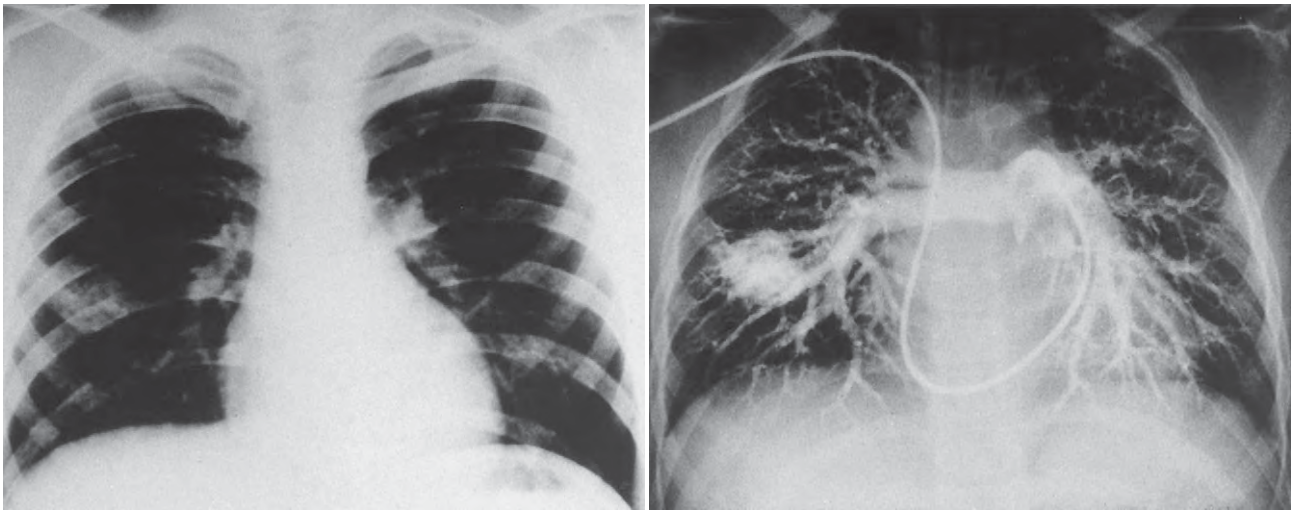

Figure 64-25 Pulmonary arteriovenous malformation. The chest radiograph *(left)* in a patient with cyanosis, finger clubbing, and a bruit heard in the right chest revealed a rounded parenchymal shadow in the right lung, which was confirmed on pulmonary arteriography *(right)* to represent a large pulmonary arteriovenous malformation.

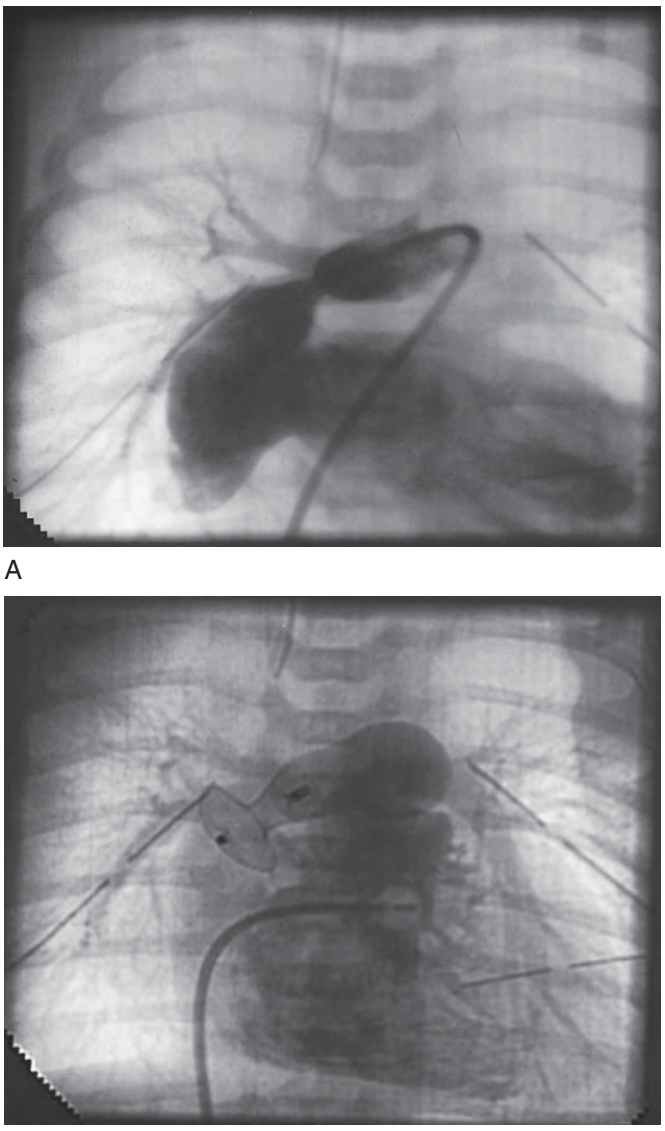

Figure 64-26 Large proximal arteriovenous fistula **(A)** in a newborn baby referred to our center at 5 days of life with cyanosis and severe desaturation unresponsive to medical treatment. During the angiogram, a ductus-occluding device (Amplatzer Duct Occluder, AGA Medical Corporation, Golden Valley, MN) was successfully deployed **(B).**

within a parenchymal malformation such as sequestration or the scimitar syndrome. These malformations function as a right-to-left shunt delivering unoxygenated blood directly into the systemic circulation. Multiple pulmonary arteriovenous malformations are found in 14% of patients with hereditary telangiectasia (Osler-Weber-Rendu disease), an autosomal dominant condition in which telangiectases may occur in any organ in the body.[319] These patients account for approximately half of the cases of pulmonary arteriovenous fistula. Primary pulmonary arteriovenous malformations form the majority of the remaining cases. They may be single but are usually multiple. The differential diagnosis includes pulmonary hemangioma, a rare lesion in this location, which may lead to shunting or hemothorax.[227,320]

Symptoms develop in up to 50% of patients with pulmonary arteriovenous malformations but sometimes only in the second or third decade.[42] When symptoms develop in the neonatal period, these usually consist of cyanosis and cardiac failure. Symptoms of a delayed presentation include bleeding with hemoptysis, or cyanosis when a large pulmonary-to-systemic vascular shunt occurs through the malformation. Finger clubbing and polycythemia may be present and a systolic or continuous murmur may be heard over the lesion. Rarely, seeding of emboli from infected lesions can cause cerebral ischemia or abscess formation. Spontaneous rupture of the lesion has been reported.[321] Evidence of telangiectasia in other organs (such as the skin), epistaxis, or gastrointestinal bleeding suggests the diagnosis of hereditary telangiectasia, and relatives should be examined for evidence of similar lesions. Single or multiple nonspecific, poorly defined parenchymal radiodensities may be seen on the chest radiograph, although pulmonary angiography or magnetic resonance angiography is necessary for definitive diagnosis (see Fig. 64-25). In the past, treatment consisted of surgical resection of the arteriovenous malformation or segment of lung involved. Currently, embolization techniques during cardiac catheterization have proved equally successful and less invasive (see Fig. 64-26). Both forms of treatment result in increased blood flow to the remaining lung, and this increase in flow may reveal additional arteriovenous malformations hitherto unnoticed, or impart additional stress on other inherently weak areas, thus leading to the development of new lesions. In these patients, vascular occlusion of the new lesions can be repeated if clinically indicated. The number of repeats, however, is limited by the accumulative reduction in the size of the pulmonary vascular bed with each attempt. Although the prognosis in patients with multiple pulmonary arteriovenous malformations remains poor, there has been some improvement with the development of embolization techniques that give superior results to lung transplant.[322] Patients with hereditary hemorrhagic telangiectasia should be screened for pulmonary arteriovenous malformations with contrast echocardiography.[323]

ALVEOLAR CAPILLARY DYSPLASIA

Alveolar capillary dysplasia is a rare malformation characterized by failure of formation and ingrowth of alveolar capillaries. It is usually accompanied by *misalignment of the pulmonary veins,* which can be seen coursing with the bronchoarterial bundle instead of the intersegmental septae on microscopic examination.[324,325] It presents in newborns with progressive hypoxia and pulmonary hypertension refractory to all forms of treatment, including high-frequency ventilation, inhaled nitric oxide and extracorporeal life support (ECLS, better known as ECMO).[326] The diagnosis may be suspected when a patient on ECLS fails to improve; it is confirmed with a lung biopsy. Although there were less than 40 cases reported before 2000, this entity is recognized with increased frequency with a protocol of early lung biopsy.[327,328] The condition is fatal and can only be cured with lung transplantation. This treatment has been used with success but is not yet widely applicable to neonates.[329] We have seen this malformation associated with congenital diaphragmatic hernia; others have seen it with Down syndrome, congenital heart disease, duodenal atresia, Hirschsprung's disease, asplenia, phocomelia, and urinary tract anomalies.[49,327,328,330-332] A familial occurrence has also been noted.[333]

LYMPHATIC MALFORMATIONS

Lymphatic development is first seen in the lung from about the 8th week of intrauterine life. By the 14th week, the lymphatic plexuses are well established, and from the 20th week, growth of other mesenchymal connective tissue elements predominates, with the pulmonary lymphatics becoming less conspicuous.[334,335]

Congenital pulmonary lymphangiectasia may result from continued proliferation of the lymphatic network beyond the 20th week of intrauterine life or from a failure of peripheral lymphatics to establish communication.[335,336] Noonan identified three groups[337]:

1. Pulmonary lymphangiectasia associated with cardiovascular malformations, particularly total anomalous pulmonary venous return and in the context of the asplenia/polysplenia syndromes. This group is often termed secondary lymphangiectasia, but the cardiovascular lesion is not always obstructive. More than half of the cases fall in this category, and their prognosis is poor.
2. Generalized lymphangiectasia, involving intestines, bone, and soft tissue, often with lymphedema
3. Isolated pulmonary lymphangiectasia, the least common, which may involve the whole lung, or rarely, a single lobe

Associated noncardiac anomalies are common, especially Noonan, Turner, and Down syndromes; familial cases have been reported.[338] A male predominance of 2 : 1 is generally recognized.[49,339] The disease may present in utero with pleural effusion and nonimmune hydrops, with fetal death or stillbirth.[336,339,340] Usually the lymphangiectatic changes are generalized over the lung surface, causing a visible network of dilated lymphatics and a pronounced lobular appearance. There are multiple small cysts less than 5 mm in diameter giving a "foam rubber" appearance on cross-section. Microscopy shows increased numbers of dilated lymphatic channels in the subpleural and interlobar septae.[49] The absence of muscular hypertrophy in the walls of the dilated lymphatic channels is used by some to distinguish primary intrapulmonary lymphangiectasia from dilation secondary to extrapulmonary anomalies of the lymphatic system such as thoracic duct obstruction. Generalized lymphangiectasia almost invariably presents soon after birth with tachypnea, intercostal recession, and usually cyanosis. On auscultation, the lungs may sound surprisingly normal. The chest radiograph classically shows a diffuse reticulonodular shadowing throughout the lung fields that fails to clear with time or diuretic treatment. In other patients hyperinflation/hyperlucency of the pulmonary parenchyma is prominent and may lead to confusion with congenital lobar emphysema if the disease is unilobar.[341] Pulmonary lymphangiectasia may be confused with pulmonary interstitial emphysema, both radiologically and pathologically.[49]

Only symptomatic treatment can be offered to these patients, and more than half die prenatally or within 24 hours of birth. Others die in the ensuing days from prematurity or their associated anomalies, especially cardiac. In recent years, some long-term survivors have been reported.[339,342] These patients often had severe respiratory compromise initially, followed by recurrent infections, but tended to improve with time. Rarely, patients with localized disease may present later in childhood, usually with infection. These lesions are amenable to surgical resection, although preoperative assessment must include investigations of associated anomalies of pulmonary vasculature.

Congenital chylothorax or hydrothorax is the leading cause of pleural effusions in neonates. It may be a manifestation of pulmonary lymphangiectasia in some cases but a specific cause is not identified in many instances. Various mechanisms implicated include rupture of the thoracic duct, a congenital defect affecting the thoracic duct or other mediastinal or pleural lymphatics. It is associated with the same syndromes as pulmonary lymphangiectasia.[232] Congenital chylothorax was formerly thought to occur from thoracic duct rupture at the time of vaginal delivery, but it has now been recognized prenatally for more than two decades, with an estimated incidence of 1 in 15,000 pregnancies.[343] For prenatally diagnosed patients, the mortality exceeds 50%, in contrast with a mortality of 15% for patients diagnosed postnatally. In the absence of severe associated anomalies (chromosomal, cardiac, or other), fetal thoracentesis is indicated for large primary pleural effusions; the diagnosis of chylothorax is confirmed when there are more than 80% lymphocytes in the pleural fluid. When a fetal pleural effusion is large and causes significant mediastinal shift and early signs of right heart failure, there is an indication for prenatal intervention such as repeated thoracentesis, or preferably thoracoamniotic shunting, to prevent mortality from nonimmune hydrops and pulmonary hypoplasia.[343,344] For unknown reasons, the effusion may regress prenatally. Chylothorax in neonates often causes respiratory distress and requires thoracentesis or the placement of a chest tube. Of note, the fluid will not have the typical milky appearance unless the child has been fed; the diagnosis can safely be made based on the relative lymphocyte count as discussed earlier. The child is kept on total parenteral nutrition until drainage stops, then fed with a medium-chain triglyceride diet initially, and switched to a regular diet if the effusion does not reaccumulate. Surprisingly, drainage often stops spontaneously within a few days after birth. Octreotide has been used successfully to decrease lymphatic flow in some cases; surgical intervention to ligate the thoracic duct or remove a localized area of pulmonary lymphangiectasia is rarely indicated, and pleuroperitoneal shunts have been used for refractory cases.[232]

Congenital Diaphragmatic Hernia

DEMOGRAPHICS

Congenital diaphragmatic hernia (CDH) is a developmental abnormality of the diaphragm that allows the abdominal viscera to enter the thoracic cavity. It occurs with an overall incidence ranging from 1 in 2000 to 4000 live births.[345,346] There is a slight male preponderance with a ratio of 1.5 : 1. The risk of recurrent CDH in future siblings is approximately 2%. Most CDHs occur through a posterolateral defect (Bochdalek hernia), with 90% of these on the left side, 10% on the right and less than 1% bilateral. Less than 5% of CDHs are located anteriorly (Morgagni hernia).[346]

THE DEFECT: EMBRYOLOGY AND PATHOGENESIS

Several theories have been proposed regarding the pathogenesis of diaphragmatic hernia. These include (1) premature

migration of the gut into the abdominal cavity after the period of extracoelomic growth, thus interfering with the development of the diaphragm ("compression theory"), (2) abnormal lung development/hypoplasia which permits the herniation of the gut into the chest, (3) problems with phrenic nerve development leading to incomplete formation of the diaphragm, and (4) delayed closure of the pleuroperitoneal fold. Recent animal studies have shed more light onto the pathogenesis of the diaphragmatic defect and contradict previously held theories. In separate studies, Greer[347] and Babiuk[348] independently demonstrated that abnormal development of the pleuroperitoneal canal leads to a posterolateral diaphragmatic defect, the most common location for CDH. Additional studies using the nitrofen model of CDH in rats have revealed that the lung hypoplasia precedes the development of the diaphragm and is thus independent of the formation of the defect in this animal model.[349]

PRENATAL DIAGNOSIS

The prenatal diagnosis of CDH has been greatly facilitated by the improved technology and interpretation of prenatal imaging studies. Indeed, CDH is readily identified on routine prenatal ultrasonography as early as 18 weeks of gestational age by the presence of the stomach in the left chest adjacent to the heart. The impact of prenatal diagnosis, however, is more difficult to evaluate. Several studies have attempted to identify factors that may be used to assess the severity of fetal pulmonary hypoplasia and pulmonary hypertension, which are leading determinants of postnatal morbidity and mortality in these patients.[350-355] Furthermore, all patients with a suspected diagnosis of CDH on prenatal imaging studies should have a thorough examination for other anomalies, particularly cardiovascular, chromosomal, and neurologic defects, because the survival of these patients has been reported to be as low as 15%.[356,357] It is also vitally important that patients with a prenatal diagnosis of CDH be referred to tertiary-care centers so that the families of these patients can be appropriately counseled regarding the prognosis, outcome and options available.

The two most commonly used prenatal predictors of postnatal morbidity in infants with CDH are liver position and lung-to-head ratio (LHR). An intrathoracic location of the liver and a low LHR (<1.0) predicts a poor prognosis.[350,352,358] The LHR is measured between 26 and 28 weeks of gestational age when the surface of the contralateral lung at the level of the standard four-chamber view of the heart is compared to the biparietal diameter of the fetal head on prenatal ultrasonography.[350,358] Fetal surgical interventions have been evaluated using these two factors in an attempt to improve the postnatal outcome of patients with these poor prognostic indicators (see later). Lung volume on magnetic resonance imaging has also been used as a prognostic indicator.[351,359]

CLINICAL PRESENTATION AND INITIAL MANAGEMENT

The clinical presentation of infants with CDH varies according to the severity of pulmonary hypoplasia and pulmonary hypertension in the immediate postnatal period. With the advantage of prenatal diagnosis, and the evaluation of liver position and/or measurement of the LHR, treatment teams can be prepared to institute a variety of interventions and therapies. In the absence of prenatal diagnosis, the newborn typically presents with respiratory distress, a scaphoid abdomen, apparent dextrocardia (since 90% of CDH are on the left) and decreased breath sounds over the involved chest. With these symptoms and signs, bag-and-mask ventilation should be avoided to minimize gaseous distention of the stomach and intestines, which would further compromise lung function. Prompt endotracheal intubation and limitation of ventilation pressures are essential. A nasogastric tube is passed and placed on suction and a chest radiograph is done (Fig. 64-27). Occasionally, the child may become symptomatic only after a few hours, sometimes days and rarely after several months or years of life. Obviously these patients do not have any significant pulmonary hypoplasia; they have a congenital defect but may not have herniation of abdominal viscera until later in life. Those presenting late often have gastrointestinal symptoms (such as bowel obstruction or gastric volvulus) rather than respiratory symptoms.[360,361]

The basic tenets of management for the infant with CDH are based on the support of the cardiorespiratory system. The clinical status of the patient is the key determinant for which therapies, if any, will be initiated. In many institutions, a protocolized management scheme is in place for all infants born with CDH. First, the patient is placed on monitoring equipment, intravenous access established (umbilical artery and vein), and pre- and postductal oxygen saturations recorded with pulse oximetry. Postductal saturations provide caregivers with an indication of the severity of pulmonary hypertension and right-to-left shunting. However, we pre-

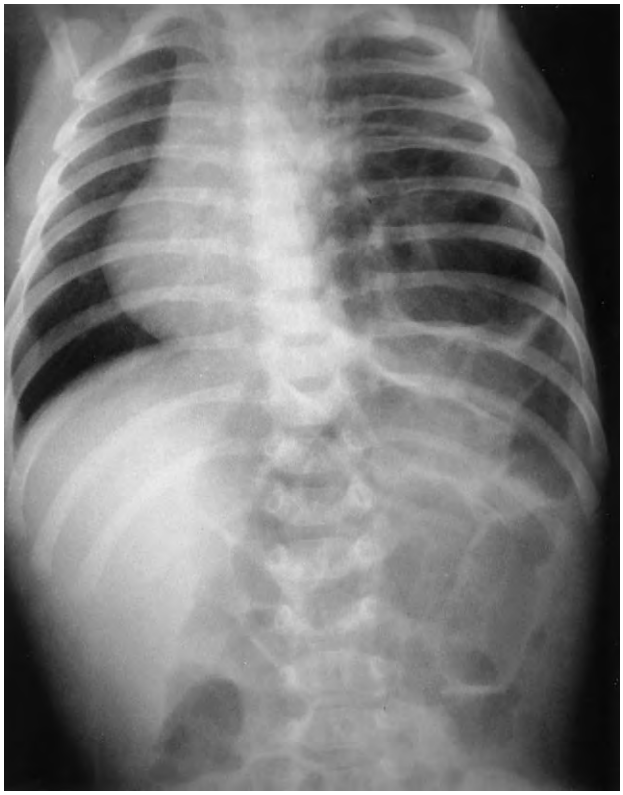

Figure 64-27 Diaphragmatic hernia. Chest radiograph of a newborn infant showing the characteristic picture seen with a posterolateral diaphragmatic hernia (Bochdalek hernia) with absence of the left diaphragmatic shadow, the left chest filled with gas-filled loops of bowel, and the heart and mediastinum shifted to the right.

dominantly use preductal oxygen saturation to assess the overall clinical status of the infant since this is what is being delivered to the cerebral and coronary circulations. If the neonate experiences respiratory distress, then the infant should be intubated and mechanically ventilated by conventional means, initially keeping peak inspiratory pressures below 25 cm H_2O. Respiratory rates should also be kept below 100 per minute if possible. A philosophy of permissive hypercapnia and gentle ventilation should be followed to prevent barotrauma and volutrauma to the lungs.[362] Partial pressures of carbon dioxide between 55 and 65 mmHg should be accepted. Positive end-expiratory pressures of approximately 5 cm H_2O may also help recruit atelectatic areas in both lungs. Sedation is necessary in most instances to allow coordination of the patient with the ventilator and to prevent pulmonary hypertensive crises secondary to agitation or discomfort. It is also important to realize that oxygen saturation targets for infants with CDH change with time. For instance, preductal oxygen saturations above 70% within the first 2 hours of life may be acceptable. However, these should rise to above 85% over the ensuing 4 to 6 hours after birth. In addition to the use of oxygen saturation measurements to assess the status of the respiratory system in these patients, we also calculate the oxygenation index [(FIO_2 × mean airway pressure × 100)/$PaO_{2(postductal)}$]. An increasing oxygenation index over time (especially if >40) on serial arterial blood gas measurements indicates deterioration of the respiratory status of the patient and the need for more advanced therapy and physiologic support. Postnatal echocardiographic evaluations are also needed in the immediate postnatal period to assess the degree of pulmonary hypertension, rule out cardiac anomalies, as well as guide management.[363] Inotropic support to improve the circulatory status of the patient may also be considered for patients with low mean arterial pressure and derangements in systemic perfusion. Excessive amounts of intravenous fluid should also be avoided because pulmonary edema with worsening pulmonary hypertension and gas exchange may ensue.

ADVANCED THERAPIES AND PHYSIOLOGIC SUPPORT

Controversies exist as to the optimal management scheme for infants with CDH, especially those that are in marked distress and for whom conventional treatment is inadequate. Several forms of advanced physiologic support are currently available for these difficult situations, but the evidence of their benefit is often lacking or anecdotal. For instance, despite observations of the relative surfactant deficiency and lung immaturity in animals and infants with CDH, for which steroid administration may be useful, the use of antenatal steroids has not been shown to be effective for infants with CDH.[364] Other therapies such as nitric oxide[365,366] and surfactant replacement[367] are also not uniformly effective for infants with CDH, despite a physiologic rationale for their use.[368,369]

The biggest changes in the management of infants with CDH in the last two decades have involved ventilatory strategies. Previous ventilator management of infants with CDH was based on observations that normal partial pressures of carbon dioxide and pH reduced pulmonary hypertension as well as shunting through the patent ductus arteriosus.[370,371] Thus, patients were hyperventilated, often with high ventilatory pressures, to achieve this goal. This strategy persisted for many years until Wung and associates[372] demonstrated that this philosophy of ventilator management led to the development of ventilator-induced lung injury which negatively impacted the outcome of these patients. Since then, strict avoidance of barotrauma through the use of lower ventilator pressures and acceptance of permissive hypercapnia have improved the outcome of infants with CDH, as well as reducing the need for ECLS in some centers.[362] Advanced ventilatory support through the use of high frequency oscillation ventilation has been proposed, as an initial therapy, to be more useful in protecting the lung from barotrauma and ventilator-induced lung injury than ventilation by conventional means in infants with CDH.[373-375] However, the evidence is not clear if its beneficial effect is solely due to the effects of oscillation or other concurrent therapies.[376]

The use of ECLS in infants with CDH has increased dramatically since its introduction for use in neonatal respiratory failure.[377] This therapy has traditionally been offered to patients with greater than 80% risk of dying postnatally as a consequence of severe pulmonary hypertension. ECLS may "rest" the lung so that local vasoactive cascades, which increase pulmonary vascular reactivity of the lung in the immediate perinatal period, may be allowed to stabilize.[378] The criteria for determining the risk of death attempt to indirectly assess the severity of pulmonary hypertension. Even with prenatal diagnosis, there are no criteria that allow for an absolute determination of outcome in this patient population. Classically, circulatory collapse/refractory hypotension, alveolar-arterial oxygen gradients greater than 600 mm Hg for more than 24 hours, oxygenation index greater than 40 on three consecutive arterial blood gases, partial pressures of oxygen less than 40 mm Hg and pH < 7.15 have been used as criteria for the institution of ECLS.[379] The main modes of ECLS for neonatal respiratory failure are venoarterial (cannulation of the internal jugular vein and carotid artery) and venovenous (double-lumen catheter inserted into the internal jugular vein). Based on the most recent extracorporeal life support database, the vast majority of centers are still using venoarterial ECLS despite the technical ease of and equivalent outcomes with venovenous ECLS.[380]

The institution of ECLS is not without risks. These risks most often relate to hemorrhagic complications resulting from systemic anticoagulation, which is still necessary during an ECLS run, despite the promise of heparin-bonded circuits. Contraindications to its use are based upon pre-ECLS states that may exacerbate these complications or upon technical limitations (i.e., cannula size). Thus, the relative contraindications for ECLS include weight less than 2 kg, gestational age less than 34 weeks, the presence of lethal systemic or cardiac disease, and the presence of intracranial hemorrhage (grade II or more). In the end, ECLS has contributed to the survival of infants with CDH who would have likely died without it. Indeed, the overall survival rate for CDH infants placed on ECLS is 53%.[381] In comparison, infants who met ECLS criteria but did not receive support had survival rates of 38.5%.[379]

SURGICAL CORRECTION

The principles for the repair of diaphragmatic hernia have not changed greatly over the past 20 years. The philosophy

regarding the timing of surgical repair has generally shifted from emergent repair to a delayed approach after stabilization of the infant.[382] However, this has come under recent debate.[376] A recent Cochrane review was unable to find a difference in outcome for those infants repaired early (within 48 hours) compared to those infants repaired in a delayed fashion (greater than 48 hours).[383] At our institution, infants undergo repair within 24 to 48 hours if the postnatal status of the infant is stable. This also allows time for a thorough evaluation of associated anomalies, especially cardiac defects, which may influence perioperative care and outcome. For patients who require ECLS or other advanced physiologic support, we wait for clinical stabilization, and in the case of ECLS, decannulation and reversal of anticoagulation, prior to definitive surgical repair. However, centers have performed diaphragmatic hernia repair while on ECLS without much increased morbidity or bleeding complications in recent years.[384]

The optimal type of closure is still the primary repair where the patient's own diaphragmatic muscle is used to close the defect. When this is not possible, a patch is often used. The overall recurrence rate with CDH repair is generally reported to range between 5% and 25%.[385,386] Although uncommon in patients receiving a primary repair, hernia recurrence is a particular problem for those patients undergoing a patch repair. Indeed, Moss and colleagues[387] described evidence of hernia recurrence, within 3 years of repair, with nonabsorbable, prosthetic patches in almost half of the 109 patients included in their review. The lack of durability of prosthetic patches (i.e., Gore-Tex) has led to the trial of bioactive materials (i.e., Surgisis, Alloderm) as a possible solution to reduce recurrence rates and improve long-term outcome. However, no difference in the recurrence rate has been observed between standard, nonabsorbable materials and newer, bioactive products.[388] Autologous muscle such as latissimus dorsi[389] or transversus abdominis[390] muscle flaps have been used with good results, although the former is more applicable to the repair of recurrent CDH. Minimally invasive techniques have also been described in the neonatal period with encouraging preliminary results.[391-393] During repair, a hernia sac, if present, should be resected; this occurs in only 10% of cases and is associated with a better prognosis.

CURRENT OUTCOME, MORBIDITY, AND LONG-TERM FOLLOW-UP

Several recent reviews have documented an improved overall outcome for infants with CDH compared to 20 years ago with survival rates as high as 90%.[362,394-397] Interestingly, infants receiving an antenatal diagnosis of CDH may have survival rates as low as 20%.[346] This has been termed the "hidden mortality" of CDH.[398] Despite advances in care, intervention, and technology, CDH still carries a high mortality rate due to associated anomalies, particularly cardiac, chromosomal, and neurologic, with prematurity and low birth weight also affecting prognosis.[346]

Until relatively recently, the long-term sequelae for infants with CDH have been underappreciated. With increasing survival of the sickest infants and the advent of multidisciplinary teams who coordinate the overall care and follow-up of these patients, it has become quite clear that the morbidity experienced by infants with CDH is not limited to respiratory consequences secondary to pulmonary hypoplasia and pulmonary hypertension.[399,400] Indeed, derangements in neurocognitive,[401-403] cardiac[395,404] and musculoskeletal function,[405] as well as problems with sensorineural hearing,[401] feeding,[406] gastroesophageal reflux,[394,395] and growth,[395,407] have been identified (Box 64-3). The use of ECLS has been found to be a significant independent predictor for the development of these problems.[408,409]

BOX 64-3 Long-term Complications of Congenital Diaphragmatic Hernia

Nutritional: Feeding aversion, gastroesophageal reflux, failure to thrive
Pulmonary: Frequent bronchitis, asthma
Neurologic: Developmental delay, hearing loss
Cardiac: Pulmonary hypertension
Musculoskeletal: Scoliosis, chest asymmetry
Recurrent CDH (especially if patch necessary)

The severity of sequelae correlates with the severity of pulmonary hypoplasia/hypertension.

FUTURE DIRECTIONS

Fetal Surgery

Intuitively, CDH should be amenable to fetal therapy. By reducing the hernia contents, repairing the defect, and allowing the lung to grow while the fetus still derives oxygen and nutrients from the placental circulation, the pulmonary hypoplasia should reverse, allowing for normal postnatal lung function. An enormous body of experimental work, mainly in animals, has allowed the evolution of fetal therapy for CDH to progress to clinical trials.[410-413]

Early experimental work in animal models of CDH revealed that the creation of a diaphragmatic hernia in fetal sheep led to pulmonary hypoplasia, vascular maldevelopment, and clinical symptoms of respiratory distress that were similar to that observed in newborns with CDH.[414] From a clinical standpoint, the survival of infants with a prenatal diagnosis of CDH during this time period was dismal despite optimal neonatal care.[398] When the in utero correction of the hernia defect in animal models led to postnatal survival and normal lung function,[415] there was much optimism that these same results could be reproduced in human fetuses. The first successful fetal surgical procedure in humans for CDH was reported in 1990.[416] Although this first patient had an excellent outcome, subsequent patients fared less well. Indeed, only 5 of 21 fetuses undergoing surgery survived despite improvements in tocolysis and perioperative fetal care.[417] The main obstacle to successful repair occurred in those patients who had "liver up" in the chest, where replacement of the liver back within the abdominal cavity led to kinking of the sinus venosus, subsequent obstruction to umbilical vein flow, and fetal death.[418] A clinical trial evaluating the efficacy of open surgical repair for fetuses with "liver down" demonstrated that the outcome of these infants was no better than

infants cared for by conventional means.[419] Thus, the optimism for open fetal surgical repair for CDH diminished, and other modalities were investigated.

Tracheal Occlusion

It was also well known during this time that the amount of fetal lung fluid present affected fetal lung growth. If lung fluid was allowed to accumulate, the lung would grow.[420] Subsequently, open tracheal occlusion in fetal lambs with CDH was noted to prevent pulmonary hypoplasia.[421,422] These findings led to a prospective study[413] evaluating tracheal occlusion in 15 human fetuses, with "liver up," and a low LHR (<1.0), criteria suggestive of severe pulmonary hypoplasia. All fetuses underwent tracheal occlusion and were delivered by the exutero intrapartum technique (EXIT).[423] The EXIT procedure allowed the fetus to remain on placental support while airway control was established and the tracheal occlusion (clip) was removed. Unfortunately, only five patients survived to discharge and most of the deaths in this series were secondary to respiratory insufficiency.[413] However, all matched control patients who did not receive tracheal occlusion died, thus suggesting a clinical role for tracheal occlusion in a specific subpopulation of fetuses with CDH.

Advances in the technique of tracheal occlusion, particularly via endoscopy, which circumvented the need for large hysterotomy incisions and the ensuing risks of preterm labor, were then developed.[423,424] Animal models utilizing this technique were able to demonstrate significant lung growth and the reversal of pulmonary hypoplasia.[425] Further studies also revealed that the length and timing of tracheal occlusion[426] affected the morphology of the lung, surfactant synthesis, type I and type II cell balance, as well as the lung compliance and the ventilatory characteristics of the lung.[427-429] Endoscopic techniques were then further refined such that tracheal occlusion using either clips,[430] inflatable balloons,[431] or foam plugs[432] could be easily accomplished with less risk to the mother and fetus. Initial clinical results using the "Fetendo" clip[433] revealed a much improved 90-day survival for high-risk infants with CDH ("liver up" and LHR < 1.4). Unfortunately, the long-term survival of these patients was reduced secondary to tracheal complications and recurrent laryngeal nerve injury. Nonetheless, the enthusiasm for tracheal occlusion in high-risk infants with CDH led to a National Institutes for Health–sponsored randomized clinical trial in the United States.[411] After 24 patients were recruited for study, the trial was stopped prematurely because of an unexpectedly high survival rate for infants in the control group. An ongoing, prospective study from Europe (FETO group)[412] evaluating fetal tracheal occlusion by inflatable balloon has presented preliminary results that are encouraging, but its limitations are the lack of a randomized design as well as standardized postnatal care.[418]

Perfluorocarbon

These clear, odorless liquids are capable of carrying large amounts of oxygen and act as surfactant surrogates since they are also able to lower surface tension. Liquid ventilation with perfluorocarbon (PFC) has been assessed in neonates and infants with respiratory failure. Despite an ability to improve oxygenation and reduce arterial-alveolar gradients and the oxygen index in small series,[434-436] prospective studies failed to demonstrate any difference in morbidity or mortality compared to conventional gas ventilation.[437] The use of liquid ventilation in infants with CDH has also been assessed, with results demonstrating an improvement in oxygenation indices and lung compliance.[438] However, prospective studies have been halted until safety issues with PFC have been thoroughly evaluated. Nonetheless, PFC may have a role as an adjunct to tracheal occlusion. Indeed, PFC-induced lung growth has been evaluated in animal models[439] and in infants[440] with CDH with encouraging preliminary results.

MORGAGNI HERNIA AND DIAPHRAGMATIC EVENTRATION

Foramen of Morgagni hernias occur in a retrosternal location and usually contain a hernia sac. These hernias are rarely symptomatic at birth, are rarely accompanied by pulmonary hypoplasia, and are often identified on imaging studies for unrelated reasons (Fig. 64-28). An association has been noted with Down syndrome, with Morgagni hernias representing 3% of malformations in this group of patients.[441,442] The transverse colon is the most common viscera contained in the hernia, but other parts of the gastrointestinal tract and part of the liver may also be found. Complications such as bowel obstruction and segmental volvulus may occur and warrant urgent surgical repair. In recent years, laparoscopic techniques have emerged as the preferred approach for repair.[443]

Congenital diaphragmatic eventration accounts for less than 5% of diaphragmatic anomalies. It is due to incomplete muscularization of the membranous diaphragm. The involvement of the diaphragm is more commonly partial than total. As with Bochdalek hernia, it is thought to result from a congenital anomaly of the pleuroperitoneal membrane but occurring at a slightly later stage.[216] Clinically, it is difficult to differentiate between a diaphragmatic hernia with a sac and eventration, because both represent a spectrum of the same anomaly. Microscopically, one expects to find some fibrous tissue within the thinned portion of the eventrated diaphragm instead of only pleura and peritoneum in a diaphragmatic hernia sac. This entity should not be confused with *diaphragmatic paralysis*, which may be secondary to a traumatic delivery or to postnatal phrenic nerve injury (most often after cardiac surgery). Brachial plexus injuries (Erb's palsy) are associated in 75% of patients with diaphragmatic paralysis from traumatic deliveries.[216] The whole diaphragm is involved and noncontractile. Spontaneous recovery may occur but diaphragmatic plication is indicated if the patient remains ventilator dependent after 4 weeks.

Congenital diaphragmatic eventration rarely may present with severe neonatal respiratory distress and pulmonary hypoplasia. More often, it is discovered incidentally, but it may lead to respiratory or gastrointestinal symptoms, including gastric volvulus. Surgery is indicated for symptomatic patients and those in whom a true congenital diaphragmatic hernia cannot be excluded based on imaging alone. This difficulty occurs mainly on the right side, where the smooth contour of the herniated liver cannot be differentiated from a thinned area of the diaphragm; the diagnosis can be clarified by thoracoscopy.

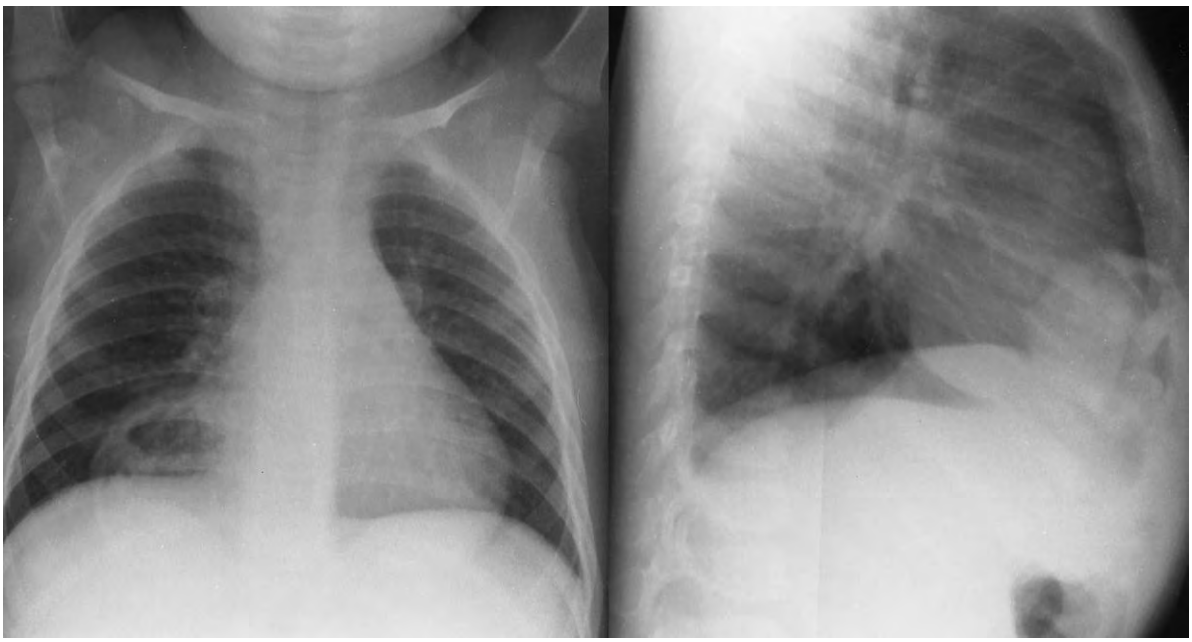

Figure 64-28 Anterior (Morgagni) diaphragmatic hernia. Anteroposterior chest radiograph showing a rounded shadow at the right heart border *(left)*, which on the lateral view appears multiloculated. This shadow represents loops of bowel entering the chest through a defect in the anterior foramen of Morgagni, and surgery is recommended in order to avoid the risk of bowel strangulation.

PITFALLS IN LUNG MALFORMATIONS

- Prenatally diagnosed lesions are not all CCAM/CPAM, and a histologic subtype should not be assigned on imaging.
- Regressing fetal lung lesions may not be apparent on postnatal chest radiography; CT scan is necessary.
- A systemic arterial supply may be encountered with any parenchymal malformation.
- Cystic pleuropulmonary blastoma often presents with spontaneous pneumothorax in infants and cannot be distinguished from CCAM/CPAM on imaging.

CHAPTER 65 Sleep-Disordered Breathing

Karen Ann Waters

TEACHING POINTS

- Obstructive sleep apnea is the most common sleep-associated breathing disorder in children.
- Pathologies underlying obstructive sleep apnea include airway structure and obesity.
- Physiologic changes that occur during sleep contribute to the associated respiratory dysfunction.
- Other respiratory disorders often deteriorate in sleep due to loss of accessory muscle activity, especially in rapid eye movement sleep.
- Disorders of respiratory control (e.g., congenital central hypoventilation syndrome) show most serious blood gas derangements in slow wave sleep.
- Treatments for obstructive sleep apnea include medical, surgical, and noninvasive pressure support.

OVERVIEW

Airway collapse and hypoventilation are conditions that are potentiated during normal sleep. Pediatric sleep units undertake comprehensive diagnostic studies during sleep to evaluate these and other forms of respiratory dysfunction. Interpretation of these studies requires an understanding of the dynamics of the upper airway and of respiratory control along with their developmental interactions with sleep. Accurate evaluation of sleep-associated respiratory abnormalities in children, using detailed clinical and investigative procedures, should include an assessment of the underlying pathology.

Obstructive sleep apnea (OSA) is the most common sleep-associated breathing disorder in children. A number of syndromes and malformations are associated with particular sleep-associated diagnoses, including increased risk for OSA. The other major diagnostic group is children with congenital and acquired hypoventilation syndromes. Respiratory failure during sleep is common in association with complex airway abnormalities, chronic lung disease, neuromuscular disorders, as well as congenital or acquired neurologic conditions leading to central hypoventilation.

Treatment of these sleep-associated respiratory disorders ranges from medical therapy to invasive ventilation. Treatment of childhood OSA includes medical and surgical therapies. Perioperative assessment and management is an important component of the therapeutic intervention. Pressure support therapies, including nocturnal ventilation to treat hypoventilation, can now be routinely delivered by nasal mask interfaces that are gaining wide application in pediatrics.

This chapter examines the current knowledge of OSA and sleep-associated hypoventilation in children. The normal pathology and the pathophysiology underlying sleep-related respiratory abnormalities are explored. Methods for identifying these disorders and their complications are discussed. The final section describes treatment modalities available for these disorders, with discussion of the circumstances in which various treatments should be implemented.

PREVALENCE

OSA can occur in all age groups from infancy to adulthood. The best studies of the prevalence of childhood OSA include questionnaires that are combined with some overnight monitoring (most commonly oximetry). The reported prevalence of habitual snoring in children varies from 3.2% to 15% of children.[1-3] Although the age groups included and the criteria for diagnosing OSA vary among studies, approximately 25% of children who snore habitually have clinically significant OSA. Prevalence estimates for OSA in children range from 0.6% to 10.3%.[4,5]

Hypoventilation is less common, but among children younger than 18 years, the causes of hypoventilation published from France include neuromuscular disease (34%), OSA and/or craniofacial abnormalities (30%), cystic fibrosis (17%), congenital hypoventilation (9%), scoliosis (8%), and other disorders (2%).[6] All studies that have reviewed the problem conclude that the number of patients currently ventilated is an underestimate of those who require the therapy. The best estimate of the incidence of sleep associated hypoventilation is a Swedish study, showing an overall incidence of 6.6 to 9.6 per 100,000.[7] However, independent studies suggest that congenital central hypoventilation syndrome (CCHS) has an estimated incidence of 1 per 200,000.[8] Assuming that CCHS comprises 9% of all ventilated children in France, the upper incidence of children requiring ventilation should be closer to 22.2 per 100,000.

PATHOPHYSIOLOGY

Upper Airway Muscles and Mechanisms of Obstruction

The upper airway extends from the nares to the larynx. From the nasopharynx to the glottis, it is a pliable tube, with walls made up of soft tissue supported only by muscle so that the

caliber of the airway can change with simple events, such as a change in head position.[9] Most postnatal changes in the size of the airway occur during the first year of life and during the pubertal growth spurt. However, during growth the airway soft tissue maintains proportionality with the facial skeleton.[10] Genioglossus activity is important in maintaining airway patency during sleep and responses vary between children with OSA compared to those without.[11-13] Upper airway reflexes protect airway patency by adjusting various muscle activities to suit the prevailing respiratory needs, and the importance of their activity in children with sleep apnea is demonstrated by changing responses after the application of topical anesthetic.[11] As reflected by these studies of genioglossus activity, the process of maintaining airway patency requires continuously responsive muscle function and upper airway patency is maintained by the dynamic interaction of muscle activity and airway size in both wakefulness and sleep. With sleep onset, there is relaxation of all postural muscles, including those of the upper airway. The activity of these muscles and the reflexes controlling them are blunted dramatically by onset of sleep, although the changes are least in slow wave sleep (SWS) and greatest in rapid eye movement (REM) sleep.[14]

Neural Control of the Upper Airway

Respiratory rhythm arises in the brainstem. The cells controlling respiration have been isolated in the medulla to the region of the pre-Bötzinger complex and the associated dorsal and ventral respiratory neuronal groups.[15,16] The dorsal respiratory group has primary output. Output from the ventral respiratory group is modulated within the dorsal group before the final integrated output. Neurons that drive the muscles of both the respiratory pump (diaphragm and accessory muscles) and the upper airway are intimately connected with those producing respiratory rhythm.[17] These respiratory centers also have intimate connections with the reticular activating system, with pontine influences particularly relevant during REM sleep.[18] The rates of development and myelination are not uniform among these neural centers, and the changing physiologic correlates during development are not well delineated.

The muscles of the upper airway are dynamically controlled throughout the respiratory cycle through coordination of these respiratory neuronal connections. Phasic activity of upper airway muscles can be demonstrated during normal respiration. The genioglossus is the major upper airway dilator muscle and is active during inspiration.[19] During infancy, there is active braking at the larynx during expiration.[20,21] Increased respiratory demand results in augmentation of normal respiratory activity, along with the additional recruitment of accessory muscles including the sternomastoid and the abdominal muscles.[22]

Reflexes Protecting the Upper Airway from Obstruction

During sleep, upper airway responses to negative pressure and to hypercapnia are preserved in normal children, although infants appear to have a different pattern of upper airway activation than older children.[23] In infants, the airway is generally stable, but the tendency to close with experimental occlusions reflects the occurrence of spontaneous occlusions.[24]

Intact brainstem reflex pathways are vital for the prevention and/or rapid recovery from sleep-associated airway obstruction. These reflex pathways involve many interconnections between sensory inputs from the oropharynx and chemoreceptors, the respiratory drive, the reticular activating system, and the motor neurons of the upper airway musculature.[25] The afferent supply to the upper airway and larynx is mostly provided by the trigeminal, glossopharyngeal, and vagus nerves.

Arousal is an important culmination of these protective intercommunications.[26] This may be in response to chemoreceptor, mechanoreceptor, or local upper airway reflex responses during sleep or simply due to increased ventilation whatever the primary stimulus.[27] Children with sleep apnea have increased arousals, but can also respond to airway obstruction with increased motor activity without the need for cortical arousal to occur, as they show an apparent lack of cortical arousal in response to airway obstruction.[28,29] It is possible that arousal occurs but at a level that is not seen on traditional investigative procedures, and a pattern of hierarchical noncortical arousals has been demonstrated in infants.[30] Prior sleep deficit, such as may occur with sleep apnea, also increases arousal thresholds, even in infants.[31]

Local and brainstem reflexes act to protect upper airway patency.[19] Laryngeal receptors respond directly to increased CO_2 and temperature. Rapidly adapting receptors have been identified within the oropharynx that produce increases in both upper airway and diaphragm muscle activity in response to vibration with frequencies similar to snoring.[32] Local receptors in the distribution of the trigeminal nerve respond specifically to respiratory stimuli.[33] The laryngeal chemoreflex and other local airway reflexes may contribute to the protective responses preventing upper airway obstruction.[34]

Muscle activity from the upper airway muscles (particularly hypoglossal) may increase or decrease in the presence of airway obstruction, depending on the timing of the stimulus during inspiration.[19] Increased activity is seen during both inspiratory and expiratory phases of the respiratory cycle, although the level of response is dependent on sleep/wake state and is increased when there is increased CO_2.[35] This increase in the electromyogram (EMG) signals may be used to quantify the severity of the obstruction in children and infants where recruitment of the genioglossus during airway occlusion is preserved during sleep, including REM/active sleep.[22]

Developmental Aspects of Respiratory and Airway Control; Age-Related Disorders

In infants, reflex responses to upper airway obstruction may produce apnea rather than respiratory stimulation. Laryngeal reflexes can produce life-threatening apnea in young animals, particularly in the presence of infections that damage the upper airway epithelium.[36] Infants have a predominance of inhibitory reflexes, and prolonged apnea has been documented in infants in the presence of nasopharyngitis and common sedatives.[36,37] It is likely that there is associated

inflammation or damage to sensory pathways within the epithelium or damage within the carotid bodies. Central apnea may also occur in response to upper airway obstruction, rather than increased respiratory effort. Hypercapnia is associated with recruitment of accessory muscles during non-REM (NREM) sleep, so ventilatory responses are less effective in REM sleep.[38] Although the initial apnea is mediated via vagal reflex pathways, for example, following a sigh, other factors contribute to the ongoing respiratory rhythm oscillation.[39]

Brainstem chemoreceptors change with development and are made more unstable by environmental changes such as altered ambient temperature. Ventilatory response testing in infants shows variability of the ventilatory response to hypoxia, although it tends to be biphasic and consistent between sleep states.[28] Ventilatory responses to changes in CO_2 levels mature faster than responses to hypoxia, where inconsistent responses are frequently observed, and a large number of apparently normal infants fail to arouse during hypoxia, especially during SWS.[28,40]

RELATIONSHIP OF AIRWAY OBSTRUCTION TO SLEEP

Tone changes associated with sleep are a critical factor in the pathophysiology of OSA. Both tonic activity and reflex responses of upper airway muscles are reduced in sleep, with the most dramatic effects in REM sleep.[22] Sleep onset is associated with reduced upper airway tone (and therefore reduced airway dimensions) and blunted reflex responses to acute events[23] (Fig. 65-1).

Characteristics of Normal Sleep

Normal sleep can be divided into five clearly distinguishable sleep states, with predictable sleep-state progression during the night. Mature human sleep is divided into stages I through IV and REM sleep.[41] Stages III and IV, also called deep sleep, or SWS, are characterized by large-amplitude, low-frequency electroencephalogram (EEG) activity. REM sleep is characterized by low-amplitude, high-frequency EEG activity, rapid (conjugate) eye movements (REMs), and loss of tonic muscle activity seen clearly in the chin (genioglossus) EMG. Once circadian rhythms are established, SWS is concentrated during the first hours of sleep, with most REM sleep occurring later, through the early morning hours. Stages I and II, also called light sleep, are interspersed throughout the night (Fig. 65-2A [infant]). Daytime sleep periods are dominated by light sleep with little, if any, REM sleep or SWS.

Infant sleep is relatively undifferentiated until the age of 6 months, and sleep stages are divided only into quiet, active, and indeterminate.[42] Active sleep is the equivalent of REM sleep in older individuals, and quiet sleep equates with SWS. During these first months of life, maturation involves the emergence of five clear sleep states and stabilization of circadian rhythms along with the distinction between day and night sleep (Fig. 65-2B [child]). The ongoing maturation of

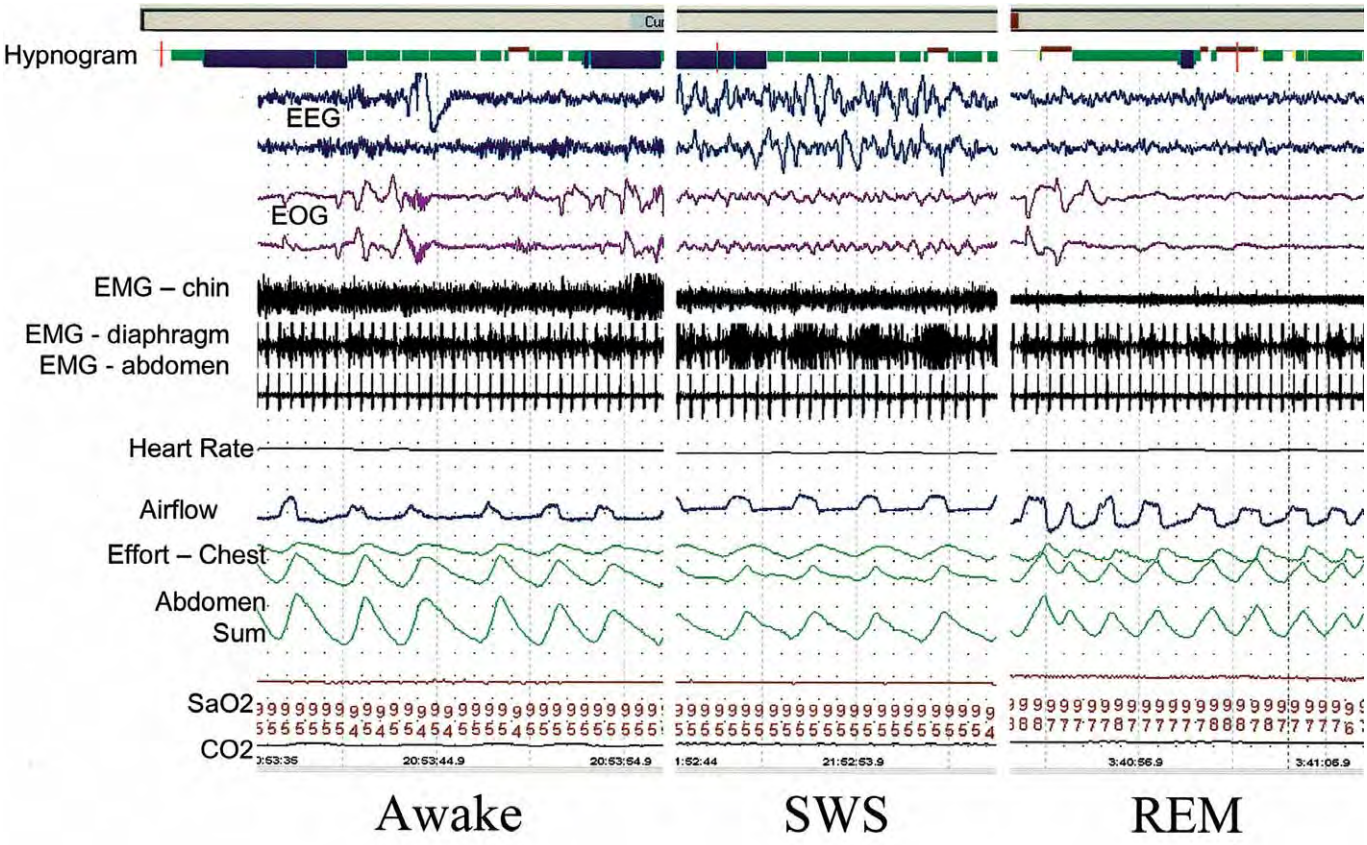

Figure 65-1 Changes in muscle tone between awake, slow wave sleep (SWS), and REM sleep.

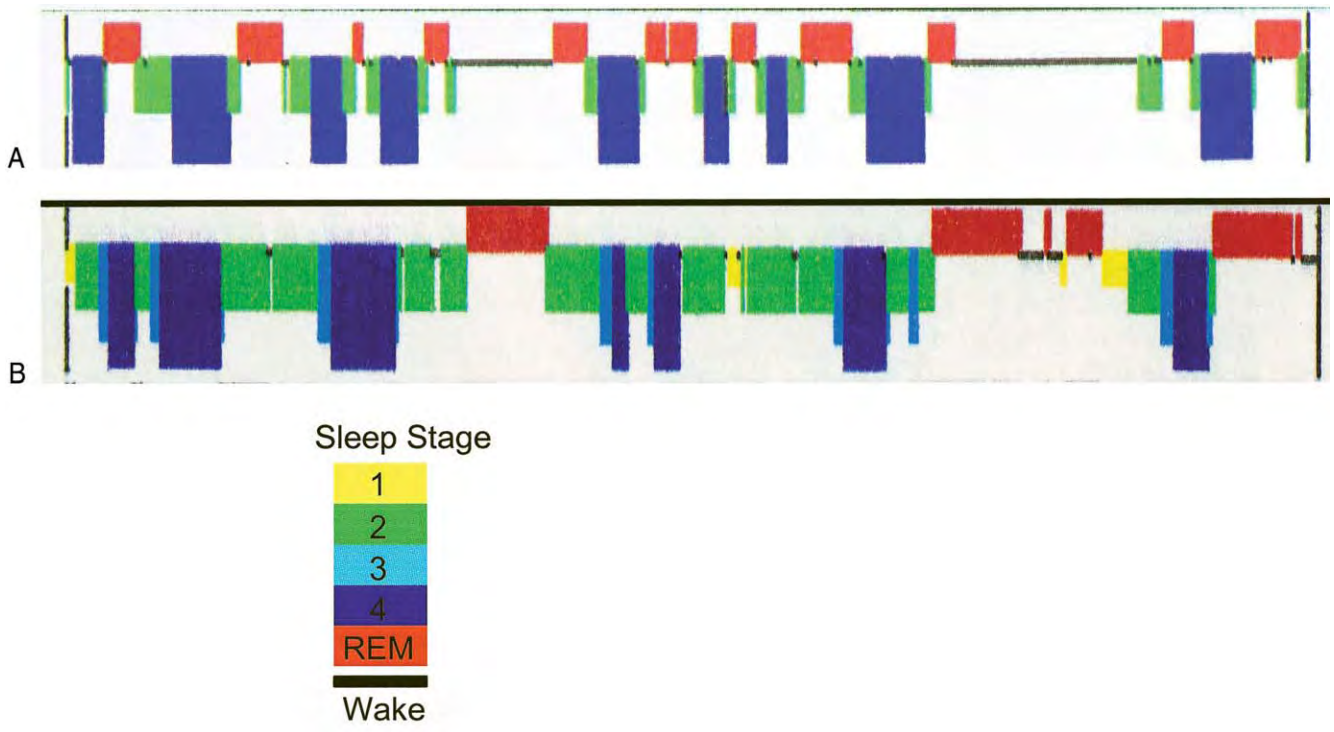

Figure 65-2 Differences in sleep architecture between an infant **(A)** and a child **(B).**

sleep states during later childhood involves substantial changes in the proportions of the different stages observed.[43]

Sleep-Associated Changes in Cardiorespiratory Patterns

SWS is associated with dampening of the arousal response, and respiration is almost completely under automatic control.[28] Respiratory control is under chemoreceptor control, and there is essentially no behavioral modification of respiratory drive. While muscle tone is maintained, arousal responses are relatively poor, and disorders of central respiratory control are most pronounced in this sleep state.

SWS is characterized by remarkable regularity of cardiorespiratory parameters, with little variability in cardiac or respiratory rate and rhythm and stable tidal volumes.[44] SWS periods in children with OSA are often characterized by prolonged periods of stable, partial upper airway obstruction demonstrated on polysomnogram (PSG) by increased phasic activity of the accessory muscles, especially during SWS. The accessory muscle activity includes chin, abdominals, and sometimes expiratory diaphragmatic activity. This can then convert to distinct periods of obstruction in REM sleep. Examples of EMG activity in normal and obstructed sleep are shown in Figure 65-3, A and B, respectively.

REM sleep is a characterized by marked variability in cardiorespiratory parameters, with behavioral control of respiratory output dominating. One of the hallmarks of REM sleep is the loss of muscle tone in peripheral muscles, including the accessory muscles and the muscles of the upper airway. Respiratory rhythm is irregular during REM sleep.[44] There is still some controversy about the degree to which there is damping of arousal and ventilatory responses (to hypoxia and hypercapnia) during REM compared to non-REM sleep.[28,44] One reason for the controversy is that the ultimate effect of any damping is lessened because of the overriding behavioral control of ventilation that also occurs. Conditions with reduced respiratory reserve can show hypoventilation in concert with reduced upper airway dilator muscle activity during (phasic) REM sleep.[44,45]

Activity of the respiratory accessory muscles is markedly reduced during REM sleep in normal subjects,[46] and, in infants, FRC may fall as a result of the loss of intercostal muscle activity.[46] Studies in infants have not consistently found the same fall in lung volumes as those that occur in adults during REM sleep. Infants and young children show persistence of phasic muscle tone in response to airway obstruction during REM sleep, and this gradually reduces with age.[47] This may be caused by persistence of some immature reflexes or due to a difference in the nature of REM sleep in the developing brain.

Respiration during light sleep (stages I and II) is associated with relative instability of respiration which can accompany transition between wakefulness and sleep. Perturbation of central control mechanisms, including drive to the upper airway, may be unmasked during this phase. An early sign of disordered breathing in sleep is prolongation of the transition time from wakefulness to sleep because of this instability of the airway.[48]

Minute ventilation is reduced in sleep, compared to wake states.[49] There is lower CO_2 responsiveness, minute volume is less for any given CO_2 level, and a rise of 2 to 8 mm Hg CO_2 is normal. Hypoxic responses are also affected. Normal oxygen saturation (Sa_{O_2}) variability with sleep is 2% or less, with P_{O_2} changing by 2 to 11 mm Hg.[50] There may be significant augmentation of this blood-gas variability in the

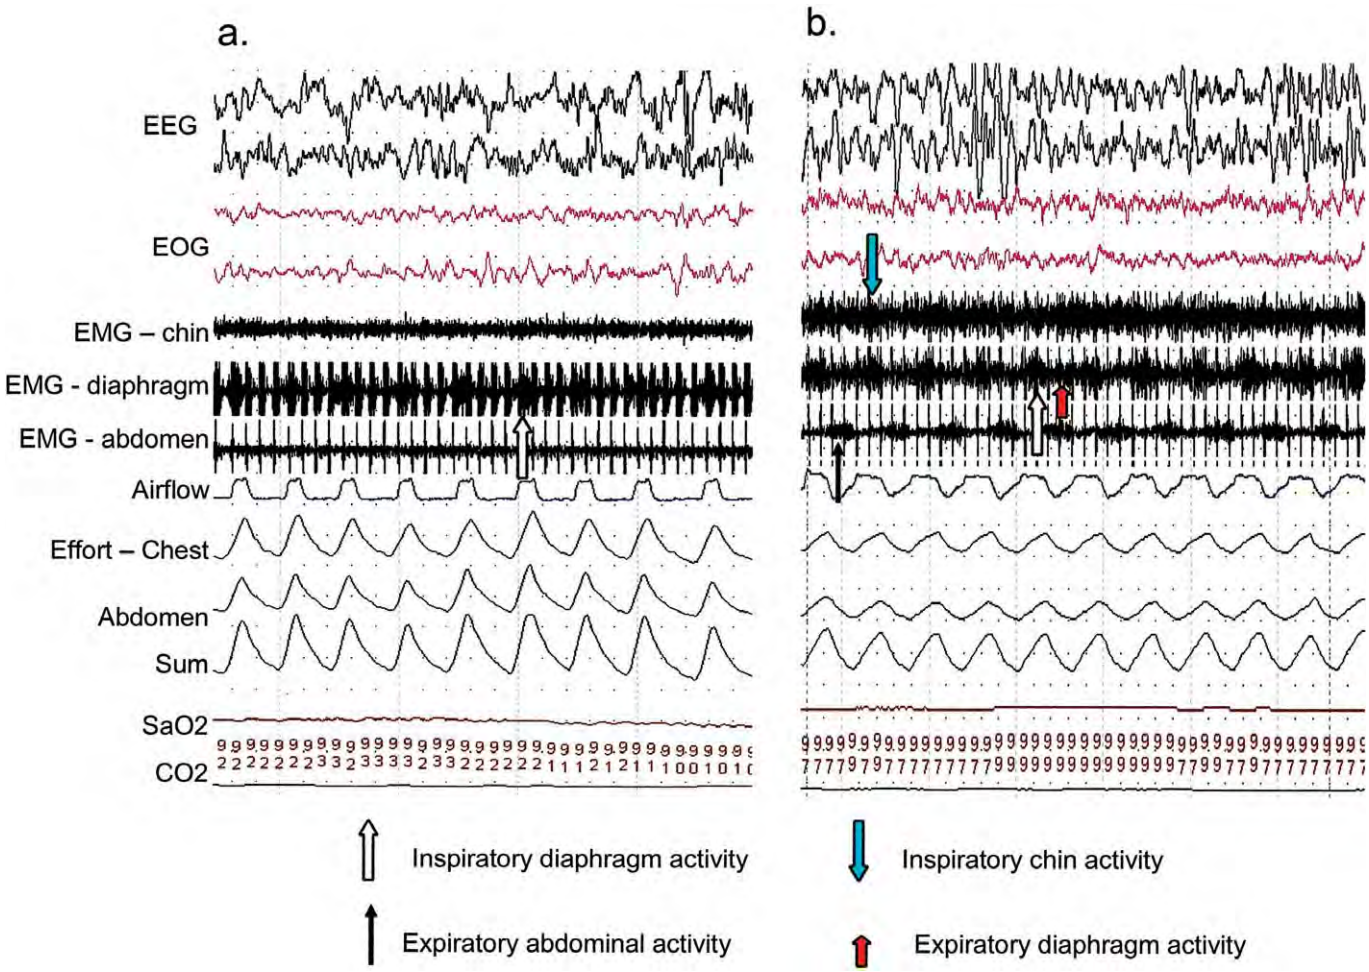

Figure 65-3 Accessory muscle activity during normal **(a)** and prolonged partial upper airway obstruction **(b)** with breathing in slow wave sleep.

presence of chronic lung disease.[50] Respiratory variability is greatest during REM sleep.

Sleep-Associated Changes in the Upper Airway

During sleep, the upper airway muscles are relaxed compared to awake, so the upper airway can be critically compromised at sleep onset because of the general fall in muscle tone and reflex functions which occurs. Sleep also alters reflex control of the upper airway, respiratory drive, and sensitivity to a variety of respiratory feedback mechanisms. The most pronounced mechanical differences are seen during REM sleep compared to the awake state. Abnormalities in chemical and respiratory drive responses are most pronounced in SWS.

Apneic events during sleep of normal children tend to be central in type, infrequent, and of short duration. These central events occur predominantly in REM sleep, although central apneas may also be seen in NREM sleep following sighs. Studies in normal children commonly show few central or obstructive apneas with indices of 0.08 ± 0.14 per hour and 0.01 ± 0.03 per hour, for central and obstructive apnea events, respectively.[51] In infants, brief central apneas (which may be called pauses) are also common, especially during stable periodic breathing. The frequency of these brief events can be up to 13.4 per hour, with periodic breathing very common in infants who were born prematurely and occupying a mean of up to $5.6 \pm 7.9\%$ of the night.[52] For monitoring purposes, apneas in infants are considered prolonged if they are longer than 20 seconds and/or if they are associated with other sequelae such as bradycardia or severe desaturations.[52]

UNDERLYING ABNORMALITIES IN OBSTRUCTIVE SLEEP APNEA

Structural abnormalities causing reduced airway dimensions, including the presence of enlarged tonsils and adenoids, have been highlighted as the underlying cause of OSA in children.[9,53] Other abnormalities associated with increased respiratory effort or more rapid oxygen desaturations may be associated with worsening of airway obstruction or its sequelae. Obesity also plays a significant role in childhood OSA.[54] Relatively small facial structure or abnormal upper airway function may be an inherited characteristic, but while there is general agreement that a genetic component exists, the origins of OSA are also thought to be multifactorial.[55,56] It is probable that some underlying abnormality in respiratory and/or upper airway control exists in many cases of sleep-associated obstructive apnea and hypoventilation.[57]

Small Upper Airway

Demonstration of structurally small airways as a mechanism underlying upper airway obstruction is easier than demon-

strating abnormal function in children. The dynamic function of the airway is likely to play a significant part in the pathophysiology of all cases of pediatric OSA.[23] Most recent studies of children's airways use technologies such as cine-MRI.[58] These have demonstrated that children with OSA have different dynamic function of the airway as well as significant compromise of airway size associated with the adenoids and tonsils.[9,58] Narrowing of the upper airway can occur at any point from the anterior nares to the larynx. This narrowing may be static or dynamic. Laryngomalacia and subglottic stenosis both increase the negative thoracic pressures required to generate inspiratory flow. Both of these types of airway narrowing predispose the affected individual to airway collapse during sleep. Children with malformations tend to have recalcitrant apnea. Persisting OSA after adenotonsillectomy may also be attributable to persisting airway abnormalities such as lingual tonsils.[59]

Some children clearly have a structurally small upper airway, for example, in Down syndrome, or craniosynostoses.[60-62] A structurally small airway, no matter what the underlying cause, may also be further compromised by adenotonsillar hypertrophy. Several studies have identified abnormal facial structure associated with OSA,[63,64] but in children who are otherwise normal, chronic airway obstruction has been associated with abnormal craniofacial structure that is reversible after treatment.[65] In others, with mucopolysaccharidoses or adenotonsillar hypertrophy, the airway lumen is crowded by extra soft tissue.[66] In the presence of reduced airway dimensions, upper airway muscles tend to maintain increased activity even in the awake state to maintain a patent airway. In this situation, the loss of muscle tone that occurs with sleep onset may be the critical factor that precipitates complete or incomplete airway obstruction.[13]

Abnormal Neurologic Control of Breathing

Abnormalities may occur in the central respiratory drive to the upper airway, or any site along the reflex pathways, the neural input of the upper airway reflexes, the central neural integration of these reflexes or the motor (output) pathways. Although abnormal upper airway reflex pathways have been postulated to cause OSA, when these reflex pathways are disrupted in conditions such as neuromyopathies or Moebius syndrome, it is generally not an isolated defect.[67-69] The processes involved with maturation of neurologic pathways, including the pathways controlling upper airway reflexes, is proposed as a potential cause of the sudden infant death syndrome (SIDS).[34] Abnormal neurologic control of the upper airway has been implicated in OSA, but this can also result from episodic hypoxia resulting in exacerbation of the disorder. Studies in adults with chronic snoring and OSA suggest that these patients have abnormal reflex control of the airway lumen, although it is not clear whether these abnormalities are the cause or the effect of the disorder.[70]

The pattern of abnormality in children with OSA tends to be preservation of the general architecture of sleep,[71] but their arousal responses to respiratory stimuli are dampened compared to controls.[72] Observed in its extreme form, children preserve sleep architecture at the expense of oxygenation and CO_2 clearance. Occasionally, children also show the converse response, of repetitive arousal in response to airway obstruction resulting in normal patterns of oxygenation and CO_2, but disrupted sleep architecture. Depressed ventilatory responses have been documented in subgroups of the pediatric population with OSA.[73] No studies to date have confirmed that arousal in response to OSA correlates with the ventilatory response activity of children, although it has been suggested that the rate of spontaneous arousals decreases as the apnea index increases.[74] These data provide some explanation as to why screening studies that measure only oxygen saturation (and/or CO_2) do not indicate the level of sleep disturbance present in those cases with vigorous arousal in response to upper airway obstruction.[75]

The congenital central hypoventilation syndrome (CCHS) occurs as a result of a genetic mutation and exemplifies the most extreme form of abnormal neurologic respiratory control.[76] This disorder results from genetic defects in the Phox-2B pathway and is associated with varying degrees of hypoventilation; the majority of affected individuals only have sleep-associated hypoventilation, but the most severely affected have hypoventilation during wakefulness and during sleep. Now that genetic testing is available, it appears that some may only present with later onset.[77] The respiratory defect is associated with abnormal autonomic function and may also be associated with Hirschsprung's disease.[78,79]

The prototypical cause of hypoventilation is the CCHS, in which central chemoreceptor responsiveness is absent due to a genetic defect in the PHOX-2B pathway. However, acquired forms of central hypoventilation may be secondary to demonstrable anatomic lesions of the brainstem, or posterior fossa.[80] Abnormal central control may coexist with or may be secondary to an anatomically small airway.[73,81] Structural lesions in the brainstem or other causes of respiratory failure, such as a muscular dystrophy, may also present with hypoventilation during sleep.[6] In the Arnold-Chiari malformation, or syringobulbia, hypoventilation may occur secondary to abnormal motor control of the cranial nerves or due to abnormal central control of respiration.[80,82,83]

It is widely theorized that the likely underlying cause of SIDS deaths is delayed maturation or abnormalities of the neural cardiorespiratory-control pathways, causing these children to be at risk of death from an otherwise inconsequential insult.[84] Such abnormal neural control may also be expressed as, or occur secondary to OSA, and studies may be able to detect a number of those children at risk for SIDS.[85,86] The abnormality may become apparent only during an upper respiratory tract infection or other acute event.[87]

Dysfunctional Upper Airway

Most children with abnormal neuromuscular control of the airway appear to have normal airway size. Palatal muscle function is abnormal in association with cleft palate, and this remains abnormal even after surgery, so that children with cleft palate appear to be at increased risk of sleep-associated airway obstruction.[88] When airway dimensions are reduced, these muscles may not be able to prevent airway obstruction.[89] Presumably the local sensory perception would also be affected, although central respiratory control is not usually affected in this disorder.

Generalized motor hypotonia contributes to upper airway obstruction and is more common in younger children and in those with disorders such as Down syndrome.[90] Sleep-disordered breathing can be precipitated or exacerbated by confounders such as obesity or scoliosis.[91] Muscular dystrophies and neuromuscular disorders are generally progressive. In Duchenne muscular dystrophy, this deterioration eventually results in respiratory and cardiac failure. However, treatment intervention when the respiratory dysfunction is critically altered during sleep will dramatically improve the quality and prolong the lives of these patients.[92,93]

OSA may occur where there is abnormal soft tissue function without demonstrable muscle weakness. In Marfan syndrome, in which the only apparent abnormality is poor connective tissue integrity, there is also a high incidence of OSA, which may then be responsible for causing or exacerbating further abnormalities such as dilation of the aortic root.[94,95] Although it seems likely that other diagnostic groups with connective tissue disorders, such as Ehlers-Danlos syndrome, would also have a high incidence of OSA, the groups affected with airway obstruction appear to be those with associated anatomical abnormalities such as micrognathia in rheumatoid arthritis or depositions causing airway narrowing in the mucopolysaccharidoses.[96,97] The skeletal abnormalities in achondroplasia cause a small foramen magnum. OSA in this group is thought to be on the basis of compression of the brainstem and upper cervical spinal cord at the level of the foramen magnum.[98]

Mechanisms of Complications

Complications of severe OSA include failure to thrive (FTT) and pulmonary hypertension. Growth failure may be caused by disturbance of growth hormone secretion, increased energy expenditure, or more generalized metabolic responses to hypoxia.[99] Obesity is associated with OSA, and there appears to be a higher risk for metabolic complications of obesity if OSA is also present.[100,101] The neurologic and behavioral sequelae of OSA have been highlighted over recent years, although many of these appear to be reversible with treatment.[102,103]

PRINCIPLES OF ASSESSMENT

To date, the diagnosis of OSA in children requires monitoring during sleep. The aim of such studies is to find the abnormalities (sleep-associated respiratory dysfunction) and classify them by criteria which are discriminatory between studies and indicate the likelihood of detrimental effects in both the short and long term.

The gold standard for assessing sleep-related respiratory dysfunction is overnight polysomnography, and these detailed overnight studies provide the most detailed diagnostic information. It can be, however, an expensive and time-consuming procedure. Some form of screening needs to be used to determine which children should undergo such studies. Clinical assessment is the start of this screening process.

CLINICAL CHARACTERISTICS

Questionnaires initially looked promising, but it is now clear that history cannot distinguish OSA from primary snoring.[104] Standardized questionnaires have been developed to assist in the process of symptom identification and prioritization.[105] The most discriminatory symptoms are breathing difficulty during sleep, witnessed apnea, snoring, and restless sleep.[106] Witnessed apneas are typically brief. Disturbed sleep, rhinorrhea, excessive sweating during sleep, and mouth breathing in the awake state are frequent but not universal features. Other features such as enuresis are reported anecdotally but may not be sufficiently discriminatory to help distinguish individual children with OSA.[107,108] Upper respiratory tract infections appear to be an infrequent cause for the acute precipitation of obstructive apnea.[109,110] Reports are inconsistent regarding reduction in the frequency of respiratory tract infections after adenotonsillectomy, but overall they appear to show a slight reduction in the frequency of events.[111,112]

There is consensus that even mild disease can have significant negative impact on the development and behavior of infants and children, although many of these effects also appear to be reversible.[103,113] This has led to increased screening of children who are otherwise deemed to have attention deficit-hyperactivity disorders (ADHDs). For individual cases, it is not generally possible to screen for developmental or behavioral abnormalities that are specifically attributable to OSA, nor is it currently possible to predict the improvement an individual might achieve after surgery.[114]

As children get older, their parents are less likely to witness children's sleep, so history appears to become more unreliable. However, factors such as a history of associated lower respiratory tract disease, secondary enuresis, or daytime sleepiness may be available. Daytime sleepiness is an infrequent complaint among children with sleep apnea, although measures have shown that children with OSA are objectively more sleepy compared to controls.[115] Less-common presentations are reported anecdotally or as "associated symptoms," such as developmental delay, night seizures, costochondritis, cyclic vomiting, hyperactivity or inattentiveness, and morning headaches.[116] OSA may also lead to exacerbation of conditions such as seizures, although this may not be apparent until there is improvement after treatment.[117]

Past history may give an indication of the severity of obstruction. There may be a history of anesthetic difficulties.[118,119] Sedative drugs or muscle relaxants may contribute to upper airway problems, and children with OSA appear to be particularly sensitive to opiates.[120] Young infants may have symptoms of noisy breathing and sweating in sleep, and some children who present as near-miss SIDS have been demonstrated to have obstructive events on subsequent sleep studies.[121] Children who have subsequently died of SIDS have had obstructive apneic events demonstrated on sleep studies performed prior to death.[86] With better access to appropriate screening studies, it is possible that children who have these abnormalities can be detected and treated.

Despite recognition that history is not able to accurately identify the presence or severity of OSA in children, surveys continue to show that most ENT surgeons use only history to make the diagnosis; objective testing for OSA occurs only in 10% to 12% of cases that proceed to surgery with a diagnosis of OSA.[122]

Underlying Conditions

Unless there has been a clear precipitating event or specific questioning for a history of sleep-disordered breathing is sought, the symptoms of obstructive apnea may not be distinguished from the developmental history of children where an underlying condition is associated with increased risk for airway obstruction. With research now demonstrating that some syndromes have an increased or high incidence of obstructive apnea, there is better screening of children with such disorders for this disease. Any cause of airway narrowing may contribute to sleep-associated obstruction, including rhinitis or nasal abnormalities.[123] Other predisposing factors include choanal stenosis, laryngeal palsy (congenital or acquired), and tracheobronchomalacia.[118,119] Infants with a history of prematurity have facial features predisposing to obstruction.[23,124] Symptoms affecting both daytime and nighttime function, including intellectual dysfunction and sleepiness, may be considered part of the inherited syndrome rather than secondary sequelae.

Studies suggest that there is a familial incidence of OSA; children with OSA often have one or more parents who are also affected. A genetic link has been proposed.[125] It is possible that there is also a link with SIDS deaths.[126,127] Further studies are required to confirm these associations.

Examination

It is increasingly rare for children with OSA to present with complications of the disease, although the link between behavioral and neurologic abnormalities has meant that children with ADHD or other behavioral disturbances may need to have a diagnosis of OSA excluded.[102] Nonetheless, vigilance is required among those groups at highest risk.

Careful daytime examination can potentially reveal a wide range of physical features associated with obstructive apnea in children or a variety of medical conditions that have now been associated with the disorder.[128] Increased upper airway (nasal) resistance can result in mouth breathing when awake.[129] The patency of the nasal airway should be assessed, including endoscopy if required.[129,130] Syndromes and malformations may be associated with other airway abnormalities,[131] as well as those specifically linked to OSA such as hypoplastic mid-face or mandible.[119] Syndromes and malformations may be present in more than a quarter of children diagnosed with OSA.[132]

The oropharynx must always be examined for enlarged tonsils, the extent of the tonsillar extension behind the tongue, and the presence and quantity of upper airway secretions. A characteristic "snorer's throat" includes edema and petechiae in the soft tissues of the oropharynx, although petechiae can also occur with recurrent tonsillitis.[133] The palate should specifically be examined for clefts and other clues of submucosal clefts, such as a bifid uvula. The presence of lymphadenopathy may support a history of recurrent tonsillitis.[133]

Respiratory examination may reveal chest deformities; Harrison's sulci are common where there is significant upper airway obstruction. Restrictive chest deformities are another common cause of respiratory decompensation in sleep, although not necessarily associated with OSA.[128]

Weight abnormalities are associated with OSA. Obesity is increasingly common and increases the risk for OSA even in childhood, and weight loss can be associated with improvement in OSA.[134] FTT occurs secondary to OSA, and may occur in up to 21% of young children (<6 years) or infants where there is also a clear growth response following effective treatment.[99] The incidence of FTT is now reported to be quite low, although it appears to be more common in infants than in older children with OSA.[121] Features of pulmonary hypertension are uncommon, except in the most severe cases and tend to be more subtle than can be observed on clinical examination.[118] Cardiologic assessment by CXR and ECG can be used, but echocardiographic examination is the most sensitive test for evaluating cardiac complications in children with severe OSA.[135,136]

Clinical features of hypoventilation vary. For children with congenital central hypoventilation, the most common presentation is apnea or respiratory failure soon after birth, although other common features may be associated with their exposure to recurrent hypoxia.[137] Where hypoventilation is secondary to neurologic abnormalities, the problem may be silent until the time of a sleep study, or it may present with other symptoms that relate to the neurologic abnormality.[82,138] Increased awareness that children with neuromuscular diseases and thoracic deformities are at risk of respiratory failure has led to increased use of anticipatory monitoring to evaluate respiratory deterioration in sleep. Although transcutaneous and end-tidal measurements are helpful, blood gases should also be measured when there is suspicion of respiratory failure. As arterial blood gas samples may be difficult to obtain in children, capillary or venous sampling and transcutaneous monitoring are valuable aids in this assessment.

FURTHER STUDIES

Initial investigations are appropriately directed toward finding the underlying cause for, or complications of, OSA. Lateral airway radiographs can show airway-occluding soft-tissue (masses) including the tonsils and adenoids. They are more readily available, although not as precise as MRI for determining the static size of the airway and the relative size of the tonsils and adenoids.[9,139] If linked to the respiratory cycle, dynamic differences in airway dimensions can also be determined by these imaging modalities.[140] Nasendoscopy is useful for a dynamic assessment of airway size and to assess space-occupying lesions.[141] CT scan is useful for determining a three-dimensional, static image of airway size. MRI, reconstructed CT images, and acoustic reflection can be used to determine an absolute volume for the airway. MRI is the most useful imaging technique for examining the brainstem, posterior fossa, and upper cervical cord.

Now that the genetic defect for CCHS has been identified, genetic testing is appropriate if CCHS is suspected and parental testing should also be undertaken for newly diagnosed cases. Ongoing research will clarify how the phenotypic features of the disease relate to the genotypic expression and it is clear that genetic mosaicism can produce less severe phenotypes.[8,78] In addition, autonomic dysfunction, as previously suspected and as is consistent with the pathways where the mutation has been identified, does appear to coexist in the majority of cases.[142]

Screening Studies

The most well-studied testing modality to screen for sleep apnea in children is oximetry.[75,143] The major difficulty with this test is that although it is specific, it is not a sensitive test for sleep apnea. As with questionnaires of clinical symptoms, a significant proportion of the results lead to a need for subsequent sleep studies, therefore limiting the cost-effectiveness of the screening.

Sleep Study Methods

Overnight sleep studies provide information about respiration during a period of sleep and, despite some controversies, they are still considered the gold standard for diagnosis.[5,144,145] These studies are usually performed because the history and/or examination suggest a diagnosis of OSA, but there are not enough facilities to provide full sleep studies for all children where OSA is suspected because of snoring. Therefore some form of screening is generally required in order to prioritize which children will have full sleep studies and which children should have surgery with adenotonsillectomy to treat upper airway obstruction.[143]

Polysomnography is the name given to a multiple-channel, physiologic recording performed during sleep. In its complete form, more than 16 variables are measured during the normal period of nighttime sleep. The clear benefit is the amount of information provided. The corollary in pediatrics is the highly demanding process of preparing children with all the attachments necessary for such a recording. Leads need to be placed accurately and firmly in order to provide good quality recordings for an 8- to 10-hour study. Sleep state is recorded by a combination of EEG, eye movements, and muscle (usually genioglossus) tone. The combination of these signals is required to differentiate all sleep stages, particularly REM. To record sleep stage, a minimum of one, but usually two to four, EEG leads are used. Eye movements and EMG signals are recorded via surface electrodes. This is costly because it is both time and labor intensive, but it provides accurate diagnoses with no significant detrimental effects on first compared to subsequent studies.[146]

Respiratory recordings include measures of both the effort exerted and the resulting effects. Effort can be recorded using EMG signals or chest/abdominal displacement. Plethysmography is the most popular measure, as the signal recorded is proportional to volume and has the potential to be calibrated. Impedance recordings are another common alternative.[147]

Respiratory-outcome measures include the presence or absence of airflow at the nose and mouth, and indicators of the blood gases (P_{O_2} and P_{CO_2}). Airflow may be measured by several methods, including pressure transducer, thermistors, and thermocouples. Oxygenation is usually measured by saturation. Transcutaneous P_{AO_2} may be recorded, but is associated with a wide margin of error and is not routine. CO_2 levels are most commonly recorded by transcutaneous and/or end-tidal monitors. More accurate measures require blood-gas analysis; these are generally used when noninvasive methods indicate abnormalities. An example of the blood gas abnormalities in OSA as recorded by Sa_{O_2} and transcutaneous CO_2 monitors is shown in the lower panel of Figure 65-4.

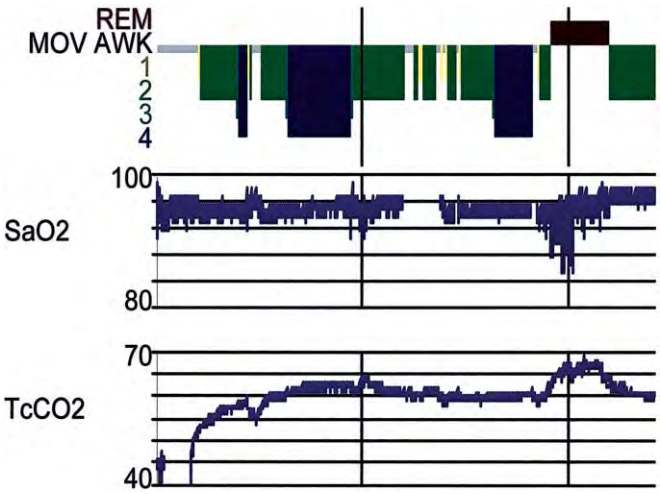

Figure 65-4 Hypnogram showing sleep stages, including REM sleep, with oxygen saturation and transcutaneous CO_2 measurements, illustrating the changes observed during REM sleep in association with obstructive sleep apnea.

The data recorded in these studies, including digital video, are virtually unlimited as storage capacities increase.

Sleep Study Interpretation

The principal aim of a sleep study is to evaluate the patterns of respiration in sleep and to quantify the changes in blood gases, levels of arousal, and sleep stage which occur in response to respiratory or other events. Criteria for sleep-stage scoring have been established across the age spectrum, although absolute EEG amplitudes (in microvolts) tend to be greater in younger age groups. Separate, specific criteria have been defined for infants. Commercial packages are increasingly accurate in the analysis of sleep and respiratory parameters, although all studies need to be manually checked for accuracy and the medical interpretation/report takes features other than the raw variables into account when evaluating the record (for example, quality of recording, nonrespiratory events and composite measures of respiratory effort).

Wakefulness is characterized by low-amplitude high-frequency EEG, the presence of conjugate eye movements, and high muscle tone. Sleep onset is heralded by rolling eye movements, associated with slowing of EEG signal frequency and a fall in muscle tone. SWS is associated with high-amplitude, low-frequency EEG, absent eye movements, and decreased muscle tone. REM sleep is characterized by low-amplitude, high-frequency EEG, the presence of eye movements, and loss of postural muscle tone. Light sleep stages have the additional characteristics of sleep spindles and K complexes. These are distinctive EEG patterns seen particularly in stage 2 sleep. Sleep spindles and K complexes are characteristic of stage 2 sleep. Sleep spindles are fast (7-10 Hz) bursts lasting 3-5 seconds and recurring at 30-second intervals. K complexes are well-delineated negative sharp waves immediately followed by a positive component. The duration of a K complex is no longer than 0.5 seconds. Detailed descriptions of each sleep scoring system are provided in the relevant reference manuals.[41,42]

Discrete respiratory events are defined as obstructive or central, depending on whether respiratory efforts continue during the apnea. An obstructive apnea indicates ongoing respiratory effort without airflow being achieved. During a central apnea there is no effort and no diaphragmatic activity. During mixed apnea airflow is absent, with diaphragmatic effort present for only a portion of the event. Criteria for scoring respiratory events in children need to account for the change in respiratory rate with age. In Australia, agreed criteria score respiratory events which disturb two or more consecutive respiratory cycles. The fall in oxygen saturation most commonly used to define a significant event is 3% to 4%. Values for normal children have now been published by several authors.[51]

The frequency of arousal and the levels of oxygen desaturation seen during the night in children with OSA are higher than in age-matched controls, but do not approach those seen in adult patients. The tolerance in children of "stable" partial obstruction does not appear to circumvent all symptoms or sequelae of obstructive apnea.[148] Detailed studies do suggest that there is an altered duration and distribution of sleep states in these children as a group.[103,134] Not all studies show consistent changes in sleep architecture since there is a tendency for children to preserve sleep architecture despite OSA.[149,150] Infants appear to have significant attenuation of REM sleep with respiratory disorders, including obstructive apnea.[151,152] REM sleep deprivation increases neuronal excitability and facilitates seizure activity, and deprivation of REM sleep during development has been shown to result in permanent behavioral changes and brain morphologic and biochemical abnormalities in animals.[153]

Children tend to have long periods of partial upper airway obstruction with minimal sleep disruption. Carbon dioxide retention can be marked during these periods, and some degree of hypoventilation occurs quite commonly in children with OSA. Sleep studies should include some measurement of CO_2 wherever possible.[154]

Studies demonstrating central hypoventilation, including central nervous system abnormalities other than CCHS, are characterized by marked blood gas disturbances in SWS. Children with CCHS fail to respond with either ventilatory or arousal responses to severe desaturations or CO_2 retention[155] although in our experience there does appear to be recovery of arousal in response to hypoxia after a period of treatment with adequate ventilation. Hypoventilation in response to neuromuscular or thoracic abnormalities is most marked during REM sleep when there is loss of accessory muscle activity, and a clinical history, examination, and detailed sleep study are required to distinguish this from upper airway obstruction.[156]

MANAGEMENT OPTIONS

Introduction

Treatment is first directed by accurate characterizations of the sleep-breathing abnormality. In the immediate sense, the significance of an apnea is determined by the physiologic changes it produces. During an obstructive event, these are the consequence of reduced or absent airflow despite sustained or increased respiratory efforts. Immediate effects include hypoxia and increased amplitude of negative intrathoracic pressure swings as well as arousal and increased sympathetic outflow.[157] Hemodynamic changes include bradycardia or tachycardia and can progress to systemic and pulmonary hypertension.[158] In contrast to OSA, central hypoventilation disorders are characterized by lack of effective effort in response to blood gas disturbances.[155]

Public Awareness

Awareness of the syndrome of OSA appears to be increasing among the public and medical communities.[159,160] Support group networks have been one effective way of disseminating information to the public. A high percentage of children with syndromes and malformations are thought to suffer with OSA, and their families frequently belong to such support associations. Increased education of clinicians as well as the public about the symptoms and signs of the disorder has been helpful in identifying children so that they reach medical attention. Most support groups have newsletters, which are an effective means of distributing such information. Surveys reveal that the majority of children present through parental action, despite their primary physician being aware of their symptomatology.

Medical Therapies

The role of pharmacologic options for the treatment of OSA in children is still being clarified. Nasal steroids are effective to reduce the severity of disease.[161] Allergic rhinitis may require topical nasal therapy whether these children have surgery or not.[162,163] Sedating agents, such as the benzodiazepines, may contribute to upper airway discoordination and increase upper airway secretions:[73] In some cases it may be possible to reduce these medications to minimize this component of the obstruction.

OSA is common in obese children.[101,164] The treatment of obesity is a difficult problem, usually involving the whole family in long-term intervention. The severity of the OSA is likely to improve after weight loss, but it is often necessary to treat the OSA acutely by other means, while commencing such a weight-control program.

Other chronic respiratory disorders may exacerbate sleep-disordered breathing. Attention should be paid to diagnosing and treating such specific problems as nasal polyps in cystic fibrosis, or frequent coughing, which will cause arousals and disturb sleep.[128] Maximizing lower respiratory tract function, including aggressive treatment of acute exacerbations will minimize the additional impact of sleep. Additional treatment, such as nocturnal nasal oxygen, CPAP, or ventilation may be necessary during sleep periods. The clinical reasons cited for commencing noninvasive mechanical ventilation (NIMV) include nocturnal hypoventilation (67%), acute exacerbations of lung disease (28%), and/or failure to thrive (21%).[6]

Nasal CPAP and Nasal Mask Ventilation

Nasal mask CPAP has been used for the treatment of adult OSA since 1981,[165] with exponential increase in the number of adult patients using this therapy since that time. Major centers acquire experience with the use of nasal CPAP in

Figure 65-5 Nasal CPAP in an infant with Robin sequence (Maskmedic Concept Mask).

children quickly and with high success rates, confirming that CPAP is a practical treatment alternative for those children who do not achieve relief of their obstruction by adenotonsillectomy.[132,166,167] Although the use of CPAP in children has been less widespread than in adults, it is now a useful alternative to tracheotomy even for palliation.[168] Two important factors have been the development of a widely applicable pediatric nose mask (Fig. 65-5), and the use of a behavioral program to introduce the therapy to children.[169,170] Children often return quickly to their previous overnight sleep requirements after the implementation of successful treatment strategies. Compliance with noninvasive treatment regimens can become difficult, although the predictors of noncompliance are not well defined.

Nasal masks can also be used for the delivery of nocturnal volume or pressure cycled ventilation in children who present with congenital or acquired central hypoventilation.[171] Again, this mode of treatment delivery circumvents the need for tracheotomy, and it has been successfully used in the home environment from infancy on.[93] Side effects may occur both acutely and in the long term, particularly the development of mid-face hypoplasia.[172] Overnight nursing assistance is usually required as with tracheostomized children who are ventilated in the home environment.[173]

Surgical Options

The mainstay of treatment for OSA is adenotonsillectomy. The proportion of adenotonsillectomies performed to treat upper airway obstructive symptoms has shown a fairly steady increase.[174] Recent rates for tonsillectomy in Australia are 2.7% of children by the age of 5 and 8.9% by the age of 15 years.[174] Adenotonsillectomy results in significant improvement in most children with OSA.[175] Reported results of surgery to relieve upper airway obstruction include relief of symptoms, catch-up growth in those who have been FTT, marked reduction in the work of breathing, improved neurocognitive function, and improved quality of life.[102,121,175,176]

It is important to be aware that the complications of adenotonsillectomy surgery are higher in children for whom the surgery is being undertaken for OSA.[177] Children with OSA have increased anesthetic risk from sensitivity to opiates,[73,120] as well as increased risks for respiratory complications of the surgery.[143,178] Associated complications are more common in the younger age groups, with those younger than 2 to 3 years particularly affected.[179] Nonetheless, this surgery is recommended as the first-line treatment of OSA in children even if there are other underlying factors such as a small airway.[122,145]

It is now also clear that surgery is not always curative.[180] It is estimated that around 10% to 20% of children have persisting OSA after adenotonsillectomy.[53,181] There is increased risk for persisting disease in children with an anatomically small or dysfunctional upper airway, obese subjects, children with a history of prematurity, and those with more severe disease before surgery.[181-183] The role for adenoidectomy alone, particularly when the tonsils are not large, is not clear because of the perceived increased risk for subsequent tonsillectomy.[184,185] Until further studies clarify this issue, these children should have follow-up monitoring. Particular syndromes may have a very high incidence of OSA, with those documented including children with Down syndrome, Crouzon, other craniostenoses, or skeletal dysplasias such as achondroplasia.[186,187] Airway obstruction has been reported after surgery to correct cleft palate.[88] Children with such syndromes or malformations can constitute a high proportion of those requiring ongoing treatment, indicating that they are more likely to have severe apnea than their counterparts with normal facial structure.[132] Other groups requiring ongoing supervision and intervention are those with progressive infiltrative diseases such as mucopolysaccharidoses.[97]

Other surgical procedures may be used to treat OSA including mid-face or mandibular advancement and rapid mandibular expansion.[188] These surgical procedures may be implemented on the basis of the cosmetic benefits expected but will also alter the character of the upper airway. Where this surgery is undertaken, there should be careful perioperative attention to the upper airway.[188,189]

Uvulopalatopharyngoplasty (UPPP) has relatively low success rates (≈50%) and will be mentioned only to caution against its application in children.[190] UPPP has very limited application in adults, and even less in children for the treatment of obstructive apnea. This surgery is associated with poor long-term response and may have significant complications, in particular, velopharyngeal incompetence.[191]

Tracheotomy remains a surgical option. This has been demonstrated to be effective in treating obstructive apnea and characteristically results in relief of sleep-associated obstruction. Catch-up growth and relief of right-heart failure have been seen in children where adenotonsillectomy alone was not successful.[188] This surgery is associated with its own morbidity and complications and is not a first-line therapy.

Diaphragmatic Pacing for Hypoventilation

Electrical stimulation of the diaphragm, using a small implantable electrode and receiver, can successfully support ventilation in children with inadequate central respiratory drive or high quadriplegia.[192] The signal is transmitted by an antennae placed on the skin, overlying subcutaneously implanted receivers. An electrical impulse is then transmitted to the thoracic phrenic nerve, resulting in diaphragmatic

contraction. The stimulus parameters that are most appropriate for children are a low stimulus frequency, short inspiratory time, and moderate respiratory rate.

A tracheotomy is required in all young children up to school age and older in order to prevent pacing-related upper airway obstruction (the larynx does not dilate during inspiration). Bilateral diaphragmatic pacing is required in children in order to achieve a sufficient level of ventilation. Due to the risk of permanent diaphragmatic and phrenic nerve injury any additional support (more than 12 to 15 hours per day) requires alternative modes of delivery. The biggest advantage of this mode of treatment is the increased mobility that it permits, although backup forms of ventilation should be available at all times. The most significant complications are infection (reported rate 6%), component failure, and mechanical nerve injury. The disadvantages of this mode of ventilation (high cost, the need for a tracheotomy, and for an external transmitter) mean that, for patients who require ventilation only at night, mask ventilation is preferable.[193]

CONCLUSION

Ongoing studies will determine the relationships between SIDS, the childhood syndrome of OSA, and the adult syndrome. With more refined studies, the precise implications of OSA in children will be elucidated. It is possible that some causative genetic or neurodevelopmental factor will be isolated in some cases of this syndrome. Current developments mean that automatically responsive pressure devices will soon be available for all age groups, making both CPAP and nasal mask ventilation more precise and therefore more comfortable to use.

Challenges in the field include development and validation of confirmatory and discriminatory testing regimens that are more easily applied than full overnight sleep studies. For each test, there is a need to determine the cutoff levels at which treatment should be instituted as well as where special perioperative precautions need to be introduced. This includes refinement of treatment intervention for mild disease that may only have behavioral or developmental, rather than significant blood gas, respiratory, or long-term cardiac complications. While recognizing the enormous practical benefit of noninvasive interfaces for CPAP and ventilation, it is also important to define the role of more definitive treatment options in children.

CHAPTER 66 Neuromuscular and Chest Wall Disorders

Oscar Henry Mayer, Karen Webster Gripp, Julian Lewis Allen, and Mary Ellen Beck Wohl

TEACHING POINTS

- There is a decrease in chest wall compliance from infancy through adulthood due to both ossification of the ribs and an increase in chest wall muscle mass.
- The component of tidal volume from rib cage excursion relative to the abdominal excursion increases from infancy through adulthood.
- The inspiratory action of the diaphragm includes decreasing intrapleural pressure, expanding the lower rib cage, and increasing intra-abdominal pressure.
- The fatigue resistance of the diaphragm can change based on the mechanical load of the respiratory system.
- Although respiratory muscle training can be useful in conditions of deconditioning, it is not recommended in patients with progressive neuromuscular disease.
- While surgery for pectus excavatum can correct the visual defect, it often does not produce a significant improvement in lung volumes or forced expiratory flows.
- Early diagnosis and treatment of scoliosis are very important in minimizing the impact on lung function.
- Congenital diaphragmatic hernia is often associated with pulmonary hypoplasia of both the affected and the unaffected sides.
- Progressive neuromuscular disease can cause both chronic respiratory failure and poor airway clearance, which can put further load on the respiratory system.

The chest wall serves as a protective cage for the heart, lungs, and great vessels of the thorax and as the respiratory pump that drives respiration. This chapter discusses normal developmental chest wall structure and function, as well as the causes and treatment of chest wall and neuromuscular disorders.

GROWTH AND DEVELOPMENT OF THE CHEST WALL

Structural Changes with Growth

Major structural changes occur in the chest wall with growth, and these changes have important functional implications for respiratory pump efficiency and function. In infancy, the orientation of the ribs is horizontal, but with growth they slowly rotate downward in a caudal declination until the normal adult pattern of downward-sloping ribs occurs at about 10 years of age[1] (Fig. 66-1). Chest wall muscle mass increases progressively with development. Ossification of the chest wall begins in utero and continues to approximately the 25th year. Progressive calcification of the costal cartilages can continue into old age.

Functional Consequences of Developmental Structural Changes of the Chest Wall

MECHANICAL PROPERTIES

Specific chest wall compliance decreases progressively with growth. In the infant, compliance of the chest wall is three to six times that of the lung.[2-5] Chest wall compliance is greater in preterm infants[3] than in full-term infants and decreases further during the first 2 years of life.[6] In school-age children, chest wall compliance is approximately twice that of the lung[7]; in the mature adult, it is equal to that of the lung, and in the elderly, it may be half that of the lung[8] (Fig. 66-2).

These changes in chest wall compliance are in part due to increasing ossification of the chest wall with development and increasing calcification with aging. Increasing muscle mass also contributes to the decrease in chest wall compliance with age.[9-11]

Although it is advantageous to have a highly compliant chest wall during the birthing process, functional disadvantages occur in infancy. With diaphragm contraction and downward diaphragm motion pleural pressure becomes negative. In a fully mature ribcage, the external intercostal muscles also contract as the ribs rotate superiorly and laterally, increasing the cross-sectional area of the thorax and expanding the lungs effectively. However, in a young or premature infant with higher chest wall compliance, due to the absence of full rib ossification and full intercostal muscle activity, the negative pleural pressure during inspiration may cause inward motion of the ribcage.[12] In addition, with the ribs rotated out in a more horizontal orientation, the diaphragm may be more flat with a smaller area of apposition to the chest wall, causing lower rib cage inward motion with diaphragm contraction, because the plane of contraction will be more horizontal.[12]

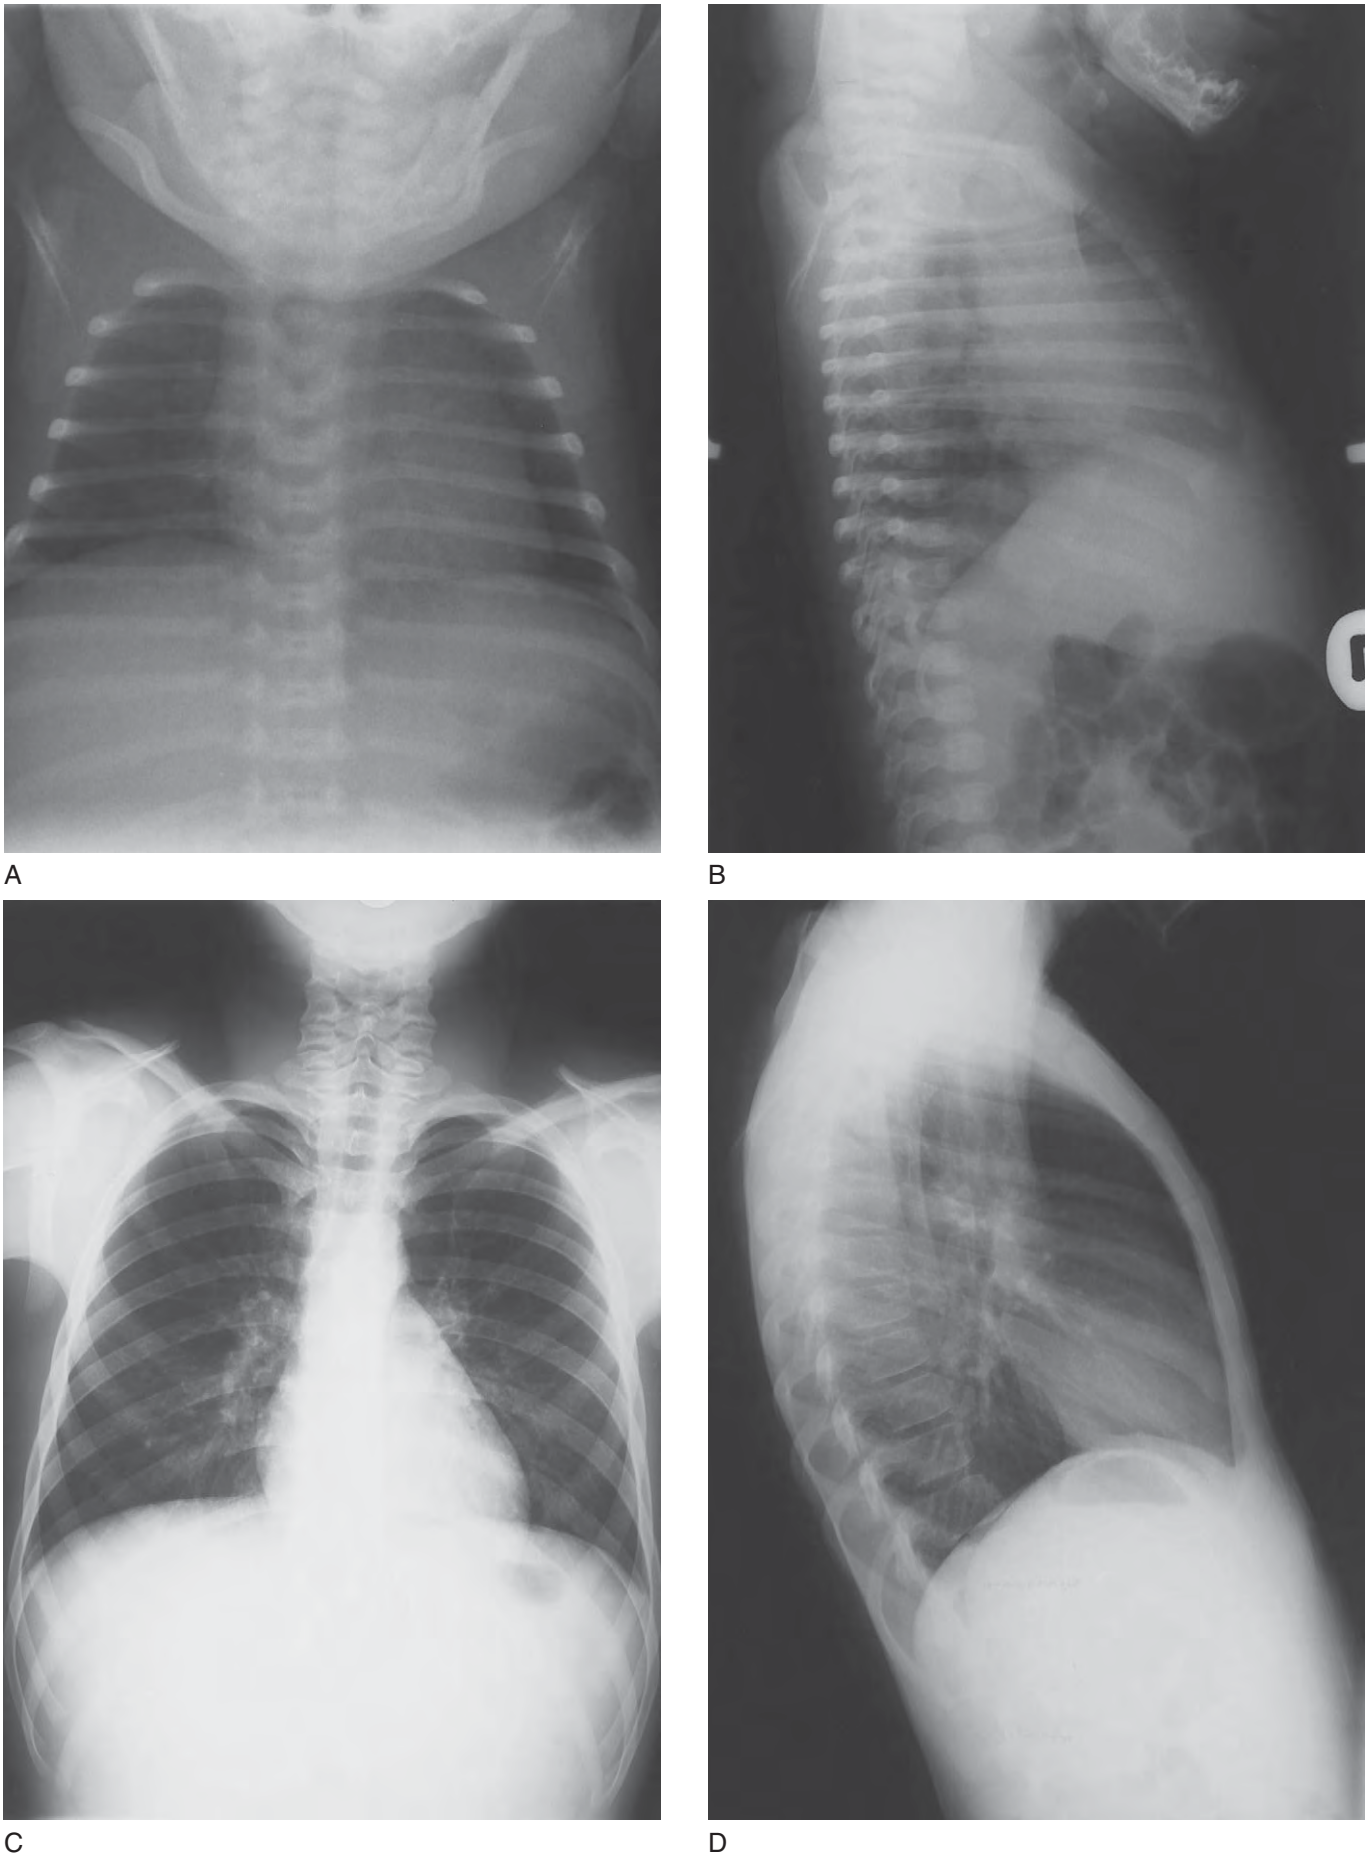

Figure 66-1 Changes in ribcage morphometry with growth. **A and B,** Posteroanterior (PA) and lateral chest radiographs of a 4-month-old infant. **C and D,** PA and lateral chest radiographs of a 14-year-old boy. In the infant, the slope of the ribs is nearly horizontal, whereas in the 14-year-old, there is a downward declination of the ribs. Progressive ossification of the sternal ossification centers can be seen in the lateral radiograph.

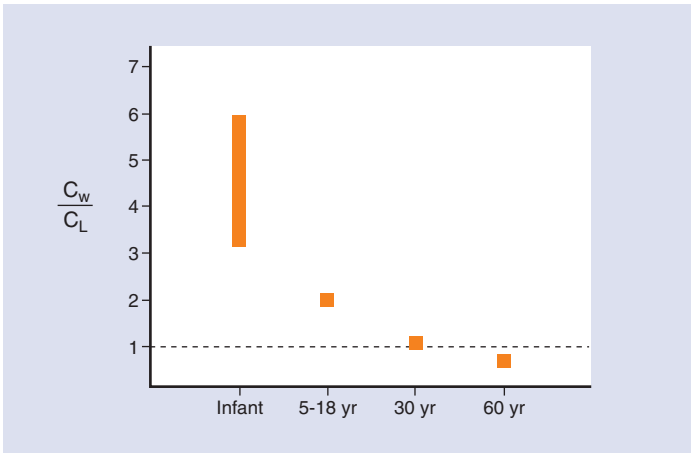

Figure 66-2 Changes in the ratio of chest wall to lung compliance with aging. Data for infants represent a range from several studies. In infants and children, the chest wall is more compliant than the lungs; in adults the chest wall compliance is close to that of the lungs, and in the elderly it is less than that of the lungs. C_W, wall compliance; C_L, lung compliance.

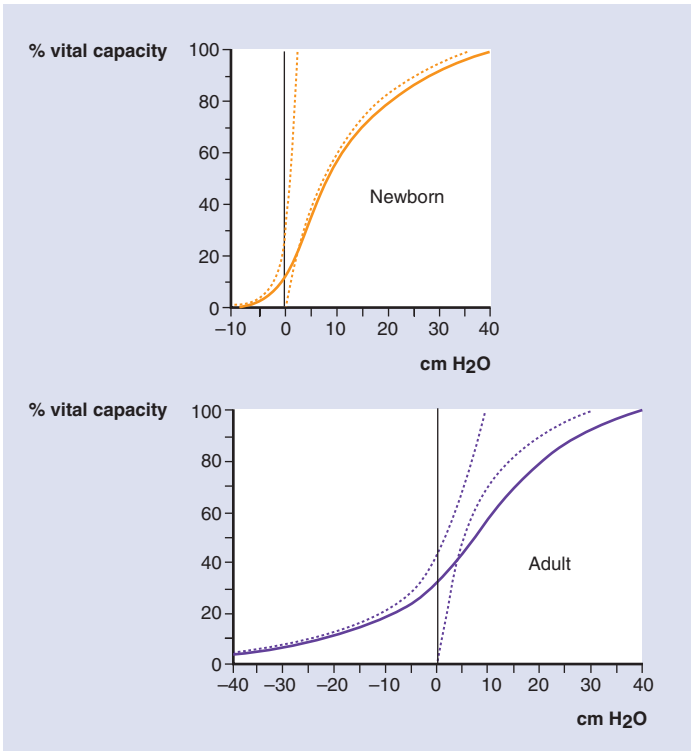

Figure 66-3 Respiratory system PV curves in the newborn and adult human. The *x*-axis represents pressure and the *y*-axis represents volume. The slope of each curve at a given lung volume represents the compliance at that volume. The *solid curve* in each diagram is the PV curve of the respiratory system. At a given lung volume, it represents the sum of the pressures resulting from the chest wall PV curve (*left dashed line*) and the lung PV curve (*right dashed line*). Passive end-expiratory lung volume is represented by the point at which the solid curve crosses the volume axis. It is lower in the newborn than in the adult because of the high compliance of the newborn chest wall curve. (Redrawn from Agostoni E, Mead J: Statics of the respiratory system. In Fenn WO, Rahn H [eds]: Handbook of Physiology, Respiration, Section 3, Volume 1. Washington, DC, 1964, American Physiological Society, p 401.)

Few studies have been done on developmental changes in chest wall resistance. The chest wall accounts for approximately 30% to 35% of total respiratory system resistance in adults[13] and 20% to 25% in infants.[6,14]

MAINTENANCE OF FUNCTIONAL RESIDUAL CAPACITY

The passive relaxation volume of the respiratory system (V_r) is determined by the balance of two opposing forces: the outward recoil of the chest wall and the inward recoil of the lung[15] (Fig. 66-3). The highly compliant chest wall of an infant provides less outward recoil and produces a low V_r. If V_r falls below the volume at which airway closure occurs, atelectasis can occur. Furthermore, during inspiration, additional energy needs to be expended to open these closed airways before inspiratory airflow occurs. This mode of breathing places an unnecessary metabolic burden on a patient.

Instead, full-term infants adopt a strategy of active maintenance of end-expiratory lung volume (EEV), consisting of an active prolongation of expiration. This phenomenon can be observed by comparing the active tidal breathing flow-volume curve with the passive flow-volume curve elicited by relaxing the respiratory muscles with a brief end-inspiratory occlusion, which activates the Hering-Breuer reflex[16] (Fig. 66-4). The active and passive time constants are represented by the slopes of the expiratory limb of these curves. The EEV can be maintained above V_r by increasing the expiratory time constant, τ, of the respiratory system relative to the time actually available for expiration.[17] This slower exhalation interrupts expiratory flow at a lung volume above the relaxed level (see Fig. 66-4) and will minimize airway closure. Preterm infants also maintain EEV above V_r, but their ability to do so is markedly sleep-state dependent, being less effective in active than in quiet sleep.

The neonate accomplishes active prolongation of expiration via two mechanisms: post–inspiratory activity of the inspiratory muscles, such as the diaphragm,[18] and expiratory "braking" by the upper airway muscles,[19,20] or vocal cord adduction. In infants with hyaline membrane disease, the more poorly compliant lungs predispose a child to an even lower V_r, and expiratory braking is clearly manifested as "grunting." Normal active maintenance of EEV diminishes with age and during the second year of life disappears,[21] likely as a result of progressive stiffening of the chest wall allowing a higher passively determined EEV.[6,22,23]

DEVELOPMENT OF THE RESPIRATORY MUSCLES

Structural and Functional Changes

The diaphragm has three major inspiratory actions.[24,25] First, the diaphragm decreases intrapleural pressure by acting as a piston, thereby creating a gradient of pressure that favors air flow from the airway opening to the alveoli. Second, the diaphragm increases intra-abdominal pressure. Because a substantial portion of intra-abdominal contents actually resides within the ribcage (Fig. 66-5), this increased abdominal pressure causes the lower ribcage to expand. Third, the diaphragm increases lower ribcage dimensions by acting through its area of apposition (see Fig. 66-5) to the inner ribcage wall to elevate the lower ribs, the "fulcrum" effect. This elevation

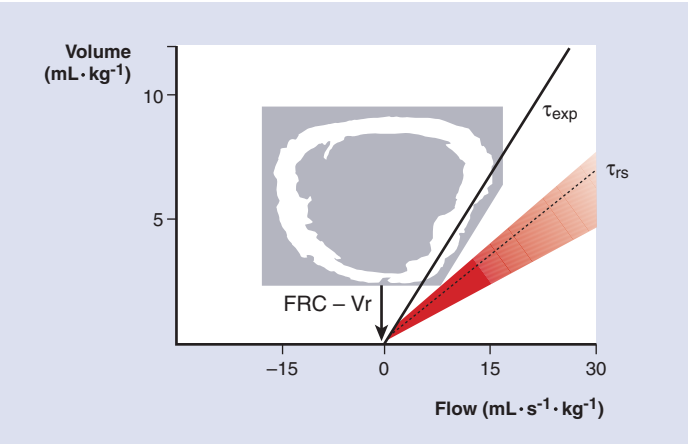

Figure 66-4 Elevation of EEV by active prolongation of the respiratory system time constant, t. A tidal flow volume curve is shown on the oscilloscope tracing. The slope of the expiratory limb of this curve ([volume, mL/kg]/[flow, mL/{sec • kg}]) has the units of seconds and represents the active expiratory time constant, t_{exp}. The slope of the dotted line represents the passive time constant of the *respiratory* system (t_{rs}) following an end-inspiratory occlusion that activates the Hering-Breuer reflex and relaxes the respiratory muscles. The lines intersect at the passive relaxation volume (V_r). The volume difference between V_r and the active flow-volume curve EEV represents the difference between functional residual capacity (FRC) and V_r and reflects active maintenance of FRC. (Reprinted with permission from Mortola JP, Saetta M: Pediatr Pulmonol 3:123-130, 1987.)

of the lower ribs also expands the lower thoracic cross-sectional area by causing the downward-sloping ribs to assume a more horizontal position, the "bucket handle" effect (Fig. 66-6).

In addition, there are a number of other factors that impact on the mechanical efficiency of diaphragm contraction. Less of the ribcage's contents are intra-abdominal and the area of apposition is smaller in the infant than that in the older child and adult. Furthermore, diaphragmatic mass is less in the infant.[11] Theoretically, these differences should

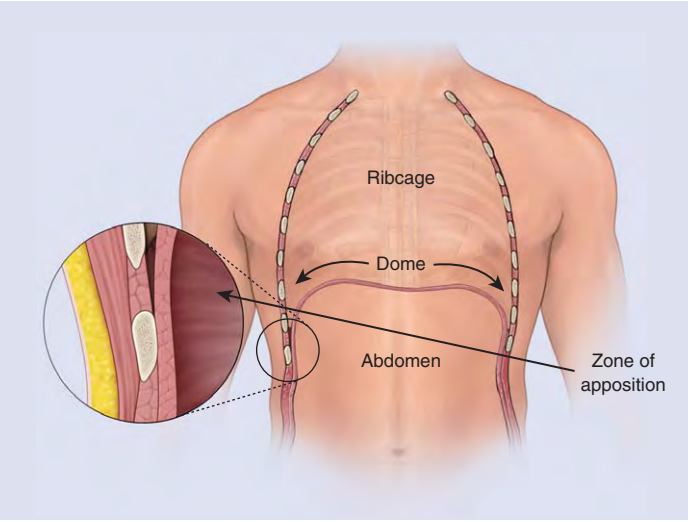

Figure 66-5 Zone of apposition. Whereas there is a substantial portion of the abdomen that is within the ribcage, there is apposition of the diaphragm and the inner chest wall (see circled area). (Reprinted with permission from DeTroyer A, Loring SH: Clin Chest Med 9:175-193, 1988.)

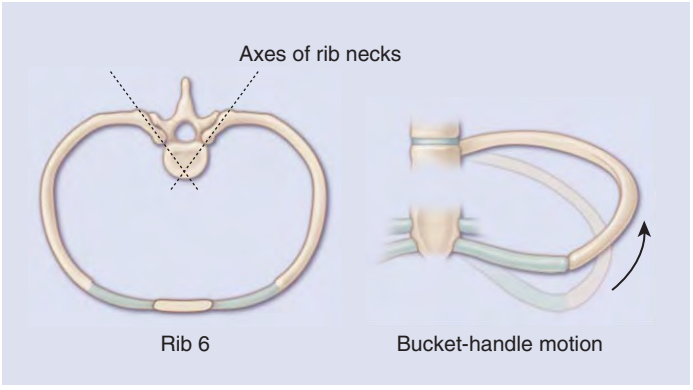

Figure 66-6 Bucket handle effect. [Reprinted with permission from DeTroyer A, Loring SH: Action of the respiratory muscles. In Macklem PT, Mead J [eds]: Handbook of Physiology. The Respiratory System. Mechanics of Breathing, Section 3, Volume III, Part 2. Bethesda, MD, 1986, American Physiological Society, p 453.)

impair the infant diaphragm's inspiratory action. On the other hand, by the law of Laplace, the smaller radius of curvature of the infant's diaphragm relative to the adult should improve its pressure-generating ability at a given level of tension.

Tidal expiration is primarily driven by the passive elastic recoil of the respiratory system. Neonates, like adults, can recruit abdominal muscles to promote active expiration,[26,27] although this is highly sleep-state dependent and is much less effective in rapid eye movement (REM) than in non-REM sleep.

Developmental Cell Biology of the Respiratory Muscles and Implications for Fatigue Resistance

It has been suggested that the mechanical disadvantage imposed by a highly compliant chest wall will predispose the premature and newborn infant to respiratory muscle fatigue and respiratory pump failure.[28-30] However, there are molecular and contractile properties that impart a certain fatigue resistance in newborn and young infants.

Developmental Changes in Respiratory Muscle Fiber Type Determined by Histochemistry

The relative proportion of type I (slow twitch, fatigue resistant) and type II fibers (fast twitch, fatigable) in respiratory muscles changes with development. The percent composition of type I fibers in the diaphragm of human premature infants, newborns, and older children (older than 2 years) is 10%, 25%, and 55%, respectively,[28] and there is a similar developmental pattern with the intercostal muscles.[28] Therefore, it would be reasonable to conclude that premature and newborn infants would be more susceptible to respiratory muscle fatigue than older children. Le Souëf and associates[29] found a paucity of type I fibers in the newborn rabbit diaphragm and an impaired ability to maintain occlusion pressure during sustained activation of the diaphragm by phrenic nerve stimulation. However, Maxwell and associates[31] found that the respiratory muscles of premature baboons were highly oxidative and fatigue *resistant*. Therefore there are other factors to consider than muscle fiber types.

Sieck[32] and Watchko[33] and associates have demonstrated that although specific force (peak tetanic force output normalized for muscle cross-sectional area) of diaphragmatic fibers increases with postnatal age, fatigue resistance decreases with age. They also found that fatigue resistance is related not only to oxidative capacity of the muscle (indexed by succinic dehydrogenase [SDH] activity), but also to myosin heavy chain (MHC) phenotype.[34] The neonatal MHC phenotype seems to impart a greater degree of fatigue resistance than do the adult isoforms. Therefore, fatigue resistance of respiratory muscle during development may relate to a balance between the energetic demands of the muscle contractile proteins (reflected by MHC isoform composition) and its oxidative capacity (reflected by SDH activity).[34] However, high oxidative capacity, while promoting fatigue resistance, may lead to oxidative damage if not balanced by increased antioxidant enzymes, such as superoxide dismutase (SOD).[35]

Recently, it has been determined that the fatigue resistance of respiratory muscles is plastic, and can change in the face of increasing resistive loads. Patients with chronic obstructive pulmonary disease (COPD) have diaphragms with an increased proportion of fatigue resistant type I fibers and an increased percentage of slow MHC isoform I compared with control subjects' diaphragms, which have fewer type I fibers and an increased percentage of fast MHC isoforms IIa and IIb.[36] Furthermore, fatigue-resistant developmental (embryonic and neonatal) MHCs have been reported in the diaphragms of patients with COPD, but their numbers are actually reduced compared with controls.[37] This may reduce the effectiveness of type I fibers in combating fatigue.

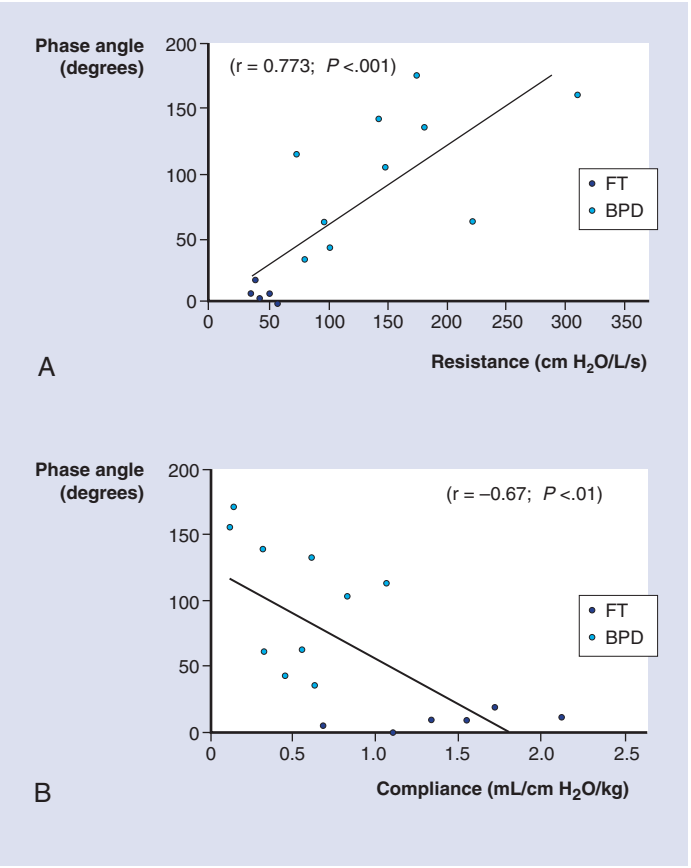

Figure 66-7 Relationship between thoracoabdominal asynchrony, quantitated by RC-AB phase angle, and lung mechanics. **A,** Phase angle versus resistance. **B,** Phase angle versus compliance. FT, full-term control; infants. BPD, bronchopulmonary dysplasia. (Redrawn from Allen JL, et al: Pediatr Pulmonol 11:37-43, 1991.)

METHODS FOR ASSESSING CHEST WALL FUNCTION

Chest Wall Motion

The quantitation of chest wall motion gives information about both chest wall and underlying lung function. The most widely used method to assess chest wall motion is respiratory inductive plethysmography; although video motion capture, strain gauges, and magnetometers have been used as well.[38]

Thoracoabdominal motion is more asynchronous with decreased or increased chest wall compliance and with increased airways resistance[39-41] (Fig. 66-7). In patients with increased chest wall compliance, the contraction of the diaphragm during inspiration produces a drop in pleural pressure and increase in abdominal pressure. The highly compliant ribcage may have inward motion at the same time the highly compliant abdomen has outward motion.[23] With increased airways resistance or decreased chest wall compliance, the diaphragm will have to contract more to generate the negative pleural pressure needed for adequate air flow and ventilation. The diaphragm motion will cause outward abdominal motion and the delay to outward chest wall excursion is dependent on the work needed to overcome chest wall compliance and/or airways resistance.

In the different situation of increased chest wall compliance as seen in premature infants and children with neuromuscular weakness such as spinal muscular atrophy, progressive increase in negative pleural pressure will cause *inward* as opposed to *outward* ribcage motion. Even at rest, to maintain adequate ventilation there will be increased outward abdominal motion.

Timing relationships between ribcage (RC) and abdomen (AB) excursion can be quantitated by measuring the period delay between maximal RC and AB excursions on a scalar tracing. This can also be measured by plotting RC versus AB motion in a Lissajous, or Konno-Mead figure[42] and calculating the phase angle based on the shape of the resultant figure (Fig. 66-8). The phase angle is an index of thoracoabdominal motion (TAM). This phase angle can range from 0 degrees (synchronous RC-AB motion) to 180 degrees (paradoxical RC-AB motion).

Premature infants normally display asynchronous or paradoxical breathing during quiet sleep (mean phase angle 58 degrees, range 0 to 157 degrees).[43] In different studies, the normal phase angle is 8 to 13 degrees in awake full-term infants,[39] 15 degrees in preschool-age children,[44] and 8 degrees in adolescents.[45] However, there are no longitudinal data through childhood to evaluate the variation of phase angle with age. There is significant variability with position, with phase angle being higher when supine than when sitting or standing and lowest in the sitting position.[44]

The magnitude of the contribution of the ribcage (RC) and abdominal (AB) compartments to tidal volume can also

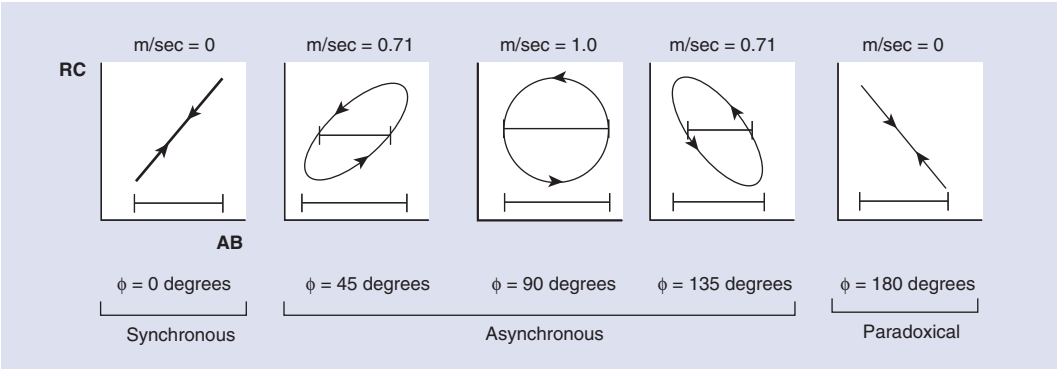

Figure 66-8 Lissajous figures of ribcage (RC) and abdominal wall (AB) motion. Phase angle, ϕ, is an index of thoracoabdominal asynchrony. Increasing thoracoabdominal asynchrony is seen as increasing width of the figure up to a phase angle of 90 degrees and then by a change from a positive to a negative slope between 90 and 180 degrees. For phase angles $0 < \phi < 90$ degrees, $\sin \phi = m/sec$; for $90 < \phi < 180$ degrees, $\phi = 180 - \mu$, where $\sin \mu = m/sec$ (see text). (Redrawn with permission from Allen JL, et al: Am Rev Respir Dis 141:337-342, 1990.)

be quantitated. Newborn infants breathe predominantly with their abdominal compartments, as opposed to adults, who are primarily ribcage breathers. The ribcage's contribution to tidal breathing during quiet sleep in the newborn is 35% of tidal volume (range 20% to 50%), increasing gradually over the first year to the normal adult value of 65%.[46]

Clinical Assessment of Respiratory Pump Function and Fatigue

PHYSICAL EXAMINATION OF THE CHEST WALL

Paradoxical motion of the ribcage and abdomen is easy to identify, although lesser degrees of thoracoabdominal asynchrony may be more difficult to discern. However, determining the amount of thoracoabdominal asynchrony relative to the phase of respiration can be very useful. Although chest wall paradox can be observed visually, the phase of respiration may be ascertained by a fingertip held at the mouth to feel airflow, a hand on the chest to feel chest wall excursion, or by chest auscultation. Inspiratory inward RC motion with outward AB motion occurs in patients with increased ribcage compliance, such as premature infants, and in some normal infants during REM sleep. It also occurs in patients with neuromuscular disease with intercostal muscle weakness but intact diaphragmatic function, such as spinal muscular atrophy (SMA) and quadriplegia. Inspiratory outward AB motion significantly ahead of outward RC motion is present in infants and children with increased airway resistance or decreased ribcage compliance. Inspiratory outward RC and inward AB motion is seen in patients with diaphragmatic dysfunction. It can also be seen in adults with severe airflow obstruction and impending diaphragm fatigue.

Roussos and associates[47] described a pattern of "respiratory alternans" during inspiratory resistive loaded breathing, in which breathing alternates between using the diaphragm and intercostal muscles, possibly postponing the onset of or attenuating respiratory muscle fatigue. One would expect this to be reflected in an alternating pattern of RC and AB motion, with outward motion primarily in the RC on one breath followed by primarily AB motion in another breath, with each compartment's displacement alternating in magnitude. Asynchronous RC/AB motion may also merely reflect the magnitude of the load itself, rather than respiratory muscle fatigue per se.[39,48,49]

Although the driving pressure for exhalation is the inward elastic recoil of the respiratory system, the abdominal muscles (particularly the rectus abdominis) may contract during active exhalation. This occurs in patients with severe obstructive lung disease, in whom passive recoil of the respiratory system may provide insufficient pressure to overcome expiratory airflow obstruction. Active expiration occurs normally during exercise. Alternately, it can be seen in some patients with inspiratory muscle weakness who may "actively" exhale below their functional residual capacity (FRC); the succeeding inspiration is then augmented by the outward elastic recoil of the chest wall from below FRC to FRC.

ASSESSMENT OF RESPIRATORY MUSCLE STRENGTH

Normal adults can develop maximal inspiratory and expiratory pressures against an occluded airway in excess of −100 and 200 cm H_2O, respectively. Occlusion pressures can be measured during crying in infants as young as one month of age. Changes in maximal inspiratory and expiratory pressures with age are shown in Table 66-1.

The gender difference in Pe_{max} and Pi_{max} is thought by some to be due to the difference in muscle mass with gender.[50] Pi_{max} has been measured and reported from both residual volume (RV) and FRC, so it is important to make note of the volume at measurement for appropriate comparisons.[50,51]

Alternately, sniff inspiratory pressure (sniff Pi) through a single nostril, with the contralateral nostril occluded and mouth closed, was shown to be a useful surrogate in patients with neuromuscular disease, some of whom may not be able to perform an adequate Pi_{max} via mouthpiece.[52] While the sniff inspiratory pressure in a cohort of children and adults with neuromuscular disease was similar to Pi_{max},[52] there was a significant difference in a separate study of healthy children.[53] However, there was a significant correlation between sniff inspiratory pressure and Pi_{max} in both studies.[52,53]

Maximal inspiratory force is an index of inspiratory muscle strength that is used by some clinicians in weaning a patient

from mechanical ventilation, although its utility is not universally accepted.[54] Transdiaphragmatic pressure (Pdi) is a measure of the pressure output of the diaphragm and is an index of diaphragmatic strength; however, it is more difficult to measure, requiring the placement of both gastric and esophageal pressure monitors.

Inspiratory muscle force is sometimes measured following either electrical or magnetic stimulation of the phrenic nerves.[55] While these techniques eliminate the variability inherent in volitional efforts, they are not widely clinically applied in pediatrics.[56,57]

ASSESSMENT OF RESPIRATORY MUSCLE FATIGUE

Measurement of the tension time index and frequency pattern assessment of diaphragmatic electromyogram (EMG) activity have been proposed as indicators of impending respiratory muscle failure.

Respiratory muscle fatigue can be defined as an inability of the respiratory muscles to maintain the force required to sustain minute ventilation in the presence of a mechanical load. The development of fatigue is closely linked to the force and duration of muscle contraction. The tension time index of the diaphragm (TTI_d) is a dimensionless product of the ratio of developed Pdi to maximal transdiaphragmatic pressure (Pdi_{max}) and the ratio of the inspiratory time (Ti) to the respiratory cycle time (T_{tot}), also known as the "duty cycle."

$$TTI_d = Pdi/Pdi_{max} \bullet Ti/T_{tot} \qquad \text{Eq 66.1}$$

The TTI_d has been used in adults to predict the development of fatigue. When the TTI_d exceeds 0.2, it is highly likely that fatigue will occur. The measurement of the TTI_d requires the ability to assess Pdi and Pdi_{max}, which can be technically difficult, because these measurements require both esophageal and gastric pressure transducers to measure the pressure generated across the diaphragm. A few studies have been done in infants and children to determine whether the same values of the tension time index are applicable.[58]

In a test analogous to the TTId, termed the TTmus, the tension time index of all the inspiratory muscles and not just the diaphragm is measured without the use of catheters. An inspiratory occlusion pressure measured at the mouth 100 milliseconds after the onset of inspiration is extrapolated to end inspiration. The mean inspiratory pressure (Pi) is calculated, and divided by the maximal inspiratory pressure measured at the mouth at FRC (MIP). The TTmus is then calculated as

$$TTmus = Pi\ (mean)/MIP \bullet Ti/Ttot \qquad \text{Eq 66.2}$$

This test has the advantage of being noninvasive and has been used to assess susceptibility to respiratory muscle fatigue in children with cystic fibrosis and neuromuscular disease[59-61] (Fig. 66-9).

Spectral frequency analysis of the surface diaphragmatic EMG during fatiguing loads has been shown to indicate diaphragmatic muscle fatigue in adults.[62] Similarly, in infants diaphragmatic fatigue produces a decrease in the high-frequency power and an increase in the low-frequency power of the EMG.[63] During weaning from mechanical ventilation, the EMG power spectrum remained normal in infants who were able to be weaned successfully, whereas in infants who failed extubation and in whom mechanical ventilation had to be reinstituted, a decrease in the high/low power spectrum ratio occurred before CO_2 retention and clinical deterioration. Because shifts in the diaphragmatic EMG power spectrum may occur in the absence of fatigue,[64] this technique has limited clinical use. Accurate placement of electrodes is critical to adequate recording of power spectra and at present this technique is seldom used for clinical purposes.

A joint statement of the American Thoracic Society and the European Respiratory Society[57] addresses many of the technical aspects of the measurement of both respiratory muscle strength and fatigue in children.

TREATMENT OF RESPIRATORY PUMP FATIGUE

General Principles

Respiratory pump fatigue can result from three mechanisms: intrinsic pulmonary disease (e.g., COPD or interstitial lung

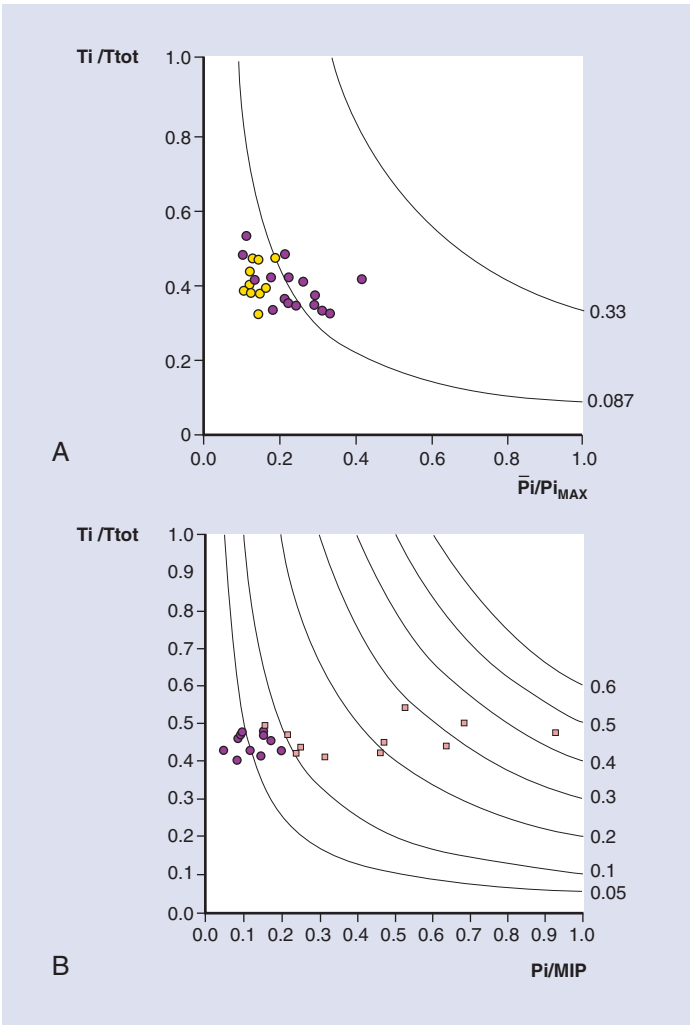

Figure 66-9 **A,** TTmus in normal children (*yellow*) and children with cystic fibrosis (*purple*). (Reprinted with permission from Hayot M, et al: Pediatr Pulmonol 23:336-343, 1997.) **B,** TTmus in children with neuromuscular disease (*square*) and healthy children (*circles*). disease) that increases the resistive or elastic work of breathing, muscle failure (e.g., neuromuscular disease), or chest wall deformity (e.g., scoliosis or flail chest) that decreases pump efficiency. All these mechanisms may be thought of in terms of Pdi/Pdi_{max}, the first term of the TTI. Whereas an increased work of breathing increases the quantity (Pdi/Pdi_{max}) by *increasing* Pdi, respiratory muscle weakness and inefficiency increases the quantity (Pdi/Pdi_{max}) by *decreasing* Pdi_{max}. Respiratory pump fatigue can be treated by respiratory muscle rest, respiratory muscle training, and the use of pharmacologic agents, all of which can increase Pdi_{max}. Obviously, reducing the work the diaphragm has to do (Pdi) by treating the underlying disorder is crucial in treating respiratory fatigue as well.

Respiratory Muscle Rest

Assisted ventilation is the most common form of respiratory muscle rest therapy. It can be done noninvasively via nasal, oral, and oronasal interfaces and also using negative pressure ventilation in subjects without upper airway obstruction. Although the technology for noninvasive ventilation was developed for adults, there are a few interfaces that are made specifically for children, but a larger number of adult masks that come in sizes small enough to use in children. Even though there are no noninvasive ventilators approved for use in children, they can be used effectively in children. Alternately, ventilation can also be done invasively via a tracheostomy tube using invasive ventilators designed for outpatient use. Ventilation can be used on an intermittent basis, on demand by mouthpiece or by nasal mask at night or during naps, for the majority of the day, or continuously with progression of disease or during periods of illness.

There are many modes of chronic ventilation used for muscle rest. Support can be full, giving complete respiratory muscle rest, or partial, with the respiratory muscles still doing some work. What is used is based both on patient need and desire.

Assisted ventilation can improve gas exchange, and the results can persist after discontinuation of ventilation.[65] This improved gas exchange can be due to improved respiratory muscle strength or may be due to a "resetting" of the respiratory control center to a lower P_{CO_2} during the period of assisted ventilation.[66,67] In addition, although brief periods of intermittent positive-pressure breathing do not alter lung mechanics,[68] the increase in tidal volume during nocturnal assisted ventilation can reexpand areas of atelectasis that had developed during nonassisted breathing.

While nocturnal ventilation can reduce respiratory muscle fatigue by effecting respiratory muscle rest, continual mechanical ventilation may actually reduce respiratory muscle endurance, probably by a "deconditioning" effect. Patients in intensive care units requiring mechanical ventilation for greater than 48 hours have reduced respiratory muscle endurance immediately after weaning, and the degree of reduction is worsened by longer duration of mechanical ventilation.[59]

Respiratory Muscle Training

Training can increase the strength and endurance of skeletal muscle. Strength and endurance training differ, as do the cellular changes that occur during each type of training. Strength training involves few repetitions of a high-intensity stimulus, and the major cellular response is muscle fiber hypertrophy. Endurance training involves frequent repetitions of a low-intensity stimulus, and the major cellular response is increased oxidative capacity, with increases in oxidative enzymes,[69] capillary density,[70] with a decrease in cross-sectional area.[71]

In normal adults respiratory muscle strength and endurance can be increased by specific training.[72] Respiratory muscle strength training has been performed using repetitions of maximal forced respiratory maneuvers and resistive loaded breathing with high inspiratory resistive loads. Endurance training has been accomplished with nonspecific (i.e., total body exercise) conditioning and specific conditioning. Specific endurance programs include voluntary isocapneic hyperventilation, resistive loaded breathing, and inspiratory threshold loading. In one recent study, athletes who underwent specific inspiratory muscle training increased strength by 25% and endurance by 27%.[73]

Respiratory muscle training has been shown to increase respiratory muscle strength and endurance in patients with quadriplegia.[74-76] A major unresolved question is when respiratory muscles should be exercised and when they should be rested. A general principle is that weak muscles should be exercised and fatigued muscles should be rested.[77,78] In Duchenne muscular dystrophy, the results of muscle training are varied from positive results that persist for a period of time after training ceases to no significant change.[79-84] It remains controversial, however, whether respiratory muscle training in patients with neuromuscular disease may lead to further muscle damage due to a decreased capacity to recover from the stress on the muscles from training.[56] Some have suggested that this risk can be minimized with endurance, limited load, high frequency training.[84] The American Thoracic Society currently does not recommend respiratory muscle training in patients with Duchenne muscular dystrophy.[56] There is some thought that other cytoskeletal components might be able to be upregulated to make the muscles of patients with Duchenne muscular dystrophy more tolerant of exertion and training.[85]

Pharmacotherapy of Respiratory Muscle Fatigue

Theophylline is the most studied pharmacologic agent for respiratory muscle fatigue. In vitro, theophylline produces a dose-dependent increase in peak twitch tension of the diaphragm[86] and can attenuate fatigue if used prophylactically.[87] In animal models, theophylline increases maximal transdiaphragmatic pressure[88] and improves diaphragmatic force generation after fatigue has developed.[89,90] In experimental spinal cord transection theophylline pretreatment as an adenosine type 1 receptor antagonist preserved diaphragm function and improved recovery, and the effect persisted after the theophylline was stopped.[91] This effect was increased with pretreatment with adenosine type 2 agonist.[91] Other work has demonstrated that sepsis-induced diaphragm fatigue may be mediated through NO-mediated lipid peroxidation of diaphragm myofibrils and that pharmacologic inhibition of inducible NO in this model prevented much of the contractile dysfunction.[92-94] Other work has shown that pretreatment with lidocaine can have a similar antioxidant effect.[95,96] However, in humans, there is only published experience with theophylline.

In healthy patients, theophylline has a potent effect on diaphragmatic contractility[97] and in patients with COPD, theophylline increases diaphragmatic strength and postpones the onset of diaphragmatic fatigue induced by resistive loaded breathing. Aminophylline increases diaphragmatic excursions in preterm infants,[98] but whether this is a central or peripheral effect is unclear.

STRUCTURAL ABNORMALITIES OF THE CHEST WALL INCLUDING THE DIAPHRAGM

Thoracic Dystrophies

A number of disorders of development of the chest wall exist, many of which are uncommon and result in early death from associated pulmonary hypoplasia, respiratory mechanical inefficiency, and respiratory pump failure.[99] If the defect occurs early enough in gestation to affect mesenchymal development it will negatively impact both airway and vascular development. If the thoracic defect occurs late in gestation or post-partum, then it may cause vascular and airway derecruitment that may be reversible after correction of the defect.

The etiologies of a number of these disorders have recently been elucidated as the genetic control of bone and cartilage growth and development becomes more clearly understood[100] and can replace classifications based on radiographic and morphologic characteristics[101,102] (Table 66-2).

Genetic Mechanisms

Congenital anomalies of the chest wall can occur due to embryologic anomalies or due to underlying gene mutations. The VATER (vertebral, anal, tracheoesophageal fistula, radial and renal anomalies) association is an example of an embryologic anomaly without a known genetic cause and no significant recurrence risk.[103] In contrast, disorders caused by gene mutations may have a recurrence risk and may be present in family members. It is therefore important to understand the inheritance pattern and to discuss this with family members at risk.

Osteogenesis imperfecta (see Table 66-2) is an example of autosomal dominant conditions that act via a dominant negative mechanism. Osteogenesis imperfecta results from a mutation in one of the genes encoding a procollagen chain.[104-107] Mature collagen molecules consist of three procollagen chains forming a triple helical structure. Incorporation of a single structurally abnormal component disrupts this complex structure and leads to the abnormal connective tissue properties and brittle bones. Another example of a disease acting by dominant negative action is Marfan syndrome, in which an abnormal fibrillin-1 gene causes abnormal fibrillin to be incorporated into extracellular microfibrils.

A second mechanism by which autosomal dominant mutations result in abnormal phenotypes is gain of function of the gene product. Achondroplasia is caused by a recurrent specific heterozygous point mutation in the fibroblast growth factor receptor 3 gene (*FGFR3*). This membrane-bound receptor has an intracellular tyrosine kinase domain that is activated upon ligand binding and ultimately regulates cell proliferation. The function of the normal receptor is negative regulation of endochondral growth, as demonstrated by skeletal overgrowth seen in mice lacking both functional copies of the gene.[108] The pathogenesis of the mutation involves constitutive activation of FGFR3, inhibiting proliferation of growth plate chondrocytes and causing short limb dwarfism.

A third pathogenic mechanism that causes autosomal dominant skeletal disorders is haploinsufficiency for the functional gene product. This mechanism most often affects protein products acting as transcription factors that control the expression of other genes. A 50% decrease of the functional protein is disease-causing in dosage-sensitive pathways, as seen in campomelic dysplasia and cleidocranial dysostosis (see Table 66-2).

A fourth pathogenic mechanism causing autosomal dominant disorders is that in which loss of function mutations in one gene copy are not functionally restored by a second,

Table 66-2
Chest Wall Disorders, Their Thoracic and Respiratory Presentation, Inheritance Pattern, and Gene Mutations

Category	Disorder	Major Findings	Thoracic Involvement	Respiratory Complications	Inheritance Pattern	Gene	Mutation
Dominant negative action	Osteogenesis imperfecta	Multiple fractures; joint laxity; blue sclera; dentinogenesis imperfecta	Rib fractures	Pulmonary hypoplasia in severe forms; unstable thorax after multiple rib fracture	Autosomal dominant	*COL1A1* or *COL1A2* (procollagen molecules)	Multiple
Dominant negative action	Marfan syndrome	Dolichostenomelia arachnodactyly; joint laxity; aortic dilatation	Scoliosis, kyphosis, and pectus excavatum or carinatum	Rarely respiratory distress due to abnormal thorax	Autosomal dominant	*FBN1* (Fibrillin 1)	Multiple
Dominant negative action	Beals syndrome	Dolichostenomelia camptodactyly; arachnodactyly; crumpled ears	Kyphoscoliosis	Rare	Autosomal dominant	*FBN2* (Fibrillin 2)	Multiple
Gain of function	Achondroplasia	Rhizomelic dwarfism; macrocephaly	Small ribcage; kyphosis	May occur in infancy; upper airway obstruction possible	Autosomal dominant	*FGFR3* (Fibroblast growth factor receptor 3)	Gly380Arg
Gain of function	Thanatophoric dysplasia	Short limbs, lethal dwarfism	Narrow thorax due to shortened ribs; flat vertebral bodies	Lethal shortly after birth, often due to respiratory insufficiency	*Sporadic cases due to new mutation*	*FGFR3*	Arg248Cys; Lys650Glu; others
Haploinsufficiency	Camptomelic dysplasia	Bowing of long bones; male to female sex reversal; micrognathia	Small thoracic cage with slender ribs or decreased number of ribs. kyphoscoliosis	Respiratory insufficiency may cause death in early infancy; failure to thrive in survivors	Autosomal dominant	*SOX9* (transcription factor)	Multiple
Haploinsufficiency	Cleidocranial dysplasia	Wide anterior fontanel with delayed closure; excess teeth; mild short stature	Partially or completely absent clavicle; narrow chest	Rare	Autosomal dominant	*CBFA1* (transcription factor)	Multiple
Loss of function	Marfan syndrome 2(1)	Dolichostenomelia arachnodactyly; joint laxity; aortic dilatation	Scoliosis, kyphosis and pectus excavatum or carinatum	Rarely respiratory distress due to abnormal thorax	Autosomal dominant	*TGFBR2* (TGF-beta receptor 2)	Multiple
Loss of function	Loeys-Dietz syndrome (2)	Joint laxity; aortic dilatation; hypertelorism; bifid uvula; micrognathia; patent ductus arteriosus; arachnodactyly;	Scoliosis, pectus excavatum or carinatum	Rarely respiratory distress due to abnormal thorax	Autosomal dominant	*TGFBR1* or *TGFBR2* (TGF-beta receptor1, 2)	Multiple
Loss of function	Ellis-van Creveld syndrome (chondroectodermal dysplasia)	Short distal extremities; polydactyly; nail hypoplasia; cardiac defects	Small thoracic cage with short ribs	Respiratory distress may occur due to the small thorax or the cardiac defect	Autosomal recessive	*EVC*	Multiple
Loss of function	Hypophosphatasia (neonatal form)	Undermineralized, hypoplastic and fragile bones; rachitic rosary; hypercalcemia	Short ribs and small thoracic cage	Death due to respiratory insufficiency in neonatal period common	Autosomal recessive	*ALPL* (alkaline phosphatase)	Multiple
Loss of function	Jarcho-Levin syndrome (spondylothoracic dysplasia; spondylocostal dysostosis)	Short neck; long digits with camptodactyly	Short thorax with multiple vertebral defects and abnormal ribs	Respiratory distress due to small thoracic volume causes death in infancy	Autosomal recessive; most cases of Puerto Rican ancestry	*DLL3* (delta-like 3)	Multiple
Unknown	Jeune syndrome (asphyxiating thoracic dystrophy)	Short limbs; polydactyly; cystic renal lesions or chronic nephritis	Small, bell-shaped ribcage; hypoplastic lungs	Usually fatal neonatal asphyxia	Autosomal recessive	Unknown	Unknown
Unknown	Cerebro-costo-mandibular syndrome	Severe micrognathia; prenatal growth deficiency	Small, bell-shaped thorax; gaps between posterior ossified and anterior cartilaginous ribs	Respiratory insufficiency may cause neonatal death	Possibly autosomal recessive or autosomal dominant	Unknown	Unknown

normal copy of the gene. While similar to the haploinsufficiency mechanism, these mutations do not usually affect transcription factors. For example, mutation in the transforming growth factor β receptors 1 or 2 (*TGFBR1* or *TGFBR*2) can cause Loeys-Dietz syndrome if only one copy of the gene is abnormal (see Table 66-2).

In contrast, autosomal recessive disorders are due to loss or function mutations in both alleles of the respective gene, causing loss of function protein products with enzymatic or transport function. Examples of these disorders include diastrophic dwarfism, achondrogenesis type 1B, and Jarcho-Levin syndrome. For example, achondrogenesis type 1B causes a clinical syndrome of extreme short stature, poor ossification of the skull and vertebral bodies, severe micromelia of the limbs, extremely short ribs, and stellate long bones.[103] The mutation resides in the diastrophic dysplasia sulfate transporter (*DTDST*) gene,[109] leading to decreased or absent sulfate transport[110] and abnormalities in cartilage proteoglycan sulfation.

Clinical Syndromes

Achondroplasia, an autosomal dominant skeletal dysplasia, is one of the most common forms of short-limbed dwarfism. It results from a mutation in the transmembrane domain of FGFR3.[100] Phenotypically, it is associated with developmental abnormalities of the ribs, thorax, long bones, and cranium. The ribs are short and flared, and the anteroposterior diameter of the thorax is narrowed, which can compress the intervening structures such as the trachea.[111] This compression may be related to the posterior ribs bowing around the transverse processes of the spine, thus "pushing" the vertebral bodies anteriorly.

The respiratory complications of achondroplasia include disordered sleep and obstructive apnea in about three quarters of subjects,[112] due to brainstem compression causing disorders in the control of breathing and midface hypoplasia. In addition to obstructive apnea, in part related to the midface hypoplasia, brainstem compression may lead to disorders in the control of breathing.[112-114] The small lung volumes mean that airways are narrower than normal and more likely to be occluded by secretions, thereby predisposing the patient to recurrent pneumonia and hypoxemia due to atelectasis and ventilation-perfusion mismatch. Related spinal cord compression can also cause respiratory muscle weakness and "pump" failure.

Despite the 10% of infants and young children with these complications, most patients with achondroplasia survive into adulthood. In contrast to the heterozygous mutation causing achondroplasia as an autosomal dominant trait, the skeletal abnormalities of homozygous offspring are so severe that most die in the first year or two of life.

Two other heterozygous mutations in the *FGFR3* gene account for the findings in thanatophoric dysplasia, which, like homozygous achondroplasia, is lethal in very early life. These are the most severe phenotypes caused by mutations in the *FGFR3* gene; achondroplasia is less severe and hypochondroplasia (HCH) is the least severe.[115]

Jeune syndrome, or asphyxiating thoracic dystrophy, is a rare autosomal recessive abnormality of endochondral bone formation characterized by a very small, shallow thoracic cage, abnormalities of the pelvis, polydactyly, and abnormal teeth. The thoracic cage does not grow normally, with ribs having a very low radius of curvature that produce a poorly compliant thorax that can only expand caudally during respiration (Fig. 66-10A). Without intervention, severe respiratory failure occurs and patients can die early in life.[116] There is the additional mechanical disadvantage of a flat low diaphragm with a lower force generating capacity due to the increased radius of curvature. In a 4-month-old child who died with Jeune syndrome, pathologic examination showed that there was a normal complement of preacinar arterioles, airways, and minimal impact on alveolar growth; however, there was evidence of vascular remodeling consistent with pulmonary hypertension.[117]

There are a number of different surgical interventions that are available to correct the thoracic limitation from Jeune syndrome, and both involve lateral expansion.

In one procedure, a vertical expandable prosthetic titanium rib (VEPTR) is placed across a thoracotomy and a series of sequential osteotomies made through the middle ribs. The VEPTR has a radius of curvature much smaller than the ribcage and when the freed ribs are sutured in place, they are moved outward from their original position (see Fig. 66-10). In time, the thoracic cage heals, with a greater thoracic cross-sectional area shown on chest CT scan (Dr. Robert Campbell, personal communication).

A separate technique, lateral thoracic expansion,[118] also uses a thoracotomy with sequential osteotomies and lateral expansion. The osteotomies are offset from each other and the periosteum is left in place and the "long" ends of adjacent ribs are attached using titanium supports for reinforcement (Fig. 66-11*A*). This expands the chest outward and leaves large gaps at every other rib level; however, within 3 weeks postoperatively, there is evidence of bone growth from the periosteum (Fig. 66-11*B*). Both techniques have been used successfully over the last decade.

Osteogenesis imperfecta, an inherited disorder of bone formation, usually results from mutations in the genes encoding type I collagen. It is associated with fractures of the bones including the ribs. The common respiratory problems relate to the fractures of the ribs produced by minimal trauma. This may cause a rapid-shallow breathing pattern, because deeper breaths are painful. The inflammatory response to fractures may cause febrile episodes that clinically are difficult to distinguish from respiratory tract infections but will increase the metabolic demand on the patient. Chest radiographs are often of no help in defining absence or presence of infiltrates because the lung parenchyma is obscured by bone and callus formation.

Jarcho-Levin, or spondylothoracic dysplasia, syndrome is an autosomal recessive disorder in which there is a combination of spinal and rib cage abnormality with truncation of normal spinal growth and a fan-shaped appearance of the ribs (Fig. 66-12). The abnormality begins with the spine, with multiple vertebral anomalies at all levels with hemivertebrae, and fused, hypoplastic vertebrae.[119] Because of the restrictive thorax, patients with Jarcho-Levin syndrome can experience chronic respiratory failure early in life. In one series, mortality was 44% by 6 months of age.[119] In addition, there also can be secondary pulmonary hypertension and congestive heart failure. Although death can occur during infancy, in a

Puerto Rican cohort those who survived infancy had an almost 3-fold decrease in hospitalizations for respiratory tract infections after 24 months of age.[119]

Surgical interventions to treat the thorax of patients with Jarcho-Levin syndrome are similar to those for Jeune syndrome and may prevent the need for or complement ventilatory support. Anterior and/or posterior spinal fusion have been performed in patients with progressive scoliosis.[120] In other situations, lateral thoracic reconstruction has been performed.[121] Chest wall expansion using VEPTR has been performed in two general patterns: lateral rib-to-rib chest wall distraction using the VEPTR after a series of thoracotomies and osteotomies to open the medial bone mass or with a rib-to-spine or rib-to-iliac crest traction spanning the defective region if there is significant scoliosis (Dr. Robert Campbell, personal communication). Outside of stabilization from the initial surgery, subsequent expansions to maintain traction on the spine can encourage spine growth.

Pectus Excavatum

Pectus deformities are among the most common abnormalities of the thorax. There are no recent data on incidence; however, in older data the incidence was 6 to 8 per 1000 children.[122] Although the causes of pectus are not clearly defined, they may be linked to upper airway obstruction during chest wall growth, overgrowth of costal cartilage, thoracic cage muscle weakness, and underlying mesenchymal abnormalities, such as connective tissue disease.[123] If pectus excavatum is discovered, a comprehensive patient and family history and physical examination should be performed to evaluate for other associated disease processes such as other skeletal abnormalities, mitral valve prolapse, and Marfan syndrome.

The nature and extent of physiologic abnormalities associated with pectus deformities are controversial.[124,125] There have been studies demonstrating that pectus excavatum produces no pulmonary function abnormalities,[126] whereas others demonstrated a mild to moderate restrictive defect,[122,127] which correlates only loosely in severity to radiographic measurements of the magnitude of the pectus. However, others have demonstrated that though restrictive defects occur, they are less common than obstructive defects.[128-130]

There are two basic approaches to pectus excavatum surgical correction. The first is the classic Ravitch procedure that involves a sternotomy and bone resection with remodeling of sternal cartilage.[131] In a minority of patients receiving the Ravitch procedure, there was a significant asphyxiating restrictive defect that occurred in the years postoperatively,[131,132] and alterations were made to correct this defect and minimize the occurrence.[131,133] The second is the Nuss procedure in which a titanium bar, bent to the expected contour of the chest after surgery, is inserted beneath the ribs laterally and rotated anteriorly to apply outward pressure on the internal edge of the sternum.[134] The bar remains in place for 2 to 4 years and the sternal remodeling remains permanent in most cases.[135]

There is wide variation in pulmonary outcomes after corrective surgery. In some patients, there is actually a decrease in lung function after surgery.[131,132] This has been related to the severity of the pectus, with the less severe patients having less improvement or a decrease in lung function.[135] The group that developed the Nuss procedure has outcome data in a cohort of 43 patients that demonstrated a statistically significant improvement of 5% of predicted value in FVC and FEV_1 and of 8% in $FEF_{25-75\%}$ after the bar was removed at a mean of 2.9 years after insertion.[135] Interestingly, the patients who were under 11 years of age had no significant improvement in pulmonary function, whereas the patients over age 11 all had significant improvement.[135] There is increased oxygen consumption at high levels of exercise before and after pectus repair, although the improvement in exercise capacity after pectus repair appears to be modest.[126]

For the vast majority of subjects who receive pectus repair there is minimal cardiac dysfunction.[136,137] However, there is some evidence for increased stroke volume after repair, increased ventricular filling, increased oxygen pulse resulting in a decreased heart rate at the same workload, and increased duration and level of exercise.[136,138]

Scoliosis

In the United States, approximately 1 in 1000 persons has a scoliotic curve greater than 35 degrees and 1 of 10,000 has a curve greater than 75 degrees, which can put them at risk for chronic respiratory failure.[139,140] This places about 30,000 patients at risk for chronic respiratory failure caused by scoliosis in the United States.[139] Patients with infantile or juvenile scoliosis typically have greater morbidity and mortality compared with patients with adolescent onset scoliosis, who can have very little morbidity if the degree is mild and/or it is detected early.[141,142] Therefore, early diagnosis and aggressive intervention are critically important.

There are a number of different causes of scoliosis. Although scoliosis is visualized on examination or on radiograph as a spinal curvature, it goes well beyond just the spine. The scoliosis can be a primary spinal defect with hemivertebra and fused or absent vertebra that alters the normal spinal growth pattern. Alternately, the curve can be secondary to lateral rib tethering from rib fusion (Fig. 66-13*A*-C) or to rib absence (Fig. 66-13*A*,*B*) with inadequate lateral support. With rib fusion, the contralateral spine grows at a faster rate than the ipsilateral spine and the curve increases with growth (Fig. 66-13C). Absence of ribs causes an incompetent thorax with adequate support on only one side, and with growth, there is a curve convex to the side with the rib absence (Fig. 66-13*A*,*B*). Patients with intercostal muscle weakness can develop scoliosis due to inadequate ribcage support with scoliosis and a more downward rotation of the ribs in a "Christmas tree" appearance, as is seen in spinal muscular atrophy (Fig. 66-14).

Scoliosis can cause a restrictive defect in which the magnitude of the restriction is related to the angle of scoliosis (Cobb angle), the location of the curve, and loss of normal thoracic kyphosis. Although the amount of the curve can be linked to respiratory compromise, the correlation is not direct or consistent. The level of curve and the amount of spinal rotation are also important in determining the amount of respiratory compromise. The more cephalad the curve, the more severely the lung on the convex side is compressed. Spinal rotation shifts the ribs laterally so that the midpoint of the sternum is lateral to the midpoint of the spine (Fig. 66-15). This further compresses or distorts the lungs by flattening them in the lateral plane and puts torsion on the diaphragm.[143] The torsion on the diaphragm may increase the radius of curvature of the diaphragm, thereby decreasing the force-generating capacity and making it less efficient.

The compliance of the respiratory system and, in particular, the chest wall is decreased in patients with scoliosis. This decrease in compliance correlates closely with the severity of scoliosis and with the decrease in FVC[140] that is well described in scoliosis. In addition, as might be expected in the convex lung, there can be peripheral airway obstruction and air trapping,[140,144] demonstrated by plethysmography; as one might expect, this has not been consistently demonstrated using the helium dilution technique. Some patients have demonstrated a significant postbronchodilator decrease in the RV/TLC ratio and an increase in FEV_1, which was thought to indicate increased airway smooth muscle tone to resist the compressive force from the scoliosis[144]; however, airway hyperreactivity was not independently assessed.

Scoliosis in certain circumstances can have a profound influence on lung development. Congenital scoliosis that is allowed to progress and significantly limit lung growth within the first few years of life can impact lung growth during the period of rapid alveolar development and limit alveolar number, although the alveolar size is appropriate for age.[145]

There are a number of different ways to intervene in treating children with congenital scoliosis. In milder cases, bracing may prevent or decrease progression of the curve through adolescence, after which time further progression should be minimal. For more severe cases, it is generally accepted that spinal fusion using instrumentation such as Harrington rods is the most reliable final solution in that it stabilizes the spine well with some correction and prevents further progression. The disadvantage of spinal fusion is the lack of potential for future growth of the fused segment, which limits its utility in younger patients.

There are two alternate methods of spinal correction that allow for spinal growth: "growing rods" and the vertical expandable prosthetic titanium rib (VEPTR). Growing rods are placed along the lateral edges of the spinal column and attached intermittently along the stabilized region (Fig. 66-16). As the patient grows, the rods can be lengthened at the connection points or replaced with longer rods to allow normal spinal growth. Whereas some believe that the advantage of this construct is that it prevents any limitation of the outward ribcage motion during respiration and keeps the correction in the perispinal region, others believe that invading the perispinal region makes the definitive spinal fusion performed later more difficult.

The VEPTR has been used in patients with congenital scoliosis with rib fusion or rib absence (see Fig. 66-13*B*). The advantage of use in these two situations is that there is both correction of the curve, to the extent possible, and rib cage stabilization. Semiannually, the VEPTR is expanded to allow normal growth. Although some have expressed concern that the placement across multiple ribs will decrease rib cage

compliance and negatively impact respiration, there is no evidence to support this assertion. Importantly, there is minimal, if any, entry into the perispinal region that is thought to make any subsequent spinal fusion after growth has ceased much easier (Dr. Robert Campbell, personal communication). Unfortunately, there is a paucity of pulmonary function outcome data after insertion using either the growing rod or VEPTR.

Considerable controversy still exists over whether Harrington instrumentation improves lung function. A meta-analysis of 173 patients indicated a significant improvement of 2% to 11%.[146] The improvement may not be immediate, and there may be initial loss of vital capacity; however, the preoperative FVC is reached by 2-year follow-up.[147,148] Much of the variability in improvement in lung function may depend on at what point the intervention is performed. If performed after the curve is not correctible with traction, the likelihood of significant improvement is minimal; however, the patient may still benefit from preventing further progression of scoliosis and restriction.

Defects in Development of the Chest Wall Muscles

The chest wall is considered broadly as the respiratory pump and the structures bordering on the lungs, including the thorax, both inspiratory and expiratory musculature, and the abdominal wall. Congenital defects in the structure of the chest wall muscles can affect the function of the respiratory pump and the development of the lung.

Congenital Diaphragmatic Hernia

Congenital diaphragmatic hernia (CDH) occurs in approximately 1 in 2500 live births,[149-151] and about 40% are associated with other congenital abnormalities (Table 66-3), including neural tube defects, cardiac anomalies, and skeletal, craniofacial, urinary, anterior abdominal wall, and other defects that may influence survival.[152,153] Of the 60% without other major congenital malformation, the magnitude of the pulmonary hypoplasia strongly influences survival.

The hernia defect is caused by a failure of the pleuroperitoneal canal to close during fetal development. Although the pulmonary hypoplasia has been attributed to mechanical compression from the herniated abdominal content, recent evidence suggests that there are a number of mesenchymal growth factors and signaling pathways that may be affected during diaphragm development.[154] These are believed to cause the abnormal branching pattern, which can leave the lung in the late canalicular or early saccular stage of development.[155] In fact, the contralateral lung itself is also smaller than normal.[155]

A number of investigators have studied lung function in school-age survivors of CDH. The data are remarkably consistent and demonstrate mild airway obstruction, normal total lung capacity, and some increase in RV/TLC ratios.[156-163] Although MIP is decreased (as would be expected), MEP is not significantly different from normal.[164] Of the flow measurements, $FEF_{25-75\%}$ is decreased proportionally to the perfusion defect[164] that probably reflects the developmental truncation of the vascular and airway tree. There is also bronchodilator sensitivity that may be due to the increased smooth muscle in the airways and small airway disease as part of the initial abnormality or as an iatrogenic effect from the early interventions and medical course.[164]

The status of the thoracic structures and the thoracic pump has not been extensively investigated. In one study of 25 subjects, there was a 46% incidence of pectus deformities and scoliosis.[164]

ABDOMINAL WALL DEFECTS (GASTROSCHISIS, OMPHALOCELE, PRUNE-BELLY SYNDROME)

The anterior abdominal wall is part of the respiratory muscle pump, and abdominal wall defects have potential influences on the developing lung. Omphalocele and gastroschisis occur in approximately 1 in 4000 to 5000 live-born children.[165] Prune-belly or Eagle-Barrett syndrome is less common and has absent or reduced abdominal wall musculature believed to be due to obstruction of the urinary outflow tract and

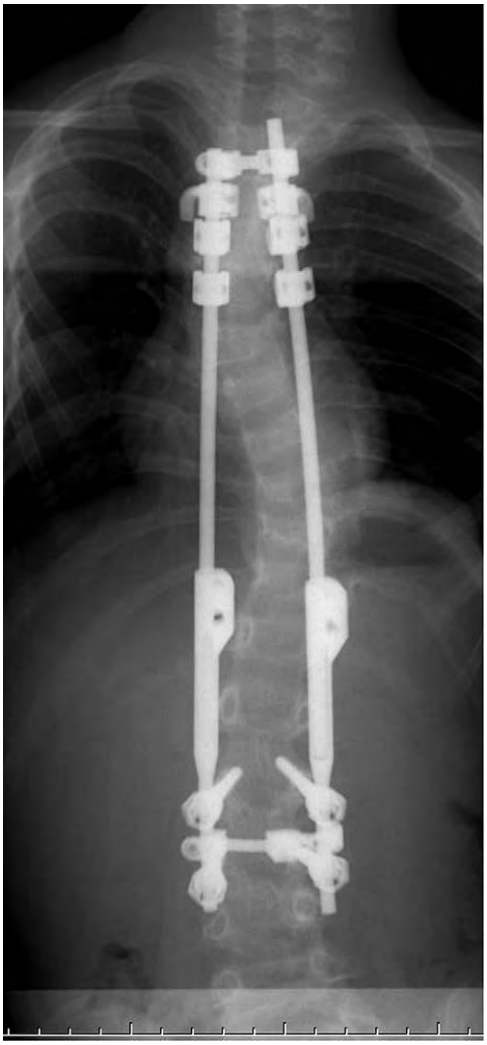

Figure 66-16 Bilateral growing rods. (Courtesy of Dr. Randall Betz.)

massive distention of the urinary tract and abdomen and abnormal mesenchymal development. Because of the increased abdominal compliance, these defects allow abdominal contents to extend beyond the usual borders of the anterior abdominal wall.

Mechanically, two problems can occur. With diaphragm contraction during inspiration, the abdominal contents will go outward more instead of serving as a "fulcrum" moving out the inferior rib cage. During forceful exhalation, there is less abdominal force generated to augment the passive recoil of the ribcage and maneuvers like coughing can be significantly compromised. In this situation, an abdominal binder can be useful.

Prune-belly syndrome presents a number of additional respiratory challenges. Some of these patients have generalized muscle weakness related to uremia and to corticosteroids administered following renal transplantation. As a result of the mechanical abnormalities, these patients have slightly reduced lung volumes, markedly reduced inspiratory and expiratory muscle strength, and impairment in exercise capacity.[166,167] The exercise impairment may be due to the marked thoracoabdominal asynchrony that occurs during exercise and may be related to abnormally large ribcage excursion during exercise.[166] Interpretation of tests of airway obstruction in these patients is difficult because expiratory muscle weakness probably contributes to reduced expiratory flow rates, particularly peak flow.

Patients with abdominal wall defects can have narrow chest walls, downslanting ribs, and reduced radiographic estimates of lung volume, suggesting a component of pulmonary hypoplasia. In fact, the radial alveolar count, an index of alveolar number, is reduced in children with giant omphaloceles as can be the lung weight–to–body weight ratio.[168]

Closure of abdominal wall defects presents both respiratory and cardiovascular challenges. Although the size of the entire coeloemic cavity has not been estimated in these conditions, the peritoneal cavity is thought to be small. Thus, when the defect is closed, abdominal pressure increases. This can be an advantage to the infant in that increased abdominal pressure may elevate and lengthen the diaphragm and decrease the radius of curvature, which puts the diaphragm at a more favorable length-tension relationship. Most artificial materials used to close the wall are nondistensible and skin is often under tension. Inspiration in these patients may be associated with large positive swings in intra-abdominal pressure, which may prevent venous return to the right side of the heart, compress the inferior vena cava, and impair cardiac output.

Lung function has been measured in some infants before and after surgical closure of abdominal wall defects. Lung volumes as measured by a forced deflation vital capacity maneuver were decreased by about 40%, and compliance of the respiratory system was reduced by about 50%, as might be expected.[169,170] In 18 adolescent patients who had a large omphalocele (>6 cm) or gastroschisis (>4 cm) repaired at birth, there was no abnormality in FVC or in cardiovascular function during exercise.[167] However, they reached their maximal heart rate sooner into exercise and had a lower maximal oxygen consumption than normal controls,[167] both of which were thought to be due to deconditioning.

NEUROMUSCULAR DISEASE

Classification of Neuromuscular Diseases

Although there are a wide variety of neuromuscular conditions with many different genetic and cellular etiologies, they are often unified by a morbidity and mortality due to respiratory failure (Table 66-4). This can result either from progressive chronic respiratory failure or from an acute event rapidly overwhelming the capacity of the respiratory system. Outside of the direct failure of the diaphragm or chest wall muscles, upper airway muscle failure, in particular the pharyngeal and laryngeal muscles, can also worsen respiratory dysfunction. Pharyngeal muscle weakness can lead to upper airway obstruction. The weakness can be exacerbated during sleep and add resistive load to the respiratory system. Laryngeal muscle weakness can decrease airway protection and put a patient at greater risk of aspiration. In addition, failure of the intercostal muscles can decrease thoracic support and cause a downward "collapse" of the ribs in a "Christmas tree" appearance (see Fig. 66-14), as in spinal muscular atrophy, or can lead to scoliosis if the weakness is asymmetric.

Table 66-3
Congenital Diaphragmatic Hernia with Respiratory Complications, Inheritance Pattern, and Genetic Abnormality

Syndrome	Major Findings	Thoracic Involvement	Respiratory Complications	Inheritance Pattern	Gene/Chromosome
Fryns	Large size; coarse face; digital and nail hypoplasia; heart and renal malformations	Diaphragmatic hernia (common)	Pulmonary hypoplasia	Autosomal recessive	Unknown
Donnai-Barrow	Hypertelorism, iris coloboma; agenesis of corpus callosum, omphalocele	Diaphragmatic hernia (common)	Pulmonary hypoplasia	Autosomal recessive	*LRP2*
Apert	Craniosynostosis, syndactyly; heart defect	Diaphragmatic hernia; anomalous tracheal cartilage	More likely from tracheal sleeve or choanal atresia/stenosis	Autosomal dominant; usually de novo mutation	*FGFR2* (one of two specific mutations)
Pallister-Killian	Coarse face; high anterior hairline; tall forehead	Diaphragmatic hernia		De novo	Mosaic tetrasomy 12p (in skin fibroblasts)
Craniofrontonasal dysplasia	Hypertelorism; craniosynostosis	Diaphragmatic hernia Pectus excavatum Clavicular pseudarthrosis		X-linked; females more severely affected	Ephrin B1
De Lange	Small stature, microcephaly; phocomelia; arched eyebrows with synophrys	Diaphragmatic hernia		Autosomal dominant	*NIPBL*
Wolf-Hirschhorn	Small stature, microcephaly, prominent glabella, cleft lip; coloboma; heart defect	Diaphragmatic hernia	Pulmonary isomerism	Chromosome deletion	Deletion 4p16.3
Chromosome anomalies	Intrauterine growth retardation; multiple congenital anomalies	Diaphragmatic hernia;		Unbalanced chromosome anomaly	Multiple, including trisomy 13, 18

Both thoracic defects will further add to the load on the respiratory system.

Neuromuscular disease can be localized anywhere from the corticospinal tract to the peripheral nervous system and the myoneural junction to the muscle itself.

The effects on the respiratory tract depend not only on the nature and location of the abnormality but also on whether it is acute or chronic. In general, lower motor neuron, myopathic lesions, and acute neurologic illness cause flaccid muscles and poor chest wall stabilization. However, upper motor neuron or cortical lesions and chronic neurologic illness often increase muscle tone and cause less mobile chest wall ligaments and joints. Although this stiffness can be treated or prevented to an extent with aggressive physical therapy to maintain range of motion, pharmacologic therapy with muscle relaxants is a common adjunct.

Spinal cord trauma is one example of the importance of lesion location. The respiratory effects of low thoracic cord lesions are minimal, although cough and forced expiratory maneuvers that rely on activation of abdominal wall muscles may be impaired. In high thoracic cord lesions, intercostal muscles are affected, causing breathing to be purely from the diaphragm. High cervical cord lesions (C3-5) affect the intercostal muscles and the phrenic nerve and diaphragm; therefore, patients with these lesions cannot breathe independently.

Pathophysiology

ALTERATIONS OF LUNG FUNCTION IN NEUROMUSCULAR DISEASE

Total lung capacity (TLC) and vital capacity (VC) may be normal in mild neuromuscular disease but are reduced in moderate to severe disease. The reductions in TLC and VC are caused by inspiratory and expiratory muscle weakness, scoliosis, and decreased lung and chest wall compliance due to a progressive decrease in lung and chest wall expansion.[169] RV may be normal or elevated as a result of expiratory muscle weakness. Therefore, an elevated RV/TLC ratio in patients with neuromuscular disease is not usually due to air trapping as is the case in obstructive lung disease.

Maximal expiratory flow rates in patients with neuromuscular disease are usually diminished as a consequence of both low lung volumes and decreased expiratory muscle strength, because both lung volume and driving force can impact maximal flow. Furthermore, patients with neuromuscular disease often have a characteristic shape of the flow-volume curve at low lung volumes, with a precipitous decrease in flows before reaching RV[171] rather than a linear decrease through lower lung volumes. This phenomenon is a result of the diminished ability of the expiratory muscles to overcome the outward recoil of the chest wall. As is the case in most

Table 66-4
Neuromuscular and Chest Wall Disorders, Their Thoracic and Respiratory Presentation, Inheritance Pattern, and Genetic Abnormality

Category	Disorder	Major Findings	Inheritance Pattern	Gene	Mutation
Muscular dystrophies	Dystrophinopathies: Duchenne	Progressive symmetric muscular weakness, proximal greater than distals, present before age 5 years Wheelchair dependency before age 13 years	X-linked	*DMD*	Multiple; lack of dystrophin expression
Muscular dystrophies	Dystrophinopathies: Becker	Progressive symmetric muscle weakness and atrophy, proximal greater than distal Activity-induced cramping (present in some individuals) Wheelchair dependency after 16 years of age	X-linked	*DMD*	Multiple; abnormal quality or quantity of dystrophin
Muscular dystrophies	Limb girdle MD: sarcoglycanopathies	Proximal limb weakness	Autosomal recessive	*SGCA* *SGCB* *SGCG* *SGCA*	R77C; Multiple Multiple Multiple Multiple
Muscular dystrophies	Limb girdle MD: calpainopathy	Proximal limb weakness	Autosomal recessive	*CAPN3*	Loss of function by multiple different mutations
Muscular dystrophies	Limb girdle MD: dysferlinopathy	Proximal limb weakness	Autosomal recessive	*DYSF*	Loss of function by multiple different mutations
Muscular dystrophies	Limb girdle MD	Proximal limb weakness	Autosomal dominant	*TTID* *LMNA* *CAV3*	Missense
Muscular dystrophies	Emery-Dreifuss	Joint contractures Muscle weakness Cardiac involvement	X-linked	*EMD*	Multiple null mutations; missense may cause milder phenotype
Muscular dystrophies	Emery-Dreifuss	Joint contractures Muscle weakness Tachyarrhythmia, dilated cardiomyopathy	Autosomal dominant	*LMNA*	Multiple missense
Muscular dystrophies	Facioscapulohumeral	Progressive muscle weakness of face, scapular stabilizers, upper arm, lower leg, and hip girdle	Autosomal dominant	D4Z4 (3.3-kb DNA repeat motif)	Deletion
Congenital and metabolic myopathies	Central core disease	Congenital myopathy; central cores on muscle biopsy	Autosomal dominant (autosomal recessive rare)	*RYR1*	Multiple missense
Congenital and metabolic myopathies	Nemaline rod myopathy	Congenital myopathy, progressive; rod-like structures in muscle fibers on biopsy	Autosomal dominant and autosomal recessive	*ACTA1* *TNNT1* *TPM2* *TPM3* *NEB*	Heterozygous missense; compound heterozygotes may show severe form
Mitochondrial disorders	Kearns-Sayre	Pigmentary retinopathy, muscle weakness, external ophthalmoplegia, cardiac conduction block, cerebellar ataxia	Maternally inherited, through mitochondrial DNA		mtDNA deletions (1.3-10 kb)
	MELAS	Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes	Maternally inherited, through mitochondrial DNA	*MTTL1* *MTTQ* *MTTH* *MTTK* *MTTS1* *MTND1* *MTND5* *MTND6*	Point mutations
	MERRF	Myoclonus epilepsy associated with ragged-red fibers; myopathy	Maternally inherited, through mitochondrial DNA	*MTTK,* others as in MELAS	Point mutations

restrictive lung disease, the FEV_1/FVC ratio is normal in patients with neuromuscular disease.

Lung compliance is reduced in patients with neuromuscular disease,[172] whereas specific compliance is usually normal.[173] This suggests that the decreased compliance is due to loss of lung units or alveolar number as opposed to an alteration of the tissue properties of the lung.

RESPIRATORY MUSCLE STRENGTH

Maximal inspiratory and expiratory pressures are reduced in patients with neuromuscular disease.[169,174,175] The degree of reduction does not seem to correlate with the reduction in general skeletal muscle strength.[174] Respiratory muscle strength is related, however, to the distribution of general muscle weakness, tending to be more severe in patients with proximal muscle weakness and less severe in patients with mainly peripheral muscle weakness.[171]

CHEST WALL ALTERATIONS

Infants and young children with neuromuscular disease often have a highly compliant chest wall,[176] although most adults with neuromuscular disease will have *reduced* chest wall compliance.[174] This suggests that intact muscle function is necessary for the development of normal intrinsic chest wall stiffness but that, with time, long-term diminished tidal chest wall excursions lead to costovertebral joint contractures and poor chest wall compliance.

CONTROL OF BREATHING

Patients with neuromuscular disease may have abnormalities of the respiratory control center as a primary or secondary event. Clearly, brainstem abnormalities can directly affect respiratory control and cause diminished ventilatory responses to hypercarbia and hypoxia, central and obstructive apnea, and excessive periodic breathing. As is the case with chronic lung disease of any sort, long-standing CO_2 retention can reset the respiratory control center to a higher CO_2 level and diminish the hypercarbic response. Furthermore, the chronic metabolic alkalosis compensating for long-standing CO_2 retention can blunt respiratory drive in response to increasing CO_2 levels by buffering hydrogen ion and reducing acidosis.

Whether patients with neuromuscular disease that is *not* of central origin, such as myopathies, have disordered control of breathing is difficult to ascertain, because most tests of respiratory control depend on intact respiratory system mechanics and muscle strength. For example, assessing the change in minute ventilation during CO_2 rebreathing assumes that such ventilatory changes are not limited by the mechanics of the system, an assumption that is not true in the presence of severe restrictive chest wall disease and muscle weakness. To overcome this limitation, the P_{100} has been suggested as a good index of respiratory drive in patients with lung mechanic abnormalities. By assessing the mouth pressure response to the first 100 milliseconds of an inspiratory occlusion, patients with neuromuscular disease can presumably reach normal values despite respiratory muscle weakness because the normal value of P_{100} (about 2 cm H_2O in adults) is well below the maximal pressures that can be generated by most patients with neuromuscular disease. Although few studies have been reported, it appears the patients with neuromuscular disease have normal P_{100} values, indicating intact respiratory drive.[177,178]

ABNORMALITIES OF COUGH IN PATIENTS WITH NEUROMUSCULAR DISEASE

A major factor predisposing to recurrent pneumonia in patients with neuromuscular disease is an ineffective cough due to weak inspiratory muscles, poor glottic closure, and weak abdominal and thoracic expiratory muscles. Patients with low thoracolumbar cord lesions and paraplegia can still maintain a fairly effective cough because of intact abdominal muscle strength. Patients with tetraplegia can use the clavicular head of the pectoralis major as a muscle of forced expira-

tion and often unconsciously adopt these muscles for coughing.[179]

Approach to the Patient with Neuromuscular Disease

In taking a history from a patient with neuromuscular disease, it is important to ask about chronic or recurrent pneumonias, gastroesophageal reflux, aspiration of secretions, snoring, and symptoms of sleep hypoventilation and obstructive sleep apnea such as morning headaches and daytime somnolence. Seizure control is important because uncontrolled seizures may predispose to aspiration pneumonias.

On physical examination, the spine should be carefully assessed for scoliosis as a possible contributing cause to lung dysfunction. Signs of cor pulmonale should be evaluated and the patient should be examined for clubbing as an indication of bronchiectasis from recurrent suppurative lung infections.

Pulmonary function tests including lung volumes and maximal inspiratory and expiratsory pressures should be performed on all patients who can do them. Chest radiographs and assessment of oxygenation and ventilation by arterial blood gas analysis, pulse oximetry, end tidal CO_2 measurement, and serum bicarbonate (as an index of the chronic CO_2 retention) should be done. A modified barium swallow, with a feeding specialist, to evaluate swallowing function and gastrointestinal anatomy and gastroesophageal reflux studies (scintiscan or pH probe) should be done in patients with histories suggestive of aspiration. Sleeping pulse oximetry or more formal polysomnography should be done in patients with histories suggestive of sleep apnea or in those at risk of sleep hypoventilation by virtue of marginal lung function (VC less than 50%, FEV_1 less than 40% of predicted). This can be a very valuable screening tool since the compensatory mechanisms that patients with neuromuscular disease develop to overcome their mechanical abnormalities may not be present or will be compromised during REM sleep. Electrocardiography and echocardiography should be done in all patients with baseline or sleeping hypoxemia to evaluate for the presence of cor pulmonale.

Respiratory Complications of Neuromuscular Disease and Their Treatments

POOR AIRWAY CLEARANCE

Poor lower airway clearance due to an ineffective cough puts patients with neuromuscular disease at increased risk of pneumonia. Once secretions have entered the lower respiratory tract, many patients are unable to clear them effectively and lower respiratory tract infections occur. In addition to standard airway clearance therapy with manual percussion with postural drainage and oropharyngeal suctioning, there are a number of other assisted airway clearance therapies available to compensate for inadequate cough.

A cough involves a deep inspiration, with a brief glottic closure during early exhalation, followed by glottic opening with explosive expiratory flow.[180] Each of these three phases can be abnormal in patients with neuromuscular disease.

Inspiration can be augmented by breath stacking with a mask with a one-way valve, glossopharyngeal breathing, manual insufflation, and using a mechanical insufflator.[181-183] This will increase elastic recoil pressure that can be used to augment exhalation.

There is no way to recreate the effect of glottic closure in patients with bulbar dysfunction or pharyngeal weakness.

Exhalation can be augmented manually with abdominal thrusts or compressions[78] or by applying negative pressure at the airway opening using a mechanical exsufflator.[182-184] Manual cough assistance can be challenging in patients with scoliosis or extremity contractures that can block access to the abdomen.[184] Exsufflation pressures above −40 cm H_2O may cause upper airway narrowing, especially in the younger patient or those with pharyngeal hypotonia. Together, mechanical insufflation and exhalation has been used successfully with pressures of up to +40 cm H_2O for insufflation and −50 cm H_2O for exsufflation in pediatric patients with neuromuscular disease.[185] Mechanical insufflation and exsufflation can be delivered through a mouthpiece, face mask, or endotracheal or tracheostomy tube, depending on the patient's situation.

Other alternatives to improve peripheral airway clearance include high-frequency chest wall oscillation (HFCWO) and intrapulmonary percussive ventilation (IPV). HFCWO is commonly used in patients with cystic fibrosis to decrease the viscosity of mucus and to shear it from airway walls, while the patient expels it with a cough or deep breathing maneuver. Although the inadequate cough in a patient with neuromuscular disease may limit its utility in this population, it has been successfully used in patients with quadriplegic cerebral palsy.[186]

IPV delivers small pulses of air at high frequency and variable pressures, with an aerosolized solution with saline or a bronchodilator delivered at the same time. IPV has been used successfully in pediatric patients with a variety of different neuromuscular conditions irrespective of their ability to cough.[56,187-189]

RECURRENT PNEUMONIA

Recurrent pneumonias are a common cause of morbidity in patients with neuromuscular disease. Other risk factors include aspiration due to excessive secretions, poor laryngeal-pharyngeal clearance, poor recognition, and poor airways clearance. Patients with a significant central nervous system dysfunction may have hypersalivation and be unable to properly recognize and clear upper airway secretions. Therefore, there can be an unfortunate combination of excessive volume and ineffective clearance that puts one at risk of aspiration.

Antibiotic coverage should include anaerobic oropharyngeal organisms in addition to gram-positive organisms (clindamycin, amoxicillin-clavulanic acid). For patients with a history of prolonged endotracheal intubation or tracheostomy, current or previous, coverage for *Pseudomonas aeruginosa* should be added. Finally, patients with neuromuscular disease are also susceptible to community-acquired organisms. For patients with recurrent aspiration, antibiotics to treat common anaerobic mouth organisms can be given either intermittently or prophylactically to prevent aspiration pneumonia.

In addition to antibiotic therapy appropriate to known or suspected pathogen, patients should get augmented airway clearance via manual chest physiotherapy or a raised volume device such as an intermittent positive breathing device or a

cough assistance device. These therapies can be used both on a prophylactic basis and in an acute care setting. Mucolytic agents such as dornase-α, hypertonic saline (3% or 6%), and acetylcysteine have been used clinically to help clear thick mucus in patients with recurrent or chronic pneumonia.

Inhaled β-agonist bronchodilators are of questionable utility in patients with neuromuscular disease without a coincident history of asthma, but they may be useful in combination with chest physical therapy, especially in the setting of acute atelectasis. They can also improve mucocilary clearance by increasing the ciliary beat frequency. CPAP or invasive or noninvasive mechanical ventilation can also be useful, both in compensating for the added load on the respiratory system from the infection and in augmenting airway clearance and providing distending pressure to maintain airway patency through a greater portion of the respiratory cycle.

SWALLOWING DYSFUNCTION AND GASTROESOPHAGEAL REFLUX

Aspiration is a major cause of recurrent pneumonia in patients with neuromuscular disease. Swallowing is a complicated mechanism involving precise timing between various pharyngeal, laryngeal, and esophageal muscles. Damage to any of these muscles or the neural pathways that support them can have a major impact on swallowing function. In brainstem or cortical injury, there may be little or no swallowing function due to the absence of proper neural signaling and coordination. With a more peripheral myopathy, swallowing dysfunction may not occur until much later in disease progression; however, swallowing efficiency may be impacted as patients have difficulty safely taking in enough calories to meet their nutritional needs.[190]

A speech therapy consultation may identify food textures that are not aspirated and modes of swallowing that can compensate for the abnormal swallow mechanism and can enable the patient to take at least part of his or her daily caloric intake by the oral route.[190] If this does not work, then a gastrostomy tube to bypass the oropharynx can be useful.

Although a tracheostomy tube with the cuff inflated can bypass upper airway obstruction and provide a reliable interface for mechanical ventilation, it does not prevent aspiration. In fact, a tracheostomy can interfere with normal swallowing function and may increase the risk of aspiration,[191,192] perhaps by fixing tracheal position and preventing closure of the airway by the epiglottis.

For a patient with or at risk of swallowing dysfunction, it is important to minimize the volume of secretions around the glottis. Upper airway secretions from rhinitis or sinus drainage can be treated effectively with decongestant and antihistamine therapy. Hypersalivation can be treated effectively on a temporary basis with anticholinergic therapy using glycopyrollate or scopolamine,[193,194] and botulinum toxin injections of specific salivary glands.[195,196] Salivary gland duct ligation and denervation can be used for patients in whom pharmacotherapy has been ineffective,[197,198] but these procedures are irreversible. The risk of any of these interventions is overdrying secretions, which can put patients with tracheostomy tubes at higher risk of airway occlusion.

For reasons incompletely understood, the prevalence of gastroesophageal reflux (GER) is higher in patients with neuromuscular disease than in the general population. In patients with cortical dysfunction, some have proposed a link between spasticity and increased intra-abdominal pressure exacerbating GER, while esophageal dysmotility and decreased upper esophageal sphincter tone can also contribute. GER is treated with motility agents such as metoclopramide or bethanechol and antacids including both H_2-receptor antagonists and proton pump inhibitors. If medical management fails, fundoplication may be performed, although the success can be compromised in patients with seizure activity or tonic-clonic activity with intermittent increases in abdominal pressure. Fundoplication may also exacerbate swallowing dysfunction if the lower esophageal sphincter is wrapped too tightly.

RESPIRATORY FAILURE

Chronic respiratory failure is the hallmark and a unifying factor among the progressive neuromuscular disorders. The level of respiratory muscle fatigue in patients with neuromuscular disease is the balance between respiratory muscle strength and the resistive and elastic load on the respiratory system. Fatigue occurs in patients with normal respiratory muscle strength when increased elastic or resistive respiratory loads are great. In patients with neuromuscular disease, modestly increased elastic loads from scoliosis and chronic pulmonary fibrosis secondary to chronic aspiration, recurrent pneumonias, and other conditions may produce fatigue.

Nocturnal ventilatory support can enhance the quality of life in many patients with nighttime hypoxemia and hypercarbia. Supplemental oxygen by nasal cannula may suffice in patients with hypoxemia caused by chronic lung disease without hypercarbia. The physiology of chronic respiratory muscle fatigue and its treatment with respiratory muscle rest are discussed earlier in this chapter.

Noninvasive ventilation has been used for over 60 years to treat chronic respiratory form neuromuscular disease. Although modern versions of the Drinker and Emerson tank ventilator "iron lung" are available today to provide negative pressure ventilation, negative pressure cannot be used in patients with upper airway obstruction. The vast majority of patients using noninvasive ventilation use positive pressure ventilation via nasal, oral, or oronasal interfaces. Although the available bilevel positive airway pressure units were originally developed for adult use, there are a number of interfaces that can be used effectively in pediatric patients.

Once the need for noninvasive ventilation extends well into the daytime hours, chronic invasive ventilation via tracheostomy tube can be useful. This is a decision that is predicated on a number of issues. The first issue is how well the ventilator and interface is working for the patient. If the ventilator can adequately augment ventilation for a substantial portion of the day, and the skin underneath the interface remains intact, then there is no need to transition to invasive ventilation. However, with progression of the neuromuscular disease and/or decreased chest wall compliance, the noninvasive ventilator may not be able to assist ventilation with a high enough pressure to inflate the lungs adequately. The final, and perhaps most important, issue is the patient's and family's wishes. For many patients and family, invasive ventilation is an intervention that exceeds their own sense of propriety. Although for some families it is a value judgment, for others there may be a lack of understanding of what life with a tracheostomy means. With a properly sized tracheos-

tomy tube, patients can still vocalize, and this can be improved substantially by using a speaking valve, which allows air in through the tracheostomy tube, but exhalation around the tracheostomy tube and between the vocal cords.

In chronic respiratory failure there is often a compensatory metabolic alkalosis. When the P_{CO_2} is reduced by mechanical ventilation, chloride supplementation is often required in order to promote excretion of the retained HCO_3^-.

Acute respiratory failure usually occurs in the setting of acute pneumonia or increased mucus plugging and atelectasis, causing hypoxic respiratory failure with ventilation perfusion mismatch. Because of this, it is critical to aggressively treat these episodes with increased airway clearance therapy, antibiotics, and ventilatory support if indicated. Patients with marginally compensated respiratory muscle strength caused by underlying neuromuscular disease are also more likely to develop respiratory pump failure during an acute infection. Patients with general muscle weakness caused by myopathies often decompensate during intercurrent systemic illness, such as viral infections. The respiratory muscles are no exception, and even nonpulmonary infections can lead to respiratory failure in this setting.

COR PULMONALE

Cor pulmonale is a common end-stage complication of neuromuscular disease, and the genesis is multifactoral. An early sign of respiratory failure is nocturnal hypoxemia, which can cause pulmonary vasoconstriction and increased right heart strain. The severe scoliosis that can develop can cause restrictive disease and a decreased FRC. The decreased FRC may decrease further during REM sleep, when intercostal muscle tone decreases. Prolonged periods of breathing at low FRC can cause airway closure and atelectasis, both of which result in hypoxemia from low $\dot{V}/\dot{Q}$ ratios due to airway closure and a decreased surface area for diffusion. In addition, hypoventilation is common in neuromuscular disease. Furthermore, the abnormal upper airway muscle control of patients with neuromuscular disease can lead to upper airway obstruction during sleep.

NUTRITIONAL STATUS

Because of swallowing inefficiency, maintaining an adequate daily intake of calories for growth can be difficult. The actual caloric need in patients with progressive neuromuscular disease is controversial, with some suggesting a basal metabolic need less than that of an age- and weight-matched child due to the relative lack of muscle mass and inactivity. The clear risk in not providing enough calories is weakening the muscles further by not meeting the basic metabolic needs, and running the risk of decreasing muscle mass further. Conversely, an overweight child has the added burden of moving a heavier chest wall and fatiguing the respiratory muscles.

OTHER CONSIDERATIONS

Many of the general principles of the care of patients with neuromuscular disease have been outlined in a recent American Thoracic Society statement.[56] General supportive measures should be stressed. Influenza vaccine should be given annually, and patients should receive all routine immunizations, including *Haemophilus influenzae* vaccine, as well as pneumococcal vaccine. Giving the palivizumab vaccine for RSV prophylaxis remains controversial. Although there are not the same published data demonstrating efficacy in reducing the morbidity of RSV infection as with patients with bronchopulmonary dysplasia and congenital lung disease, many clinicians will use it in patients under 2 years of age with more severe conditions, such as SMA type 1 and nemaline rod myopathy. The enormous financial and psychological burdens of patients with chronic progressive neuromuscular disorders and their families are best addressed by a multidisciplinary approach, with collaboration among the treating primary and subspecialty physicians, nurses, physical therapists, nutritionists, and social workers.

CHAPTER 67 Respiratory Ciliary Dysfunction

Jonathan Rutland, Lucy Morgan, and Robbert de Iongh

TEACHING POINTS

- Cilia line the respiratory tract (upper and lower) and form the basis for effective mucociliary clearance, a major component of the respiratory tract host defense system. Some other organs also have ciliated epithelium—some only in embryonic life.
- Ciliary structure and/or function may be defective, resulting in recurrent and chronic respiratory tract disease.
- Patients with defective cilia may develop a variety of clinical features—which correlate with the anatomical distribution of cilia throughout the body, including bronchitis, bronchiectasis, sinusitis, organ malrotation, and infertility.
- Primary ciliary dyskinesia is a rare cause of respiratory tract disease caused by a heterogeneous group of genetic disorders that are usually autosomal recessive.
- The diagnosis of primary ciliary dyskinesia may be suspected on the basis of clinical features and the results of measurements of mucociliary clearance and/or nasal nitric oxide, but ciliary ultrastructure and function studies are required for confirmation.
- There is no accepted specific therapy available for primary ciliary dyskinesia. Management is aimed at the treatment of respiratory tract infection and minimization of end organ damage based on the principles of treatment of other chronic respiratory tract diseases.

A relationship between abnormal ciliary function and respiratory disease was first suggested in the mid-1970s.[1,2] An association between bronchiectasis and situs inversus was first noted by Siewert[3] in 1904, but it was not until the 1930s that Kartagener reported a series of patients with sinusitis, situs inversus, and bronchiectasis.[4] In time this became known as Kartagener syndrome. The underlying pathogenesis was not known. In 1975, sperm immotility and absence of dynein arms in the axonemes of sperm from patients with Kartagener syndrome were reported,[5,6] thus linking male infertility with this syndrome. Subsequent studies of respiratory tract cilia (which have the same axonemal structure as sperm) revealed defective ciliary motility and deficient dynein arms.[1,2] Initially it was thought that these patients had immotile cilia and the term *immotile-cilia syndrome* was suggested.[7] Subsequent studies demonstrated a wide range of ciliary motility, ranging from complete absence to almost normal motility.[8,9] The ciliary motility in these patients was often noted to be uncoordinated or dyskinetic. The term *primary ciliary dyskinesia* (PCD) is now in wide use.[10]

A range of ultrastructural abnormalities of the ciliary axoneme has been found in patients with PCD. These cause defective ciliary function with resultant impairment of mucociliary clearance. Chronic and recurrent upper and lower respiratory tract disease result.

CILIARY STRUCTURE AND FUNCTION

Distribution of Human Cilia

Cilia are widely distributed throughout the animal kingdom. Throughout the phylogenetic tree, there is little variation in the ultrastructural features of motile cilia involved in the propulsion of mucus and water. These types of cilia have the characteristic 9 + 2 microtubular structure (see later) and are distributed in various organs, including the respiratory tract, oviduct, epididymis, and the ependymal lining of the brain ventricles (Fig. 67-1). There are also cilia with a 9 + 0 microtubular structure that occur transiently during development (embryonic nodal cilia) or on many cell types (e.g., corneal endothelium, thyroid epithelium, glia, neurons, chondrocytes, fibroblasts, and kidney cells) as rudimentary, primary, or monocilia cilia.[11,12] In photoreceptors, 9 + 0 cilia connect the outer and inner segments and, although not motile, they function in the transport of cellular materials (intraflagellar transport) between these parts of the cell. Cilia can also be specialized to act as receptors, as occurs in the olfactory epithelium. Whereas many of these cilia have poorly defined functions, there is increasing evidence that defects of these primary cilia are associated with a range of human diseases, such as polycystic kidney disease, hydrocephalus, forms of retinal degeneration, and Bardet-Biedl syndrome.[11-14] Moreover, the cilia that are present in the node during early embryonic development have a vortical beat pattern and have been implicated in regulating the orientation of the viscera and assignment of laterality (left-right symmetry) during development.[15,16]

Flagella, including sperm tails, have a similar internal structure (axoneme) to the 9 + 2 motile cilia.

Structure of Respiratory Cilia

When ciliated epithelium is adapted for mucus transport, as in the human respiratory tract, cilia are shorter and more numerous and beat mainly within a low-viscosity, periciliary fluid layer, moving a more viscous overlying mucus layer (see Fig. 67-1). The tips of the cilia enter the mucus layer only during the effective stroke and retract beneath the mucus

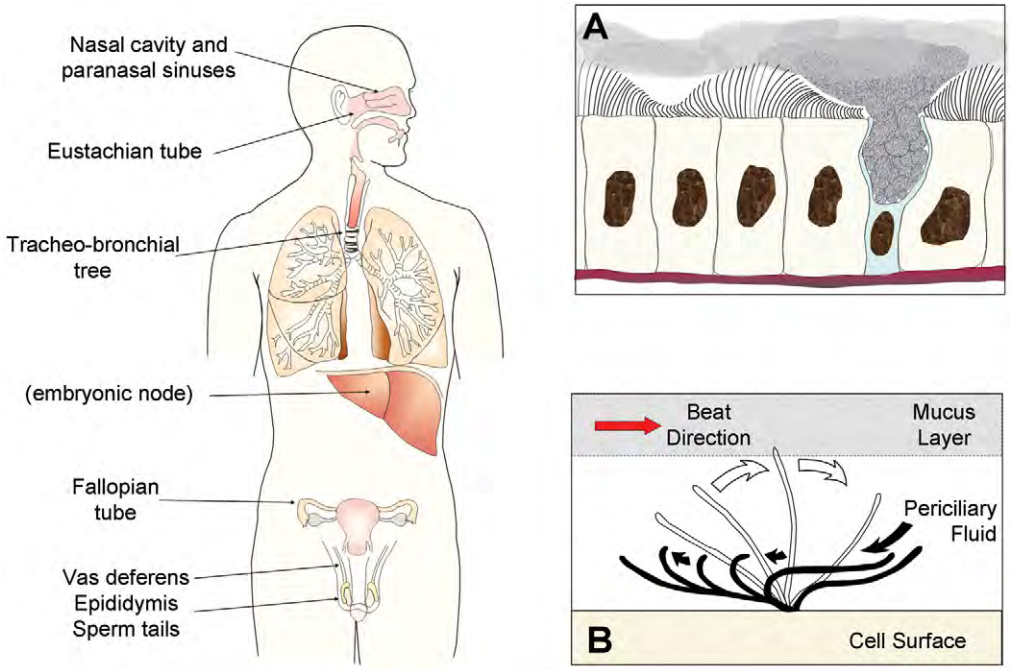

Figure 67-1 Distribution of ciliated organs. The tracheobronchial tree, nasal cavity, and paranasal sinuses are lined by pseudostratified ciliated epithelium, which functions in the clearance of inhaled particles, secretions, cellular debris, and bacterial products from the upper and lower respiratory tract. Ciliated cells are also present in the middle ear, eustachian tube, ependyma, male genital tract, and female genital tract. Other cells can express cilia transiently during embryogenesis. Cilia in the embryonic node are thought to regulate the situs of organs such as the heart and other viscera. **A,** Diagram of a portion of ciliated epithelium. Cilia on the surface of the epithelial cells beat rhythmically in a wavelike motion that moves the overlying mucus produced by the goblet cells within the epithelium and the subepithelial mucus glands. **B,** The beat cycle of a single cilium. The mucus is moved in the same direction as the effective stroke *(open arrows)*. The recovery stroke is shown by the *solid arrows*.

layer during the recovery stroke so that the mucus is moved in one direction only (see Fig. 67-1).

The human tracheobronchial tree is lined by pseudostratified, ciliated epithelium from the larynx down to the level of the terminal bronchiole (see Fig. 67-1). The nasal cavity (apart from its most anterior portion) and the paranasal sinuses are also lined by ciliated epithelium, the predominant direction of clearance being toward the oropharynx. Respiratory epithelium undergoes a continual turnover, with cells being replaced approximately once every 4 to 8 weeks.

Human respiratory tract ciliated cells bear 200 to 300 cilia on their surface. Cilia are elongated motile cylindrical projections from the apical cell membrane, approximately 0.25 μm in diameter, that contain microtubules and cytoplasm in continuity with that of the cell. Human tracheal cilia are 5 to 8 μm long, becoming shorter in more distal airways. Ultrastructural examination of a transverse section of a respiratory tract cilium (Fig. 67-2*B*,C) reveals that the axoneme consists of a characteristic 9 + 2 structure of nine pairs of microtubules (composed of the proteins, α- and β-tubulin) arranged around two single central microtubules that are surrounded and held together by the central sheath. The peripheral doublets are linked to neighboring doublets by fine filaments (nexin links) composed of a protein called nexin. Radial spokes are thicker filaments that project centrally from the "A" microtubule and end in a terminal knob, a short distance from the central sheath and central microtubules. Projecting at regular intervals from the "A" microtubule toward the "B" microtubule of the adjacent outer doublet are the inner and outer dynein arms, which are curved or hooklike filamentous structures. The dynein arms contain proteins with adenosine triphosphatase (ATPase) activity and, according to the sliding microtubule hypothesis of ciliary bending,[17] attach intermittently to the adjacent "B" microtubule, and change shape, with resultant sliding of doublets in relation to each other. Such a cyclical movement of different microtubule pairs in relation to each other causes ciliary bending, first in one direction and then in the other. The microtubules, radial spokes, and nexin links are considered to form a "skeletal" structure for the cilium. This confers properties of elasticity and rigidity on the cilium and may transfer bending forces through the cilium and help the cilium to resume its initial shape after each beat.

The peripheral doublets extend along the length of the cilium and, at the base, continue into the cell in a modified form, becoming triplets and, in association with several accessory structures, form a basal body. Striated or ciliary rootlets extend from the basal extremity of the basal body into the apical cytoplasm. Together with the basal body, they anchor the cilium and maintain the orientation of its direction of beating (see Fig. 67-2*A*). Projecting laterally from the basal body in the direction of the active stroke of the cilium is a structure called the basal foot (see Fig. 67-2*A*). All basal feet in a cell and in the whole epithelium are normally oriented in approximately the same direction,[18,19] so that the effective strokes of all cilia move in the same direction.

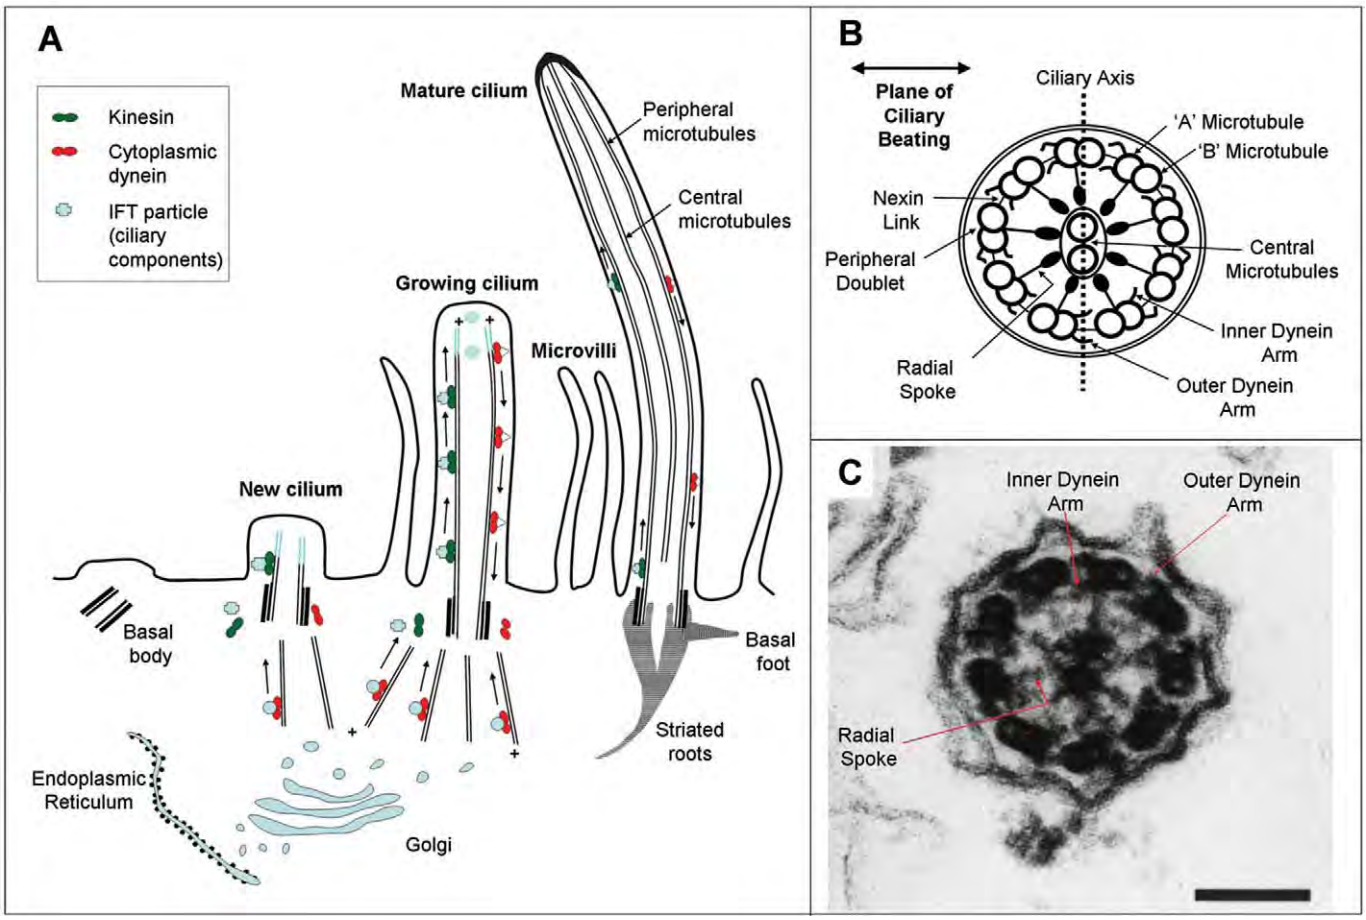

Figure 67-2 **A,** Ciliogenesis and model of intraflagellar transport (IFT). During ciliogenesis, a basal body is formed from centrioles and moves to the apical cytoplasm of the cell. Elongation of the cilium occurs by intraflagellar transport. Ciliary proteins, synthesized in the endoplasmic reticulum and processed by the Golgi complex, are transported in vesicles to the base of the cilium via cytoplasmic dynein complexes operating on microtubules. At the base of the cilium, proteins are processed and concentrated in IFT particles that are transported by kinesin II, interacting with the B tubule, to the tip of the flagellum. Kinesins move toward the plus end of the microtubules. At the tip kinesin II is inactivated and components of the axoneme are added to the growing tip. Cytoplasmic dynein, moving toward the minus end of the microtubules, carries particles back to the base of the cilium. These processes continue to maintain the mature cilium. The final stages of ciliogenesis involve the addition of the ancillary structures that anchor the cilium in the apical cytoplasm (basal foot and striated roots). **B,** Diagram of cilia in transverse section showing the organization of the axoneme. **C,** Electromicrograph of a cilium in transverse section showing normal axonemal structure. Inner and outer dynein arms and radial spokes are indicated. (Scale bar, 0.1 μm. Adapted from References 14, 18, 19, and 46.)

Much of the molecular regulation of ciliary beating has been elucidated from studies of the unicellular, diflagellate green alga *Chlamydomonas reinhardtii*, for which the flagella have been characterized biochemically, and there are numerous genetic mutants that have assisted in identifying genes involved in flagellar motility. From such studies, it is known that the axoneme consists of approximately 250 proteins,[20] and considerable information is available on the composition of the dynein arms and how mutations of the genes encoding these proteins affect flagellar motility.[21-23] Dynein arms, which generate ciliary motility, are large polypeptide assemblies, variably composed of different dynein chains, including 14 heavy (400-500 kDa), 7 intermediate (45-110 kDa), and 15 light (8-55 kDa) chains. Moreover, the outer and inner dynein arms have different compositions: the outer arms are composed consistently of three heavy, two intermediate, and eight light chains, whereas the inner dynein arms have a much more diverse composition of one or two heavy, two or three intermediate, and two or three light chains.[24]

The most recent findings indicate that each component of the axoneme plays a key role in regulating ciliary or flagellar motility. For instance, inner dynein arms are sufficient for generating bending, and together with the central microtubule apparatus and radial spokes determine the size and shape of the waveform, but outer dynein arms provide the power and increase the beat frequency.[22] Increasingly, studies are focussed at studying the roles of individual dynein isoforms in outer and inner dynein arms in regulating the beat cycle.[22,25] Many of the genes identified in *Chlamydomonas* have human homologs, and this has permitted translation of findings to human cilia and provided a basis for identifying mutations that cause ciliary dysfunction in humans (see later).

Physiology of Respiratory Cilia

Human nasal and tracheal cilia beat at a rate of approximately 10 to 15 Hz (600 to 900 beats/min). Each beat consists of two phases: an effective and a recovery stroke.[17] During the

effective stroke, the cilium is extended and moves rapidly around its point of attachment to the cell, extending into and engaging the overlying mucus, thus moving it forward. This is followed by a slower recovery stroke, when the cilium bends on itself and in a different plane to that of the effective stroke, retracting below the mucus layer, within the periciliary fluid, to resume its original position for a short resting phase before the next effective stroke (see Fig. 67-1*B*).

Ciliary beating is coordinated so that each cilium beats slightly later in the beat cycle than the one in front. This results in waves of coordinated beating (metachronal waves) that progress across a field of ciliated cells (see Fig. 67-1*A*). Control of the initiation of ciliary beating is thought to be regulated by calcium ion fluxes within the ciliated cell.[26-29] Two other factors that play a part in ciliary coordination are mechanical stimulation of ciliary activity (as may occur from foreign material) and hydrodynamic forces (which may influence nearby cilia).[17,30] Electric coupling of the cells via gap junctions allows for transmission of calcium fluxes throughout the epithelium.[26,31]

If ciliary beating is impaired or discoordinated, mucus transport is slowed. Effective clearance of mucus requires coordinated ciliary beating, the optimal physicochemical properties of mucus, and efficient interaction of the cilia with the overlying mucus layer. The direction of ciliary beating must be consistent, and the beat patterns must be coordinated and normal.

Ciliogenesis and Intraflagellar Transport

As cilia lack ribosomes, they do not have the machinery required for protein biosynthesis. Thus, all the components of the cilium need to be synthesized and often assembled in the cytoplasm before being transported into the cilium by a process called intraflagellar transport (IFT). The ciliary microtubules not only function in generating ciliary bending but also act as "highways" along which molecular motors, such as kinesin and dynein proteins, transport proteins and particles (see Fig. 67-2*A*). Kinesins and dyneins travel in different directions along the microtubules: kinesins travel toward the plus end of the microtubule and thus move cellular components towards the tip of the cilium (anterograde transport), whereas cytoplasmic dyneins travel toward the minus end of the microtubules and thus move cellular components toward the base of the cilium (retrograde transport).[32,33]

Ciliogenesis involves four stages: (1) formation of new centrioles in the cytoplasm, (2) migration of centrioles to the apical cytoplasm, (3) elongation of cilia, and (4) formation of basal body–associated structures (striated roots, transitional fibers, and the basal foot).[18] Cilium elongation is thought to be initiated at the basal body and involves IFT due to microtubular motors assembling on the outer microtubules of the basal body. The cycling transport (anterograde and retrograde) of particles along the microtubules allows for ciliary components to be added to and removed from the microtubule tips.[34] During ciliogenesis, the basal feet are randomly oriented, but as the ciliary beat cycle becomes established, the basal feet become oriented in the direction of the active stroke. It is thought that this reorientation is achieved by basal body rotation and involves the cytoskeleton in the apical cytoplasm.[35]

The importance of IFT for ciliary function in various cell types has been highlighted by the increasing number of diseases that have been associated with disruptions of IFT genes as well as studies showing that mutations of IFT genes result in phenotypes that model disease processes.[12,13,34,36,37] Thus far, the mutations detected, which have been associated with polycystic kidney, retinal degeneration, and Bardet-Biedl syndrome, appear to affect these processes in primary cilia, which are specialized for sensory function, rather than the motile cilia of the respiratory tract. However, mutations of several IFT genes, particularly kinesin genes (*Kif3a* and *Kif3b*), have also resulted in abnormalities of left-right symmetry (random situs of organs). It remains to be determined whether mutations of IFT genes have a role in PCD or Kartagener syndrome, particularly in patients with abnormal situs and normal ciliary motility or ciliary aplasia.

RECOGNIZED DEFECTS OF RESPIRATORY CILIA

Most patients with PCD have deficient dynein arms (inner, outer, or both). There is a wide spectrum of dynein arm defects, ranging from partial to complete absence (Fig. 67-3). Consistent with findings in *Chlamydomonas*, there are distinct correlations between defects of inner and outer dynein arms and ciliary motility in humans. There is a positive correlation of ciliary motility with the numbers of outer dynein arm numbers seen on electron microscopy but not with numbers of inner dynein arms, indicating that the outer dynein arms are essential for ciliary motility.[38] In patients in whom inner dynein arms are defective, in vitro measures of ciliary beat frequency can be normal but mucociliary clearance (MCC) is still abnormal, suggesting that, while outer dynein arms are sufficient to produce motility in an aqueous in vitro environment, they are ineffective under a mucus load.[38]

A number of other defects have been identified, such as radial spoke defects[39] (see Fig. 67-3*D*), absence of nexin links,[40] and microtubule translocation defects,[41] in which a peripheral doublet passes to the center of the axoneme to substitute for absent central tubules. Abnormal ciliary orientation has been identified in patients with PCD.[19,38,42-48] In some PCD patients, axonemal ultrastructure is normal, but ciliary orientation and/or ciliary function are not.[43,46,49-51]

Abnormally long[52] and short[53] cilia, complete ciliary aplasia,[54-56] abnormal basal bodies,[57] and axonemal cysts[58] have also been reported (Table 67-1). These ciliary structural abnormalities are suggestive of defects of IFT. However, to date, there are no studies reporting mutations of IFT genes in PCD patients with such defects.

CLINICAL FEATURES

Several excellent reviews have been written about the clinical features of PCD and their significance.[59-63]

Patients with PCD usually present with respiratory tract disease. The clinical features range widely in severity, extent, and time of onset (Fig. 67-4). Children may present with neonatal respiratory distress[64] or recurrent lower respiratory

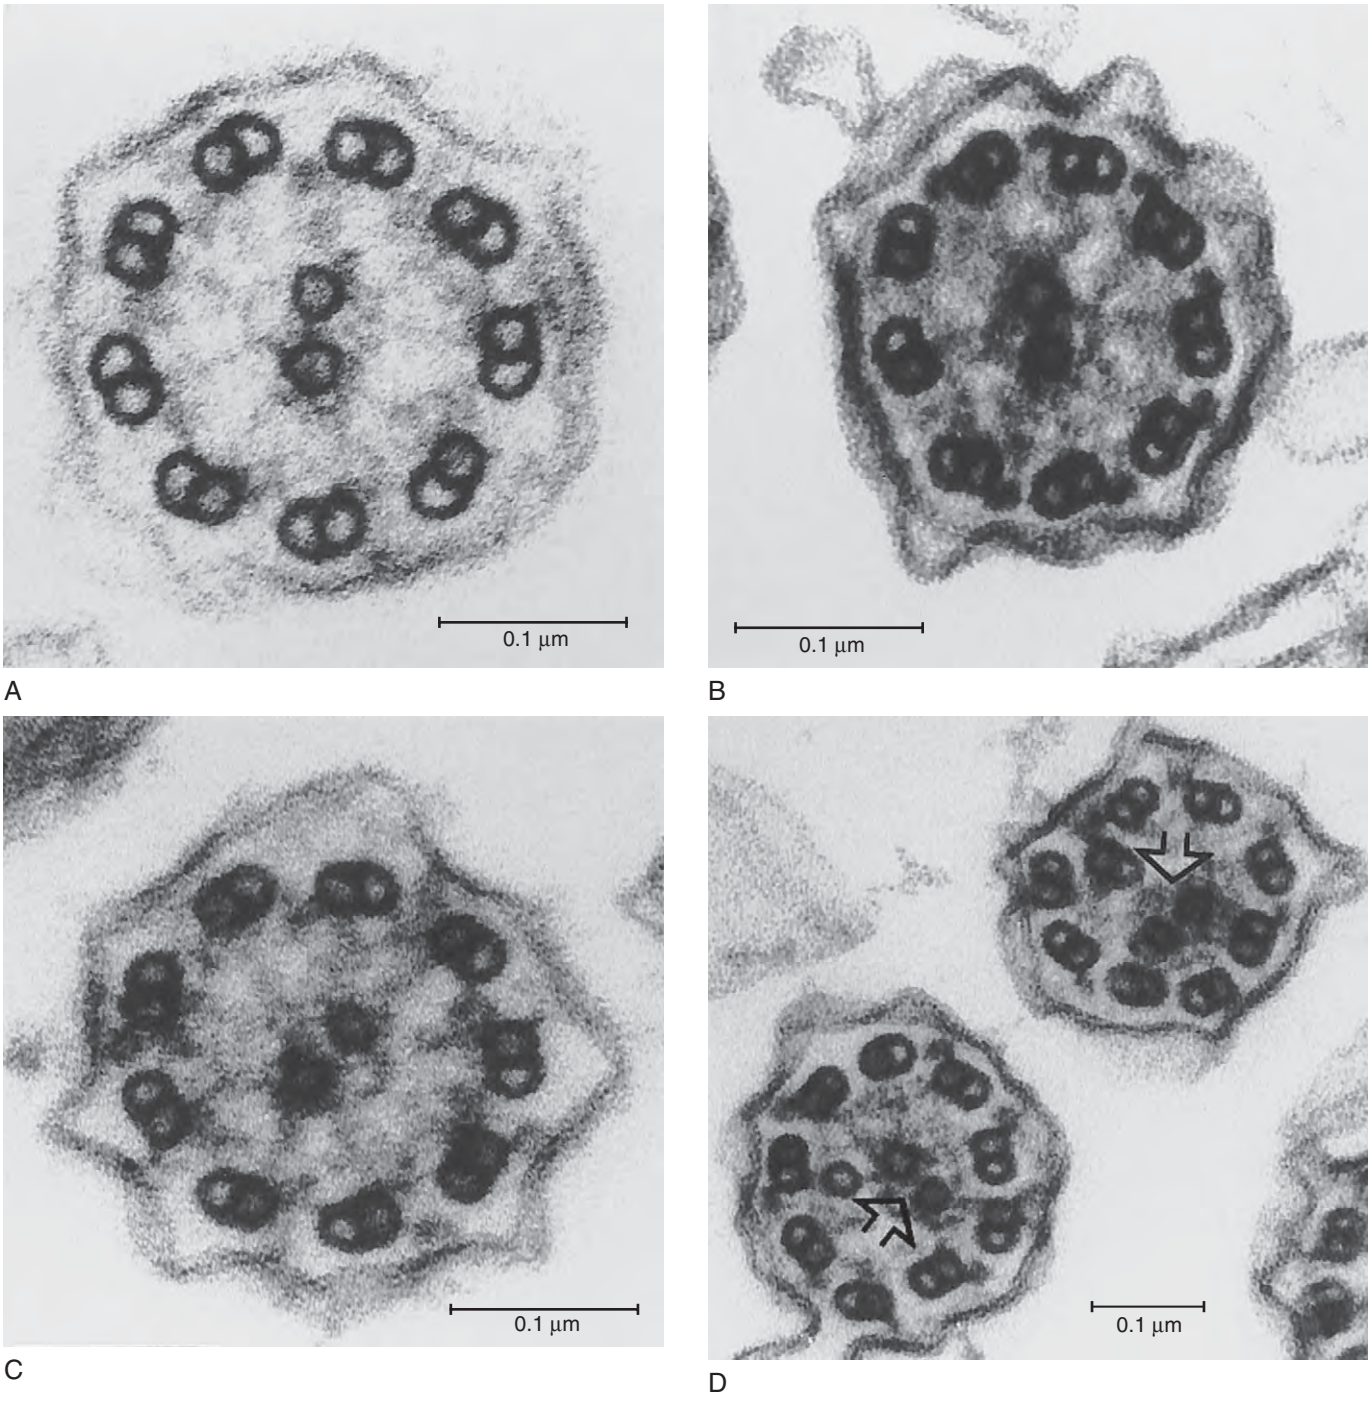

Figure 67-3 Electronmicrographs of ciliary profiles from four patients with primary ciliary dyskinesia, showing a range of dynein arm defects. **A,** Absence of inner and outer dynein arms; cilia from this patient had no motility. **B,** Absence of inner dynein arms; cilia from this patient had beat frequencies within the normal range. **C,** Absence of outer dynein arms; cilia from this patient had very low motility. **D,** Absence of inner dynein arms and radial spoke defects; cilia from this patient had grossly abnormal beat patterns and reduced beat frequencies. *Arrows* indicate eccentrically located central tubules, a feature of the radial spoke defect. (Adapted from de Iongh RU, Rutland J: Ciliary defects in healthy subjects, bronchiectasis, and primary ciliary dyskinesia. Am J Respir Crit Care Med 151:1559-1567, 1995.)

tract infections. These patients almost always have a chronic cough (often productive) as a result of recurrent and, later, chronic bronchitis. In many, this progresses over years to bronchiectasis. The symptoms and clinical findings in these patients are not different from those found in patients with bronchiectasis not caused by defective cilia and may include digital clubbing.

Upper respiratory tract infections are usual, with most patients having chronic sinusitis and recurrent otitis media.[65] Mucopurulent secretions are usually present in the nasal cavity, and nasal obstruction, rhinorrhea, postnasal drip, anosmia, and nasal polyps are common.

Males are almost always infertile; spermatozoa are present in normal numbers but usually have defective motility.

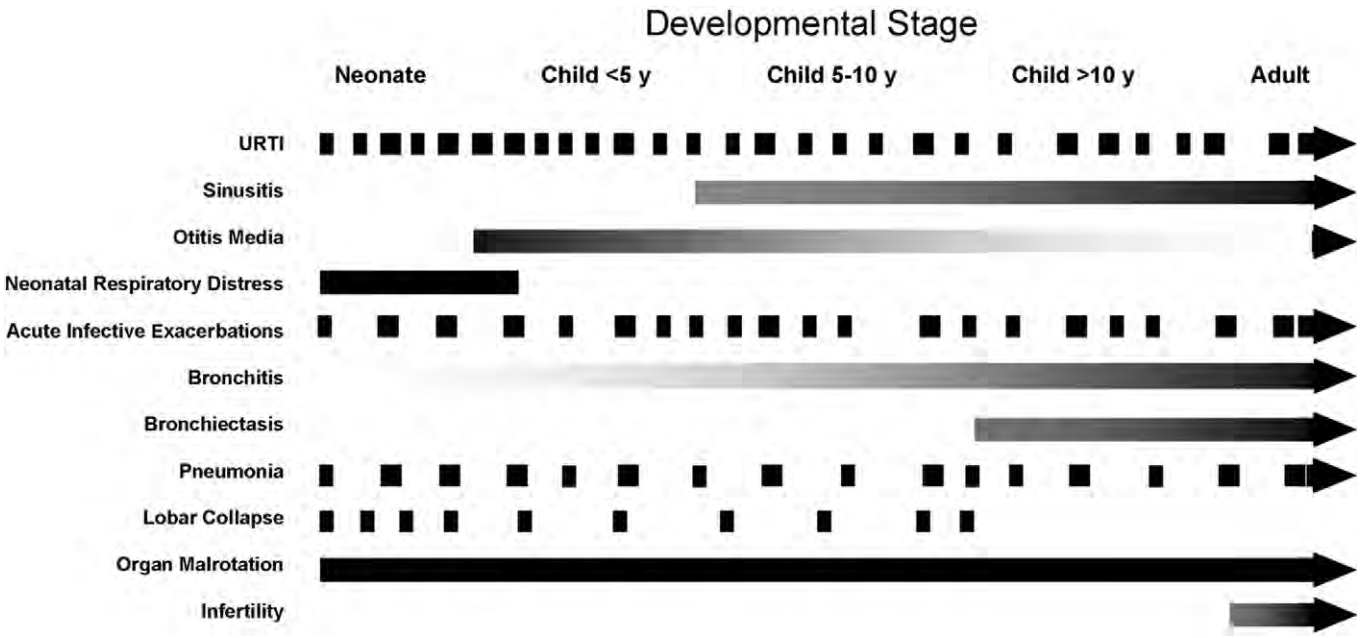

Figure 67-4 Schematic diagram of major clinical features seen in patients with PCD at varying ages. Some (e.g., acute infective exacerbations) occur intermittently, whereas some (e.g., bronchitis, bronchiectasis) develop with time. The presence of neonatal respiratory distress, lobar collapse, and/or organ malrotation should raise suspicion of possible PCD.

Females are usually fertile, despite possible impaired fallopian tube ciliary function.

Malrotation of internal viscera is common. Patients may have dextrocardia, abdominal situs inversus, or situs inversus totalis. Hydrocephalus[66,67] and biliary atresia[68,69] have been reported, but a causal link with PCD has not yet been clearly established.[63,70]

Radiographs of the paranasal sinuses often reveal mucosal thickening, opacification, or fluid levels. Chest radiographs may reveal changes consistent with bronchiectasis that can be imaged by high-resolution computed tomography scanning. When indicated, both rhinoscopy and bronchoscopy reveal excessive and often purulent secretions.

When measurements of MCC are available, this is always reduced. Other investigations of respiratory function reveal abnormalities of variable severity. These may include airway obstruction, gas trapping, and arterial hypoxemia.

Kartagener's original description[4] was of a triad consisting of chronic sinusitis, bronchiectasis, and situs inversus totalis (now commonly interpreted as the presence of any organ malrotation: dextrocardia or situs inversus viscerum). A study[59] of the clinical features of patients with recurrent respiratory tract disease caused by PCD compared with patients without PCD showed that although patients who manifested the triad were likely to have PCD (86%), the use of these criteria alone was an insufficient basis for suspecting PCD; of the patients with PCD, only 29% presented in this way. It is often not appreciated that most patients with PCD do not present with Kartagener syndrome. The diagnosis of PCD may be delayed despite the presence of sentinel symptoms,[71] and many patients are not diagnosed until adulthood. Delay in diagnosis may lead to poor outcomes such as learning and behavioral difficulties caused by deafness and inappropriate upper and lower respiratory tract surgery. In most patients, the respiratory disease progresses slowly. Prognosis is good and, for most affected subjects, life expectancy is normal.[62]

Table 67-1
Types of Ciliary Ultrastructural Defects Identified in PCD

	Ciliary Defect	Reference(s)
I	Dynein arm defects Inner dynein arms Outer dynein arms Inner and outer dynein arms	1, 2, 5-7
II	Radial spoke defect	39
III	Microtubule translocation defect	41
IV	Normal ultrastructure but impaired function	49-51
V	Random ciliary orientation	19, 23, 43-48
VI	Ciliary aplasia	33, 54, 56, 66
VII	Abnormally long cilia	52
VIII	Abnormally short cilia	53
IX	Abnormal basal bodies	57
X	Axonemal cysts	58

GENETICS

The estimated prevalence of PCD varies from 1 : 12,500 to 1 : 60,000, based on the assumption that PCD is at least twice as common as Kartagener syndrome.[72,73] It affects both sexes and has been found in all racial groups. Although the incidence appears to increase with consanguineous parentage, it is not affected by increased parental age. Cytogenetic studies generally show normal karyotypes.[73] Inheritance is predominantly autosomal recessive, although there are reports of autosomal dominant and X-linked modes of inheritance.[72,74]

PCD is a congenital defect, and the structural and functional abnormalities have been shown to be present in motile cilia from different tissues (nasal, tracheal, sinus, oviduct) and also to be similar in affected siblings. Although clinical findings are homogeneous, PCD appears to be caused by a group of heterogeneous genetic disorders, based on the observation of the various ultrastructural defects. Indeed, genome-wide scans and linkage analyses indicate that even within groups of patients with similar ultrastructural findings, there is significant heterogeneity of linked loci.[75] Proteomic analysis of human cilia[76] indicates that there are approximately 240 distinct polypeptides in the axoneme; thus, the potential for mutations to affect axonemal structure and function is large.

Two main approaches have been used to identify genes that cause PCD: (1) the candidate gene approach uses the known function of genes in animal models of ciliary function or laterality disorders, whereas (2) linkage studies investigate the association of numerous specific chromosomal markers with disease in PCD families. Despite the large number of genes involved in the axoneme and the numerous candidate genes and loci that appear to be associated with ciliary dysfunction or laterality defects in animals, mutations in only three genes—*DNAI1* (Online Mendelian Inheritance in Man [OMIM] 604366),[77] *DNAH5* (OMIM 603335),[78] and *DNAH11* (OMIM 603339)[79]—have thus far been shown to be responsible for ultrastructural defects of respiratory cilia in patients with PCD. Mutations in these genes, encoding intermediate and heavy chain dyneins, have been implicated in outer dynein arm deficiencies (including shortened and absent outer dynein arms) as well as situs inversus.[80-87] Linkage studies have identified numerous potential PCD loci at various chromosomal regions (4q, 5p, 6p, 8q, 10p, 11q, 13q, 15q, 16p, 17q, and 19q), but gene mutations causing PCD at these loci have not yet been identified.[72,88]

LEFT-RIGHT AXIS ASYMMETRY

Approximately 50% of patients with PCD have abnormal situs of the viscera and/or dextrocardia (Kartagener syndrome). In his original paper, Afzelius[2] proposed that motile cilia, present on cells of developing organs in the embryo, were responsible for positioning the organs during development and that the loss of motility of these cilia led to random organ positioning. Several studies have since shown that in the early mouse embryo (E7.5) cells in the node of the primitive streak, which is located in the posterior tip of the gastrulating embryo and is the major organizing center of the embryo, have single cilia[89,90] that project ventrally into the extracellular fluid. These nodal cilia have a vortical beat pattern and have been shown to generate an asymmetric leftward flow of extracellular fluid across the embryo.[15,89,91-93] The fluid is hypothesized to contain morphogens, which initiate the differential patterns of gene expression in the left and right sides of the embryo[94] that specify the left-right axis. This nodal flow model of left-right determination has recently been modified to incorporate cilia that act as mechanosensors of the nodal flow. It is proposed that these mechanosensory cilia transduce the flow generated by the nodal cilia and elicit cellular signals that contribute to the asymmetric signaling and gene expression between the left and right sides of the embryo.[95] While several genes have been identified in mouse models as having key roles in regulating nodal cilia and laterality, very few have been implicated in PCD/Kartagener syndrome.

DIAGNOSIS

The presence of PCD should be considered in all patients with recurrent or chronic lower and upper respiratory tract infections when no other cause, such as cystic fibrosis or immunodeficiency, has been demonstrated. A number of specialized investigations assist in establishing the diagnosis of PCD (Fig. 67-5).

Nitric Oxide

Studies of nitric oxide (NO) concentration in exhaled air have demonstrated a marked reduction in patients with PCD.[96-100] Reduced airway NO concentrations have also been demonstrated in cystic fibrosis[99-103] and in systemic sclerosis with pulmonary hypertension.[104] The use of nasal NO measurements (nNO) has proved far more discriminatory than exhaled NO. Nasal NO measurements (available in some specialized units) have been shown to be a reliable and noninvasive screening tool in PCD in children who are old enough to cooperate with the breath-hold required.[97-100] A nNO concentration greater than 250 ppb excludes the presence of PCD.[97,99] However, it should be noted that a low nNO concentration does not confirm the diagnosis of PCD. This must be done by studies of ciliary function and structure.

Mucociliary Clearance

Mucociliary clearance is abnormal in PCD and can be measured by the rate of clearance of an inhaled radiolabeled aerosol from the lung, or mucus transport rate of a marker can be measured directly in the respiratory tract. These specialized investigations are not widely available and have limited application in pediatric practice. Nasal MCC may be gauged with the saccharin technique[105-107] in older children. This involves placement of a small particle of saccharin (approximately 1 mm^3) on the inferior turbinate. The time taken for the particles to be carried posteriorly to the oropharynx, where they stimulate taste receptors, is measured as the nasal clearance time. This is normally less than 30 minutes.[106,107] Many factors affect the reliability of this technique and its usefulness is limited to that of a screening test. Mucociliary clearance is impaired in many respiratory diseases (such as cystic fibrosis, sinusitis, and postviral infections) and a finding of impaired MCC alone does not necessarily indicate the presence of a ciliary defect.

Ciliary Function

Suitable samples of ciliated epithelium may be obtained by mucosal brushing at bronchoscopy or rhinoscopy.[108] Ciliary beat frequency can be measured in vitro and has been shown to be correlated between the nasal cavity and lower respiratory tract.[109] The use of nasal mucosal brushings avoids the morbidity often associated with the use of nasal biopsy forceps and the requirement for local anesthesia. Ciliary

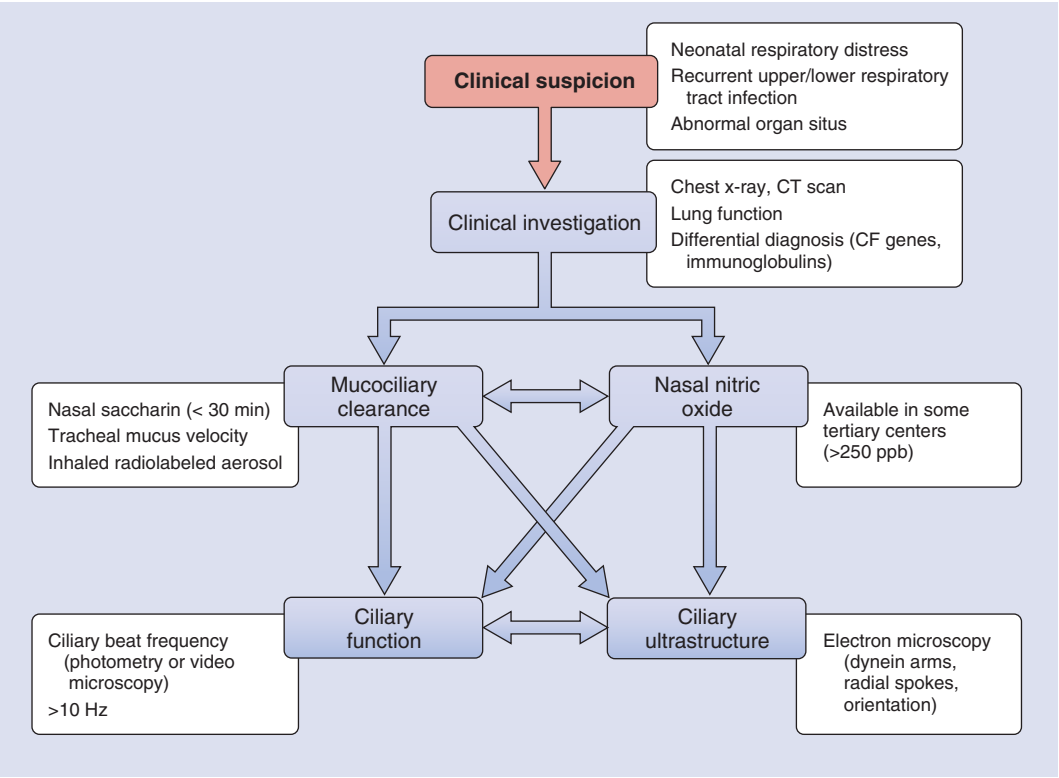

Figure 67-5 Algorithm of investigations in suspected PCD; different tests are available in various institutions.

beating may be observed in mucosal brushings suspended in nutrient medium by light microscopy and can be measured by microscope photometry[108,110] and other techniques such as high-speed cinematography and video.[111,112] Ciliary beat pattern and coordination can be observed and filmed but not readily quantified.

Ciliary Ultrastructure

Mucosal brushings can also be placed into fixative for examination by high-magnification (×100,000 to ×200,000) electron microscopy[113,114] (see Figs. 67-2 and 67-3). There is concordance between the nasal cavity and lower respiratory tract in ciliary ultrastructure.[115] If possible, abnormalities of structure and function should be studied in more than one body site or on more than one occasion, particularly if the diagnosis is in doubt. In postpubertal male patients, sperm motility and ultrastructure can be determined. However, because spermatozoan and ciliary axonemes may be regulated by different genes,[120] ultrastructural defects in spermatozoa and cilia may not be concordant in some patients. Ciliary ultrastructure has been quantified by many investigators,[38,42,114,116,117] and several distinct types of ciliary ultrastructural defects that lead to respiratory disease have been identified (see Table 67-1). The orientation of cilia can also be studied and quantified.[19,118,119] In various studies, up to 10% of cilia in normal subjects may have ultrastructural defects. These are usually microtubular defects or compound cilia.[38,42,116,117] Transitory ciliary defects have been reported in cilia from patients with respiratory tract infection,[121,122] and these reflect a secondary ciliary dysfunction. Ideally, patients should not be studied at times of acute infection and ultrastructural studies should be complemented by measurements of ciliary function.

TREATMENT

No specific therapy is yet available for the management of PCD. This is a chronic condition and the main directions of management are aimed at the treatment of lower respiratory tract infections and minimization of end organ (particularly lung) damage. Immunization against respiratory pathogens is essential. For patients who have progressed to bronchiectasis, physical removal of secretions by postural drainage and other forms of physiotherapy is helpful and may limit progression of disease. In acute infective exacerbations, antibiotics and physiotherapy are appropriate. A number of drugs such as β-adrenergic agonists and xanthines have been shown to stimulate ciliary beating in vitro and to increase mucociliary clearance in patients,[123] but their efficacy in clinical practice in patients with defective cilia has not been documented. In one study[124] bronchodilation was enhanced more by exercise than by inhaled β_2-agonists. In another, aerosolized uridine triphosphate improved MCC in patients with defective cilia.[125] Mucolytics have not been shown to be effective in patients who have PCD. Antitussives are to be avoided because, in patients with impaired MCC, cough may be the only remaining mechanism for removing respiratory tract secretions. Early diagnosis and treatment of respiratory tract infections may slow progress to bronchiectasis. Surgical resection of affected lung is rarely necessary and should be avoided because the basic defect is not confined to one part of the lung. Insertion of myringotomy tubes should be undertaken with caution, because of concern that chronic purulent otor-

rhea may result.[61] In rare instances, lung disease may progress sufficiently for lung transplantation to be considered (normal ciliary function has been shown to continue in the transplanted lung).[126-129] Patients with PCD are best managed in a multidisciplinary environment.

Future directions for research include the use of nebulized mannitol, which has been shown to increase MCC in bronchiectasis,[130,131] and more specific therapies such as inhaled purines and possibly L-arginine.[131-133]

SECONDARY CILIARY DYSFUNCTION

Delayed MCC often occurs secondary to respiratory tract diseases, particularly those in which purulent secretions are common, such as bronchiectasis, cystic fibrosis, and sinusitis. During viral and bacterial infections, the rheologic properties of mucus may change, becoming less elastic during viral infection[134] or more viscous in bacterial infections.[135] Similarly, viral or bacterial infections may cause changes in the ciliated epithelium, both structural and functional, and thus cause impairment of MCC.[136-138] Purulent infection has been shown to cause reduced ciliary beat frequency and abnormal ciliary beat patterns (ciliary dyskinesia).[139] Disruption of ciliary function and structure can also be caused by cell products such as elastases and proteinases liberated by leukocytes in inflammatory lung disease.[140]

Secondary ciliary dyskinesia may result from factors produced by bacteria. Organisms that are known to affect ciliary activity or integrity of the ciliated epithelium and thus affect mucociliary clearance include *Pseudomonas aeruginosa*, *Haemophilus influenzae*, *Staphylococcus aureus*, *Mycoplasma pneumoniae*, *Bordetella pertussis*, and *Streptococcus pneumoniae*.[140]

CONCLUSION

Impairment of MCC may occur as the result of a congenital defect (PCD) or a secondary ciliary dysfunction. Situs inversus can be due to defects of embryonic nodal cilia, which share many genes with respiratory cilia. Secondary ciliary dysfunction can be caused by a variety of microorganisms. In PCD, impaired mucociliary clearance, affecting particularly the upper and lower respiratory tracts, leads to sinusitis, bronchitis, and bronchiectasis. Mutations in three dynein genes have been identified in patients with PCD. Measurement of MCC and nasal NO are useful for screening patients with a clinical suspicion of PCD. However, a definite diagnosis is still usually made by studies of ciliary function and structure. No specific effective treatment is currently available for PCD.

CHAPTER 68 Abnormalities of the Pleural Space

Danna Tauber and Daniel V. Schidlow

TEACHING POINTS

- The pleura allows for mechanical coupling of the lung and chest wall throughout the respiratory cycle.
- Pleural fluid accumulates in the pleural space either by an increase in fluid production or by obstructed fluid drainage.
- Pleural effusions can present with dyspnea, cough, pain, tachypnea, and diminished breath sounds.
- Treatment of purulent effusions includes antibiotics, antibiotics plus chest tube drainage, chest tube drainage plus fibrinolytic therapy, and early debridement by video-assisted thoracoscopic surgery (VATS).
- Pneumothorax presents with the sudden onset of chest pain, tachypnea, and dyspnea.
- Treatment of pneumothorax depends on the size, cause, extent of respiratory distress, and presence of underlying lung disease.

The pleural space is a cavity surrounded by two membranes. The visceral pleura covers the entire surface of the lung, and the parietal pleura covers the inner surface of the chest wall, mediastinum, and diaphragm. The two membranes meet at the hilar root of the lung. The normal pleural space is approximately 18 μm wide at its least dependent point and widens to about 20 μm in the dependent regions.[1] Under normal conditions, the pleural space contains 0.1 to 0.2 mL/kg of fluid with a protein concentration of less than 1.5 g/dL that flows down gravity-dependent gradients.[2,3] The pleural membranes and the space they define play an integral function in respiration. The pleura allows for mechanical coupling of the lung and chest wall throughout the respiratory cycle, providing support to the lung tissue while allowing the lung to move extensively in relation to the chest wall. The anatomy and structure of the pleural space are essential to an understanding of its function and abnormalities.

EMBRYOLOGY AND ANATOMY

By the third week of gestation, the pleural, pericardial, and peritoneal spaces begin to develop. All of these cavities are lined by visceral and parietal membranes made up of mesothelial cells. As the lung develops, the lung buds invaginate into the visceral pleura and become invested in this layer. The mesothelial cells can be flat, cuboidal, or columnar in shape. They have microvilli projections on their free surface. Mesothelial cells are capable of multiple functions, including active transport of small particles,[4] secretion and organization of components of the extracellular matrix such as collagen, elastin, and connective tissue glycoproteins,[5] secretion of neutrophil and monocyte chemotactic factors,[6] phagocytosis of particles,[7] and production of fibrinolytic and procoagulant factors.[8]

Stomata are 2- to 12-μm openings between mesothelial cells of the parietal pleura.[2] These stomata communicate the pleural space and lymphatics, allowing for clearance of large particles and blood cells.[9] The fluid flows into lacunae, spider-like submesothelial collecting lymphatics, which drain into intercostal lymphatics. From there, fluid drains into mediastinal, parasternal, and periaortic nodes, subsequently into the thoracic duct, and ultimately into the systemic venous system[2] (Fig. 68-1).

The parietal pleural is fed by the intercostal arteries. The visceral pleura is supplied by the bronchial circulation and is drained by the pulmonary veins.[10,11] Because the pulmonary venous system is a low-pressure system, the perfusion pressure is lower in the visceral pleura.[10] The parietal pleura has sensory nerve fibers supplied by intercostal and phrenic nerves, whereas the visceral pleura has no sensory nerve innervation.

PHYSIOLOGY OF THE PLEURAL SPACE

Pressure in the pleural space is subatmospheric. Gases do not accumulate in the pleural space because the sum of all partial pressures of gases in venous blood and tissue is lower than that of atmospheric or alveolar gas. There is a 60-mm Hg pressure gradient that maintains dissolved gases in the venous blood and promotes absorption of gases from the pleural space.

The small amount of fluid contained within the pleural space is the result of a dynamic balance between fluid filtered from subpleural capillaries into the intrapleural space and removal of fluid from the space via lymphatics. Sufficient fluid must remain in the pleural space to provide lubrication for the lungs to move but not so much as to uncouple the mechanical forces of the chest wall and the lung.[12]

Starling forces across both the parietal and visceral membranes favor filtration of fluid out of the capillaries and into the interstitial spaces.[4] Fluid then filters from the interstitial spaces into the pleural space because the pleural liquid pressure is subatmospheric and therefore lower than interstitial pressure.[4,12,13] Fluid, cells, and protein are then removed

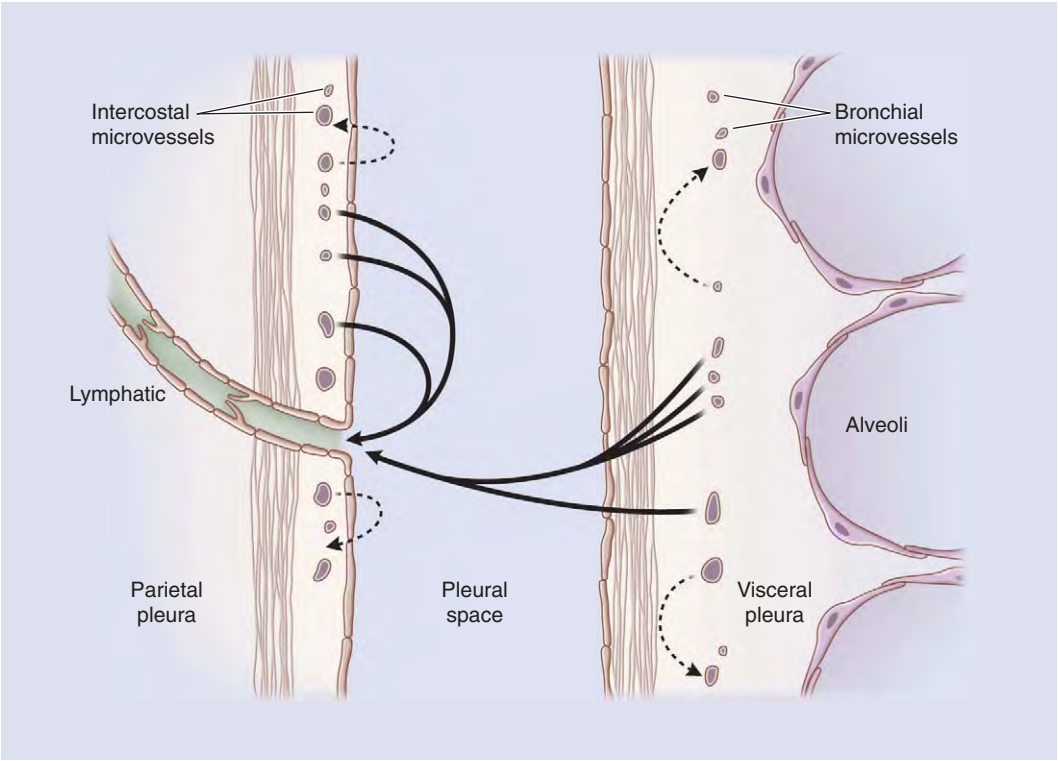

Figure 68-1 Schema showing normal pleural liquid turnover. The initial microvascular filtrate in the parietal and visceral pleura is partly reabsorbed (*dashed arrows*). The remaining low-protein interstitial liquid flows across the leaky pleural mesothelial layers into the pleural space. The pleural liquid exits the pleural space via the parietal pleural lymphatic stomata. (Redrawn from Staub NC, Wiener-Kronish JP, Albertine KH:Transport through the pleura: Physiology of normal liquid and solute exchange in the pleural space. In Chretien J, Bignon J, Hirsch A [eds]: The Pleura in Health and Disease [Lung Biology in Health and Disease, Vol. 30]. New York: Marcel Dekker, 1985, p. 182.)

from the pleural space by the lymphatics of the parietal pleura via bulk flow and not by diffusion or active transport.[4,13] There are two essential mechanisms for fluid accumulation in the pleural space: (1) changes in the balance between hydrostatic and oncotic pressures result in increased fluid production as can changes in the permeability of the capillary membrane or (2) fluid removal is disturbed by obstruction of the lymphatic drainage (Table 68-1).

CLINICAL MANIFESTATIONS

The severity of presenting signs and symptoms of pleural effusion directly correlates to its size and nature. Small effusions rarely cause symptoms. Larger effusions cause dyspnea, dry cough, and orthopnea due to lung compression. Pain results from stretching of the sensory nerve fibers of the parietal pleura, which worsens with inspiration and can radiate to the chest or shoulder. Breath sounds are diminished over the affected area, as are tactile and voice fremitus. There is increased resonance of the voice (egophony) and dullness to percussion. Larger effusions can cause tachypnea, decreased rib excursion, ipsilateral bulging of the intercostal spaces, and contralateral displacement of the heart and trachea.

A chest radiograph is the first laboratory examination that should be done when considering a diagnosis of pleural effusion. With larger effusions, a meniscus is present at the costophrenic angle when the patient is in the upright position.[14] Lateral decubitus films are useful in cases where a "white-out" is seen to differentiate solid underlying lung collapse or consolidation from pleural effusion. The fluid "layers out," allowing abnormalities such as mediastinal masses or lung consolidation to be visualized. Ultrasound and computed tomography (CT) are helpful in differentiating empyema from simple effusions. An ultrasound examination can estimate the size of an effusion and can differentiate free from loculated fluid and can also identify septations in pleural fluid collections.[15,16] CT scans assist in delineating loculated pleural fluid and parenchymal lung abnormalities such as a lung abscess, as well as defining possible mediastinal pathology or mediastinal tumors.[17,18]

DIAGNOSIS

The best method of determining the cause of an effusion is sampling of the fluid accumulation. Thoracocentesis is impractical if the effusion is small or if the cause is known (i.e., congestive heart failure, nephrotic syndrome, ascites, or peritoneal dialysis). Thoracocentesis may be safely performed when a layer of at least 1 cm of fluid is present on decubitus films. If no fluid shift is seen, ultrasound may reveal loculated fluid and guide thoracocentesis or chest tube insertion. Complications of thoracocentesis are pneumothorax, pain, and bleeding due to improper insertion of the needle into the nerve, blood vessel, or lung parenchyma. Intercostal nerve damage, puncture of the liver or spleen, and secondary empyema have been reported.[19-21]

Table 68-1
Pathophysiology of Pleural Fluid Accumulation

Effusion Type	Mechanism	Clinical Diagnosis
Transudate	Increased capillary hydrostatic pressure	Overhydration, congestive heart failure, venous hypertension, pericarditis
	Decreased hydrostatic pressure of the interstitial space	Trapped lung with chronic pleural space, post-thoracentesis
	Decreased plasma oncotic pressure	Hypoalbuminemia, nephrotic syndrome, hepatic cirrhosis
Exudate	Increased permeability of the capillary membrane	Infection—pleural or parenchymal, circulating toxins
		Connective tissue disease: systemic lupus erythmatosus, rheumatoid arthritis, sarcoidosis
	Impaired/obstructed flow	Malignancy: lymphoma, leukemia, neuroblastoma, chest wall sarcoma, Wilms tumor, hepatoma
		Pancreatitis
		Subphrenic abscess
		Superior vena caval syndrome
	Increased oncotic pressure of the interstitial space	Pulmonary infarction
Chyle	Leakage from lymphatic vessels	Thoracic duct injury post cardiac surgery
	Obstruction of lymphatic vessels or vena cava	Tumors (i.e., lymphoma)
		Tuberculosis
		Sarcoidosis
	Congenital abnormalities (thoracic duct atresia or abnormal connections)	Trisomy 21, Noonan syndrome, extralobar sequestration, lymphangiomatosis, or lymphangiectasia
Blood	Vascular leak	Trauma, spontaneous rupture, vascular erosion by neoplasm, hemorrhagic disease

Table 68-2
Pleural Fluid Appearance

Fluid Appearance	Cause
Grossly purulent fluid	Empyema; rarely pancreatitis, ruptured esophagus
Thick, tan-brown	*Staphylococcus aureus*
Putrid	Anaerobes
Also bloody	Group A *Streptococcus*
Milky fluid	Chylothorax
Bloody fluid	Hemothorax, traumatic thoracocentesis, malignancy, tuberculosis, uremia, or empyema due to group A *Streptococcus*
Yellow-green fluid, debris	Rheumatoid arthritis
Black fluid	*Aspergillus niger*
"Anchovy" brown fluid	*Entamoeba histolytica*

Table 68-3
Laboratory Studies to Be Obtained in All Cases of Pleural Fluid Accumulation

Specimen	Laboratory Study
Pleural fluid	Protein
	Lactic dehydrogenase (LDH)
	Glucose
	pH
	Cholesterol
	Bacterial culture and Gram stain
	Differential cell count
	Staining and culture for acid-fast bacilli
	Amylase
Serum	Complete blood cell count
	Complete metabolic panel including:
	LDH
	Total protein
	Glucose
	Albumin
	BUN/creatinine

Pleural fluid appearance varies with the cause (Table 68-2). Transudates are serous or straw colored, whereas chylous effusions are milky. There are a number of laboratory studies that should always be performed on the sampled fluid (Table 68-3). Analysis of the fluid should first determine if the effusion is transudative or exudative[22] (Table 68-4). Exudative effusions arise from inflammation of the pleural membranes or lymphatics resulting in leaky capillary membranes that allow passage of large particles such as proteins.[23] Therefore, exudates have elevated protein, lactic dehydrogenase (LDH), and cholesterol. LDH levels rise as a result of tissue breakdown from inflammation and thus serves as a marker for inflammation. Transudates are not associated with inflammation, so their protein and LDH levels are low. Additional studies should be performed in cases when certain characteristics of the pleural fluid are seen (Table 68-5).

TRANSUDATES

A transudate develops from an imbalance of hydrostatic or oncotic pressure. Inflammation is not present; therefore, transudates have a low cellular count and low protein concentration. Correction of the forces governing pleural fluid homeostasis will lead to resolution of the transudate; drainage is required only for immediate symptomatic relief. Disorders associated with transudative effusions in children include atelectasis, nephrotic syndrome, left ventricular failure, free peritoneal fluid, and hypothyroidism.

Table 68-4
Distinguishing Exudate from Transudate

Exudate	Fulfill at least one of the following criteria:
	Pleural fluid/serum lactic dehydrogenase (LDH) > 0.6
	Pleural fluid/serum protein >0.5
	Pleural fluid LDH > $^2/_3$ upper limit of normal serum values
	Pleural fluid cholesterol >55 mg/dL
Transudate	Fulfill none of the above criteria

Table 68-5
Additional Studies to Be Obtained in Specific Cases

Effusions	Studies
Purulent	Blood culture Sputum culture Serum C-reactive protein
Lymphocytic	Fluid cytospin/cytology Fluid triglyceride level Tuberculin skin test Effusion and serum antinuclear antibody, rheumatoid factor, and complement Fungal titers and skin tests
Bloody	Fluid hematocrit Fluid triglyceride level Fluid hemosiderin-laden macrophages

Atelectasis, trapped lung, and upper airway obstruction can cause effusions by generating excessive negative pleural pressure.[13] Parietal pleural pressure becomes more negative when lung separates from parietal pleura or when inspiratory effort against an obstruction increases.

In nephrotic syndrome, a decrease in oncotic pressure from hypoalbuminemia coupled with an increase in hydrostatic pressure from fluid overload favors movement of fluid into the pleural space.[13] The resulting effusions are generally small and bilateral and resolve with correction of the hypervolemia and protein concentration. Thoracocentesis is indicated with chest or abdominal pain, unilateral or large effusions, fever, or pulmonary infiltrates. If effusion persists after correction of renal function, thoracocentesis should be performed to evaluate for infection, thromboembolism, or collagen vascular disease. Therapeutic thoracocentesis should be performed with caution because removal of a large amount of fluid can result in hypotension.

Patients with cardiac disease develop effusions when left atrial or pulmonary capillary wedge pressure is elevated.[23,24] Effusions are usually bilateral; if unilateral, they are typically right sided.[25] Fluid collections that persist for several months can become exudative due to reabsorption of water over protein.[26] In some cases, repeated thoracocentesis or pleurodesis is necessary to control symptomatic effusions that result from refractory heart failure.[27]

Free fluid in the peritoneal cavity can traverse small openings in the diaphragm and enter the pleural space. Effusions caused by ascites usually occur on the right side,[28] whereas effusions secondary to dialysis are usually bilateral and small.[13,29] Hypothyroidism has been reported to cause effusions as a result of significantly lowered metabolic state. These are often associated with heart failure, pericardial effusions, or ascites and respond to thyroid replacement.[30]

EXUDATES

Exudative effusions result from inflammation of the pleura or obstruction of lymphatic flow. Inflammation leads to leakage of fluid and protein from pleural capillaries and blocks reabsorption of the fluid by the lymphatic lacunae of the parietal pleura. Diffuse destruction or obstruction of lymphatic vessels, which occurs in malignancy or granulomatous disease, also can result in pleural fluid accumulation. The cause of an exudative effusion is not often evident from the clinical presentation. The diagnosis can be narrowed by the appearance of the fluid and the principal cell type found in the fluid (Table 68-6).

NEUTROPHILIC PREDOMINANCE (PURULENT EFFUSION)

Purulent or parapneumonic effusions are a rare but recognized complication of bacterial pneumonia. Studies have cited an incidence of 0.4 to 6 cases per 1000 pediatric hospital admissions.[31] Empyema is defined as the presence of pus in the pleural space. There are three distinct phases of development of an empyema[32] (Table 68-7). Early in the process, in the *exudative phase*, the fluid that accumulates is thin and free flowing, with normal values of glucose, pH, LDH, and a low white blood cell count. In the *fibrinopurulent phase*, there is a deposition of fibrin in the pleural space leading to septation (fibrous strands) and loculation (parietal-visceral pleural adhesion) of infected fluid. The white blood cell count increases as the fluid thickens. The pH and glucose fall as the LDH level rises secondary to the bacterial consumption of glucose and release of lactic acid. In the final, *organizing phase*, fibroblasts invade the cavity, forming a dense peel on both pleural surfaces while the fluid becomes a thick, gelatinous mass. This visceral pleural peel contracts, leading to compression and trapping of the lung. The pH and glucose levels are extremely low, whereas the LDH is very elevated. This stage has also been referred to as complicated empyema. Further complications are uncommon in children but include bronchopleural fistula, lung abscess, or even perforation through the chest wall (empyema necessitatis).

Identification of a causative organism from the pleural fluid or blood is made difficult by the use of antibiotics before the diagnosis of parapneumonic effusion is made. The most frequently recovered pathogens include *Streptococcus pneumoniae*, *Streptococcus pyogenes*, and *Staphylococcus aureus*.[33] Of these, *S. pneumoniae* has emerged as the predominant pathogen in childhood empyema. Polymerase chain reaction (PCR) can be used in culture-negative cases and has identified a pathogen in 75% of those cases.[34] *S. aureus* causes a more severe pneumonia and empyema than other pathogens. The increasing incidence of methicillin-resistant *S. aureus* in the community poses a new challenge to successful treatment. Other pathogens include *Klebsiella* spp, *Pseudomonas* spp., anaerobic organisms, and viruses.[35]

Clinical manifestations of parapneumonic effusions are very similar to those of classic pneumonia—fever, cough, lethargy, malaise, poor appetite, and lower exercise tolerance. However, in the presence of a purulent effusion, the child will appear sicker with pleuritic chest pain and splinting of the affected side. Suspicion for a parapneumonic effusion should be raised in the case of pneumonia that does not respond to traditional treatment within 48 hours.[36]

Diagnosis of a parapneumonic effusion is made on chest radiograph. Staging of the effusion can be made with either computed tomography or ultrasound (Fig. 68-2). Recent studies point to the advantages of early ultrasound in diagnosing effusions in the fibrinopurulent or organizing phase. Ultrasound is able to differentiate loculated, septated fluid from free-flowing effusions as well as identify a pleural peel.[16] CT

Table 68-6
Categories of Exudative Pleural Effusion

Type	Cell Characteristics	Cause
Purulent	>5000 leukocytes/mm^3	Parapneumonic effusions Pancreatitis Perforation of the esophagus Pulmonary infarction Pericardial or myocardial injury
Lymphocytic	>50% lymphocytes, usually 1000-1500 cells/mm^3	Tuberculosis Malignancy: lymphoma (predominantly), leukemia, neuroblastoma, chest wall sarcoma, Wilms tumor, hepatoma Uremia Connective tissue disorder: rheumatoid arthritis, systemic lupus erythematosus Fungal infections
Monocytic	>20% monocytes, usually <5000 cells/mm^3	Viruses: adenovirus, influenza, herpes, varicella, measles, and cytomegalovirus *Mycoplasma* pneumomia
Eosinophilic	>10% eosinophils	Recent pneumothorax or blood in pleural space Drugs: dantrolene, nitrofurantoin Uremia Fungal infections Parasitic infections: histoplasmosis, coccidiodomycosis, ascariasis, paragonimiasis, echinococcosis, amebiasis
Chylothorax	Pleural fluid triglyceride >110 mg/dL	Injury to thoracic duct Tumors: lymphoma Tuberculosis Sarcoidosis Neonatal: Trisomy 21, Noonan syndrome, extralobar sequestration, lymphangiomatosis, lymphangiectasia
Hemothorax	Fluid hematocrit >50% blood hematocrit	Trauma Erosion of vessels by central venous catheters Pulmonary infarction Malignancy Thrombocytopenia Hemophilia Rupture of bronchopulmonary sequestration Rupture of arteriovenous malformation Rupture of intrathoracic vessel

provides detailed images of the pleural cavity as well as differentiating empyema from abscess.[17] However, CT may miss multiloculations or septations within fluid collections. Ultrasound has the additional advantage over CT in that it is portable, involves no radiation, and does not usually require sedation.

Treatment of parapneumonic effusions has been an ongoing focus of debate. Early surgical intervention in the form of video-assisted thoracoscopic surgery (VATS) for debridement of the empyema has become more prevalent. Most authors agree that the goals of treatment include elimination of the empyema, reexpansion of the lung, decreased duration of symptoms, and a shortened length of stay.[37] In all cases, treatment with antibiotics is essential. Most uncomplicated cases will respond to a single agent, such as a second- or third-generation cephalosporin or a beta-lactam antibiotic or a beta-lactamase inhibitor such as ampicillin-sulbactam or ticarcillin-clavulanate at high dose[33] (Table 68-8). Small effusions in association with pneumonia can be treated with antibiotics alone. Larger effusions in the early, exudative phase can be treated with intravenous antibiotics plus chest tube drainage.[38,39]

Treatment with simple chest tube drainage is insufficient for effusions in the later stages, once septations, loculations,

Table 68-7
Stages of Purulent Effusion

Phase	Characteristics
Exudative	Thin, free-flowing fluid Normal glucose, pH, LDH Low WBC count
Fibrinopurulent	Deposition of fibrin leading to septations and loculations High WBC count Low pH and glucose High LDH
Organizing	Fibroblasts invade, fluid thickens, dense peel forms Extremely low pH and glucose Extremely elevated LDH

Table 68-8
Antibiotic Treatment for Purulent Effusion

Bacteria	Antibiotic
Streptonomis pneumoniae	Second-generation cephalosporin Third-generation cephalosporin Ampicillin-sulbactam Ticarcillin-clavulanate
Staphylococcus aureus	Oxacillin
Methicillin-resistant *S. aureus*	Vancomycin Linezolid
Mycoplasma/Chlamydia	Erythromycin Azithromycin

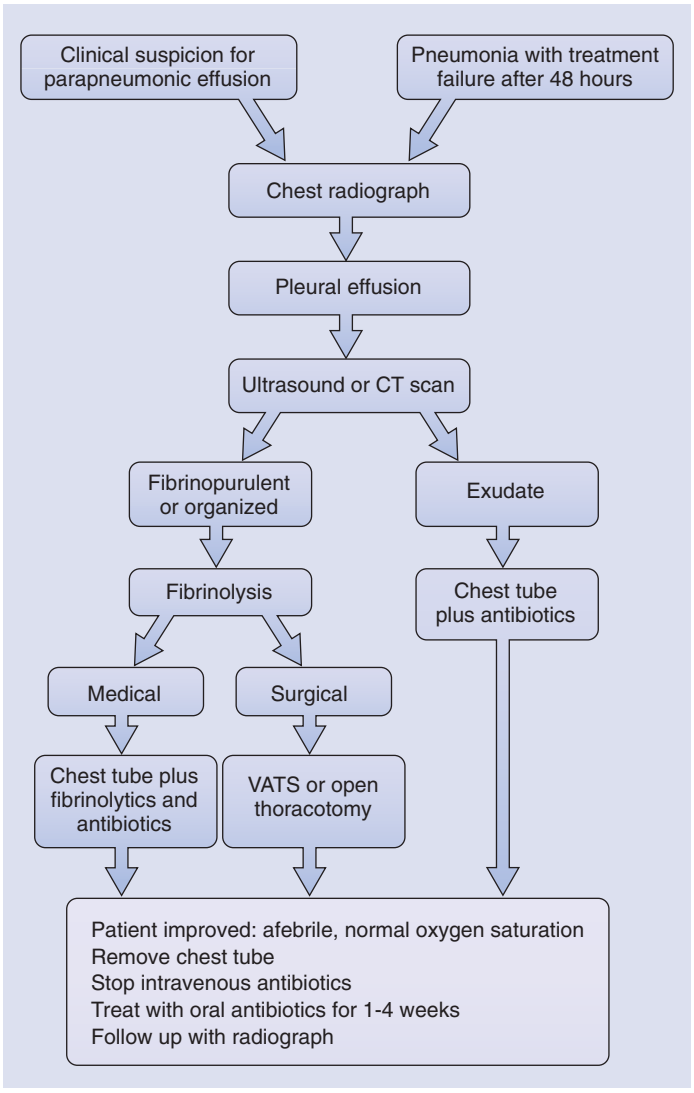

Figure 68-3 Treatment algorithm for parapneumonic effusion. VATS, video assisted thorascopic surgery.

or pleural peels have been identified. Other options include the instillation of fibrinolytics into the pleural cavity or surgical decortications through VATS or open thoracotomy. Fibrinolytics degrade fibrin and allow better drainage of the pleural space with the chest tube and antibiotics. Urokinase and streptokinase seem to be effective, with success rates of 60% to 90%.[40-45]

Early surgical debridement of the pleural cavity via VATS has been used with increasing frequency and success. Two trocars (one for the video equipment, the other for surgical tools) are inserted through two small incisions in the chest wall. Under direct visualization, loculations are broken down and pus is drained from the pleural cavity. This method of treatment is associated with a shorter length of stay, shorter duration of fever, fewer days with a chest tube, lower failure rates, and lower complication rates.[46-50] Open thoracotomy has been the definitive treatment for empyema over the past century.[51,52] Pus is evacuated from the cavity, and the pleural peel is resected or stripped of all fibrous tissue. The incision is larger, and issues with postoperative pain and cosmesis are significant. Published studies comparing the different treatment options are retrospective reviews, and therefore difficult to interpret and lack sufficient data regarding the stage of effusion before treatment. There is no consensus, and the decision to proceed to VATS versus treatment with fibrinolytics is left to the practitioner. A treatment algorithm has been proposed by some authors[33,36] (Fig. 68-3).

In addition to purulent effusions there are other categories of exudative effusions. For a complete list and their causes, please refer to Table 68-6.

PNEUMOTHORAX

Pneumothorax is defined as the abnormal collection of air in the pleural space outside of the lung. Air can enter the pleural space by a leak in either the visceral or parietal pleura. Pneumothorax can be categorized as spontaneous or traumatic. Traumatic pneumothorax occurs as the result of blunt or penetrating trauma to the chest wall or an injury from a diagnostic or therapeutic procedure. Spontaneous pneumothorax occurs without identified trauma and can be further subdivided into primary and secondary. In primary pneumo-

thorax, there is no identifiable lung disease that would lead to air leak. Many patients with primary pneumothorax have apical blebs of unknown etiology that are often diagnosed at the time of surgery or on CT examination.[53] Secondary pneumothorax occurs as a complication of underlying lung disease such as cystic fibrosis. The incidence of primary spontaneous pneumothorax is highest between 15 and 34 years of age.[54] The incidence of secondary spontaneous pneumothorax is highest later in life due to its association with chronic obstructive lung disease. Primary spontaneous pneumothorax typically occurs in tall, asthenic patients and more commonly in males in both the adult and pediatric populations.[55,56] Smoking increases the risk of pneumothorax.[57] A complete list of causes of pneumothorax is listed in Table 68-9.

Two causative mechanisms for pneumothorax have been proposed. The first mechanism suggests that large increases in transpulmonary pressure cause alveolar distention and high-pressure gradients cause the alveolus to rupture. Superficial alveoli can form subpleural blebs that rupture directly into the pleural space. In the second mechanism, direct injury to the visceral pleura secondary to underlying lung disease leads to pneumothorax. A tension pneumothorax develops when air enters the pleural space during inspiration but cannot exit during exhalation. This will lead to collapse of the affected lung and shift of the mediastium away from the affected side.

The cardinal manifestation of pneumothorax is the sudden onset of chest pain. Other common clinical manifestations include tachypnea, dyspnea, tachycardia, and cyanosis. The severity of symptoms depends on the volume of air in the pleural space, rapidity of onset, and the degree of respiratory compromise before the occurrence of the pneumothorax, which is influenced by the presence of underlying lung disease. Pain can range from localized acute retrosternal pain to overwhelming pleuritic pain as well as ipsilateral shoulder pain. Physical examination findings include decreased breath sounds, decreased thoracic excursion, and hyperresonant percussion on the affected side. In cases of tension pneumothorax with shift of the mediastinum, the trachea will be displaced, as will the point of maximal cardiac impulse. Subcutaneous emphysema results from air moving to areas of lower resistance and can reach the neck, upper extremities, abdominal wall, and peritoneum. In cases where the pneumothorax is small, the patient will frequently be asymptomatic and it is usually an incidental finding on radiograph.

Table 68-9
Causes of Pneumothorax

Type of Pneumothrax	Cause
Traumatic	Penetrating or blunt chest trauma
Iatrogenic	Mechanical ventilation (barotrauma)
	Central vein catheterization
	Procedures on airways: intubation, endoscopy, transbronchial biopsy
	Laparoscopic procedures
	Percutaneous biopsies
Primary spontaneous	Aesthenic body habitus
	Idiopathic
	Cocaine or marijuana inhalation
Secondary spontaneous	Airway disease: asthma, cystic fibrosis
	Postinfection: measles, *Pneumocystis carinii,* tuberculosis, necrotizing pneumonia or abscess, parasitic (ecchinococcal)
	Interstitial lung disease: sarcoidosis
	Langerhans cell granulomatosis
	Connective tissue disease: Marfan, Ehlers-Danlos, rheumatoid arthritis, systemic lupus erythematosus, polymyositis, dermatomyositis
	Malignancy: lymphoma, metastasis
	Aspiration: foreign body, other
	Catamenial pneumothorax
	Congenital malformations

Diagnosis of a pneumothorax is accomplished with a chest radiograph. Anteroposterior and lateral views reveal the characteristic findings of air in the pleural space outlining the visceral pleura (pleural line) and hyperlucency and attenuation of vascular and lung markings on the affected side. CT of the chest is helpful to detect bullae and blebs in patients with recurrent pneumothorax and in cases where the radiograph is inconclusive.[58,59] Arterial blood gas measurements should be obtained in cases of respiratory distress. Hypoxemia occurs due to collapse and poor ventilation. Hypercapnia is not usually seen in cases of pneumothorax without underlying chronic lung disease.[53] In cases of severe tension pneumothorax with mediastinal shift and cardiac displacement and rotation, an electrocardiogram can reveal changes in the amplitude of the QRS complex and the cardiac axis.

Treatment depends on the size and cause of the pneumothorax, the extent of respiratory distress, and the presence of underlying lung disease. The goals of treatment are removal of air from the pleural space and prevention of recurrence.[53,60] Treatment can range from observation and supplemental oxygen to simple needle aspiration or chest tube to pleurodesis and, in some cases, more invasive surgery. Information on pediatric spontaneous pneumothorax is limited and management guidelines are based on published adult data.

Observation. In the case of a small pneumothorax (<15% of the involved hemithorax) when the patient is asymptomatic, simple observation can be instituted.[61,62] In a younger child, hospitalization is recommended. In the older child, observation may be done on an outpatient basis.

Supplemental oxygen. The rate of resorption of air from the pleural space is increased with the use of supplemental oxygen.[63] The increased alveolar oxygen tension creates a large gradient between capillary and pleural gas partial pressure of nitrogen, resulting in faster reabsorption of intrapleural air. Use of 100% oxygen via a nonrebreathing facemask has been suggested with a minimal flow rate of 15 L/min.

Needle aspiration. Evacuation of air is required for symptomatic patients where the pneumothorax has been identified to occupy more than 15% of the involved hemithorax. Simple aspiration is done via a large-bore intravenous catheter connected to a large syringe with a three-way stopcock. Air is withdrawn manually until no more can be aspirated. If air continues to be aspirated, this indicates a persistent air leak and a tube thoracostomy should be performed. If no further air can be aspirated, the stopcock is closed and the catheter is secured to the chest wall. A chest radiograph should be performed after 4 hours of observation and if adequate lung reexpansion is seen, the catheter can be removed and the patient observed. Published success rates vary and depend on

whether the pneumothorax is primary or secondary.[60] The recent ACCP guidelines did not support simple needle aspiration in any clinical circumstance.[64]

Thoracostomy tube. This is indicated for patients who have large pneumothoraces, are clinically stable or unstable or who have recurrent spontaneous pneumothorax.[64] This involves the use of a one-way Heimlich valve or water seal device to prevent reaccumulation of air. In the ACCP guidelines, half of the group recommended clamping of the tube 4 hours after the last evidence of an air leak. A repeat chest radiograph should be taken 5 to 12 hours after the last evidence of an air leak in preparation for removal of the tube.

Pleurodesis. This involves injection of a sclerosis agent such as talc, tetracycline, doxycycline, autologous blood patches, or fibrin glue at the time of thoracostomy tube placement. This method is less favorable than surgical intervention for persistent air leak.[65] Mechanical pleurodesis by direct abrasion with gauze, or laser or chemical pleurodesis with talc or doxycycline at the time of surgery has support in the literature to prevent recurrence.[64]

Surgical intervention. This involves stapling or oversewing ruptured blebs (bullectomy) or tears in the visceral pleura and resection of abnormal lung tissue. Mechanical and chemical pleurodesis can also be done with bullectomy. This can be done via VATS, minithoracotomy, or open thoracotomy, although many physicians prefer VATS. Surgery is indicated to treat persistent air leaks and to prevent recurrence. Surgery is recommended at the time of the first occurrence of a secondary spontaneous pneumothorax[65] and at the second occurrence of a primary spontaneous pneumothorax.[66]

Data regarding prognosis after spontaneous pneumothorax in children are limited. One reported series showed a 37% incidence of recurrent spontaneous pneumothorax.[67] In pediatric patients undergoing surgical management, the reported risk of recurrence was 6% to 9%.[68,69] A recent study[70] evaluated primary versus delayed surgery for pediatric patients with primary spontaneous pneumothorax. The authors found that patients who had VATS-directed bullectomy and pleurodesis at the first presentation of spontaneous pneumothorax had a 29% recurrence rate compared with 0% in the group of patients undergoing VATS on the second occurrence.

CHAPTER 69 Bronchiectasis

Marcus Herbert Jones and Paulo José Cauduro Marostica

TEACHING POINTS

- Bronchiectasis should be suspected in children with chronic respiratory symptoms.
- A chest radiograph may not detect bronchiectasis.
- High-resolution computed tomography is the gold standard for the diagnosis of bronchiectasis.
- Cystic fibrosis should be considered in children with bronchiectasis.
- Postinfectious bronchiectasis is still frequent in developing countries.
- Antibiotics and chest physiotherapy are recommended by most experts.
- Patients with localized disease may benefit from surgery.

Bronchiectasis is a structural abnormality characterized by dilatation of the medium-sized bronchi. The usual clinical presentation is chronic productive cough and may lead to significant social and physical problems. Although bronchiectasis is observed in some congenital conditions, it usually occurs as a sequel to severe or repeated insults of respiratory infections or chronic aspiration.

Bronchiectasis has been considered an irreversible abnormality. However, since high-resolution computed tomography (HRCT) has become available, some radiologically diagnosed cases in children were found to be reversible.[1] This is a challenge to the paradigm of a permanent finding suggesting that either different HRCT criteria for bronchiectasis in children should be used or this condition should be deemed as actually reversible in childhood. Most children with idiopathic bronchiectasis and those with nonprogressive causes have a good prognosis, with an almost normal life span, whereas those with background diseases like cystic fibrosis (CF) have a much worse prognosis, related to the progressive nature of the underlying illness.

EPIDEMIOLOGY

Estimates of the prevalence of bronchiectasis are scarce. There are few reports of prevalence and incidence available, and further epidemiologic studies should be carried out to better assess the impact of this condition. The scarcity of prevalence studies reflects the lack of a noninvasive, simple, and accurate test that can be used in population investigations, so most diagnosed cases represent the more severe ones.[2-4]

Although the prevalence of bronchiectasis is unknown, it seems to be higher in developing countries, where tuberculosis and childhood preventable diseases like pertussis and measles are still common.[3,5]

In developed countries, the introduction of widespread immunization, improvement of social conditions, breastfeeding encouragement policies, and the access to antimicrobial therapy for tuberculosis and pneumonia have caused a decline in the incidence of bronchiectasis. However, bronchiectasis is still prevalent among indigenous peoples such as the Australian Aboriginal,[6] Alaskan,[7] Pacific and Maori children from New Zealand.[8,9] The prevalences reflect the socioeconomic conditions of a particular population.[4,10]

At present, there has been a rise in tuberculosis rates directly related to the AIDS epidemic. This will cause an increase in the incidence of bronchiectasis, which will probably be diagnosed later during adulthood.

PATHOPHYSIOLOGY

Usually a chronic or an intense insult, such as a severe viral infection, causes the initial lung damage, eventually leading to the emergence of bronchiectasis. Damage to the mucociliary clearance system evolves, leading to stasis of pulmonary secretions and further lung injury. There is a change in the epithelium from ciliated to cuboidal and squamous, reserve cell hyperplasia, and mucosal thickening. With progression, there is damage to the muscular and elastic layers. Inflammatory mediators and release of elastase from leukocytes lead to additional damage and eventual bronchial wall destruction with erosion of bronchial cartilage, especially in advanced saccular bronchiectasis. Elastase and cathepsin G are found in elevated concentrations in bronchoalveolar lavage fluid (BALF) from patients with bronchiectasis compared with normal controls, suggesting a decrease in downregulation of such enzymes by antiproteinases. Interleukin-8, a proinflammatory cytokine, is also overly expressed in BALF from patients with this disorder.[3] Once secondary infection is present, a cycle of infection and inflammation predisposes to further mucosal and bronchial wall injury[3,11,12] (Figs. 69-1 and 69-2).

Localized bronchiectasis is usually related to a single bronchial obstruction, such as in foreign body aspiration or congenital malformations.

In chronic cases, there may be vascular proliferation of the adjacent bronchial arteries that anastomose with pulmonary arteries and predispose the child to hemoptysis.[3]

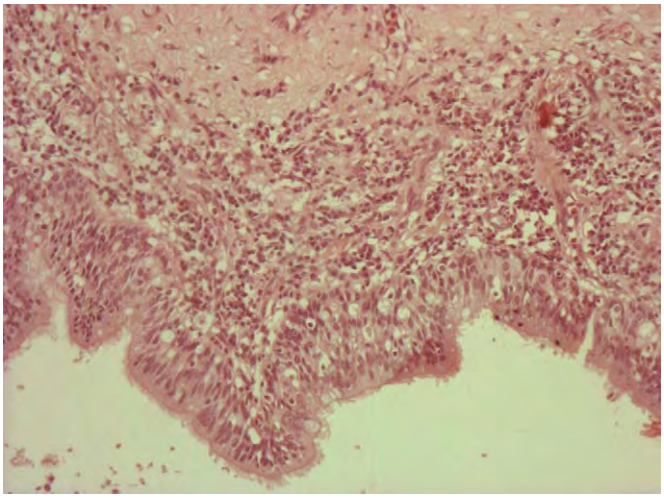

Figure 69-1 Reserve cell hyperplasia, a dense mononuclear inflammatory infiltrate, and fibrosis. (Hematoxylin and eosin stain, original magnification ×100.)

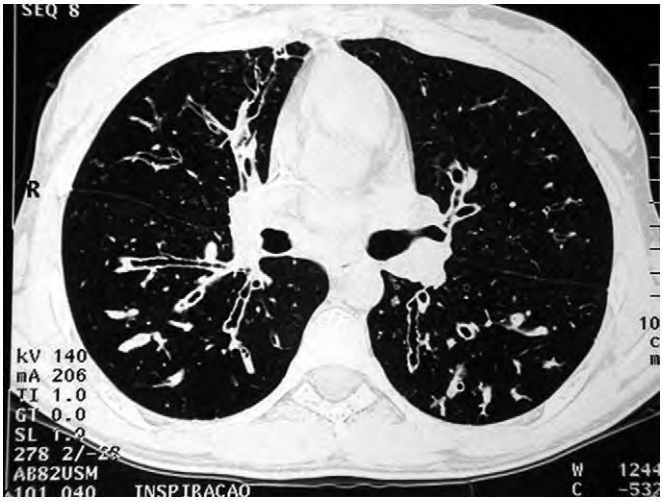

Figure 69-3 HRCT scan of a 14-year-old cystic fibrosis patient showing cylindrical bronchiectasis in lower lobes.

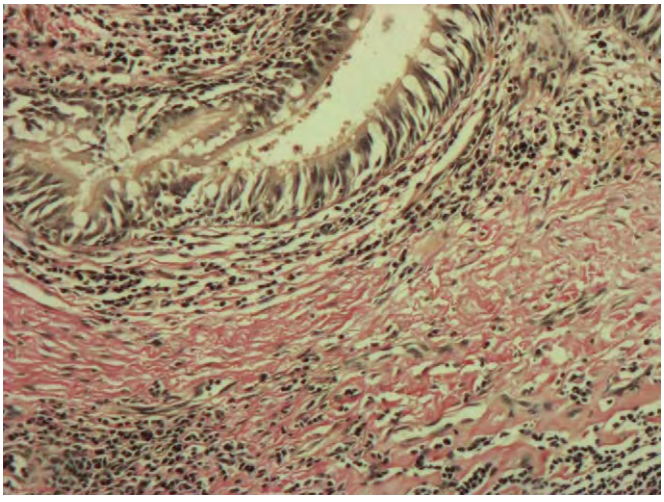

Figure 69-2 The fibrotic area is stained in red, surrounding a bronchus with mononuclear infiltrate. (Verhoeff stain, original magnification ×100.)

Figure 69-4 HRCT scan of a 4-year-old patient with postinfectious bronchiolitis obliterans and localized cystic bronchiectasis in the right lower lobe.

The shape of the bronchiectasis is variable. The classic Reid classification[13] divides bronchiectasis into three different patterns: (1) cylindrical, where a uniform dilatation is found, (2) varicose, with constrictions superimposed on cylindrical bronchiectasis, and (3) cystic or saccular, where progressive dilation occurs, usually associated with more advanced disruption of the lung architecture, although such correlation is not always evident.[4] Figures 69-3 and 69-4 show the typical pattern of bronchiectasis on HRCT.

CAUSES

In many situations, bronchiectasis is secondary to a specific disease, but often no cause will be identified, despite a comprehensive etiologic investigation. In recently published series, 25% to 38% of pediatric patients did not have an identifiable underlying etiology for bronchiectasis. The most common causes in children include CF, severe respiratory infection, immunodeficiency, congenital malformations, and aspiration syndromes.[11,14,15] Box 69-1 presents a list of known causes of bronchiectasis in children.

In developing countries, infectious cases secondary to tuberculosis and pneumonia are still prevalent. In South America, postviral (especially adenovirus) bronchiolitis obliterans is a relatively common cause of bronchiectasis.[16,17] In a case-control study with Australian Aboriginal children, a strong and significant association was noted between hospitalized pneumonia and bronchiectasis, especially for recurrent and more severe pneumonia episodes with requirement for oxygen and longer hospital stays.[12]

After the development of new antiviral drugs for the treatment of AIDS, vertically infected children are surviving longer and bronchiectasis is becoming a more frequent finding among such patients. Tuberculosis, lymphocytic interstitial pneumonia, and bacterial or *Pneumocystis carinii* pneumonia are frequently associated conditions with HIV-infected children.[18-20]

BOX 69-1 Causes of Bronchiectasis in Children

Infectious

Bacterial pneumonia
Pertussis
Measles
Adenovirus
Influenza
Tuberculosis

Immunodeficiency

Hypogammaglobulinemias
Neutrophil deficiencies
Complement deficiency
AIDS

Other

Cystic fibrosis
Primary ciliary dyskinesia
Allergic bronchopulmonary aspergillosis
Foreign body aspiration
Aspiration syndromes
Autoimmune diseases
Young syndrome
Mounier-Kuhn syndrome
Ehlers-Danlos syndrome
Marfan syndrome
Yellow nail syndrome
Alpha-1 anti-trypsin syndrome

Asthma itself is rarely, if ever, associated with bronchiectasis. In this situation, physicians should consider a different diagnosis or associated allergic bronchopulmonary aspergillosis or infection.[5,7,21]

When localized disease is the case, one should consider an obstruction such as a foreign body or a congenital malformation. In cases of more diffuse disease, a systemic cause like CF, immunodeficiency, or primary ciliary dyskinesia is usually implicated.[5]

CLINICAL FINDINGS

Chronic respiratory complaints are the usual clinical findings. A productive cough is frequently present, and the association with wheezing or dyspnea often misleads physicians to the diagnosis of difficult asthma. As normal children often have respiratory tract infections, the presence of abundant sputum production may remain undetected, leading to diagnostic delay. Fetid sputum may also be present, although in the authors' experience, it is only found, as is hemoptysis, in the more severely affected. Crackles and rhonchi are the usual auscultatory findings, more often detected during disease exacerbations. Digital clubbing is a variable finding, being reported in up to half of the patients, and does not necessarily correlate with severity of the disease.[9] There may be chest deformities. Malnutrition is frequently present in patients.[3,5,12,21-23]

DIAGNOSTIC METHODS

Bronchiectasis should be considered in all children with chronic respiratory symptoms, particularly if associated with a history of a severe respiratory infection in the past, digital clubbing, and malnutrition.

HRCT of the chest has largely replaced bronchography for the diagnosis of bronchiectasis. It can accurately localize lesions, identify mucus plugging and bronchiolar abnormalities to the level of sixth-order bronchi and also identify focal areas of air trapping secondary to small airway disease.[11,21] Occasionally, bronchography is performed as a presurgical evaluation and when the diagnosis is uncertain.[24] Bronchography is associated with a risk of allergic reactions to the contrast media and with the possibility of ventilatory failure in patients who already have some degree of respiratory insufficiency. Most surgical series currently published do not mention bronchography as a mandatory preoperative test.[25]

Ventilation-perfusion scintigraphy can be used to evaluate vascular perfusion and the extent of gas exchange in different areas.[26]

Chest radiographs can be indicative of bronchiectasis, but they are not very sensitive. In the series by Eastham and coworkers,[22] 66% of the HRCT diagnosed cases would have been missed by chest radiography alone; HRCT should be performed when the clinical picture is compatible, despite a normal chest radiograph. Usual radiographic findings are increased linear markings, the so-called tram lines, crowding of bronchi, cystic spaces, air-fluid levels, and honeycombing.[4,27]

The standard HRCT technique is a thin section (1.0- to 1.5-mm collimation), at 10-mm intervals, with a high-frequency reconstruction algorithm. Usual window levels are –600 to –700 HU, and window width is 1000 to 1500 HU.[27,28]

One of the classic signs of bronchiectasis in HRCT is a bronchial/adjacent pulmonary artery ratio greater than 1, which corresponds to bronchial dilatation; this is also known as the "signet ring" sign. It has been suggested that a 1.5 ratio should be used instead, because healthy people can have ratios as great as 1.5. Other classic signs include parallel bronchial walls that do not taper, the tram line appearance, or demonstration of bronchi in the peripheral third of the lung, mainly within 1 cm of the pleura.[4,11,28,29] In the retrospective series of bronchiectasis by Kang and coworkers,[28] 87% of 47 resected lobes from adolescents and adults were correctly identified by the presurgical HRCT scans. Because all the patients had clinical indication for surgery, they probably represent the more symptomatic children.

Areas of decreased attenuation can often be seen in HRCTs of patients with bronchiectasis. Pifferi and coworkers were able to identify attenuations in 37% of pulmonary lobes from 16 patients with bronchiectasis.[29] These areas correlated well with ventilatory and perfusional scintigraphy findings but did not necessarily correspond to the same areas where bronchiectatic changes could be observed. These changes could represent hemodynamic changes surrounding bronchiectasis.

Pathologically, bronchiectasis consists of dilated bronchi, with inflammation and fibrous distortion of the bronchial wall, but biopsy specimens are not usually required, because image studies usually suffice for the diagnosis.[28]

Interestingly, many cases of HRCT-diagnosed bronchiectasis have been demonstrated to be reversible. Either more strict criteria should be used to interpret HRCT in childhood, or some mild cases may actually be reversible. Gaillard and coworkers suggest that the persistence of clinical and CT findings for a period of 2 years is required to confirm the presence of true bronchiectasis.[1,22,30]

Although some diseases can show a more frequent pattern of distribution of bronchiectatic lesions, none of the HRCT findings should be considered diagnostic, because there is great overlap.[4,11] In CF, upper lobe involvement is frequent, in contrast with other diseases where bronchiectasis tends to be more evident at other sites, especially in the lower lobes.[7,11,25] Aspiration typically causes more lower lobe bronchiectasis. In the series of Li and coworkers,[11] 80% of such patients had bronchiectasis in the lower lobes. According to Hansel,[4] the middle lobe was more commonly involved in hypogammaglobulinemia. Li and coworkers[11] found a preponderance of lower and right middle lobe involvement in children with various types of immunodeficiency. Typical cases with an underlying cause such as CF, primary ciliary dyskinesia, or immunodeficiency usually show a multilobar involvement, in contrast to localized disease caused by infection.[5]

MICROBIOLOGY

Haemophilus influenzae, *Streptococcus pneumoniae*, *Moraxella catarrhalis*, *Haemophilus parainfluenzae*, *Staphylococcus aureus*, and *Pseudomonas* spp. are the usual pathogens in children with bronchiectasis.[11,21-23] In CF, the most frequent bacteria are *S. aureus*, *Pseudomonas aeruginosa*, *H. influenzae*, and *Burkholderia cepacia*.[31]

LUNG FUNCTION TESTS

In non-CF patients, the correlation between bronchiectasis, assessed by an HRCT score, and lung function is weak.[32,33] Patients with bronchiectasis limited to a segment or lobe probably would have minimal abnormalities on spirometry. In CF patients, there is a mismatch between HRCT scores and spirometry, with a faster worsening of the bronchiectasis compared with lung function parameters.[34,35] However, some authors detected a moderate correlation between forced vital capacity (FVC) and forced expiratory volume is 1 second (FEV_1) and HRCT scores in CF patients.[25,29,36] Children with bronchiectasis may have abnormal exercise with increased oxygen consumption and heart rates compared with controls, although exercise abnormalities have a poor correlation with HRCT scores or spirometry.[33]

MANAGEMENT

The management of bronchiectasis should focus on the care of the underlying condition, when this is the case, and the management of the suppurative lung injury itself. The former is beyond the scope of this chapter.

Physiotherapy, one of the main treatments for CF patients, has not been appropriately evaluated for the care of non-CF bronchiectasis, but most experts recommend this therapy.

No antibiotic strategies have been adequately evaluated with well-designed randomized controlled trials, mainly because bronchiectasis patients are not a homogeneous group and the studies that have been done are difficult to compare because of diverse study designs.[37]

Infectious exacerbations should be treated with antibiotics. Some patients will need frequent courses of antibiotics for infection control. Some authors have suggested long-term antibiotic courses, aiming to reduce the bacterial population in order to avoid further inflammation and tissue destruction.[37]

Inhaled tobramycin has been tried in adults with bronchiectasis infected with *P. aeruginosa*, and improvement in clinical outcomes was noted.[38] Although a safety study has already been conducted with inhaled gentamicin, the issue of its efficacy in children still needs to be addressed.[39] Macrolides have both an antimicrobial as well as anti-inflammatory and mucoregulatory effects. Different studies have shown the benefits of this class of drugs in patients with CF. Macrolides decrease interleukin-8 and neutrophil elastase in BALFs, improve spirometry parameters, and decrease the number of exacerbations and hospital admissions in most of the studies.[40] They are usually recommended in most centers for CF patients with moderate pulmonary involvement and especially for those chronically colonized by *P. aeruginosa*. In an uncontrolled study in adults, a decrease in pulmonary exacerbations and improvement in lung function in patients with non-CF bronchiectasis receiving azithromycin for a median period of 20 months was demonstrated.[41] Similar studies in children are needed to define the role of macrolides in non-CF bronchiectasis

DNase, a mucolytic agent that causes lysis of DNA originating from bacteria and defense line cells, has been useful in the management of CF patients with bronchiectasis. However, it was found to be ineffective and potentially harmful in two studies of adults in stable condition with idiopathic bronchiectasis.[42,43]

Surgery is usually indicated when adequate control is not achieved with clinical management. In adults, persistent symptoms following a 2-year treatment program is considered an indication for surgery, as is major hemoptysis. In children, social and general well-being issues, such as a failure to comply with a chest physiotherapy program, poverty, or failure to thrive, should be considered as possible indications for a surgical approach.[23,25,26]

Good outcomes are obtained in children with localized disease, especially when there is no underlying disease that predisposes to new bronchiectasis formation and when all diseased segments can be resected. In one series, 44% of children eventually underwent surgery for localized disease.[15] Postoperative mortality is very low in most centers.[23,26]

CHAPTER 70 Atelectasis

Kai-Håkon Carlsen and Bjarne Smevik

TEACHING POINTS

- Atelectasis may be caused by obstruction in the bronchial lumen or by compression of lung tissue from outside.
- The most common causes of atelectasis are obstructed airways by inflammatory processes such as in asthma or lower respiratory tract infections, or foreign bodies in the bronchial tree.
- During anesthesia, atelectasis may be a frequent, insignificant finding.
- Early intervention may reduce long-term morbidity.

Atelectasis was first described by Laennec in 1819[1] on observation at autopsy. The term *atelectasis* means "imperfect expansion" and comes from the Greek words *atelez (ateles)* for "imperfect" and *ektasiz (ektasis)* for "expansion." Atelectasis of the lung (or parts of the lungs) is an incomplete expansion of pulmonary tissue. This may be due to a congenital defect (congenital or primary atelectasis) but is mostly used to describe the collapse of lung tissue (acquired or secondary atelectasis). Atelectasis is defined as "1. incomplete expansion of a lung or portion of a lung, occurring congenitally as a primary or secondary condition, or as an acquired condition; 2. airlessness of a lung that had once been expanded; 3. collapse of a lung."[2]

ETIOLOGY AND PATHOGENESIS

Etiology

Atelectasis may be caused by several different conditions: (1) obstruction of the bronchial lumen, (2) compression of lung tissue from outside the lung, (3) muscle weakness of respiratory muscles such as the diaphragm and intercostal muscles (neuromuscular disease), and/or (4) reduction in surface tension of the the periciliary fluid lining the respiratory tract. The different causes for atelectasis are dealt with in the chapters describing other respiratory disorders, and a short list of the causes is given in Box 70-1.

The most common causes of atelectasis are airways obstructed by inflammatory processes as occur in asthma or lower respiratory tract infections or foreign bodies in the bronchial tree.

Disease Mechanisms

In congenital malformations, parts of the lung tissue may be without communication with the main bronchial tree, without the normal aerification of lung tissue developing at birth. The affected parts of the lung have never been inflated and have not undergone the normal pulmonary adaptation.[3] This is a primary atelectasis, but secondary atelectasis may develop shortly after birth, due to a congenital malformation occluding or narrowing the bronchial lumen.[4]

In secondary atelectasis, normal lung tissue may collapse due to an occluded bronchial lumen or compression. This is the most usual form of atelectasis. More than 100 years ago, Kohn[5] described collateral communications between neighboring alveoli, and at the preductal level, collateral communication between the peripheral bronchioles and adjacent alveoli has been described.[6] These collateral communications help to ensure an even ventilation/perfusion ratio in the lung. At the more proximal bronchial levels, no such collateral communications exist, and occlusion of the bronchial lumen therefore leads to trapping of the air in the lung tissue peripheral to the occlusion. The trapped air is then gradually absorbed by the blood perfusing the occluded lung tissue, and the occluded part of the lung collapses accordingly. The rate of absorption into the bloodstream depends on the solubility of the trapped gases. Atmospheric air will be absorbed within a few hours, whereas oxygen is absorbed much more rapidly, within minutes.[7] During ventilation with 100% oxygen, atelectasis may therefore develop more rapidly than during normal air breathing. This may partly explain the increased risk of atelectasis during anesthesia,[8] which is even more pronounced in the presence of respiratory tract symptoms such as cough.[8]

Secondary to the occlusion of the bronchial lumen, vasoconstriction of the pulmonary vessels perfusing the affected lung tissue will occur due to hypoxia.[9] Hypoxic pulmonary vasoconstriction appears to be the major cause of increased vascular resistance in the atelectatic lung tissue, thereby regulating the ventilation/perfusion ratio. Nevertheless, the magnitude of shunting has been found to be related to the atelectatic area seen during anesthesia.[10] In experimental studies, the dynamic compliance of atelectatic dog lung lobes increased during inflation with air, and this was found to be mainly due to increased static vascular compliance, suggesting that atelectasis results in a stiffer pulmonary capillary bed.[11]

All processes or procedures occluding the bronchial lumen may cause atelectasis or pulmonary collapse. This includes misplaced tracheal intubation, which may cause total collapse of one lung, when the distal part of the tracheal tube is located in a main bronchus (usually the right one).

BOX 70-1 Causes of Pulmonary Atelectasis

Intraluminal Bronchial Obstruction

Foreign body
- Nuts
- Plastics
- Misplaced tracheal tube

Primary Atelectasis

Congenital malformation

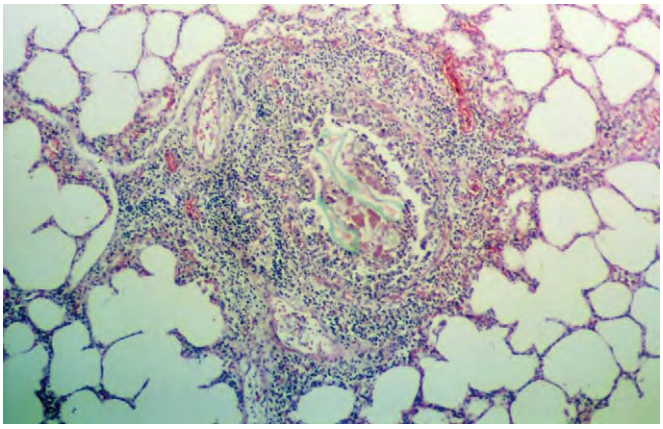

Figure 70-1 Section of lung tissue from a 20-month-old boy with bronchiolitis. The section shows mucosal and peribronchial inflammation with epithelial destruction and increased intraluminal mucosal secretions and mucus plugging. (Hematoxylin-eosin stain.) (Courtesy of Aud D. Svindland.)

Foreign bodies of the airways may result in complete or partial occlusion of a bronchus. In cases of complete occlusion, atelectasis will occur. However, even when the bronchial lumen initially is not totally occluded, total occlusion may gradually develop. Some foreign bodies will swell when exposed to the humid respiratory mucous membranes, and thereby cause complete obstruction. Impaction of a foreign body into the bronchial lumen may initiate inflammatory processes of the respiratory mucous membranes. Swelling of the mucosa may occur together with increased bronchial secretions and possibly bronchial smooth muscle contraction, resulting in total obstruction of the bronchial lumen and atelectasis.[12]

Among the most common causes of obstruction of the bronchial lumen, leading to atelectasis, are inflammatory processes within the bronchial tree, including eosinophilic inflammation due to asthma,[13-15] infections such as bronchiolitis due to respiratory syncytial virus,[16] or bacterial pneumonias. In asthma and bronchiolitis, the right middle lobe and the lingula segment are the most common areas of atelectasis, so common that this has been given the name of *middle lobe syndrome*.[17,18] Enlargement of hilar lymph nodes compressing the middle lobe bronchus has been denoted as the probable cause of this preferential localization.[18] The compression enhances the obstruction caused by inflammatory mucus, mucosal edema, and bronchial constriction. Positive bacterial culture findings in bronchoalveolar lavage fluid and in sputum from a majority of children with middle lobe atelectasis in asthma[16] or respiratory syncytial virus infections[13] have led to a suggested role of bacterial infection in longstanding atelectasis of asthma and bronchiolitis.

A number of cytokines and mediators are involved in the airways inflammation in asthma, bronchiolitis, and other respiratory tract illnesses. They have a number of effects upon the bronchial mucosa. In addition to increased mucus secretions, the following occur: edema of the mucous membranes, bronchial smooth muscle constriction, destruction of bronchial epithelium, and cessation of ciliar function with stagnating sticky mucus within the bronchial lumen (Fig. 70-1). In the atelectatic lung, altered cellular immune function has been described.[19] Airway inflammation may lead to destruction of airway epithelium, as occurs in asthma,[20] and this may alter the periciliary fluid lining the airways epithelium, reducing the effect of surfactant proteins and thereby further enhancing the tendency to bronchial collapse. Illnesses affecting the surfactant function of the airways are known to be complicated by the formation of atelectasis. This is the case for both the respiratory distress syndrome of the newborn (chronic lung disease of the newborn) and the adult respiratory distress syndrome.[18] Also, aspiration of irritating fluids

such as acids, alkali, amniotic fluid,[17] and meconium have this effect. In atelectasis of lobes or major lung segments, totally obstructed lobar or segmental bronchi may be found on bronchoscopy. All diseases that increase the susceptibility to respiratory tract infections and to stagnation of mucus are at risk for the occurrence of atelectasis. This includes several types of immunodeficiencies, congenital or acquired ciliar dysfunction,[21] and cystic fibrosis.

Processes affecting the bronchial wall causing narrowing of the bronchial lumen predispose to atelectasis. This includes airway stenosis complicating longstanding intubation, tracheobronchomalacia, vascular rings, and tumors such as polyps, papillomas, and bronchial carcinoid.[22,23] Bronchiolitis obliterans will gradually cause fibrotic obliteration of bronchi, leading to atelectasis.[24] Bronchiectasis is often caused by longstanding airways inflammation, which also may be complicated by atelectasis. Bronchiectasis may also contribute to atelectasis formation due to stagnation of bronchial secretions.

Normal lung tissue may be compressed due to extrapulmonary processes without bronchi being affected. This is seen in patients with congenital heart defects and cardiomegaly[25] but may also be due to pneumothorax (Fig. 70-2) or hemothorax.

Rounded atelectasis is a special form of atelectasis seen more often in adults than in children. It is most often asymptomatic and is thought to be associated with chronic pleural disease, lung fibrosis, or pleural effusions. It consists of infolding of atelectatic lung tissue intermingled with blood vessels, pleura, and, sometimes, bronchi.[26]

Atelectasis of lung tissue is a common manifestation in neuromuscular diseases of various types. Several mechanisms contribute in the atelectasis formation in these children. Muscular hypotonia, with reduced movement of the diaphragm, reduces ventilation and contributes to collapse of lung tissue, in addition to causing difficulties in the clearing of bronchial secretions with increased susceptibility to respiratory tract infections. The same pattern is seen in acute spinal cord injuries.[27] Hypoventilation may also be the cause of the pulmonary collapse not infrequently seen during anaesthesia in children.[8]

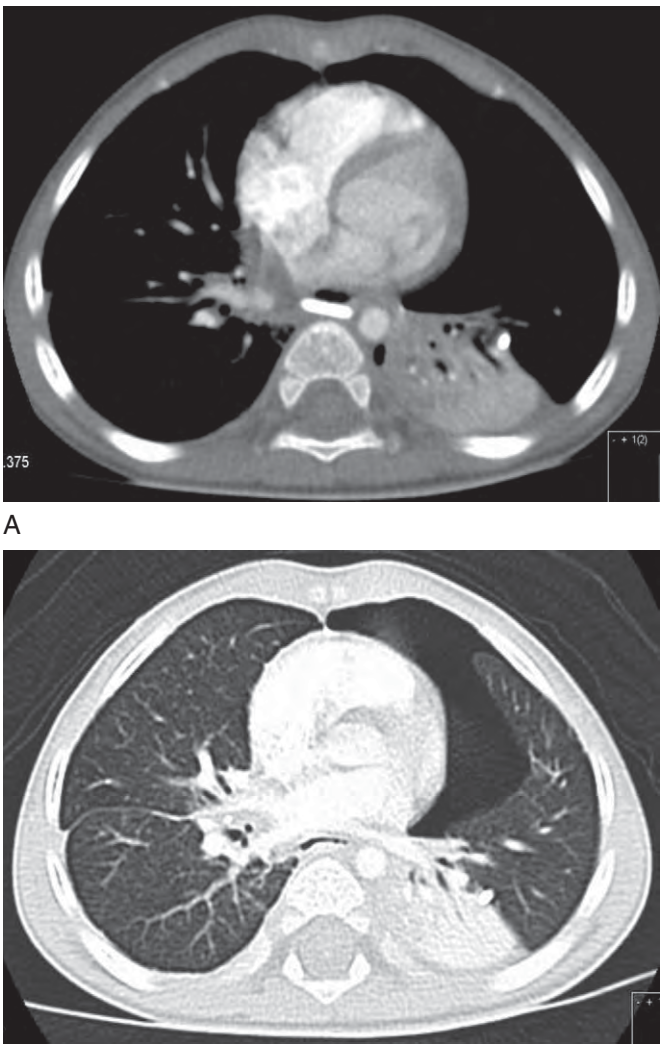

Figure 70-2 Seventeen-month-old boy with atelectasis of left lower lobe. **A,** CT scan with mediastinal window setting shows a paravertebral atelectasis on the left side. **B,** CT scan with lung parenchyma window shows a pneumothorax clearly.

CLINICAL FEATURES

The symptoms and signs of atelectasis depend on the extent of atelectasis and on the rate of formation, in addition to the age of the patient and the causative illness. In infants with bronchiolitis, atelectasis of a lung lobe, occurring suddenly, may cause a severe exacerbation in an infant who is already critically ill. Acute respiratory disturbance may also occur from the aspiration of a foreign body in a previously healthy child. On the other hand, even extensive atelectasis may pass totally unnoticed clinically. In the case of total obstruction of a bronchus, the hypoxia of the bronchial and pulmonary tissues peripheral to the obstruction will cause pulmonary vasoconstriction in the affected lung segment, thereby regulating the ventilation/perfusion ratio.[9] The net result of the atelectasis will thereby be minimized. However, in the case of atelectasis occurring during anaesthesia or in the postoperative period, significant reductions in PaO_2, FEV_1, and FVC will be seen, correlating to the size of the atelectatic area.[23]

Symptoms of pulmonary infections may occur due to atelectasis, as stagnation of secretions predisposes to secondary bacterial infections originating in the atelectatic area.

The findings during clinical examination will also depend on the size and localization of the atelectatic area. When an entire lung lobe is affected, diminished respiratory sounds may be evident on auscultation, as well as reduced resonance on percussion. With careful examination, an asymmetric expansion of the thorax may be observed with restrained expansion over the atelectatic area. In atelectasis of large areas, such as an entire lung, displacement of the heart and the mediastinum may take place.

When smaller areas of lung tissue are atelectatic, the clinical signs are scarce and difficult to observe. The diagnosis may depend entirely on chest radiography results.

DIAGNOSIS

The diagnosis of atelectasis in children must recognize the atelectasis as such, and if possible, the underlying cause of

the collapsed lung must be found. The diagnosis of atelectasis must be based on an understanding of the etiology, pathophysiology, and anatomy relevant to its development.

Usually the first imaging modality is chest radiography. Depending on the patient's age and clinical condition and the complexity of the process, the study may include frontal, lateral, and oblique views. When lung tissue collapses and atelectasis occurs, the volume of the lung tissue is reduced, and the typical radiographic changes will include elevation of the diaphragm, shift of the mediastinum, and narrowing of the rib spaces on the affected side. These signs may be missing when both lungs are affected or when compensatory emphysema develops in parts of the ipsilateral lung. In most cases, biplane chest radiographs will give adequate information about the extent of the collapsed lung parenchyma. In the majority of children, repeat chest radiographs will suffice to ascertain that the therapy is effective and that the atelectasis has finally cleared. The atelectasis will frequently be seen as an area of increased density that may vary with the location and size of the collapsed area. An atelectatic lung will present itself as a radiopaque homogeneous hemithorax (Fig. 70-3). A lobar atelectasis will often be more dense centrally than in the periphery of the lesion. When volume reduction is pronounced, it will often lead to herniation of parts of the contralateral lung across the midline (Fig. 70-4). The lower lobes are most frequently affected by atelectasis.

Different characteristic signs are associated with different locations and types of atelectasis:

- Right upper lobe atelectasis is often encountered in children after surgery. The lobe increases somewhat in density, and the interlobar fissure may be elevated (Fig. 70-5).
- Left upper lobe atelectasis may produce a density in the upper hilar region on the left side, and the mediastinal structures may be shifted to the left, together with an elevation of the left hemidiaphragm.
- Middle lobe atelectasisis is also often referred to as *right middle lobe syndrome* because of its frequent involvement with malignancies or infection causing hilar node enlargement. It is also the most commonly involved lobe in asthma patients.[15,22] The right cardiac contour is indistinct, and the atelectasis is usually better recognized on lateral films where the triangular density points to the hilus with its apex (Fig. 70-6). Compensatory emphysema may produce concave borders.
- Right and left lower lobe atelectases will produce a dense triangle medially, with the base at the diaphragm and the apex near the hilus (Fig. 70-7). The shadow of the heart may obscure this feature unless the radiograph is well exposed. In the lateral projection, the fissure is shifted posteriorly and downward.
- Segmental atelectasis affects parts of a lobe and may be more difficult to delineate (Fig. 70-8). Oblique views are more often necessary to determine the exact location.
- Focal atelectasis occurs when a subsegmental bronchus is affected, and the density is usually located in the basal lung fields and presents as a thin horizontal or plate-like line, often disappearing or "moving" between studies.
- Rounded atelectasis may be confused with a tumor on plain chest films. The computed tomography findings are quite characteristic: a rounded mass adjacent to a thickened pleural surface in the periphery of the lung with blurring of the margin closest to the hilus caused by the entering vessels and bronchi.
- Alveolar atelectasis is commonly encountered in premature babies suffering from the respiratory distress syndrome (Fig. 70-9).

Fluoroscopy may be necessary to determine the exact location of a density and may be helpful in the differential diagnosis (Fig. 70-10). It is also used when a foreign body is suspected to be the cause of the lung density.

Computed tomography (CT) often reveals atelectasis that is not recognized on chest radiographs.[23] The axial projection

has advantages when the lesion is located in the periphery of the lungs close to the chest wall (Fig. 70-11), near the heart and great vessels, close to the diaphragm, or in the apical regions. This advantage is utilized in children with malignancies in the search for lung metastases. However, CT of the chest often necessitates general anesthesia in children, and the well-known tendency of general anesthesia to produce dependent atelectases[28] is of major concern to the pediatric radiologist (Fig. 70-12). In our experience, general anesthesia produces atelectasis in more than 90% of children, as opposed to less than 10% when light sedation is used. Multislice CT with reconstructions in two and three dimensions may help to complete the diagnostic picture in complex congenital malformations of the heart and lungs leading to atelectasis (Fig. 70-13). Magnetic resonance imaging (MRI) may also clearly depict atelectasis in the axial plane. This modality is superior when the process is located in the apical regions or near the diaphragm, because of the ability of MRI to produce pictures of equally good quality in any plane. Modern multislice CT with short examination time, thin slices, and coronal or sagittal reconstructions may offer the same diagnostic advantage, but the patient is of course exposed to ionizing radiation. The MRI signal patterns of atelectasis have been described, and obstructive and nonobstructive atelectasis may be differentiated to some extent on the basis of T2-weighted images.[29] Consolidation and atelectasis will produce different patterns both on CT and MRI.

Ultrasonography of the collapsed lung may be of some use when the density is large enough to provide an acoustic window. An underlying tumor as cause of the atelectasis may then be recognized.[30,31]

Bronchography is well suited for the diagnosis of several conditions leading to atelectasis. Bronchomalacia, short peripheral stenosis, and extrinsic compression may be revealed by this technique.

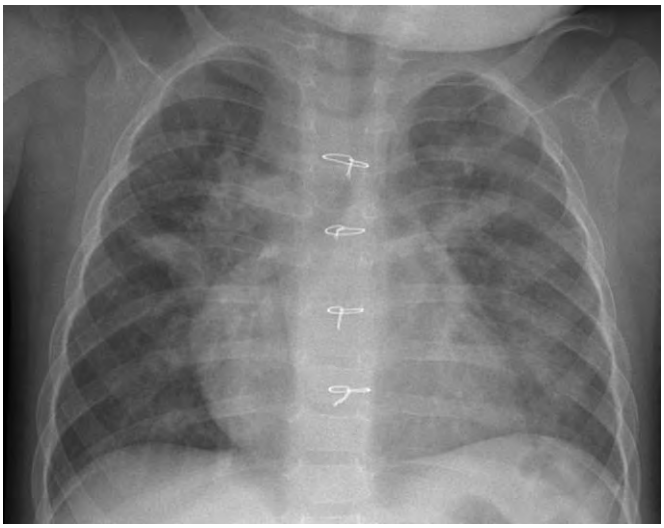

Figure 70-8 One-year-old girl with segmental atelectasis in the postoperative period after heart surgery.

Diagnosis of Atelectasis in Neonates

Alveolar atelectasis is an important aspect of the respiratory distress syndrome. Neonates (usually premature infants) often need mechanical ventilation, and during intubation, the tracheal tube may inadvertently be situated too low. This may give rise to atelectasis in the contralateral or ipsilateral lung (Fig. 70-14). Atelectasis may also be encountered in meconium aspiration and in advanced cases of chronic lung disease of the newborn.[18]

Other Diagnostic Procedures

In order to diagnose the cause of atelectasis, bronchoscopy with flexible fiberoptic bronchoscopes or rigid bronchoscopes is an important procedure. Foreign bodies in the airways

may be diagnosed, localized, and removed via the bronchoscope. Thus, bronchoscopy in such cases is the diagnostic and the therapeutic tool of choice.[32] Vascular rings and other narrow areas in the bronchi that predispose to atelectasis may be seen through the bronchoscope. Furthermore, mucus plugs (Fig. 70-15) may be visualized and removed by suctioning or bronchoalveolar lavage, followed by suctioning. Biopsy samples taken through the bronchoscope may occasionally reveal the causal diagnosis of atelectasis, such as ciliar dyskinesia.[21]

TREATMENT AND MANAGEMENT

It is important to observe that atelectasis is not a disease by itself but rather a sign of disease. Atelectasis may have several different causes, and the treatment depends on the underlying illness. Primary atelectasis seen with a congenital malformation may require surgical intervention. Atelectasis is also a frequent complication with bronchial and pulmonary tumors, even if these occur less frequently in childhood than among adults. In such cases, it is especially important to diagnose and treat the underlying cause.

When atelectasis occurs due to airways inflammation such as bronchiolitis caused by respiratory syncytial virus or acute attacks of bronchial asthma or pneumonias, the atelectasis often resolves spontaneously in a few weeks. Inhalation therapy with nebulized bronchodilators such as racemic epinephrine or β_2-agonists and saline may help in the resolution by loosening mucus plugs and dilating the airways. Such measures are often combined with chest physiotherapy, consisting of positioning, vibrations of the thorax, and suctioning.[33] The use of nebulized DNase has also been demonstrated to rapidly improve or dissolve acute atelectases caused by infections.[34] Measures such as continuous positive airways pressure breathing and positive end-expiratory pressure ventilation have also been used.[35-37] However, experience shows that physical activity of different kinds may be the most effective physiotherapeutic regimen in mobilizing mucus plugs and resolving atelectasis in children.

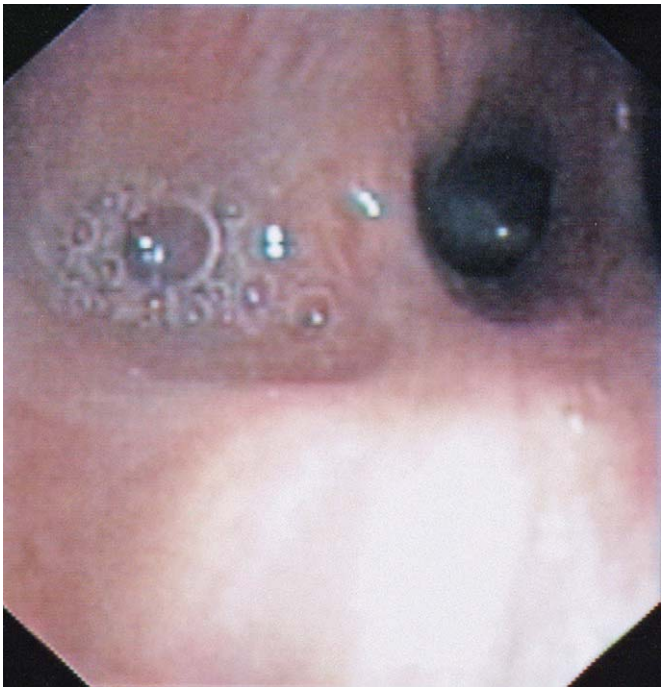

Figure 70-15 Bronchoscopy demonstrating mucus plugging of the lower lobe apical segmental bronchus on the right side. (Courtesy of Gunnar Hansen.)

Because positive bacterial culture findings from bronchoalveolar lavage or sputum often are present in atelectasis,[13,15] antibiotic treatment may be useful.

Although atelectases occurring secondary to pulmonary infections and bronchial asthma usually resolve spontaneously, this is not always the case. Diagnostic or therapeutic procedures such as bronchoscopy may then be needed.

Bronchoscopy is increasingly used in the treatment of atelectasis and is the treatment of choice for removing foreign bodies; rigid bronchoscopy is usually used.[32] When the atelectasis has been present for longer than 6 weeks, bronchoscopy is used for both diagnostic and therapeutic measures. Early intervention, after 1 month of persistent atelectasis in the right middle lobe syndrome, through diagnostic and therapeutic measures including flexible bronchoscopy and broncho-alveolar lavage, was shown to be effective in resolving the atelectasis in more than 60% of cases.[38] In many cases, mucous plugs are removed by suctioning and lavage, and the atelectasis resolves.[39] Selective bronchial suctioning in the absence of bronchoscopy has been used.[40] Instillation of surfactant through a bronchoscope has also been demonstrated to be effective in clearing lobar atelectasis in children of different ages.[41] Attempts at insufflating atelectatic lung segments have been made using a balloon-tipped catheter introduced through the nostrils or an endotracheal tube[42] or a fiberoptic bronchoscope.[43] Insufflation has mostly been used in adults. During such procedures, it is important to realize that nonatelectatic portions of the lung have higher compliance than the atelectatic portions[11] and that insufflation may result in overexpansion of the normal parts of the lung.

In neonates, the standard regimen for the resolving of atelectases consists of postural drainage with suctioning and, in some cases, also selective intubation with suctioning of a major bronchus.[44] Recently, an approach by bronchoscopy under direct vision without interrupting the mechanical ventilation has been used with success in 10 cases.[45]

When longstanding atelectasis is a sign of underlying severe lung pathology with formation of bronchiectasis, standard therapeutic measures may be inadequate. Chronic atelectatic portions of the lung are susceptible to recurrent bacterial infections. If there is no other lung pathology, lung resection may be useful, and it has been used for several different causes of atelectasis such as bronchial malformations and stenosis, sequestrations, cysts, lobar emphysema, bronchiectasis, and chronic pneumonia.[46]

As atelectasis most often is caused by airways inflammation, optimal treatment of the causative disease may be an effective prophylactic measure against atelectasis. This is the case in bronchial asthma with prophylactic anti-inflammatory therapy, in immunodeficiencies with immunosubstitution, as well as in cystic fibrosis. In patients with chronic pulmonary symptoms, it is important to use inhalation therapy with nebulized drugs in order to make the mobilization of bronchial secretions easier and to prevent mucus stagnation and plugging.

CHAPTER 71 α_1-Antitrypsin Deficiency

Robert A. Sandhaus

TEACHING POINTS

- α_1-Antitrypsin deficiency is one of the most common genetic causes of liver and lung disease.
- Although labeled as a protein deficiency, liver injury is related to excess protein accumulation.
- Screening of immediate family members of an affected individual may help identify those at risk of associated diseases.
- Reduction of environmental and infectious risk factors is key.
- Augmentation therapy is available to slow progression in those with lung disease.

The hereditary deficiency of the body's major circulating antiprotease has gone by many names since its first description in 1963: α_1-antitrypsin deficiency, α_1-proteinase inhibitor deficiency, or, more simply, alpha-1. This confusing lexicon seems even more perplexing as our understanding of the diseases associated with this condition has led to the conclusion that the major pediatric manifestation, liver injury, is due to an *overabundance* of abnormal α_1-antitrypsin protein (AAT) within the hepatocyte rather than a deficiency. Because of this, the condition will be referred to in this chapter as AATD and one is free to interpret the "D" as *deficiency* or *dysfunction*.

AATD was first described in Sweden by Eriksson and Laurell,[1] a young hepatologist and his mentor, respectively. They were studying unusual serum protein electrophoretic patterns and their initial manuscript described the association between a serum deficiency of AAT and familial, precocious emphysema in young adults. The association between liver disease and AATD was still 6 years away. Often forgotten in references to this publication is that several of the individuals described were adults without clinical sequelae associated with their AATD. It is important to remember that this condition does not invariably lead to disease. All indications are that, in the absence of environmental, infectious, or additional genetic risk factors, many individuals with AATD will lead normal healthy lives, unaffected by significant related disease.

After Sharp described the association between AATD and fulminant liver failure in newborns in 1969,[2] the stereotypical presentations of this condition became embedded in the training and experience of physicians: AATD leads to liver failure in the first months of life or emphysema in young adults. In retrospect, this understanding has hampered identification of the many affected individuals who do not fit these stereotypes, including more elderly individuals with chronic obstructive pulmonary disease (COPD), adults with liver disease, and adolescents with abnormal liver function, all due to AATD.

AATD is most commonly associated with panlobular or panacinar emphysema often predominantly affecting the lower lung fields. The National Institutes of Health Registry of Individuals With Alpha-1 Antitrypsin Deficiency documented that this lower zone predominance is not universal, with a significant proportion of affected individuals presenting with upper zone and sometimes centrilobular disease.[3]

In addition to pulmonary emphysema and liver disease, a number of other conditions have been associated with AATD, including bronchiectasis, Wegener granulomatosis, and necrotizing panniculitis.[4] This last condition is associated with a vasculitic inflammation of the vessels nourishing the subcutaneous fat, leading to necrotic, painful skin lesions. Augmentation therapy, usually reserved for the treatment of pulmonary emphysema due to AATD (see later), has been effective at reducing or eliminating panniculitis.[5] A number of other diseases have been statistically associated with abnormal AAT phenotypes, including chronic active hepatitis, nontuberculous mycobacterial infections, and a variety of other inflammatory conditions. These secondary associations often rely on demonstrating an unexpectedly high prevalence of AAT mutations in individuals already identified as having these conditions. Unfortunately, because large population-based studies identifying the exact prevalence of these abnormal AAT variants are currently lacking, conclusions about a particular prevalence being "unexpectedly high" may be subject to error. A recent summary of existing literature has suggested that over 20 million Americans carry at least one abnormal gene for AAT.[6]

There is an increased risk of hepatocellular carcinoma in individuals with AATD.[7] This increased risk was initially attributed to the increase in hepatic scarring associated with the liver disease of AATD and the known association of scarring with carcinoma risk. However, subsequent studies have found no relationship between the presence of scarring and the risk of hepatocellular carcinoma in AATD.[8]

Testing for AATD has become confusing in recent years as a proliferation of testing methodologies and reporting conventions has led to occasional misinterpretations. The simplest test, a serum level of AAT protein, is reported using

three different units of measurement depending on which laboratory is performing the test (see Diagnosis, later). A level that is severely low using the milligrams per deciliter (mg/dL) scale can appear to be within the normal range if misinterpreted as the micromolar (μmol/L) scale. The limitations of more specific testing, looking at AAT protein phenotype or directly at the genotype, must be understood to accurately assess the results.

Finally, the use of specific therapy for the lung disease of AATD has been controversial since its marketing approval in the United States in late 1987, followed by approvals in several European countries.

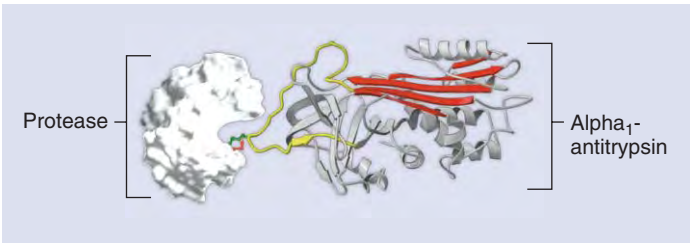

Figure 71-1 Interaction of the AAT molecule *(right)* and a representative serine protease *(left)*. The cleavage of the *(yellow)* bait loop of the AAT molecule leads to a dramatic conformational change in the complex, translocating the protease to the opposite side of the AAT molecule while inactivating its proteolytic activity. (From Carrell RW, Lomas DA: Alpha$_1$-antitrypsin deficiency—a model for conformational disease. N Engl J Med 346:47, 2002.)

EPIDEMIOLOGY, RISK FACTORS, AND PATHOGENESIS

Prevalence

The prevalence of homozygous AATD in the general U.S. population has been calculated to be between 60,000 and 100,000 individuals. This is based on a classic study by Silverman from 1983,[9] in which all St. Louis blood donors during one donation cycle (7 weeks) were tested for AATD. Recently, however, several programs have begun testing individuals with the diagnosis of COPD for AATD. These programs have reported finding between 1% and 2% of those diagnosed with COPD have undetected AATD. With a known prevalence of about 15 million individuals in the United States with diagnosed COPD, this suggests a much higher number of individuals with AATD in the general population, perhaps approaching 500,000 when individuals with AATD who have liver disease and individuals who are healthy are added to the COPD population. One explanation for the underestimate of the original study is that individuals with liver or lung disease are unlikely to be blood donors.

Structure and Function

The gene for AAT resides toward the end of the long arm of chromosome 14 (14q32.1) within the PI (protease inhibitor) locus and codes for a 394–amino acid protein with a 52,000 Da molecular weight.[10,11] The PI locus includes a number of related genes coding for a variety of protease inhibitors, many of them inhibitors of proteases with a serine in their active site. These inhibitors form the superclass of serine protease inhibitors, or serpins, and AAT has been among the most important members of the serpin family. AAT has activity against a broad range of serine proteases but is known primarily for its unique ability to effectively block the activity of the serine elastases, especially the elastase contained within the azurophilic granules of the human neutrophilic leukocyte (human neutrophil elastase [HNE])[12] (Fig. 71-1). AAT also appears to have anti-inflammatory properties that are independent of its antiprotease function.[13]

Individuals with AATD have approximately 10% to 15% of the normal circulating levels of this protein. Initially, the slight biochemical differences between "normal" AAT protein and the abnormal variant were identified using starch gel electrophoresis. Using this technique, it was soon discovered that there were individuals with aberrant gene products that did not migrate in the position of either the normal or the deficient protein. Some of these individuals had levels below normal and some had normal levels. A naming convention was devised called the PI system,[14] which assigned letters of the alphabet to these various AAT proteins (and thus their genes) according to their migration in these starch gels. The electrophoretic technique was designed to cause the normal protein to migrate to the center of the gel. The normal protein was given the letter M (PI M), the initially described deficient protein migrated much more slowly in this system and was labeled Z (PI Z), and others were added as they were identified. Isoelectric focusing (IEF) in the pH 4 to 5 range has proved to be more consistent and reproducible than the original electrophoretic techniques (Fig. 71-2). Over the years, more than 100 mutations of the AAT gene have been identified by IEF and/or DNA sequencing. Once all the letters of the alphabet were consumed, names were added based on the city of discovery and other characteristics. A group of these variants produces no measurable AAT protein. This group is known as the PI Null alleles. In all, approximately one third of the mutations to the AAT gene appear to cause the production of a Null, deficient, or dysfunctional AAT protein. The most common variant in the United States and Europe is the PI S allele, which leads to a mild deficiency of AAT in the circulation of individuals who are homozygote for this allele. The most commonly identified severe deficiency allele remains the PI Z variant. Table 71-1 lists the best-characterized AAT genotypes and their characteristics.

DISEASE MECHANISMS

Lung Injury in α_1-Antitrypsin Deficiency

Exogenously administered elastolytic proteases were shown as early as 1964[15] to be capable of causing emphysema in a variety of laboratory animal species. It was not until the first description of HNE in 1968[16] that an endogenous source of elastase was identified that might play a role in the lung destruction of human emphysema. During the 1970s, intratracheal administration of HNE was shown to be quite effective at producing emphysema in laboratory animals and AAT was shown to be an effective inhibitor of this protease and its emphysema-producing properties.[17,18] In addition, it was demonstrated that components of cigarette smoke, primarily oxidants, were capable of destroying the antielastase capacity of AAT.[19] Thus, a "protease pathogenesis" model of human

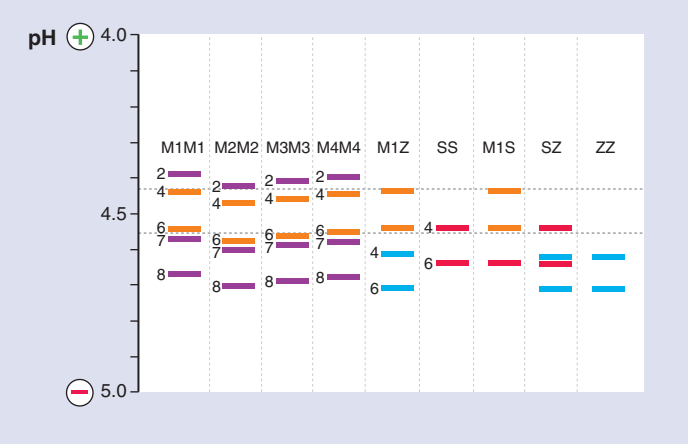

Figure 71-2 Diagrammatic representation of the banding patterns of common AAT phenotypes when evaluated using serum protein isoelectric focusing from pH 4.0 to 5.0.

pulmonary emphysema was proposed: Unbridled HNE activity is the cause of the lung destruction characteristic of pulmonary emphysema. In most individuals, the antielastase activity of AAT is used to protect against this destruction. In those with insufficient antielastase activity, due to the action of cigarette smoke on AAT or its hereditary deficiency, normal pulmonary connective tissue can be destroyed by HNE. Although most dinicians still accept that this model explains the lung destruction associated with AATD, the picture in smoking-related COPD is now considerably more complex, with contributions from other connective tissue degrading proteases and more complex oxidant–antioxidant interactions.

Several explanations have been proposed to account for the predilection for the lung as the primary target organ associated with a systemic deficiency of this important protein. The lung is an organ that is exquisitely dependent on its connective tissue architecture, and destruction of this architecture tends to be irreversible. The lung has the largest capillary bed of any organ, and its function depends on putting this large blood supply in intimate contact with the outside world. The neutrophil is one of the primary sentries guarding the lung from invasion by bacteria and other inhaled agents. While diapedesis and phagocytic ingestion of bacteria looks elegant under the microscope, in fact, neutrophils have been shown to spill their proteolytic contents into the surrounding environs during this process. In most individuals, there is sufficient AAT bathing the pulmonary connective tissue to prevent this destructive cocktail from degrading normal lung tissue. This appears to be true even in individuals with AATD. However, when the protease load is too large or there has been local inactivation of AAT by environmental oxidants such as cigarette smoke, destruction of elastin and other connective tissue will occur. In most other organs of the body, such environmental factors do not play as direct a role.

Clearly, the coexistence of AATD and cigarette smoking is to be avoided. But the other side of the protease-antiprotease balance is upset in AATD as well. Individuals with AATD, even without documented lung disease, have a higher percentage and number of neutrophils in their lungs, as judged by bronchoalveolar lavage.[20] Events that stimulate the migration of neutrophils to the lungs such as pulmonary bacterial infections move this balance even farther in the direction favoring accelerated connective tissue destruction. Whereas most investigations have focused on this connective tissue destruction, recent studies have evaluated the cellular components that make up the alveolar unit and found that pulmonary epithelial apoptosis is also increased during processes that produce connective tissue injury.[21]

Liver Injury in α_1-Antitrypsin Deficiency

Our understanding of the pathophysiology of the liver disease of AATD has taken longer to evolve and is still incomplete. When the association between AATD and neonatal liver disease was first described, an unusual histologic feature was noted during microscopic evaluation of livers from affected individuals. Large inclusions were found in the periportal hepatocytes of these specimens. These inclusions stained with periodic acid–Schiff (PAS) and were diastase resistant.[2] Speculation about the nature of these inclusions ended when immunostaining demonstrated that this material was predominantly AAT.[22]

When the three-dimensional structures of PI M and PI Z AAT were evaluated and compared, the differences between the two forms suggested the possibility that the PI Z form might be susceptible to polymerization.[23] This was demonstrated in vitro, and polymerized PI Z AAT was also identified by immunoelectron microscopy within the hepatocyte inclusions from the livers of affected individuals.[24,25] Using these techniques, it was concluded that the PAS-positive hepatocyte granules represent rough endoplasmic reticulum engorged with polymerized AAT. These inclusions exist in all individuals with PI Z AATD, and in those heterozygous for this abnormal allele (PI MZ). There does not appear to be a relationship between the size or the number of these inclusions and the development of liver disease. In contrast, however, individuals with two Null genes, whose hepatocytes make no AAT protein, have no hepatocyte inclusions and do not appear to have an increased risk of liver disease, suggesting that these inclusions are at least necessary for the development of liver injury. Recent preliminary data have suggested that a second inherited defect in the intracellular trafficking of misfolded proteins may account for the severe perinatal liver disease seen in about 2% of those born with AATD (Richard Sifers, Baylor University, personal communication).

GENETICS

As with most non–sex-linked genetic traits, each individual carries two AAT genes, one inherited from each parent. The expression of the AAT trait is codominant rather than recessive. In codominant expression, each gene appears to contribute equally to the quantity of translated protein made in the cell. Thus, whereas an individual with AATD has about 10% to 15% of the normal AAT level in serum, a heterozygote for AATD, such as PI MZ, will have a level intermediate between normal and deficient. Certain heterozygote combinations have an increased risk of lung disease including PI SZ and PI MNull. There are about 8 million individuals in the United States with the PI MZ phenotype. A meta-analysis of case-

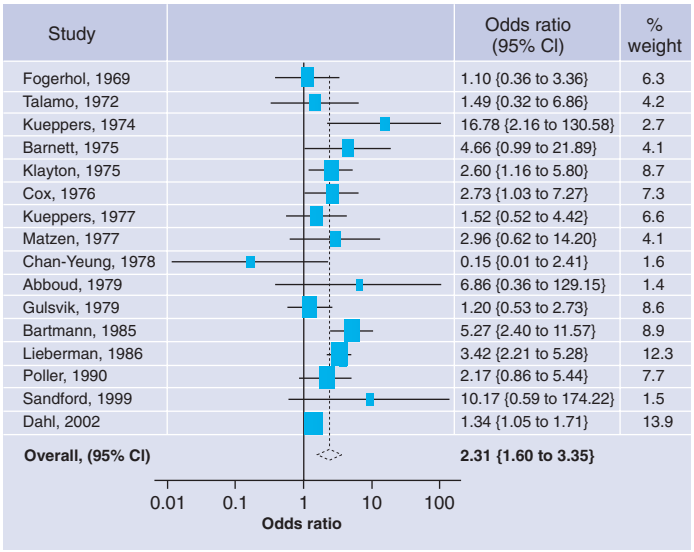

Figure 71-3 Summary results of meta-analysis of case-control and cross-sectional studies of COPD in AATD heterozygotes. (From Hersh CP, Dahl M, Ly NP, et al: Chronic obstructive pulmonary disease in α_1-antitrypsin PI MZ heterozygotes: A meta-analysis. Thorax 59:843, 2004, reproduced with permission from the BMJ Publishing Group.)

control studies in individuals with PI MZ demonstrated an increased risk of developing COPD compared with the general population (odds ratio, 2.31; 95% confidence interval, 1.60 to 3.35)[26] (Fig. 71-3).

CLINICAL FEATURES

When AATD is detected in the pediatric setting, it is usually because of liver disease in the child or because a family member has been diagnosed and family screening has been recommended. The majority of infants born with severe AATD (PI ZZ) will have abnormal liver function tests as an infant, primarily characterized by transaminase elevations.[27] Approximately 5% will develop clinically significant liver disease during their first year of life and, of these, approximately 40% (2% overall) will develop liver failure, with the remainder returning to normal liver function. While elevated transaminase levels are usual, when overt liver disease occurs in AATD, it is often accompanied by jaundice, an enlarged liver, and failure to thrive. A predominantly cholestatic picture can be seen, usually in those with more severe disease. Whether the presence of AATD can aggravate typical neonatal hyperbilirubinemia has not been fully evaluated.

Early studies suggested a strong family clustering of childhood liver disease, and, in fact, some recommended that parents of a child with AATD-related liver disease should strongly consider avoiding having additional children.[28] However, although there is a degree of this clustering, more recent data have shown that these early studies represented an extreme not seen in common practice.

Lung disease associated with AATD is extremely rare before the age of 20, and even those cases reported as AATD-related lung disease during childhood may well represent congenital cysts or blebs, rather than true emphysema due to AATD. The role of AATD as a risk factor for childhood and adult asthma is not well established. Whereas it is true that most individuals who develop lung disease as an adult have a history of childhood or adult asthma, until a prospective evaluation of asthma incidence is performed, it is difficult to evaluate these self-reported data. Animal studies have found that AAT can decrease bronchial hyperreactivity.[29] In humans, early research suggested airway hyperresponsiveness was associated with certain specific heterozygous phenotypes of AATD.[30] Recent work, however, with larger numbers of patients has not supported AATD as a risk factor for asthma.[31]

Whether a major inflammatory lung disease such as severe pneumonitis could overwhelm the antiprotease capacity of the child with AATD and lead to more lung damage than might otherwise take place seems a possibility but has been difficult to study. Recent epidemiologic reports have concluded that one risk factor associated with lung disease in adults with AATD is parental smoking during childhood.[32] This suggests that lung injury occurring during childhood may manifest itself later in life in those with AATD.

Neonatal screening for a variety of genetic conditions is becoming more common, and it is likely that testing for AATD will be included in such panels. Therefore, it will become more common for the pediatrician to be confronted with a healthy baby diagnosed with AATD and be asked to discuss the implications and risks associated with this finding. Currently, recommendations for the healthy child identified with AATD include immunization against influenza and viral hepatitis, smoking prevention, avoidance of second-hand smoke, and rapid treatment of pulmonary infections.

Because AATD is a condition that can affect the entire family of the identified individual, screening of family members is often recommended. Currently, there are risks associated with screening of healthy individuals; these risks are primarily related to potential genetic discrimination in obtaining health or life insurance or in employment. Some states have provided full or partial remedy to these risks through legislation that prohibits such discrimination. Another form of testing risk relates to studies that have demonstrated that some parents of healthy children identified as having AATD have reported treating those children differently from their other children without AATD, viewing the child with AATD as more vulnerable or ill.[33] All these potential risks must be weighed against the benefits of preventing future lung and liver disease.

The majority of adults identified with AATD, when not identified by family screening, are diagnosed because of precocious emphysema or emphysema out of proportion to their smoking history. Unfortunately, this diagnostic bias toward those with early onset disease often prevents the clinician from considering the testing of individuals with more usual COPD. Individuals with mild lung disease due to AATD may have normal spirometry and other tests of pulmonary physiology but have emphysema noted on computed tomography of the chest (chest CT). Bronchiectasis, often asymptomatic, is a frequent additional finding on chest CT of adults with AATD. Testing for AATD should be included in the work-up of any individuals with unexplained bronchiectasis.[34]

Autopsy studies from Sweden have demonstrated that liver disease is more common in adults with AATD than previously thought. In that study, more than 50% of adults over 65 years of age with AATD had histologic evidence of

liver scarring, although these changes were asymptomatic in most individuals.[35]

DIAGNOSIS

In the mid-1990s, Stoller and coworkers.[36] found that, on average, it took evaluations by at least three different physicians over approximately 7 years from the time symptoms first appeared until the diagnosis of AATD was made. Follow-up studies published in 2006 found little had changed over the decade since that original publication.[37,38]

The diagnosis of AATD can be made with a simple blood test, but the choice of which test(s) to do and how to interpret the results may not be simple (Table 71-2). The least expensive and most widely available test is a blood or serum level of AAT protein and usually requires drawing a tube of blood. However, even this simple test has its limitations. As mentioned, the results of an AAT level can be expressed using three different units of measurement. These are milligrams per deciliter (mg/dL), micromoles (μmol/L), and grams per liter (g/L, used mostly in Europe). Thus, it is important to check which units are being used by the laboratory performing the test and to check that laboratory's normal range, because these are laboratory specific. Assuming the units have been considered, a level measurement can identify individuals with severe AATD such as PI ZZ, PI ZNull, and PI NullNull. Although AAT is an acute phase reactant and even severely deficient individuals can raise their levels somewhat in response to stress such as inflammation or infection, in general, individuals with a severe deficiency cannot raise their level into the normal range. Severe deficiency is generally defined as a level at or below 58 mg/dL, 11 μmol/L, or 0.58 g/L. In most settings, the risk of adult lung disease is a function of the level of AAT in the blood and tissues and the phenotype/genotype predicts the level for the most common abnormalities of the AAT gene (Fig. 71-4).

Level testing has other limitations as well. Because heterozygotes can have levels approaching or within the normal range, level testing is not the best way to detect these carriers of a single abnormal gene or individuals with mutations that do not cause severe deficiency. In addition, there are rare phenotypes such as PI F and PI $M_{pittsburgh}$ that lead to production of normal or near-normal levels of a dysfunctional protein.

When an unusual variant is suspected or when carriers of a single abnormal gene need to be detected, such as in family screening, additional testing in the form of *phenotyping* (electrophoretic evaluation of the circulating AAT protein) or *genotyping* (evaluation for abnormal AAT genes) should be done. Phenotyping requires a tube of blood to obtain a plasma

Table 71-2
Testing Methodologies

Test Type	Method	Sample Needed	Benefits	Limitations
Level	Quantification of α_1-antitrypsin antigen in blood or serum (results expressed in μmol or mg/dL)	Tube of blood	Inexpensive, readily available	Confusion regarding units and normal range. Cannot definitively detect heterozygotes or unusual mutations.
Phenotype	Isoelectric focusing of α_1-antitrypsin protein in plasma or serum	Tube of blood	Detects most molecular variants of α_1-antitrypsin. Detects heterozygotes.	Expensive. Requires training and experience to read accurately. Will miss Null variants.
Genotype	Nucleotide probes used to identify mutations of interest in α_1-antitrypsin gene of leukocytes	Tube of fresh blood, or dried blood spot on special filter paper, or buccal swab	Automated, high-volume testing requiring minimal experience to read.	Can only detect variants for which probes are available. Often uses only probes for Z and S alleles. Will miss rarer variants and nulls as method is usually applied.

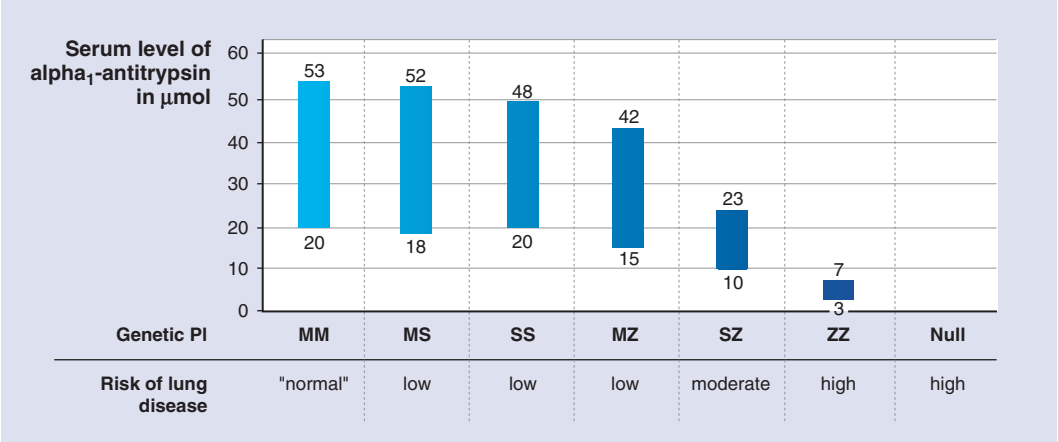

Figure 71-4 Relationship between AAT phenotype, blood, and risk of lung disease in adults with AAT deficiency.

or serum sample. Genotyping can be performed using a fresh tube of anticoagulated blood or a specific finger stick or buccal swab kit. One might assume that genotyping would be the gold standard in testing, because it looks at the AAT gene itself. However, as currently implemented in most laboratories, genotyping uses probes for specific abnormal genes, usually the genes coding for the Z variant and the S variant. Thus, other, rarer abnormal genotypes can be missed using this technique.

For most testing situations requiring more than a simple blood level, phenotyping of circulating AAT protein using isoelectric focusing is the test of choice. Many commercial laboratories offer this service. It is a very labor-intensive methodology and requires experience on the part of the person reading the gels to identify rarer phenotypes.

One specific area of some concern to the pediatrician is identification of carriers of a Null allele. When two Null genes are present, the diagnosis is readily apparent, for the patient has no circulating AAT protein. A carrier of a single Null gene presents a silent gene to phenotyping and usual methods of probe-based genotyping. Thus, a physician can be presented with the situation in which the child of a parent identified as PI MM is tested and reported to be PI ZZ. Questions of paternity or hospital nursery error are often the first thoughts that come to mind. However, if, in fact, one parent is actually PI MNull, it is possible this parent and his or her PI ZNull child were incorrectly identified as homozygotes for the more easily identified M and Z genes.

For the most unusual or questionable cases, reference laboratories studying AATD can perform gene sequencing. To identify sites with extensive experience in identifying unusual phenotypes/genotypes and where sequencing can be done, one can call the Alpha-1 Foundation (888-825-7421). Regardless of the method used to detect an individual with AATD, it is generally recommended that positive results be repeated for confirmation.

TREATMENT

The treatment of AATD depends on the clinical presentation of the affected individual. Individuals identified with AATD but demonstrating no clinical disease need no treatment except education and regular follow-up for signs of liver or lung problems. Family testing should be considered. Risk factors for disease should be reduced or eliminated. This includes smoking prevention or cessation, avoidance of second-hand cigarette smoke, avoidance of chronic exposure to dusts or organic fumes, and prevention and treatment of target organ infection. The role of alcohol consumption in the promotion of liver disease is assumed but not well documented. The best evidence for this is the fact that adults with AATD and elevated serum liver enzymes often see a normalization of their liver function with abstinence from alcohol. Therefore, moderation of ethanol intake should be recommended.

The liver disease associated with AATD does not have a specific therapy at present. Usual supportive therapy for liver injury is the norm. This includes promotion of adequate nutrition, prevention of vitamin deficiency, treatment for ascites if present, and control of potential hemorrhagic complications associated with coagulopathy and/or portal hypertension. Those with liver failure due to AATD may be candidates for liver transplantation. AAT deficiency is a major cause of liver transplantation in children and a growing cause in adults. Successful liver transplantation provides an interesting result in AATD because replacing the failing liver with a normal donor liver also corrects the plasma and tissue deficiency AAT. Although the other cells of the body still have the abnormal genotype, and thus such transplant recipients can still pass an abnormal gene on to their offspring, the transplanted liver now has a normal genotype and releases normal amounts of AAT protein.

Avoidance of risk factors for liver injury is key, although no specific risk factors for severe neonatal cirrhosis have been identified. In older children and adults with AATD, exposure to infectious agents that target the liver and exposure to liver toxins should be prevented by appropriate immunization and counseling in the avoidance of excessive alcohol consumption and occupational exposures to certain organic chemicals, primarily cyclic/aromatic molecules.

Similar to liver disease, the treatment of the lung disease of AATD is based on the usual treatment of chronic obstructive lung disease from any cause (Table 71-3). Smoking cessation is of primary importance in individuals with lung disease due to AATD, as is avoidance of second-hand smoke. Prevention of pulmonary exacerbations is paramount in slowing the progression of COPD in general, including those with COPD due to AATD. Inhaled therapies with bronchodilators and steroids have been documented to reduce the incidence of such exacerbations. Treatment of exacerbations should be aggressive to minimize the time that lung tissue is exposed to an increased protease burden. Many recommend immediate initiation of antibiotic therapy and short burst oral steroids for severe exacerbations.

In addition and in contrast to the liver disease of AATD, there is specific therapy available for AAT deficient individuals with emphysema. This therapy, known as augmentation or replacement therapy (currently in the United States: Prolastin from Talecris Biotherapeutics, Aralast from Baxter Healthcare, and Zemaira from CSL Behring), relies on intravenous infusion of purified human AAT protein derived from the plasma of healthy donors. Given as a weekly infusion of 60 mg/kg, augmentation therapy is widely used in the United States and Europe. It is only approved for use in adults with documented pulmonary emphysema. Emphysema due to

Table 71-3
Treatment of Lung Disease Due to α_1-Antitrypsin Deficiency

Treatment	Goal	Improve Survival?
Smoking cessation	Reduce inflammation	Yes
Immunizations	Reduce infection	Not documented
Avoid inhaled agents	Reduce risks	Not documented
Bronchodilators	Prevent exacerbations	Not documented
Inhaled corticosteroids	Prevent exacerbations	Not documented
Pulmonary rehabilitation	Improve quality of life	Not documented
Antibiotics	Treat exacerbations	Not documented
Supplemental oxygen	Reverse hypoxemia	Yes
Augmentation therapy	Replace deficient protein	Yes

AATD rarely occurs in individuals younger than the third decade.

Based on the known pathophysiology of the lung destruction of AATD, it is widely accepted that augmentation therapy slows the progression of emphysema in AATD. Although no randomized controlled trial has supported the efficacy of augmentation therapy, a number of large case-control studies have demonstrated significant beneficial effects on such outcomes as rate of decline of lung function,[3,39,40] incidence of pulmonary exacerbations,[41] and survival[3] for individuals receiving augmentation therapy compared with similar AATD patients not receiving such therapy.

The most severely lung-affected individuals are often candidates for surgical intervention. Lung transplantation, either single or double, is effective at improving the pulmonary function and quality of life in individuals with a successful procedure. It now appears likely that survival is also prolonged in those receiving a lung transplant, although the documentation of this improved survival is just now accumulating. Lung volume reduction surgery (LVRS) is also considered in some patients. The National Emphysema Treatment Trial (NETT) suggested that the classic AATD patient is unlikely to be a good candidate for LVRS, however. NETT demonstrated that individuals with diffuse destructive lung disease and/or a low diffusing capacity of the lung for carbon monoxide (DLCO) are likely to have a significantly higher mortality from LVRS than those managed without surgery.[41] The lung disease of AATD is often characterized by its diffuse nature (panlobular emphysema) and resultant low DLCO.

CLINICAL COURSE AND PROGNOSIS

As with many medical conditions, especially those with gene by environment interactions, the clinical course of individuals with AATD is highly variable. While it was initially assumed that all individuals with AATD would develop precocious, life-shortening pulmonary emphysema, this is now considered the exception rather than the rule. As more affected individuals are identified, the spectrum of "disease" includes a population of unknown total size who will never develop any medical problems related to their AATD; those with liver disease, from mild to severe and with an age of onset from the newborn to elderly; and those with lung problems ranging from mild asthma to severe emphysema and/or bronchiectasis beginning in the early decades of adult life and extending to individuals whose symptoms start in their eighth or ninth decades.

Augmentation therapy appears to improve the prognosis of those with the lung disease of AATD. In addition, it has been documented that an integrated patient-directed disease management program has beneficial effects on both quality of life and health care utilization in this same population. Still, as a whole, individuals with AATD tend to have shortened life span, increased disability, and poorer quality of life compared with the general population. In addition, there is the added psychological burden of passing this condition on to one's children (Box 71-1).

SUMMARY

AAT is one of the body's major defenses against proteolytic attack and has potent anti-inflammatory properties. The hereditary deficiency of this protein is among the most prevalent genetic risk factors for disease in humans and the most common genetic cause of COPD. AATD increases the risk of lung and liver disease and predisposes to a variety of other clinical sequelae. Still, the diagnosis is often delayed, with many affected individuals complaining of significant symptoms for many years before being identified. A variety of interventions have proved to be effective at improving quality of life and slowing the progression of symptoms.

BOX 71-1 Pitfalls and Controversies

Controversy	Results in:
Underdiagnosis	• Incorrect follow-up and therapy • Tens of thousands of individuals with undiagnosed AATD • No appropriate genetic counseling
Effectiveness and cost/benefit of augmentation therapy in question	• Expensive therapy without definitive documentation of effectiveness • General impression of and case-control evidence for effectiveness • Therapy not available in many countries
Potential for genetic discrimination	• Cases of employment discrimination • Individuals denied health insurance and life insurance

CHAPTER 72 Thoracic Tumors

Robin R. Deterding and Gregory S. Montgomery

TEACHING POINTS

- Pediatric thoracic neoplastic tumors can present with subtle clinical findings that mimic other disease.
- Consideration of the most likely types of thoracic lesion by location can guide differential diagnosis and the evaluation.
- Examination with computed tomography scanning or magnetic resonance imaging plays an important role in the evaluation of pediatric thoracic lesions.
- Tumors of the mediastinum and thoracic wall are more commonly malignant.
- Malignant masses found in the pulmonary parenchyma are often secondary metastatic disease from solid tumors.

Each year, 166 of every 1 million children aged 0 to 19 years are diagnosed with malignancies.[1] Fortunately, with therapeutic advances, the overall 5-year survival for these children is now greater than 75%. Primary and secondary thoracic tumors are even more rare, although they result in significant morbidity and mortality. Early recognition is desirable and requires clinicians to consider a tumor diagnosis in the context of the patient's history, physical examination, and evaluation. Diagnosis can be complicated by signs and symptoms that mimic more common and less concerning pulmonary disease.

Malignant tumors are classically described as primary, originating from the site of occurrence, or secondary, metastasizing from another primary site. This classification is helpful, once a diagnosis is established, to understand the nature of the tumor and clinical course. However, patients present clinically with different signs and symptoms depending more on thoracic location, which drives the generation of a differential diagnosis and evaluation. This chapter reviews pediatric thoracic tumors by thoracic location to focus attention on diagnosis and evaluation. A discussion of primary verus secondary malignancy is included for each section. Table 72-1 provides an overview of malignant pediatric thoracic tumors by anatomic location, malignancy type, and possible signs and symptoms.

AIRWAY TUMORS

Tumors arising from the conducting airways are almost exclusively primary tumors. They often manifest in affected children as nonspecific signs and symptoms of bronchial obstruction, masquerading as asthma.[2,3] Findings may include chronic cough and wheezing that fail to completely respond to asthma-focused therapy. Clinicians must have a high index of suspicion to make the diagnosis of an endobronchial tumor. Poor response to medical therapy, fixed obstructive airflow on pulmonary function testing, and associated findings that may include recurrent or persistent localized pulmonary infections, chest pain, and hemoptysis should prompt the consideration of an airway tumor. Investigations geared toward confirming the diagnosis include bronchoscopy and computed tomography (CT) scans of the chest. Specific diagnoses are confirmed by histology at the time of resection. Malignant airway tumors in children are often classified within two broad categories: bronchial adenomas and bronchogenic carcinomas.

BRONCHIAL ADENOMAS

Endobronchial tumors within this classification arise from the airway epithelium and tend to display glandular histologic features. Importantly, many "adenomas" in this category are actually slow-growing tumors that possess the potential for malignant transformation. Commonly occurring malignant airway tumors in this category include bronchial carcinoids, cylindromas, and mucoepidermoids.

Bronchial Carcinoid

The most common airway tumor in children is the bronchial carcinoid, representing nearly half of all malignant pediatric primary lung tumors.[2,4] These tumors arise from abnormally proliferating neuroendocrine cells within the bronchial epithelium, often appearing as polypoid projections into the airway lumen (Fig. 72-1*A*, *C*). For carcinoid tumors, somatostatin receptor scintigraphy (SRS), using the somatostatin analogue octreotide, may have a higher diagnostic yield than conventional imaging for localizing primary and metastatic tumor sites[5] (Fig. 72-1*B*). Final diagnosis and prognosis are assessed through pathologic classification. The more common "typical" or well-differentiated carcinoid tumor generally suggests a reduced likelihood of metastasis and excellent long-term survival. The less common "atypical" or poorly differentiated carcinoid is considerably more aggressive, often with metastatic lesions notable at the time of presentation. Therapy in children is frequently limited to local surgical resection of the tumor. Often, sleeve resection of the tumor (Fig. 72-1*D*) allows substantial preservation of functional lung

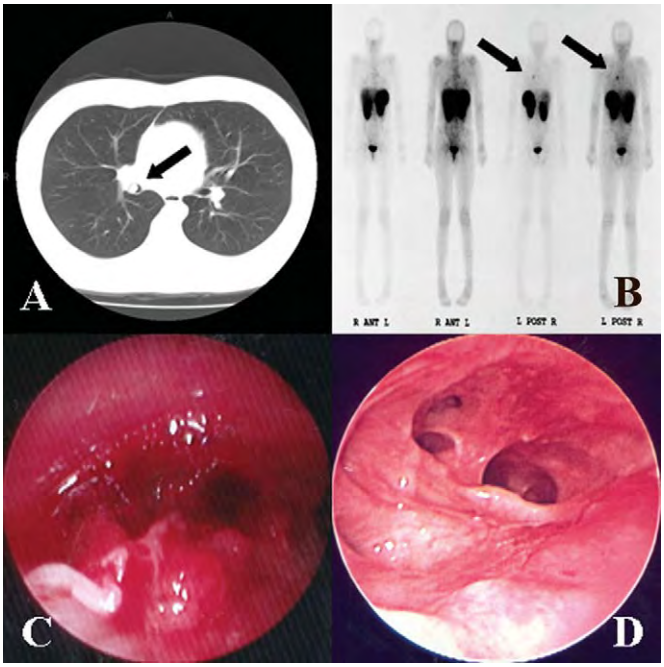

Figure 72-1 Radiographic assessments and surgical intervention in three cases of childhood bronchial carcinoid tumor. **A,** A 1.5-cm endobronchial lesion within the bronchus intermedius of an 18-year-old man as noted on computed tomography scan of the chest. **B,** Scintigraphy with a radiolabeled somatostatin analogue identified residual carcinoid tissue in the right lung of an 11-year-old girl, despite previous surgical removal. Rigid bronchoscopy demonstrated an obstructing polypoid mass **(C)** in the bronchus intermedius of a 7-year-old girl but a widely patent airway **(D)** following sleeve resection of the carcinoid tumor.

parenchyma. The "carcinoid syndrome" of excessive secretion of vasoactive peptides from carcinoid tumors has rarely been reported in association with pediatric lung tumors.

Cylindroma/Adenoid Cystic Carcinoma

Few cases of cylindroma tumors have been reported in children.[6] These tumors are perhaps the most malignant of the bronchial adenomas, with a predisposition for local infiltration, metastasis, and recurrence. Treatment options concentrate on complete surgical resection.

Tracheobronchial Mucoepidermoid

The mucoepidermoid is a slow-growing bronchial tumor arising from mucus glands within the bronchial submucosa. Histologically similar tumors occur within the salivary glands. Cytogenetic analysis of mucoepidermoid tumors often identifies the chromosomal translocation t(11;19).[7] These tumors may be locally invasive, but evidence of low-grade histologic findings suggests a favorable long-term prognosis in children.[8] As with other bronchial adenomas, treatment is focused on complete surgical resection.

BRONCHOGENIC CARCINOMAS

In children, bronchogenic carcinomas occur much less frequently than in adults. Most tumors in this category are of the undifferentiated or adenocarcinoma variety.[6] Squamous cell tumors are notably rare given the prevalence among adult tumors. As in adults, bronchogenic carcinomas are typically

Malignant Pediatric Thoracic Tumors

Anatomic Location	Malignancy	Possible Signs and Symptoms
Airways	Bronchial adenomas	Asymptomatic
	Bronchial carcinoid	Cough, wheeze, fixed obstruction, hemoptysis, atelectasis, persistent pneumonia
	Cylindroma	
	Mucoepidermoid	
	Bronchogenic carcinomas	
Anterior mediastinal	Lymphoma or leukemia	Cough, airway compression, superior vena cava compression, atelectasis
	Germ cell tumors	
	Teratoma	
Posterior mediastinal	Ganglion cell	Asymptomatic
	Neuroblastoma	Incidental finding
	Ganglioneuroma	Respiratory distress
	Ganglioneuroblastoma	Cord compression
Parenchymal	Metastatic solid tumor	Asymptomatic
	Wilms tumor	Respiratory distress
	Hepatoblastoma	Solitary pulmonary nodule
	Osteosarcomas	Multiple nodules
	Rhabdomyosarcoma	
	Papillary thyroid cancer	
	Lymphoma	
	Hodgkin disease	
	Non-Hodgkin lymphoma	
	Posttransplantation	
	Lymphoproliferative disease (PTLD)	
	Primary tumors	
	Bronchioloalveolar carcinoma	
	Pleuropulmonary blastoma	
Chest wall	Ewing sarcoma	Cough, dyspnea, painful and palpable chest wall mass
	Askin tumor	
	Rhabdomyosarcoma	
	Lymphoma	

aggressive in children. Metastases are frequent at the time of presentation, often associated with symptoms of systemic involvement—weight loss, bone pain, and anemia. Radical surgical excision remains the mainstay of therapy; no standardized chemotherapy regimen has been developed.[9] The prognosis in children is generally poor.

BENIGN AIRWAY TUMORS

A number of benign endobronchial lesions may occur in children. The capillary hemangioma is a developmental proliferation of tightly packed, trabeculated blood vessels that may arise along the surface of the conducting airways. Bronchoscopic or surgical removal may be indicated in children with symptoms of airway obstruction or hemoptysis. Inflammatory myofibroblastic tumor, also known as pulmonary inflammatory pseudotumor and plasma cell granuloma, is a non-neoplastic reactive lesion.[3] The majority are benign and amenable to complete surgical resection. Other benign pediatric airway tumors described in the literature include true mucous gland adenomas, leiomyomas, and myoblastomas.

MEDIASTINAL TUMORS

The mediastinum is traditionally conceptualized as anterior, middle, and posterior compartments based on a lateral chest radiograph. This provides a framework for addressing underlying structures and predicting disease processes and symptoms. Because the majority of malignant mediastinal tumors arise from the anterior and posterior compartments, the middle mediastinum, which can contain abnormalities associated with adenopathy or foregut malformations, is not discussed here.

Anterior Mediastinum

The *anterior mediastinum* is defined as the area posterior to the sternum and anterior to the heart and contains the thymus.[10] Masses in this region can be asymptomatic or potentially life threatening from airway compression depending on mass size and must be approached very cautiously during evaluation.[11] Nonspecific signs and symptoms of cough (especially when the child reclines), atelectasis, and superior vena cava obstruction can be seen.[12]

LYMPHOMA

Lymphomas are one of the more common pediatric malignancies with an incidence of 11.3 per 1 million for Hodgkin lymphoma (or Hodgkin disease [HD]) and 8.4 per 1 million for non-Hodgkin lymphoma (NHL) (ages 0-19 years) and the most common cause of mediastinal masses in children.[1,13] Both NHL and HD frequently present with a primary mass and adenopathy in the anterior mediastinum.[14] Chest radiographs can be abnormal with an enlarged thymic or unusual shadow anteriorly (Fig. 72-2*A*), and calcifications are rare. A contrast CT scan provides the best characterization of the mass.[12] A complete review of the different subtypes of HD and NHL is beyond the scope of this review. In general, treatment consists of combination therapy with radiation and chemotherapy regimens.[15-17] Prognosis has markedly improved over the past three decades with improving therapeutic advancements, resulting in 5-year survival rates of 95% for HD and 81% for NHL (ages 0 to 19 years).[1]

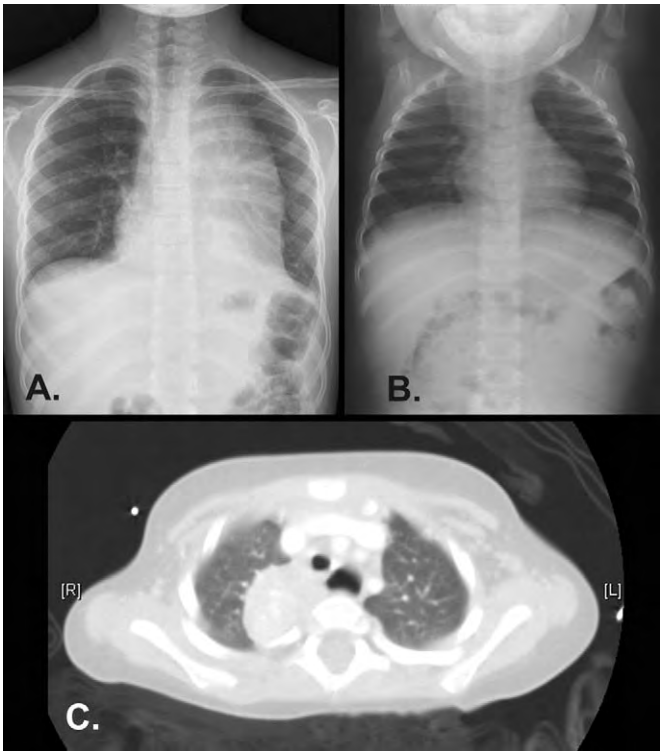

Figure 72-2 Radiographs of mediastinal neoplasms. **A,** Large T-cell lymphoblastic lymphoma arising from the anterior mediastinum seen on a chest radiograph in a 12-year-old. A posterior mediastinum neuroblastoma in a 3-year-old seen on a chest radiograph **(B)** and a computed tomography scan of the chest **(C),** which also demonstrates calcifications.

GERM CELL TUMORS

Germ cell tumors are the third most common tumor of the pediatric mediastinum, accounting for 6% to 18% of tumors in this location.[18] Germ cell tumors have varied histology, with the most common being different grades of teratomas. Other nonteratoma germ cell tumors include seminoma, embryonal carcinoma, choriocarcinoma, yolk sac tumors, and mixed types. Most germ cell tumors arise in the anterior compartment and, like lymphoma, can cause respiratory symptoms and distress from airway compression. Masses can be large and visible on chest radiographs. CT images are helpful for localizing the lesion and determining the attenuation of fluid, soft tissue, calcium, and fat, which can be suggestive of the diagnosis.[12] Survival has improved with treatment approaches that focus on a tailored surgical resection and neoadjuvant chemotherapy.[19]

NONMALIGNANT MISCELLANEOUS DISORDERS

Other differential diagnoses to consider in the anterior mediastinum include thymus and vascular abnormalities, infections, benign tumors, and miscellaneous disorders.[12]

Posterior Mediastinum

The *posterior mediastinum* is defined as the area posterior to the heart and trachea to the thoracic vertebral margins.[10] Normally occurring structures include the thoracic aorta, esophagus, azygos veins, autonomic ganglia and nerves, thoracic duct, and lymph nodes.

Masses in this region account for 30% to 40% of pediatric mediastinal tumors, and 90% of these tumors are of neuro-

genic origin.[12,20] Patients with posterior tumors can be asymptomatic and the tumor found incidentally on a chest radiograph or symptomatic from local mass effect or intraspinal extension. All unusual masses in the posterior mediastinum must be investigated regardless of the presence of symptoms.

GANGLION CELL TUMORS

Ganglion cell tumors are the second most common pediatric mediastinal tumor and include neuroblastomas, ganglioneuromas, and ganglioneuroblastomas.[21] Radiographically, ganglion cell tumors are not distinguishable. One of the most important considerations for distinguishing between the different tumors is median age of occurrence, with neuroblastoma occurring at a median age of 2 years and 95% by 10 years, ganglioneuroblastomas occurring at a median age of 5.5 years, and benign ganglioneuromas occurring later in childhood, after 10 years.[12]

Neuroblastoma is a major pediatric malignancy, accounting for 10% of all childhood cancers and 15% of cancer deaths.[22] It is commonly found as a primary in the thorax. Patients may be asymptomatic with an incidental chest radiograph finding (Fig. 72-2*B*), symptomatic with respiratory distress or cord compression from the primary tumor, or symptomatic with symptoms of disseminated disease such as fever, weight loss, or bone pain.[21,23] A CT scan is commonly used to assess the soft tissue in the paraspinal area and may show calcifications up to 80% of the time[12] (Fig. 72-2C). Magnetic resonance imaging (MRI) can be useful to determine the extent of tumor involvement in the chest, and nuclear scintigraphy is helpful to further stage the disease. Survival is best determined by age at diagnosis and stage of disease.[23]

OTHER MISCELLANEOUS DISORDERS

Although less common, non-neurogenic primary malignant posterior mediastinal masses can include Ewing sarcoma, germ cell tumor, and rhabdomyosarcoma. Less frequent nonmalignant disorders to consider in the differential diagnosis include vascular abnormalities, infections, adenopathy, benign tumors, and miscellaneous conditions.[12]

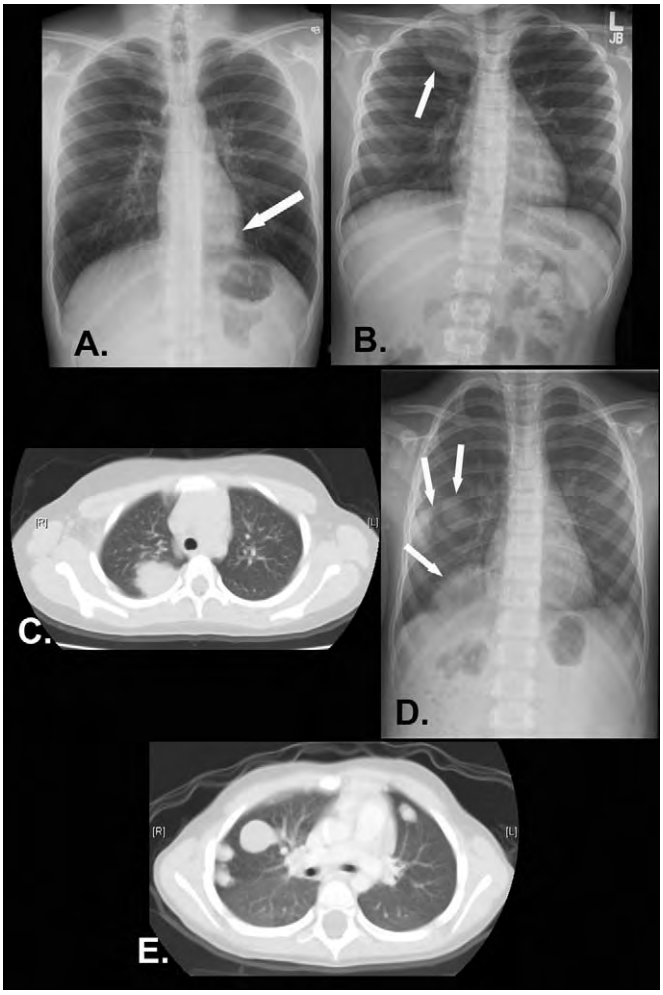

Figure 72-3 Radiographs of pulmonary parenchymal lesions. **A,** A 1.7-cm solitary pulmonary nodule seen on a chest radiograph in an 18-year-old man, ultimately diagnosed with a rare and benign pulmonary sclerosing hemangioma. A single metastatic lesion from a Wilms tumor in an 8-year-old seen on a chest radiograph **(B)** and a computed tomography scan of the chest **(C).** Multiple metastatic Wilms tumor lesions in a 5-year-old seen on chest radiograph **(D)** and a computed tomography scan of the chest **(E).**

PARENCHYMAL TUMORS

Unlike mediastinal and chest wall tumors in children, the majority of parenchymal nodules usually represent a granulomatous infection and are rarely neoplastic. Secondary metastatic nodules or masses are much more common than are primary tumors. When parenchymal malignancies occur, patients can be asymptomatic or have only mild or nonspecific complaints. Large masses create more symptoms that can progress to respiratory distress. Because of their rarity and subtle findings, most thoracic malignancies are diagnosed at advanced stages.[8] Important history such as malignancy or transplantation and radiographic information can help guide clinical reasoning and structure the diagnostic evaluation.

PULMONARY NODULES

Solitary pulmonary nodules (SPNs), or "coin lesions," are defined as round lesions that are surrounded by lung parenchyma and less than 3 cm in diameter[24] (Fig. 72-3*A*). The majority of coin lesions are benign in healthy children, representing infectious granulomas or hamartomas. Although less common, malignant lesions to consider in the initial differential would include carcinoid tumor, very rarely a bronchogenic carcinoma, post transplant lymphoproliferative disease (PTLD), and a solitary metastatic lesion in a child with a current or previous malignancy.[6,9,24-27] Previous chest radiographs can be examined, and if the nodule has not grown in size over 2 years, there is a high likelihood that the nodule is benign.[28] High-resolution CT is better than chest radiographs in providing current clues to the diagnosis. Certain findings support the diagnosis of a benign lesion, such as calcifications within a nodule, a laminated or central pattern consistent with a granuloma, a classic "popcorn" pattern, or evidence of intranodular fat suggestive of a hamartoma.[24,29] If lesions remain suspicious, noninvasive evaluations for malignancy and granulomatous infections can be undertaken, and the healthy patient with low probability of malignancy can be followed with serial radiographs. Positron emission

tomography (PET) is usually not indicated in healthy children who have a low likelihood of malignancy and are more likely to have an infection (which results in a false-positive PET scan) or a carcinoid tumor (which results in a false-negative PET scan).[30] For nodules that remain suspicious and carry a higher probability for malignancy, surgical removal and histologic evaluation are necessary to make the diagnosis.

PULMONARY MASSES

In contrast to nodules, lesions larger than 3 cm are considered masses. Masses are more likely to be malignant than are nodules. Except for a small percentage of pediatric lymphomas that can present with pulmonary parenchymal involvement,[14] most masses are associated with metastatic disease from a known solid tumor in children. Common childhood solid tumors that metastasize to the lung include Wilms tumor, osteosarcoma, rhabdomyosarcoma, hepatoblastoma, and, rarely, thyroid cancer.[23,25,26,31] Metastatic masses or nodules can be solitary (Fig. 72-3*B*, C) or multiple (Fig. 72-3*D*, *E*) and could be found at the time of diagnosis of the malignancy or as a recurrence of disease.[26] One fourth of hepatoblastomas present with metastatic disease, and 30% of these metastases occur in the lung.[23] Osteosarcoma has a high recurrence rate in the lung.[32] Wilms tumor can be associated with metastatic disease at the time of diagnosis and as recurrent disease.[33] The primary treatment, if possible, for lung metastases is resection. Survival is dependent on the underlying primary malignancy.

Nonmalignant conditions to consider depending on the clinical presentation include infectious etiologies, inflammatory noninfectious etiologies (Wegener granulomatosis), vascular lesions, and congenital abnormalities.[29]

OTHER CONDITIONS

Congenital cystic adenomatoid malformations (CCAMs) have been associated with primary pulmonary malignancy transformation into bronchioloalveolar carcinoma, rhabdomyosarcoma, and pleuropulmonary blastoma (PPB).[34-36] Type 1 CCAMs have been found to contain microscopic foci of bronchioloalveolar carcinoma.[34] Type 4 CCAMs have demonstrated some histologic overlap with PPB and malignant transformation has also been postulated.[37] Thus, resection of CCAMs and careful histologic evaluation are required for an appropriate diagnosis.

PPB is a rare and aggressive primary parenchymal tumor in early childhood that carries a poor prognosis. Patients present with a pulmonary- or pleural-based cystic mass and respiratory symptoms, with or without fever.[35] Pleural or mediastinal involvement is associated with worse outcomes. Resection is the primary therapy but recurrences are common. Five-year survival ranges from 42% to 83% depending on the PPB tumor classification, which is based on cystic or solid tumor characteristics.[35]

An aggressive form of lymphoma associated with immunosuppression after transplantation is PTLD. Epstein-Barr virus (EBV) infections are associated with the development of this life-threatening condition. EBV-PTLD can involve the lung and other extrapulmonary sites. In the lung, the lesions can vary from single to multiple nodules or masses. In bone marrow transplant patients, the highest risk period appears 5 months post transplant with associated risk factors for PTLD including T-cell depletion of the donor marrow, unrelated or mismatched donor, and use of anti–T-cell antibodies for graft-versus-host disease (GVHD).[27] EBV-DNA load in peripheral blood can be measured by quantitative PCR and provide support for a diagnosis of PTLD. Histology confirms the diagnosis. Treatment is directed at lowering immunosuppression; rituximab has also been successfully used.[27,38]

CHEST WALL TUMORS

Primary chest wall tumors are also rare in children, but a high percentage of these tumors are malignant.[39] These aggressive tumors can primarily arise from the soft tissues of the chest wall or as extensions from bony structures or the mediastinum. Symptoms of neoplastic chest wall lesions include a painful, palpable chest wall mass, cough, and dyspnea.[40] Conversely, benign lesions tend to be asymptomatic. Imaging plays a central role in evaluation and diagnosis.

The most common chest wall tumors are a group of tumors called either Ewing sarcoma family of tumors (ESFT) or malignant small round cell tumor (MSRCT).[40,41] This group includes primitive neuroectodermal tumors of the chest wall known as Askin tumor, Ewing sarcoma of bone, and extraosseous Ewing. Pulmonary metastasis can also be found at the time of diagnosis. Imaging with CT, which is better at demonstrating lung metastasis, and MRI, which can be superior to CT for showing invasion into the chest wall, often shows a thoracic lesion with adjacent rib erosion.[39] ESFT or MSRCT are aggressive tumors with a poor prognosis and a high rate of recurrence.[41] Complete tumor resection provides the best possibility for cure.

Rhabdomyosarcomas constitute the second most common group of chest wall tumors and are also very aggressive with a poor prognosis.[40] Imaging usually demonstrates a large heterogeneous mass with rib destruction and occasionally a pleural effusion. Resection is the primary treatment. Lymphomas appear as a primary within the chest or as a direct extension from the mediastinum with evidence of lytic destruction of the ribs or the sternum. Likewise, neuroblastomas can also invade the chest wall from the posterior mediastinum. Less common malignant chest wall tumors include congenital fibrosarcoma, chondrosarcomas, and primary osteosarcomas.[40]

Other, more benign chest wall lesions to consider in the differential diagnosis in children include a wide range of possibilities such as lipomas, neurofibromas, lymphangiomas, hemangiomas, hamartomas, tuberculosis, Langerhans cell histiocytosis, osteochondromas, and anatomic variations of the thoracic cage.[42]

CONCLUSION

Pediatric thoracic tumors are a rare group of diverse disorders that can be associated with significant morbidity and mortality. Patients may present with only subtle signs and symptoms requiring a high index of suspicion. Understanding the most common disorders in each thoracic location can aid the diagnosis and evaluation.

CHAPTER 73

Bronchiolitis Obliterans*

Rees L. Lee and Carl W. White

TEACHING POINTS

- The pathogenesis of bronchiolitis obliterans often relates to infection, especially adenovirus or *Mycoplasma pneumoniae;* drugs, inhaled toxins, and toxic gases; transplant (lung, heart-lung, bone marrow); or collagen vascular diseases.
- Bronchiolitis obliterans is suspected in a patient with a consistent history, airways obstruction without reversal by inhaled β-adrenergic agents, or "burst" glucocorticoids, usually with increased lung volumes.
- High-resolution chest computed tomography scan shows a variegated or mosaic pattern with persistent areas of alternating hyperinflation and hypoinflation.
- Lung biopsy may reveal bronchiolar obstruction by fibroblasts and/or myofibroblasts.
- Immunosuppressive therapy often has limited success.

Bronchiolitis obliterans (BO) is a rare, irreversible obstructive lung disease resulting from bronchiolar inflammation and luminal obliteration by circumferential peribronchiolar fibrosis. It can be the uncommon aftermath of a severe pulmonary infection. More recently, BO has gained prominence as the major cause of lung transplant failure beyond the immediate post-transplant period. It is also a significant cause of morbidity after bone marrow transplants. Few treatments have been shown to be effective and a fatal progression can occur, particularly in post-transplant patients.

HISTOPATHOLOGY

BO is a primary bronchiolar disease process[1,2] characterized by the circumferential peribronchiolar fibrosis leading to constriction of the bronchiolar lumen and, in the worst case, complete luminal obliteration[3-5] (Fig. 73-1). Synonymous terms are *constrictive bronchiolitis* and *obliterative bronchiolitis*.

There has been significant confusion regarding the term *bronchiolitis obliterans*. Many early descriptions of BO, including the first description by Lange,[6] would today be termed *cryptogenic organizing pneumonia* or *bronchiolitis obliterans organizing pneumonia* (BOOP).[1] Despite the very similar terminology of BO and BOOP, these disease processes have very different histologies (Table 73-1). BOOP is a distinct histopathologic disease with bronchiolar intraluminal polyps composed of mucopolysaccharide-rich fibroblasts that can extend into the alveolar ducts and alveoli, leading to organizing pneumonia.[3,5] In fact, the involvement of the bronchioles may be relatively minor with the organizing pneumonia being the primary pathology.[7]

By contrast, BO is a uniquely bronchiolar disease. There are no changes to the distal alveoli or lung parenchyma.[3] Instead, there is circumferential bronchiolar thickening of the submucosa from collagenous scarring. This results in distortion of the airway architecture and narrowing of the lumen. In a Brazilian study of children with the clinical presentation of BO, 97% showed evidence of constrictive bronchiolitis. Mucous stasis further complicated the luminal narrowing and one third had evidence of bronchiectasis.[4] Chronic inflammation can be seen and may account for the progressive nature of BO. Inflammatory infiltrates of foamy macrophages and lymphocytes are observed in the majority of postinfectious BO biopsy specimens.[4] Increases in both $CD4^+$ and $CD8^+$ lymphocytes are observed.[8]

A submucosal lymphocytic infiltrate (lymphocytic bronchitis/bronchiolitis) also characterizes post-transplant BO.[9] The accumulation of myofibroblasts and fibroblasts with collagen deposition results in granulation tissue and ultimately a fibrous scar that obstructs the bronchiole.[10] The presence of lymphocytic bronchiolitis in post–lung transplant patients is a significant risk factor for the development of BO.[11,12]

PATHOGENESIS

Because BO is a common cause of death after lung transplantation, a significant amount of effort has been expended trying to understand the pathogenesis of BO. BO may be an injury response of repeated or chronic insults to the airway epithelium.[13,14] In human lung transplant patients, even mild rejection (grade A1) experienced recurrently increases the risk of developing BO.[15]

Epithelial damage appears to be important. In a heterotopic tracheal allograft rat model, marked lymphocytic infiltration with loss of the epithelium precedes complete fibrous

Disclaimer: The views expressed in this article are those of the authors and do not necessarily reflect the official policy or position of the Department of the Navy, Department of Defense, or the United States Government.

obliteration of the graft airway.[16] Similarly, 2 weeks after proteolytic removal of the tracheal epithelium, airway obliteration is noted. Reseeding the grafts with epithelial cells significantly mitigates the obstructive changes,[17] emphasizing the importance of epithelial layer disruption to the development of BO. In human transplant patients, detection of specific antibodies to the donor airway epithelial cells precedes development of BO and may contribute to airway epithelial damage.[18] In an intriguing animal study, progression to BO was prevented by reepithelialization of the donor graft with *recipient-derived* epithelium,[19] reinforcing the hypothesis that immune-mediated injury to the epithelium is key to BO development.[20,21]

Epithelial damage with the loss of basement membrane integrity could allow lymphocyte access to the airway mucosa similar to the lymphocytic bronchiolitis noted in pathologic specimens. Infiltrating $CD4^+$ and $CD8^+$ T-lymphocytes[22] release a variety of inflammatory cytokines, especially Th1 cytokines such as interferon-γ and interleukin-2 (IL-2).[23] As part of this inflammatory response, fibroblasts and myofibroblasts lay down collagenous scar tissue as documented by increases in profibrotic factors[24] and procollagen I and III mRNA[25] in BO animal models.

The inflammation, epithelial damage, and fibroblastic response leading to BO appear to be a T-cell–mediated process. $CD8^+$ T cells may play a particularly important role in the fibroblastic response as depletion of $CD8^+$ T cells significantly reduces the fibrosis and airway obliteration in the mouse model.[26] Activation of T cells depends on (1) recognition of MHC class I and II antigens on antigen presenting cells (APC) by $CD8^+$ and $CD4^+$ T-lymphocytes, respectively; and (2) co-stimulatory interactions between CD28 on the T cells and B7 ligands on the APC. Both arms of T-cell activation are important. Alloreactivity against the donor MHC-I and II antigens by the recipient $CD4^+$ and $CD8^+$ T-lymphocytes can induce BO in experimental animal models,[27] and MHC mismatch remains a significant risk factor for development of BO in human transplant recipients.[28,29] Blockade of CD28 binding to the B7-2 ligand results in a significant decrease in airway obliteration in the rat model,[30,31] emphasizing the importance of the co-stimulatory interactions. Additional studies supporting the importance of the T cell–APC interaction have used the compound FTY720 to reduce the T-cell population by inducing apoptosis and sequestering circulating lymphocytes. Similar to CD28/B7-2 blockade, rats treated with FTY720 also show decreased obliterative airway changes.[32] Simultaneous blockade of CD28/B7-2 together with the administration of FTY720 not only prevents airway obliteration but also preserves the airway epithelium.[32] Finally, interference with the interaction of activated T cells with B cells by blocking the CD40 co-stimulatory pathway can mitigate the development of BO.[33]

The importance of microvascular changes in the development of BO has recently been appreciated. Angiogenesis and vascular remodeling are important aspects of the fibroproliferative process,[34] and transplant patients with BO show significant increases in airway microvascular vessel counts compared with patients without BO.[35] In rat tracheal allografts, overexpression of vascular endothelial growth factor (VEGF) results in luminal occlusion. This obstructive

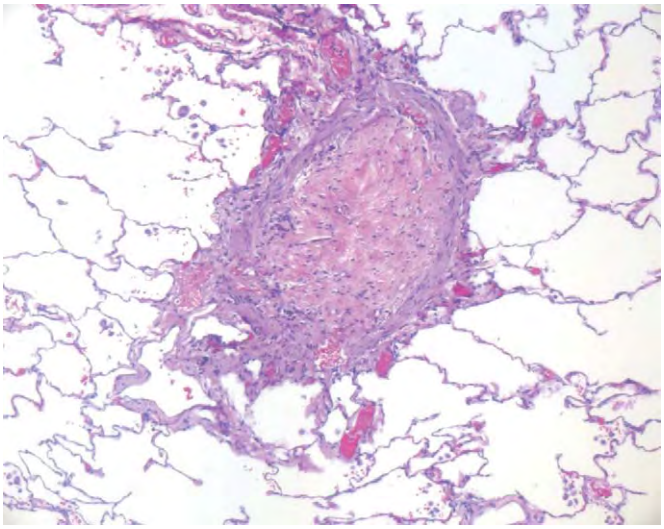

Figure 73-1 Pathology of bronchiolitis obliterans (BO): Bronchiole with a thickened airway wall and collagenous scar tissue which has obliterated the lumen. process appears to operate through platelet-derived growth factor (PDGF) as inhibition of this pathway with imatinib (a PDGF tyrosine kinase inhibitor) prevents luminal occlusion.[36] Despite this animal finding, the significance of VEGF in human BO pathology remains unclear. Instead of increased VEGF, the BAL from lung transplant patients has significant depressions in VEGF, especially immediately after transplantation, during periods of rejection, and in patients with active BO.[37] In fact, low BAL VEGF levels at 6 months post-transplant were significantly correlated with the development of BO (BO patients: 86 ± 19 pg/mL versus non-BO patients: 158 ± 18 pg/mL)[37] and may be most useful as a marker of at-risk patients rather than being causal in the etiology of BO.

More recent investigations have explored VEGF-*independent* chemokine-mediated angiogenesis. A series of investigations by Belperio and colleagues[38] examined the role of CC chemokines and ELR$^+$ CXC chemokines. ELR$^+$ CXC chemokines contain a Glu-Leu-Arg immediately before the first cysteine residue at the NH_2 terminus and serve as important mediators of early neutrophil and monocyte inflammation and later angiogenesis as part of the fibroproliferative response. In murine models, the CC chemokine monocyte chemoattractant protein 1 (MCP-1) operating through the receptor CCR2 has been related to the mononuclear cell recruitment associated with BO formation.[39] In humans, elevated BAL levels of MCP-1 has been found in patients with acute and chronic rejection.[39] With regard to vascular remodeling and angiogenesis, research using the mouse tracheal allograft model of BO indicates that the ELR$^+$ CXC chemokine receptor 2 (CXCR2) and its ELR$^+$ CXC ligands are significant. In CXCR2$^{-/-}$ animals, the angiogenic and fibrotic response to tracheal allografts is dramatically reduced compared to CXCR2$^{+/+}$ wild-type animals.[35] A similar effect occurs if ELR$^+$ CXC chemokine binding to CXCR2 is blocked by anti-CXCR2 antibodies.[35] In human transplant patients, significant elevations of ELR$^+$ CXC chemokines in the BAL fluid are present in patients with bronchiolitis obliterans syndrome (BOS) compared with healthy transplant patients.[35] This elevation persists in some ELR$^+$ CXC chemokines (especially CXCL8) despite treatment of the BOS. This BAL fluid from BO patients has substantial biologically active angiogenic activity when assessed by human lung microvascular endothelial cell chemotaxis assay. This angiogenic activity can by neutralized with specific antibodies to CXCR2 but antibodies to VEGF have no effect.[35] This exciting research into VEGF-independent angiogenesis may ultimately lead to anti-angiogenic/antifibrotic therapies that target the ELR$^+$ CXC chemokines or their receptors.[40]

The etiology of BO in nontransplant patients is less clear but, similar to the post-transplant situation, is likely the result of a chronic inflammatory insult to the airway epithelium. In children with postinfectious BO, biopsy specimens show increases in CD4$^+$ and CD8$^+$ T-lymphocytes as well as prominent foamy macrophages.[4,8] Comparing an animal model of toxin-induced BO[41] to a tracheal transplant model, both sets of animals show similar increases in cytokines including TGF-β and interferon-γ.[42] The histology of the BO is identical in the two models. However, the rapid increase in osteopontin seen after toxicant injury but not seen in the transplant model implies that although the mechanisms leading to BO are similar, they are not necessarily identical.[42] Instead, BO likely represents a "final common pathway" following severe and/or repeated airway injury.[14] This injury induces a primarily lymphocytic, T-cell–mediated inflammatory response that includes fibroproliferation leading to the classic circumferential scar formation and progressive obliteration of the airway lumen (see Fig. 73-1).

PREVALENCE

The incidence of nontransplant BO is difficult to estimate due to its rarity. In a large retrospective review of 2897 autopsies and 244 lung biopsies at a children's hospital, only 19 cases of BO were documented, 12 of which were clinically diagnosed prior to death/biopsy.[43] This would give a prevalence in this selected sample of 0.6%. By contrast, post-transplant BO is relatively common and accounts for the majority of lung graft failures outside of the immediate post-transplant recovery period. Approximately 40% to 50% of lung transplant patients who survive 5 years develop BO and it remains the most common cause of death beyond 1 year post-transplant (approximately 40% of pediatric deaths and 27% of adult deaths).[44,45] The recent use of induction suppressive therapy does not appear to have affected this prevalence.[45] In bone marrow transplants, the prevalence of BO is approximately 9%.[46] The prevalence after allogeneic hematopoietic stem cell transplantation is 1.7%.[47]

ETIOLOGIES AND RISK FACTORS

Few large studies of nontransplant BO have been conducted from which to derive good estimates for developing risk assessments. Box 73-1 lists the reported etiologies of BO. Infection remains the most commonly identified etiology of BO, with adenovirus being the most prevalent infectious agent,[4,48-51] followed by *Mycoplasma pneumoniae*.[49] Perhaps due to the fact that BO may be diagnosed well after the acute phase of the illness, the etiology is often not determined with certainty (idiopathic BO).

Currently, the most common cause of BO is post-transplant BO, particularly after lung transplantation. A number of risk factors have been identified predisposing to more rapid development of BO.[52] Primary among these is the occurrence of acute rejection.[52] The presence of lymphocytic bronchiolitis has also been associated with BO,[11] but it may simply represent the pathologic correlate of graft rejection. Supportive of the importance of inflammation related to graft rejection is the observation that the development of BO is associated with subtherapeutic cyclosporine levels.[11] Nonimmunologic risk factors are less well defined. Early associations noted with cytomegalovirus infection[53,54] may be less important with the increased use of ganciclovir prophylaxis.[55,56] The role of other viruses such as RSV, parainfluenza, metapneumovirus, and adenovirus remains controversial, but a number of recent studies have documented trends toward the development of BO in patients contracting these infections post-transplant.[57-59]

Gastroesophageal reflux (GER) is very common in transplant patients, and aspiration of the refluxed material may contribute to BO.[60] In a retrospective study of 128 lung

transplant patients, 73% had pH probe-confirmed GER disease (GERD). Those who underwent fundoplication showed an average of 24% improvement in FEV_1 when assessed 6 months later.[61] Early identification and treatment of GERD appears to yield better outcomes.[62] While it is reasonable to speculate that GERD may play a significant role in nontransplant BO, such an association has not been reported.

Box 73-2 lists risk factors that have been associated with post-transplant BO. Causal relationships have yet to be definitively determined.

Box 73-2 Potential Risk Factors for Post-Transplant Bronchiolitis Obliterans[52]

- Immunologic risk factors
  - Acute rejection
  - Subtherapeutic immunosuppression
  - Lymphocytic bronchiolitis
  - HLA mismatch between donor and recipient
- Nonimmunologic risk factors
  - Post-transplant viral infection
  - Recipient of young age
  - Donor of older age
  - Prolonged graft ischemia
  - Gastroesophageal reflux
  - Positive methacholine challenge[172]

CLINICAL PRESENTATION AND DIAGNOSIS

The clinical onset of BO is often insidious. Following an acute respiratory insult such as a viral pneumonitis or toxic inhalation exposure, the patient may appear to show recovery. However, the exertional dyspnea, chronic cough, and wheeze persist. While sometimes the physical examination results normalize, the majority of cases have abnormal physical examination findings (Table 73-2). Even in patients who are asymptomatic, the classic finding is an irreversible decline in FEV_1. In a study of Korean and U.S. nontransplant BO patients, 26% presented with hypoxia at rest and an additional 22% had evidence of nocturnal or exercise-induced hypoxia.[49]

In transplant patients, there is usually an initial period of good graft function. However, there is an insidious onset of exertional dyspnea and chronic cough. Occasionally, patients can present with acute wheezing and low-grade fever and may initially be diagnosed with asthma. Unlike asthma, these patients show an irreversible decline in FEV_1 and the response to oral corticosteroids is minimal or nonexistent. Occasionally, BO patients may have a reactive, bronchodilator, and/or corticosteroid responsive component in addition to the predominantly irreversible fixed airways obstruction. The pulmonary functions of these patients never normalize.

The clinical diagnosis of BO relies on the presence of irreversible obstruction (decreased FEV_1) on spirometry. In the absence of a definitive biopsy diagnosis and in the appropriate clinical situation, irreversible decline in FEV_1 may be sufficiently suggestive of BO to diagnose BOS. In a 1993 consensus statement from the International Society for Heart and Lung Transplantation, BOS was defined as a 20% or greater drop in FEV_1 compared with the baseline.[63] Baseline is the mean of the two highest post-transplant FEV_1 values obtained 3 to 6 weeks apart, and the drop in FEV_1 must be documented for more than 1 month in the absence of acute infection, acute rejection, or airway anastomotic stenosis. BOS is graded from BOS 0 (no BOS) to BOS 3 (severe BOS) (Table 73-3). More recently, a "potential BOS" stage was added (BOS 0-p).[64] BOS 0-p is defined as a drop in FEV_1 of 10% to 19% below baseline *or* a drop in $FEF_{25-75\%}$ greater than or equal to 25% below baseline. The BOS 0-p stage includes the recognition that declines in $FEF_{25-75\%}$ may be a more sensi-

tive measure of early BOS in some patients as well as the importance of even a mild FEV_1 decline in identifying at-risk patients. While controversy remains as to the best spirometric value to measure (FEV_1 or $FEF_{25-75\%}$), it appears that BOS 0-p has post-transplant prognostic value (sensitivity 71% to 80%, specificity 83% to 93%).[65,66] In one study, 81% of patients who met BOS 0-p FEV_1 criteria went on to develop BOS or died.[65]

The chest radiograph findings are nonspecific. In patients with early BO, chest radiographs may appear normal or show mild hyperinflation. More advanced disease may show areas of volume loss, atelectasis, bronchiectasis, and linear opacities.[67,68] High-resolution chest CT (HRCT) has become a very useful tool in the diagnosis of BO. A mosaic pattern of hypolucencies due to air-trapping is noted,[67,69-71] which becomes more prominent on expiratory-phase HRCT views[72] (Fig. 73-2). Expiratory-phase HRCT has a sensitivity of 80% to 93% and a specificity of 80% to 94%.[72-74] Unfortunately, a prospective trial of adding HRCT to the annual post-transplant patient evaluation did not enhance the ability to detect BO.[75] The extreme form of air-trapping with unilateral hypolucency is the Swyer-James/MacLeod syndrome.[76] Vascular attenuation, bronchiectasis, and atelectasis can also be noted on HRCT.

Ventilation-perfusion ($\dot{V}/\dot{Q}$) scans of the lung show matched defects.[77,78] Regional hypoperfusion is likely due to reflex vasoconstriction secondary to hypoxia in the affected hypoventilated lung segment. Routine $\dot{V}/\dot{Q}$ scans of post-transplant patients do not enhance the ability to detect BO.[79]

Exhaled nitric oxide (eNO) may be a useful adjunct in the diagnosis and monitoring of BO. In a 2-year observation trial of post–lung transplant patients, 12 of 13 patients who developed BOS had two or more eNO measurements above 15 ppm, whereas only 3 of 19 without BOS satisfied this

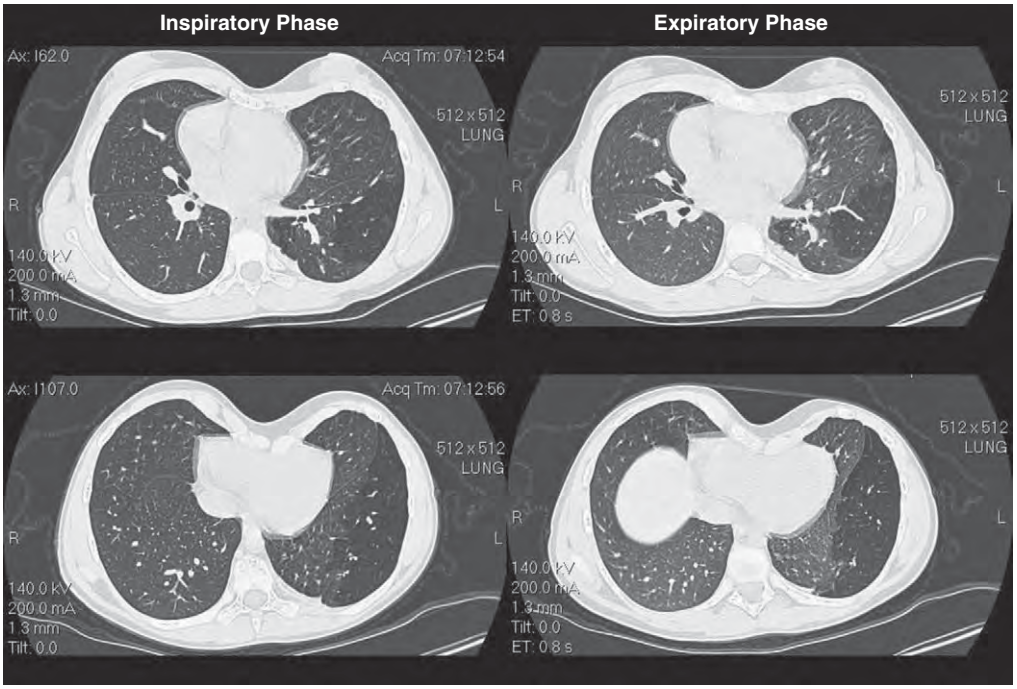

Figure 73-2 A 12-year-old girl with irreversible obstructive lung disease consistent with bronchiolitis obliterans (Swyer-James changes). Large hypolucent areas of the left lower lobe are noted which become more prominent on expiratory phase CT scan. Failure of these areas to compress significantly during expiratory phase is consistent with air-trapping. (Child also has moderate pectus excavatum. The round opacity within the right lung field of the lower right CT scan is the diaphragm extending upward during expiratory phase.)

criteria.[80] Using eNO to guide immunosuppressive treatment has also been suggested.[81,82]

The definitive diagnosis of BO requires a lung biopsy specimen showing the characteristic histology described previously. The pathologist may need to evaluate multiple sections through one or more blocks in order to find the *focal* pathognomic obstructive airway lesion. The clinician must maintain a high index of suspicion, especially with a suggestive history, physical findings, and HRCT. The pathologist should be encouraged to continue the search if classic findings are not immediately apparent. Due to the patchy nature of BO, the sensitivity of a transbronchial biopsy is quite variable (15% to 82%) and cannot be used to reliably rule out the diagnosis.[83-85] However, a positive result from a transbronchial biopsy specimen may be helpful in confirming the diagnosis of BO because such a positive finding has high specificity and predictive value.[84] With the advent of video-assisted thoracoscopic surgery (VATS) techniques for both adults and children, lung biopsies may be better tolerated than previously reported[86] and make a definitive diagnosis through lung biopsy a more realistic goal.

TREATMENT AND PROGNOSIS

Nontransplant Bronchiolitis Obliterans

The natural history of nontransplant BO is difficult to determine due to the varied etiologies, relatively small numbers of affected patients, and the widely variable outcomes noted in the literature. Postinfectious BO is the most common form of BO in children. In a retrospective study by Kim and associates[49] of 31 Korean and U.S. children with mostly postinfectious BO, only one patient (3%) had died of the disease over a follow-up period of 1 to 10 years. However, three patients (10%) required lung transplantation. The authors noted that nontransplant BO in children has "a good overall prognosis and a relatively low mortality rate."[49] By contrast, Hardy and colleagues[43] noted 9 deaths in 19 cases of BO (47% mortality) between 1960 and 1985. In a series of 31 Brazilian children with postinfectious BO followed for an average of 3.5 years, two-thirds had persistent symptoms, 23% showed clinical remission, and 10% died.[87]

No specific treatment exists for postinfectious BO. The use of both inhaled and oral corticosteroids is controversial, but benefits have been reported in some patients.[49] Despite being on steroids, lung inflammation often persists.[8] The use of bronchodilators may be counterintuitive in a disease defined as irreversible airway obstruction. However, regular use of bronchodilators in some patients may be beneficial.[49] In our personal experience, we find that the majority of postviral BO patients have some reactive airways component and benefit from bronchodilators and/or steroids. Patients with severe obstruction, hypoxia, and functional impairment may require lung transplantation.

Rheumatoid arthritis (RA) is the most common collagen-vascular disease leading to BO.[88] It is sometimes unclear whether this is a direct result of RA or a result of the medications used to treat it, such as penicillamine or gold salts. Unlike postinfectious BO, which can stabilize or even have some remission, most patients with RA-associated BO die within 1 to 5 years.[88-90] Treatment with corticosteroids or other immunosuppressive agents has been disappointing. Regular use of erythromycin was shown in a small study of 15 patients to stabilize or improve symptoms.[91] A recent case report of a 55-year-old woman with rapidly progressive BO and RA documents marked improvement after use of methotrexate and etanercept (TNF-α inhibitor).[92]

Post-Transplant Bronchiolitis Obliterans

The greatest challenge in the treatment of BO has been the attempt to halt its development in transplant patients, especially those receiving lung transplants. BO remains the most common cause of death more than 1 year post–lung transplant.[44,45] Despite improvements in immediate post-transplant survival, the ability to either prevent BO or alter the progression of BO has met with only marginal success.

Three distinct patterns of pulmonary function decline have been described in post-transplant patients.[93] The first pattern is one of rapid, relentless decline in FEV_1 with no stabilization. A second pattern also has an initial rapid FEV_1 decline but is followed by a period of partial stabilization. The final group shows a slow but inexorable decline in pulmonary function. In no group is there improvement or recovery of lung function (Fig. 73-3).

Since the occurrence of acute rejection episodes and inadequate immunosuppression has been correlated with BO development, preventive strategies have concentrated on determining the optimal immunosuppressive regimen. The traditional immunosuppressive regimen has consisted of cyclosporine, azathioprine, and corticosteroids. There has been evidence that tacrolimus (FK506) and mycophenolate mofetil (MMF) may provide superior prevention and treatment of BO in lung-transplant patients.

Tacrolimus is a calcineurin inhibitor similar to cyclosporine. It acts to inhibit lymphokine production by helper and cytotoxic T-lymphocytes.[94] Tacrolimus use as part of the post-transplant immunosuppressive regimen has shown some superiority versus using cyclosporine. In vitro studies on cul-

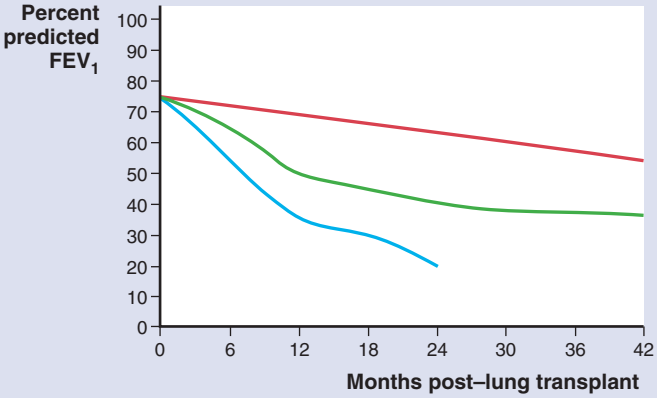

Figure 73-3 Stereotypical patterns of pulmonary function decline in single lung–transplant recipients. *Blue line*: Rapid, relentless decline in FEV_1 with no stabilization. *Green line*: Initial rapid FEV_1 decline followed by period of partial stabilization. *Red line*: Slow, inexorable decline in pulmonary function. (Based on data from Nathan SD, Ross DJ, Belman MJ, et al: Bronchiolitis obliterans in single-lung transplant recipients. Chest 107:967-972, 1995.)

tured $CD4^+$ T-lymphocytes show that tacrolimus is at least 100 times more potent than cyclosporine in inhibiting cytokine secretion, including the cytokines IL-2, IL-3, IL-4, and interferon-γ.[95] In the pig lung transplantation model, transplant survival was superior in the tacrolimus-treated animals.[96] Early prospective clinical trials in humans comparing tacrolimus to cyclosporine as part of post–lung transplant maintenance therapy showed fewer episodes of acute rejection[97,98] and development of BO.[98] Additionally, observational data from the Registry of the International Society for Heart and Lung Transplantation shows that the combination of tacrolimus and MMF has the lowest overall rate of rejection.[44] However, more recent prospective randomized trials have been less impressive but may be limited due to the short follow-up period to date. An open randomized trial in progress involves MMF and steroids with either tacrolimus or cyclosporine as the calcineurin inhibitor. Induction therapy consisted of rabbit antithymocyte globulin for 3 days. Reports after 6 and 12 months post–lung transplant show no significant differences in the number of patients free of acute rejection.[99,100] A trend toward a decrease in the number of rejection episodes treated per 100 patient-days in the tacrolimus group was noted. Of interest, 11% of the cyclosporine group had to be switched to tacrolimus in order to control ongoing rejection, but none of the tacrolimus group switched to cyclosporine. Perhaps a longer follow-up period will reveal more substantial differences between the two therapies. Regardless, the data supporting the superiority of tacrolimus (versus cyclosporine) have been sufficiently persuasive to prompt a clear trend among lung-transplant centers toward using tacrolimus as part of the post-transplant maintenance immunosuppressive therapy. In 1999, about 70% of lung-transplant patients at 1 year were receiving cyclosporine and only 26% received tacrolimus.[101] In 2005, this ratio had shifted such that 23% were on cyclosporine while tacrolimus had expanded to be part of 62% of the patients' immunosuppressive regimens.[44] A similar trend has been noted in pediatric lung-transplant patients.[45]

The use of tacrolimus as part of the post-transplant maintenance therapy also delays the onset of BO. In a prospective trial of 133 patients comparing tacrolimus and cyclosporine, BO developed in significantly fewer patients in the tacrolimus group (21.7%) compared with the cyclosporine group (38%).[98] A more recent trial (reported in abstract form) of 110 patients also found that those treated with tacrolimus had a lower incidence of BOS (10%) compared with those treated with cyclosporine (41%).[102] Tacrolimus presumably affects BOS by more effectively controlling the graft inflammation, which is the causal event leading to BO.

In addition to being used in the post-transplant maintenance regimen, tacrolimus has become an accepted part of the rescue therapy for lung graft rejection as well as BOS. However, no prospective trials involving large numbers of patients have evaluated the switch to tacrolimus. Multiple nonrandomized observational studies have documented partial stabilization of pulmonary function in patients with BOS or recurrent rejection as well as a decrease in the frequency of rejection after switching from cyclosporine to tacrolimus.[103-108] A retrospective study of 244 patients with either recurrent rejection or BOS showed significant decreases in the frequency of rejection within 3 months of switching from cyclosporine to tacrolimus as well as short-term stabilization of FEV_1.[109] Stabilization of exhaled nitric oxide levels once tracrolimus is started mirrors the effect on pulmonary function.[82] Taken as a whole, the current literature appears to support the use of tacrolimus in the treatment of BOS and recurrent/chronic graft rejection.

MMF is an purine synthesis antagonist (inosine monophosphate dehydrogenase inhibitor) that suppresses T- and B-cell proliferation. A large, retrospective study of 303 lung-transplant patients showed that the risk of developing BOS 2 or 3 was reduced by half (odds ratio 0.51) in those receiving MMF.[110] However, in prospective studies evaluating MMF versus azathioprine as part of maintenance immunosuppressive therapy, no significant differences in the two groups have been noted with respect to the frequency of acute rejection or the development of BO out to 3 years of follow-up.[111-113] MMF does appear to be better tolerated by patients than is azathioprine.[111] As a combination therapy with tacrolimus, MMF has the lowest rate of acute rejection episodes[44] and has become the preferred purine synthesis antagonist (MMF: 46% of lung transplant patients at 1 year; azathioprine: 30%).[44]

Numerous other agents have been investigated as treatments for BO, but only a few of the more interesting therapies are discussed here. Steroids have always had a role in the treatment of post-transplant BO. High-dose pulse therapy has been used with some success. In post-BMT patients with BO, high-dose pulse methylprednisolone led to stabilization of lung function in 7 of 9 patients.[114] Inhaled therapies hold the promise of delivering high doses of medications to the airway while minimizing systemic absorption and side effects. A small clinical trial (N = 10) of patients with BOS showed significantly higher FEV_1 values while on 2000 μg/day inhaled fluticasone propionate versus placebo.[115] However, a larger study (N = 30) with a dosage of 1500 μg/day fluticasone propionate could not reproduce these findings.[116] It remains to be determined if even higher doses of inhaled steroids would be beneficial. Currently, inhaled steroids cannot be routinely recommended but may be useful in individual patients. Other inhaled medications being explored include inhaled cyclosporine.[117] In a 2-year randomized controlled study (N = 58) of aerosolized cyclosporine (300 mg 3 days per week) started within 6 weeks of lung transplantation, significant improvements in overall survival and BOS-free survival were noted.[118] Only 3 deaths among the aerosolized cyclosporine group were noted whereas there were 14 deaths in the placebo group (relative risk = 0.20). BOS-free survival was also improved significantly as evaluated by spirometry (RR = 0.38) or by histology (RR = 0.27). The long-term effect of inhaled cyclosporine on BO is not known, but these early results are very encouraging. Further studies involving larger number of patients are clearly needed to confirm the benefits of inhaled cyclosporine.

Animal models have indicated that tumor necrosis factor-α (TNF-α) appears to be an important aspect of the inflammatory cascade and its blockade can halt the progression to BO.[24,119-121] In an exciting case report involving a post-BMT child with BO, the monoclonal anti-TNF-α antibody infliximab showed dramatic resolution of the BO and no recurrence over a 9-month follow-up period.[122] Further study is clearly indicated.

Macrolide antibiotics have been shown to have anti-inflammatory properties, which have been useful in the treatment of diffuse panbronchiolitis and cystic fibrosis.[123,124] Recent trials of azithromycin in post-transplant patients have suggested similar benefits. In a retrospective study examining azithromycin as part of a rescue therapy for BOS in lung transplant patients, 250 mg azithromycin every other day resulted in FEV_1 increases after 3 months that persisted for the 11-month follow-up period in many patients.[125] Similar findings have been documented by other studies.[126-128] Studies involving large patient numbers or evaluating the ability of azithromycin to prevent or delay the onset of BO have not been conducted. However, the early data are encouraging and warrant further study.

Development of bronchiolar fibrosis is an important part of the pathology of BO. Antifibrotic medications hold the promise to stem this aspect of BO. In a mouse model of BO, the antifibrotic drug pirfenidone was able to prevent the onset of obstructive airway changes[129] and may serve as a model for future drug development in humans.[130] The mammalian target of rapamycin (mTOR) is a downstream protein kinase of the phosphatidylinositol 3′-kinase–Akt signaling pathway.[131,132] mTOR may drive or contribute to fibromuscular proliferation. Antagonism of mTOR with medications such as sirolimus and everolimus may be beneficial. A pilot study of post-transplant BO patients added sirolimus to a calcineurin inhibitor and prednisone and demonstrated stabilization of pulmonary function but at the cost of significant adverse effects.[133] Everolimus used in lieu of azathioprine for maintenance therapy results in fewer acute rejection episodes and BOS at 12 months post-transplant. At 24 months post-transplant, the BOS effect is lost and only the decline in acute rejection remains.[134] Similar to sirolimus, there are significant side effects of the medication. The dosing and indications for the use of sirolimus and everolimus need to be more fully explored before they can become part of routine care. Finally, with the new knowledge regarding the role of angiogenesis in the fibroproliferative phase of BO, development of antiangiogenic compounds, especially those which target the ELR^+ CXC chemokines, may provide additional therapies in the future.[40]

CONCLUSION

Although is an entity rarely seen by most physicians outside of the pulmonary specialties, the expanded use of lung transplantation in both the adult and pediatric populations makes continued research in this area vital. With the growing understanding of the pathophysiology of BO, we can anticipate exciting novel therapies. It is hoped that such understanding and new therapies will yield longer post-transplant survival.

CHAPTER 74

Psychiatric Aspects of Respiratory Symptoms

Frederick S. Wamboldt and Marianne Z. Wamboldt

TEACHING POINTS

- Central nervous system (CNS) reflexes devoted to protecting respiration can at times become hyperactive and dysfunctional, producing breathing disorders.
- The process of "central sensitization" may explain how intense or repeated stimulation of CNS reflexes designed to protect respiration can become hyper-responsive.
- The "somatic" anxiety disorders (panic attacks, hyperventilation, and panic disorder) likely arise due to induced hyperresponsiveness of brainstem respiratory control centers and mid-brain "fear" centers.
- Vocal cord dysfunction likely arises from central sensitization of reflexes designed to protect the glottis.
- Habit cough may function similarly, with central sensitization of reflexes, but also needs to be distinguished from a phonic tic, which has a different etiology and treatment.
- All of these disorders, once recognized and appropriately diagnosed, respond well to simple, targeted treatments that improve quality of life and decrease iatrogenic morbidity and wasteful health care utilization.

> Each person is born to one possession which outvalues all his others—his last breath.
>
> MARK TWAIN—*Following the Equator* (1897)

An important subset of patients presenting to pediatric pulmonologists, as well as these children's parents, suffer from knowing this quote by Mark Twain all too intimately, having pondered the possibility of losing their, or their child's, last breath during respiratory crises. It is not surprising that having an episode of breathlessness, or observing such in your child, may be one of the most anxiety-provoking experiences that many people ever have. This chapter reviews the etiology, pathophysiology, and treatment of two common disorders of breathing—"somatic" anxiety disorders and paradoxical vocal cord dysfunction (VCD)—in which the prominent concurrence of psychiatric and respiratory symptoms is caused by hyperresponsiveness of the intricate set of controls, monitors, and protective reflexes in the central nervous system (CNS) that link the control breathing with affective, anxiety, and cognitive centers. Understanding this CNS physiology will help the physician successfully treat pediatric patients presenting with these common respiratory syndromes. We also review the frequent pediatric problem of habit cough. Although certain cases of chronic cough, including habit cough, also fit very nicely into this model of CNS reflex hyperresponsiveness, as will be seen, a more extensive differential diagnosis is required to effectively manage and treat patients with habit cough.

"CENTRAL SENSITIZATION" OF CENTRAL NERVOUS SYSTEM RESPIRATORY CONTROL CENTER

The basic dynamics of respiration, such as rate and rhythm, are controlled by medullary and pontine centers in the brain. These same centers monitor not only the status of respiration but also other associated systems, such as the status of the airway. When respiration is in danger (e.g., smoke inhalation) these centers use a variety of short-term protective reflexes (e.g., cough, glottic closure, and "fight-or-flight" panic anxiety) to protect the individual until the source of respiratory danger has ended. Considerable evidence has accrued that CNS respiratory control centers can become sensitized so that these short-term protective reflexes become hyperactive, leading to a family of related clinical syndromes in which neuropsychiatric factors produce and maintain common respiratory symptoms, such as cough, dyspnea, and wheezing, thereby mimicking or confounding asthma and other pulmonary disorders.

Some of the best evidence supporting this hypothesis comes from animal models in which early exposure to various lung irritants (e.g., capsaicin, environmental tobacco smoke, upper respiratory viruses) can cause central sensitization of CNS respiratory centers, resulting in persistent hyperactivity of respiratory reflexes.[1,2] For example, Bonham and colleagues[1] exposed juvenile guinea pigs to environmental tobacco smoke for 5 weeks and elegantly demonstrated that this exposure activated vagal C-fiber afferents to the nucleus tractus solitarius (NTS), causing increased responsiveness of caudomedial NTS neurons to subsequent respiratory irritant exposure. Furthermore, these animals also displayed CNS hyperactivity outside of irritant exposure, including altered respiration (more rapid and shallow breathing), lowered cough threshold, increased mucus production, and increased bronchial hyperresponsiveness. This increased CNS excitability was sustained throughout the life of the exposed animals.

Morrison and colleagues[3] have invoked a similar model of CNS "neural plasticity" to explain the irritable larynx syndrome (ILS). Specifically, they hypothesized that ILS develops due to "CNS changes that leaves sensorimotor pathways in a hyperexcitable state" with the underlying mechanisms proposed as being either an adaptive response to "nerve or tissue injury" or "repeated noxious stimulation." In a series of 39 patients diagnosed in their clinic, the most common probable etiologic factors were reported to be gastroesophageal reflux disorder (GERD), recent viral upper respiratory infection (URI), "psychogenic," and concurrent chronic respiratory disorder. Once such CNS changes have placed the larynx in a "spasm-ready state," they observed that a wide variety of nonspecific triggers can produce symptoms, with airborne odors (especially perfumes and cleaning products), GERD, foods, emotions, voice use, coughing, and exertion described as particularly frequent triggers.

These concepts of *central sensitization* and *neural plastic hyperexcitability* are widely accepted as important mechanisms in chronic pain syndromes[4,5] but, in general, are not widely invoked as neuropsychiatric mechanisms in the production of respiratory symptoms. We review relevant literature for three common clinical syndromes frequently encountered in pulmonary clinics, "somatic" anxiety disorders, paradoxical VXD, and habit cough, in which these CNS mechanisms often play an important pathophysiologic role.

"SOMATIC" ANXIETY DISORDERS: PANIC ATTACKS, PANIC DISORDER, AND HYPERVENTILATION

These common conditions are discussed together for two reasons. First, there exists great overlap between the phenomenologic and pathophysiologic expression of these conditions, despite the fact that they are not totally overlapping syndromes. Second, principles of effective treatment are more or less the same across these disorders.

In general, all these conditions include some combination of the following clinical paroxysmal signs and symptoms: (1) intense feeling of discomfort or fear; (2) autonomic arousal; (3) vague, diffuse, "atypical" bodily sensations; (4) overbreathing; (5) catastrophic cognitions (e.g., fear of losing control, going crazy, or dying); and (6) avoidance behavior. The onset of full criteria for these conditions is most common in late adolescence or early adult years, although prepubertal onset has been reported.[6-9] However, subsyndromal symptoms are common in younger children, and early identification and intervention may help prevent progression to full disorder. All are prevalent yet underdiagnosed disorders in primary care as well as pulmonology and cardiology specialty clinics. They are major sources of preventable morbidity and mortality in these settings because safe, reliable, and effective treatment strategies exist.

Panic Attacks and Acute Hyperventilation

Panic attacks are an extremely common experience, with one quarter to one third of the U.S. population reporting lifetime occurrence of at least one panic attack.[10-12] The term *panic attack* refers to an acute episode of sudden intense fear or discomfort that rapidly builds in a crescendo fashion over a period of minutes and that is associated with a number of somatic or cognitive symptoms. Accordingly, the diagnostic label *panic attack* is a phenomenologic or descriptive one, implying nothing about etiology or pathophysiology. The specific *DSM-IV-TR* diagnostic criteria for panic attack are listed in Box 74-1.[13]

It is important to note according to these criteria that the patient needs to report either intense fear or *discomfort*. Up to 40% of patients presenting to medical (as opposed to psychiatric) settings have been reported to have "panic without fear"; that is, although they feel intense somatic discomfort during attacks, they do not experience anxiety or fear, typically remaining stoic.[14-16] Such patients also tend to develop less avoidance behavior in response to recurrent panic attacks but otherwise are indistinguishable from patients with fearful responses during panic attacks. What does this mean that one can have a panic attack without fear? The likely answer is that during a panic attack the vast majority of patients hyper-

BOX 74-1 Signs and Symptoms of a Panic Attack

A. A discrete period of intense fear or discomfort
B. During which four or more of the following symptoms developed abruptly and reached a peak within 10 minutes:
   1. Palpitations, pounding heart, or accelerated heart rate
   2. Sweating
   3. Trembling or shaking
   4. Sensations of shortness of breath or smothering
   5. Feeling of choking
   6. Chest pain or discomfort
   7. Nausea or abdominal distress
   8. Feeling dizzy, unsteady, lighthearted, or faint
   9. Derealization or depersonalization
   10. Fear of losing control or going crazy
   11. Fear of dying
   12. Paresthesias
   13. Chills or hot flushes
C. Other signs/symptoms associated with panic attacks hyperventilation:
   1. Electrocardiogram changes (e.g., ST-segment depression, T-wave inversion)
   2. Musculoskeletal pain, stiffness, "fibrositis"
   3. Weakness, listlessness, exhaustion
   4. Poor concentration, forgetfulness, confusion
   5. Euphoria
   6. Frequent sighing, yawning, thoracic breathing
   7. Dry mouth, aerophagia, flatulence
   8. Blurred vision
   9. Syncope, seizures
   10. Focal neurologic signs and symptoms (often left sided)
   11. Extreme sensitivity to stimulant side effects of medications
   12. Hallucinations (rare)
   13. Tetany (rare)

Criteria A and B are required to make a diagnosis of panic attack using *DSM-IV* criteria.

ventilate.[17] Hyperventilation, as is described in detail later, is the direct cause of most of the somatic sensations that arise during a panic attack. Fear develops during a panic attack when a patient misattributes these somatic sensations as indicating that they are in danger.[18] In other words, patients suffering from panic without fear perceive the physiologic effects of hyperventilation but have benign cognitive appraisal of these sensations.

Acute hyperventilation is the physiologic state of overbreathing in which breathing is occurring in excess of metabolic requirements, leading to an acute reduction in $PaCO_2$ and the consistent set of physiologic changes that occur in response to this state. Most typically, acute hyperventilation occurs because of a modest increase in tidal volume (e.g., 750 mL/min) in conjunction with a "normal" respiration rate (e.g., 16 to 17 breaths/min). Hence, clinically significant overbreathing is often not grossly visible.[19]

The multiple physiologic changes that occur during and in immediate response to acute hyperventilation are the proximal cause of many of the somatic and CNS symptoms that occur during a panic attack. The immediate effect of overbreathing is that the $PaCO_2$ drops, blood pH rises, and an acute state of hypocapnic, respiratory alkalosis is induced, typically in 1 minute or less. In response to this state of respiratory alkalosis, a variety of secondary physiologic changes occur in a rapid, sequential cascade.[20-22] First, there is a shift in the oxyhemoglobin dissociation curve so that oxygen is bound more tightly (the Bohr effect), resulting in less efficient delivery of oxygen. Second, hypocapnia leads to CNS vasoconstriction. The resulting reduced cerebral flow is assumed to be the cause of a variety of the CNS symptoms observed, such as light-headedness, dizziness, depersonalization, blurred vision, confusion, and even focal neurologic signs. Third, paresthesia and pain symptoms commonly arise in response to the combination of direct effect of persistent alkalosis on peripheral nerves, mechanical muscle fatigue, and peripheral vasoconstriction and spasm. Fourth, mouth breathing and aerophagia can contribute to the symptoms of dry mouth, abdominal distress, and flatulence. Fifth, as the patient attempts to interpret these sensations a variety of catastrophic cognitions can (but, as mentioned earlier, do not always) arise, feeding back to lower brain centers and worsening the attack. Finally, this physiologic cascade is mitigated or terminated as renal compensation restores normal arterial pH by increasing bicarbonate excretion and as relative cerebral hypoxia induces vascular dilation restoring CNS blood flow.

Several important long-term effects can occur as a result of the renal compensation of the acute hyperventilation episode that increase the likelihood that a diathesis toward future panic/hyperventilation episodes is maintained. First, although renal compensation restores normal blood pH, both arterial $PaCO_2$ and bicarbonate levels remain low. Because the chemoreceptor system's control function for CO_2 is nonlinear (i.e., whereas at $PaCO_2$ levels above 35 mm Hg any rise in $PaCO_2$ is strongly opposed by the chemoreceptor system promptly increasing ventilation, at $PaCO_2$ levels below 35 mm Hg this system provides virtually no change in ventilatory drive), in the "compensated" state, small changes in ventilation can rapidly lower an individual's $PaCO_2$ with no opposition from the control system.[22] Furthermore, if episodes of acute hyperventilation continue long enough, continued renal compensation can lead to depletion of the bicarbonate buffer system, thereby amplifying the physiologic effects of low $PaCO_2$.[21] Hence a vicious cycle can be established in which a few sighs or deep breaths can lead to intensified and continued episodes of acute panic and hyperventilation.[19,22] Indeed, chronic hyperventilation has been purported to underlie various states of chronic fatigue and incapacity.[21,23]

Panic Disorder

Panic disorder is diagnosed when there is the presence of recurrent, unexpected panic attacks followed by at least 1 month's duration of persistent concern about having another panic attack, worry about possible implications or consequences of the attacks, or a significant behavioral change as a result of the attacks. Two features of panic disorder should place it near the top of a physician's differential diagnostic list in most patients suffering from recurrent panic attacks or hyperventilation. First, panic disorder is an extremely prevalent condition. Epidemiologic research suggests a lifetime prevalence rate of 2% to 5%.[10,24,25] Furthermore, panic disorder is estimated as the major clinical problem in 10% to 15% of patients entering primary care as well as pulmonology, cardiology, and gastroenterology subspecialty practices.[16,26-30] Second, the pathophysiology of panic disorder has become increasingly clear with safe and effective treatments available.[20,31,32]

The leading current pathophysiologic models of panic disorder posits that a hyperresponsive mid-brain "fear center" (most likely in the amygdala) responds in an exaggerated fashion to incoming "danger" signals, in particular to false "suffocation alarms" from brainstem respiratory control and monitoring centers (primarily in pons and medulla), leading to prompt activation of associated defense and escape systems (e.g., in the locus ceruleus and periaqueductal gray region).[20] This hypersensitive response to perceived respiratory danger triggers a 2- to 3-fold increase in minute ventilation leading to the physiologic cascade of a panic attack.[20,32,33] In support of this proposition, inhalation of CO_2 or sodium lactate infusion causes increased ventilation, and both challenges are potent and specific panicogens in susceptible individuals.[34,35] Furthermore, effective antipanic treatment (using either medication or cognitive behavior psychotherapy) has been shown to be able to block the respiratory stimulatory and panic-inducing effects of these laboratory challenges.[36] Finally, patients with panic disorder have greater baseline evidence of chronic, compensated hyperventilation as well as more chaotic breathing patterns at rest and during sleep, than normal controls, indicating observable abnormalities in the control of breathing even outside of panic episodes.[35,37,38]

Klein[39] proposed a useful temporal and logical sequence for the symptom clusters that are seen in panic disorder. First is the acute panic anxiety elicited during the panic attack. Such anxiety is especially potent given its intense visceral, bodily nature and the sense of inexplicable catastrophe that typically accompanies the episode. Individuals who suffer from panic attacks tend to be oversensitive to interoceptive signals, usually have no solid, logical explanation of why the

event occurred, and therefore with recurrent attacks can feel helpless and confused and often grasp for answers that will allow them to escape from these attacks.

The second feature, anticipatory anxiety, arises as a response to the intense conditioning stimuli of an acute panic attack. In more common terms, the patient's level of chronic anxiety or "nervousness" rises out of the uncertainty and worry about when the next attack will occur. Three important clinical correlates of this more generalized and chronic anxiety state are that such patients may be more likely to (1) appear to have "excessive stress" or "psychologic overlay" as they enter the health care setting, thereby receiving poorer quality of care[27]; (2) establish a state of chronic hyperventilation, thereby being vulnerable to experience more frequent and intense recurrences[22,35]; and (3) have higher cortical learning involved in the pathophysiology of their panic attacks. The relevance of this last point is highlighted by recent findings from CO_2 inhalation challenges demonstrating that aspects of the social context in which the challenge is conducted (e.g., the patient's perceived level of control or the presence of a "safe person," can influence the likelihood that the patient will have a panic attack during the challenge).[40,41]

Third, up to one third of patients begin to phobically avoid situations that they come to believe trigger acute episodes (e.g., leaving their house, driving their car, or taking baths or showers), likely as a conditioned-fear response.[20] Such agoraphobic behavior greatly increases the psychosocial morbidity of panic disorder because of the interpersonal and sociovocational difficulties that arise as the patient's significant others, friends, and employers react to this seemingly "irrational," avoidance behavior.[42] Additionally, significant demoralization or frank depression frequently arises. Up to three quarters of patients with panic disorder become clinically depressed, and suicide rates for patients with panic disorder are among the highest for any psychiatric disorder.[43,44]

Panic, Hyperventilation, and Chronic Pulmonary Illness

It is well established that these "somatic" anxiety disorders are especially common comorbid psychiatric disorders in patients with chronic pulmonary illness.[26,28,30,45,46] Indeed, the CNS-lung connections described here lead to a very complex intertwining of these anxiety disorders and chronic respiratory disease. Hyperventilation (even when isocapnia is maintained) can precipitate bronchial constriction, with isocapnic hyperventilation often used to measure airway hyperresponsiveness.[47] Conversely, the $PaCO_2$ increase during an acute asthma attack can trigger a panic attack in patients with panic disorder.[48] Additionally, although the symptoms of air hunger, shortness of breath, chest discomfort, and acute fear are similar across these conditions, the treatments are not. In fact, certain asthma treatments, such as β-agonists, can increase autonomic arousal, thereby precipitating or worsening panic attacks. Hence, both patients and their health care providers need to discriminate these two entities during acute episodes,[46,49] as well as recognize and aggressively treat comorbid "somatic" anxiety to effectively manage chronic pulmonary patients over time.[29,48,50,51]

Treatment

Fortunately, acute panic attacks and hyperventilation, as well as more chronic panic disorders, even when complicated by significant agoraphobia, are readily treated. Basic guidelines for treatment follow.

BEGIN WITH EDUCATION

Panic attacks and episodes of acute hyperventilation are horribly frightening experiences. Patients are generally frightened, confused, and very uncomfortable. They may feel that something is terribly wrong with their bodies. The physician can greatly improve chances of a successful outcome by taking several minutes with the patient, and with the child patient's parents, to cover the following points, thus providing them with a clear, cogent explanation of the panic attack. First, panic attacks are extremely common, even though most people never talk about them. They are not a sign of impending insanity or a flawed character. Second, panic attacks cause a real bodily experience because "hyperactive breathing control centers in the brain" have given the body a "false alarm," but the body has had no way of knowing that the alarm was not a true one. Using the analogy of the relationship between a furnace (lungs) and its thermostat (CNS breathing control centers) can help many pulmonary patients grasp this systemic relationship between CNS control and monitoring and lung function in a fashion that gets their "head" into the equation without implying that their problem is "all in their head." Third, certain medical problems can cause symptoms similar to those the patient has experienced (Box 74-2), but these already have been considered, checked, and ruled out by the physician. Fourth, although such attacks may disappear without treatment, safe and effective treatment exists, and it is highly recommended that patients begin these treatments. Such treatment consists of medication and some breathing and behavioral changes, the combination of which will help patients gain control over their attacks over a period of several weeks.

PHARMACOLOGIC BLOCKAGE OF PANIC

Medication treatment should be instituted to block or blunt the attacks. For the vast majority of adult patients with panic disorder, the medication of choice is a selective serotonin reuptake inhibitor (SSRI).[31,52] A number of other commonly prescribed antidepressant medications, most notably trazadone and bupropion, have little to no antipanic activity. Because a potentially large subset of patients with panic disorder are inordinately sensitive to the stimulatory effects of these antidepressant medications (e.g., agitation, restlessness, insomnia),[53] therapy should begin with low dosages (e.g., paroxetine 5 mg every morning in adults). In adults, aggressive use of antidepressant medications is particularly necessary in the case of panic disorder complicated by major depressive disorder because depression appears to significantly diminish the efficacy of the behavioral treatments described in the following sections.[54] Due to important concerns about the risks of using SSRIs in children and adolescents, the behavioral interventions described below should always be attempted first in pediatric populations.[55]

A recent meta-analysis found that in adults, the commonly used, high-potency benzodiazepine alprazolam is less effec-

Heat exhaustion/heatstroke
Pregnancy/luteal phase of menstrual cycle (via progesterone)
Liver disease/failure

tive treatment of panic attacks than are the SSRIs.[56] Furthermore, given the potential for benzodiazepines to cause tolerance, dependence, and respiratory depression, their use should be limited in individuals with milder pulmonary illness (1) who have very infrequent panic attacks not requiring daily medication or (2) during the initial weeks of treatment in patients with more intense anxiety symptoms while awaiting the response to SSRI medication. Benzodiazepines are *not* recommended as a first-line medication for children with panic anxiety.

RESPIRATORY CONTROL, COGNITIVE BEHAVIORAL, AND EXPOSURE TREATMENTS

Coincident with the start of pharmacologic treatment, patients should be instructed in respiratory control strategies to prevent or limit the hyperventilation that occurs during an attack.[51,57-59] There are two important aspects to such training. First, patients should be informed that once a CNS breathing alarm occurs, the body's natural response is hyperventilation, and that it is this hyperventilation that causes most of the discomfort experienced during a panic attack/hyperventilation episode. Second, patients benefit from training in slow, regular, diaphragmatic breathing, with specific comments to avoid mouth breathing, thoracic breathing, or excessive sighing or yawning as appropriate. Patients often require practice and the help of a coach (therapist or family member) to remember to commence such breathing during the "heat" of an impending panic attack. Training in more general relaxation techniques is often advocated, although such training is most likely a nonspecific adjuvant therapy.

In addition to respiratory control techniques, formal cognitive behavioral therapy for panic disorder also focuses on reframing how the patient interprets the frightening, somatic symptoms that arise during a panic attack.[57,60,61] Such treatment clearly lessens the catastrophic thinking usually seen during acute panic, and also most likely promotes higher cortical learning effects that over time inhibit or reduce the hypersensitivity of mid-brain fear and/or brainstem breathing control centers. As stated above, successful cognitive behavioral treatment for panic does alter the hyperresponsiveness to CO_2 seen in panic patients.[36]

Given that significant avoidance (agoraphobic) behavior complicates the clinical presentation in up to 30% of patients with panic disorder, in vivo exposure treatment of the avoidance behavior is often required for recovery. Principles of such treatment are well described.[54,57] In essence, exposure treatment involves graduated real-life exposure of the patient to the fear-producing situation until he or she becomes desensitized to the discomfort of being in the situation. The patient uses respiratory control and cognitive reframing techniques to manage the panic experienced during the exposure. Typically, ability for the patient to tolerate the previously dreaded and avoided situation occurs after 2 to 10 repetitions of the exposure. For children, often it is avoidance of school that is seen with this type of anxiety, and it is necessary to teach the parent(s) how to coach their child with breathing exercises and positive cognitions to get them over the transition to school. Typically, once in school, these children do fine.

Additional treatments, such as family therapy, should be considered when appropriate, especially if the parents, themselves, are too anxious about the child's symptoms to be able to appropriately coach them. Treatment ends by reemphasizing the "tools" that the patient has learned to gain control over their panic anxiety symptoms, with the explicit prediction that although relapse is possible, any recurrence of symptoms would diminish promptly once the patient reinstitutes these newly learned cognitive-behavioral strategies.

VOCAL CORD DYSFUNCTION

Paradoxical VCD is a common, poorly understood condition in which the vocal cords paradoxically close on inspiration, producing airflow obstruction at the larynx and causing audible wheeze or stridor. VCD most frequently is diagnosed as a mimic or confound in difficult-to-treat asthma or another chronic respiratory disorder, but also can be seen in diverse groups of patients including "perfectionistic" teenagers, elite athletes, active duty military personnel, and patients with other allergic and/or inflammatory disorders involving the upper airway (e.g., GERD, sinusitis, occupational irritant exposures, and post-URI). Typical clinical episodes range from transient, mild asthma-like symptoms (i.e., chest tightness, shortness of breath, wheezing, and cough) to total upper

airway occlusion. Although arterial blood gases usually are normal during symptomatic episodes, both hypoxia and hypocapnia have been reported. The acute presentation is often dramatic and misdiagnosed, leading to unnecessary intubation, tracheotomy, or treatment with high doses of corticosteroids, often resulting ultimately in iatrogenic complications.[62-64]

Clinical Presentations and Prevalence

The clinical syndrome was first documented in 1842 by Dunglison,[65] who described it as an adduction of the laryngeal muscles in hysterical female patients and called it "hysteric croup." The prescribed treatment was "cold water thrown over the face and neck and compound spirit of ammonia held to the nostrils." "Functional upper airways obstruction without organic abnormalities" was described in three patients in 1981,[66] all of whom had acute upper airway obstruction, hypoxia, and tracheotomies. These were the first patients in whom the vocal cord abnormalities were documented by visualization of the adduction of the true and false vocal cords during symptomatic episodes. The term *vocal cord dysfunction* was coined by Christopher and associates[67] in 1983, who described five cases of adults in whom paroxysms of wheezing and dyspnea were refractory to standard therapy for asthma. Laryngoscopy confirmed that wheezing was caused by adduction of the true and false vocal cords throughout the respiratory cycle, which was essentially normal when patients were asymptomatic. The patients could not reproduce the vocal cord abnormality voluntarily.

Although the exact prevalence of VCD is unknown, it does not appear to be rare. The literature is almost entirely comprised of myriad case reports describing VCD-like clinical conditions, from a variety of disparate and nonoverlapping literatures (e.g., anesthesia, otolaryngology, emergency medicine, psychiatry, pulmonology, and pediatrics), often with highly evocative names such as Munchausen stridor,[68] factitious asthma,[69] emotional laryngeal wheeze,[70] and episodic laryngeal dyskinesia.[71] In terms of quantitative data, Newman and colleagues reported that nearly 40% of adult patients presenting to a prominent national pulmonary referral center for evaluation of asthma that failed to respond to aggressive treatment ultimately were diagnosed with VCD, with essentially half being diagnosed with VCD alone and half with VCD associated with chronic asthma.[63] The patients with VCD alone had been misdiagnosed as having asthma on average for 4.8 years, and at intake were taking an average oral corticosteroid dose equalling nearly 30 mg of prednisone. In the prior year they averaged nearly 10 emergency department visits and 6 hospital admissions. Young adults, females, health care workers, and individuals with stressful life circumstances and/or psychiatric illness are overrepresented in reports of VCD, but this disorder is clearly not limited solely to such populations.[64,72] For example, Rundell and Spiering[73] reported presence of inspiratory stridor (and presumed VCD) during exercise challenge in 5% of elite athletes training at the Lake Placid United States Olympic Training Center. Such inspiratory stridor commenced soon after onset of intense physical performance, resolved within 5 minutes after cessation, and showed no response to inhaled β_2-agonist. Females competing in outdoor sports predominated. Slightly over half also had coexistent exercise-induced bronchospasm. Similarly, VCD confirmed by laryngoscopy has been reported as the cause of nearly 10% of children and adolescents presenting with exercise-induced dyspnea.[74]

VCD can cause stridor, shortness of breath, wheezing, chest tightness, and cough. The syndrome is suspected when the patient does not reveal an organic cause of upper airway obstruction or respond to adequate asthma therapy. The symptoms often start and cease abruptly, and the patient is asymptomatic between attacks. Often patients indicate that they feel throat tightness or that their voice changes during an acute attack. Patients who have "pure" VCD may indicate that bronchodilators do not help, and often worsen their breathing. Although stridorous wheezing can sometimes be heard over the larynx, it also can be transmitted to the lower airways from the larynx; thus the physical examination can be unreliable in distinguishing a VCD attack from an asthmatic episode. However, if at the time of acute symptoms the patient is able to hold his or her breath or pant, this is suggestive of VCD because patients suffering an acute asthma attack will be unable to comply. While asymptomatic, patients with pure VCD have normal pulmonary function tests, which may help distinguish them from asthmatics, who often have increased residual volumes, indicating air trapping from small airways closure. During acute symptoms, the patient with VCD may have a truncated inspiratory or expiratory limb of the flow-volume loop, indicating variable obstruction. The ratio of expiratory flow to inspiratory flow at 50% of forced vital capacity is usually greater than 1.5. However, even during an acute VCD attack, the alveolar-arterial oxygen difference is usually normal. It is important (and relatively easy) to exclude other conditions that can cause acute stridor and wheezing in children and adolescents, including a foreign body in the upper airway, epiglottitis and croup, and hereditary angioedema[75] (Fig. 74-1).

The diagnosis is definitively established by laryngoscopic visualization of the vocal cords while the patient is having symptoms. "Classic" VXD is characterized by adduction of the anterior two thirds of the vocal cords with a characteristic "posterior chink" observed during inspiration. Wood and Milgrom[64] provide an excellent description of this procedure, including recommendations of how to differentiate true VCD from vocal cord movement induced by the laryngoscopy procedure itself (e.g., via the cough or gag reflex, or through inadequate anesthesia). It is important to note that

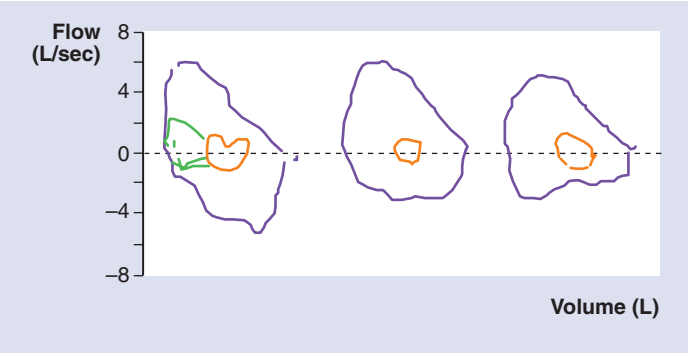

Figure 74-1 Characteristic spirometric abnormalities seen in VCD: Variable notching and truncation of the inspiratory portion of the flow-volume loop.

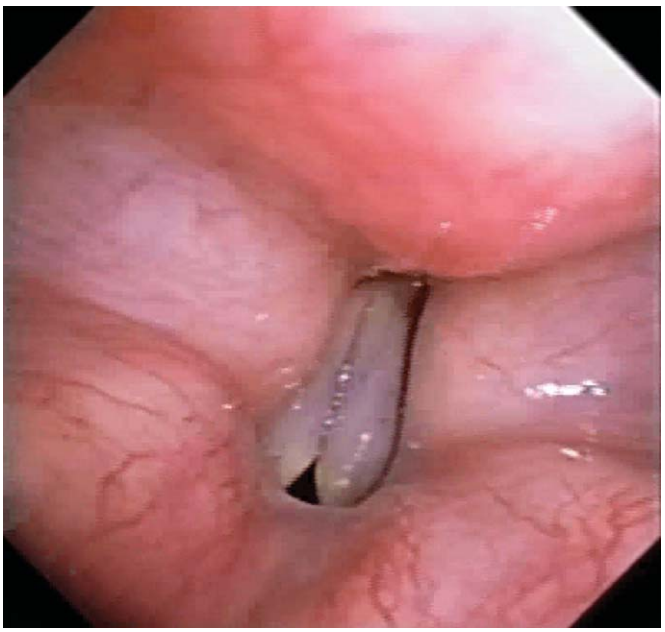

Figure 74-2 Photograph of classic vocal cord adduction during inspiration with posterior chink.

a normal laryngoscopy in the absence of symptoms does not exclude the diagnosis of VCD. In one series approximately half of the unstimulated laryngoscopies done on patients ultimately diagnosed with VCD were normal.[63] Accordingly various challenge procedures have been recommended prior to laryngoscopy, including methacholine or histamine, specific irritant, and exercise.[64,72,76] If the vocal cords are not seen to adduct during an acute episode, the diagnosis of VCD must be seriously questioned (Fig. 74-2).

Pathophysiology

The etiology and pathophysiology of VCD remain largely unknown. It is widely recognized, however, that one of the primary physiologic functions of the larynx is protection of the airway via the cough, glottic closure, and other CNS reflexes. Morrison's "irritable larynx syndrome" does provide a clinically useful integration of the various pathways whereby various "threats" to breathing that are of sufficient intensity and/or sustained over time could cause these normally protective reflexes involving the vocal cords to become sensitized, hyperresponsive, and dysfunctional.[3] Evidence supporting some of the most common threat pathways that may be causally related to VCD are discussed below.

RESPIRATORY IRRITANTS, INFLAMMATION, AND ALLERGY

The best support for the role of irritant and inflammatory processes in VCD comes from Bucca and colleagues, who have described a syndrome of extrathoracic hyperresponsiveness (ETHR) in over 500 patients with asthma-like symptoms that bears strong resemblence to VCD.[77-79] Specifically, following a histamine challenge when asymptomatic, they have demonstrated that the vast majority of patients exhibited some type of airway hyperresponsiveness: approximately 25% of patients had only ETHR, as defined by the provocative concentration of histamine required to produce a 25% drop in maximal mid-inspiratory flow rate from baseline ($PC_{25}MIF_{50}$) being less than 8 mg/mL; around 10% had only lower airway reactivity, as defined by a provocative concentration of histamine to produce a 20% drop in FEV_1 ($PC_{20}FEV_1$) of less than 8 mg/mL; and another 40% of patients demonstrated both. Results of laryngoscopy revealed that although all examinations of the glottis were normal at baseline, following histamine challenge marked mucosal edema, pharyngoconstriction, and adduction of the vocal cords during inspiration were observed in patients showing ETHR but not in those showing only bronchial hyperreactivity. ETHR was associated with postnasal drip, dysphonia, and sinusitis, suggesting that it is sustained by chronic irritation and/or inflammatory processes affecting the upper respiratory tract. Over 75% of subjects with ETHR were female. Similar findings have also recently been reported in children.[80] Even more important, successful treatment of coexistent rhinosinusitis and GERD improves ETHR.[79-81] It seems likely that ETHR occurs across a spectrum, with severe VCD residing at one extreme endpoint.

Perkner and associates have described 11 patients who developed onset of VCD within less than 24 hours after a single, albeit often intense exposure to occupational respiratory irritants.[82] All cases were confirmed to have the pathognomic laryngoscopic findings including a "posterior chink" despite the fact that these examinations were performed weeks to months after the occupational exposure. Our experience working with such patients suggests that sometimes the exposure results in permanent damage to the airway that produces ongoing activation of the glottic closure and/or cough reflex, thereby perpetuating the VCD symptoms. However, much more commonly, the initial exposure and airway injury sets up a vicious cycle of cough, mucous drainage, inflammation, and vocal cord sensitivity that prevents adequate resolution, thereby sustaining itself. Similar mechanisms may explain VCD onset after viral URIs[3,83,84] and during postsurgical recovery.[85-87]

During Intense Athletic Competition and Military Experience

A second set of "threats" to breathing come from various case studies and series reporting on VCD occurring in healthy, physically fit individuals in contexts that demand intense, peak-level physical performance.

McFadden and Zawadski[88] reported seven cases of elite athletes in whom acute exercise-induced dyspnea was ultimately determined to be due to VCD based on spirometric and/or laryngoscopic testing during bronchoprovocative challenges. Interestingly, exercise-induced VCD also could be differentiated from exercise-induced bronchospasm (EIB) by the clinical history of the attacks, with VCD episodes coming on during rather than after intense exercise, not consistently occurring with exposure to similar stimuli, and not responding to prophylactic or rescue asthma treatments. The patients were described as "highly competitive, success oriented, and either personally intolerant of failure or . . . the offsprings of parents so inclined." The authors conclude that the cause of these VCD episodes was "psychological stress" leading to "choking" during competition (in both the medical and sports connotations), and "probably a conversion disorder."

Rundell and Spiering[73] found the prevalence of exercise-induced inspiratory stridor (confirmed only by laryngeal auscultation) to be slightly greater than 5% in a cohort of 370 elite athletes participating in training through the U.S. Olympic program at Lake Placid, New York. Similar to the aforementioned report, they also found that these presumed cases of VCD could be differentiated from EIB by onset during, not after, exercise; rapid resolution following cessation of exercise; and lack of response to bronchodilator treatments. Inspiratory stridor was most common in female athletes participating in outdoor sports. The authors do not make any specific causal statements about why inspiratory stridor occurred in these world-class athletes, but do mention that competition is a "psychologically stressful" situation.

Morris and colleagues[89] found a 15% prevalence rate of laryngoscopically confirmed VCD in a group of young U.S. Army soldiers who were unable to pass a required 2-mile running physical fitness task due to exertional dyspnea. They acknowledge that many have suggested that VCD represents a conversion reaction, or another form of psychopathology, and comment that the Army training undertaken by the young recruits of their cohort is "generally considered to be a time of great emotional, psychological, and physical stress."

Another feature of exercise-induced VCD that likely has contributed to investigators seeing this as a psychologically induced problem is that exercise-induced VCD episodes are not reliably provoked by hyperventilation or methacholine challenges; instead, variable responses to differing challenges commonly are observed both within and across subjects.[76,88,89]

Despite the assertion that psychological factors have a direct causal role in exercise-induced VCD, several other observations argue against this. First, brief, simple speech therapy and breathing retraining interventions appear to be extremely effective for exercise-induced VCD, with the vast majority of those affected being able to return to baseline performance during competition.[90,91] Although effective treatments exist for psychological disorders, such interventions are almost universally more time and effort intensive, and except in a few specific disorders, somewhat less effective. Second, VCD-like episodes have been observed in thoroughbred race horses exhibiting stridorous breath sounds during competition,[92] suggesting that the CNS mechanisms do not require either higher levels of conscious psychological or unconscious psychodynamic processes. Third, a leading cause of pulmonary barotrauma in military personnel being trained in SCUBA diving is laryngeal closure arising as an involuntary panic reaction during ascent, consistent with a hypothesis that VCD arises when protective reflexes misfire at inappropriate times.[93] Fourth, VCD has been described as a side effect in patients treated with vagal nerve stimulation for intractable seizure disorders,[94,95] suggesting that VCD arises from a dysfunctional CNS reflex response, rather than from psychological maladjustment. It is important to remember that many body reflexes are augmented by both psychosocial stress and increased muscle tension, so the observed association of VCD with stress may simply reflect reflex facilitation rather than direct causation. Consistent with this supposition are the clinical observations that patients with VCD typically focus their attention on the larynx and airway, and indeed, have palpable tension of the laryngeal musculature.[3,96]

PSYCHIATRIC DISORDERS AND VOCAL CORD DISORDER

The role of psychological stress in VCD has been discussed earlier. In this section, we turn to the issue of overt psychiatric disorders in VCD. Despite the fact that VCD is quite frequently labeled a "functional" or "psychogenic" disorder in the literature, the role of psychiatric factors in the pathophysiology of VCD remains murky, with many seriously flawed assertions (e.g., patients with VCD use a lot of medical services, patients with somatization disorder use a lot of medical services, therefore patients with VCD have somatization disorder). We examine the evidence around two key questions: Are any specific psychiatric conditions associated with VCD? Are any causally related to VCD?

Cormorbidity of Psychiatric Disorders in Vocal Cord Disorder

A very wide range of specific and phenomenologically distinct psychiatric diagnoses have been reported to occur in patients with VCD, including conversion disorder, family conflict, depression, anxiety disorder, factitious disorder, personality disorders, and posttraumatic stress disorder. Several studies have compared patients with VCD to patients with moderate to severe asthma and reported no group differences in overall rates of psychopathology.[63,71] Rates of psychopathology in these studies ranged up to 73% in the Newman study, but it is also clear that VCD exists in patients without psychopathology, arguing against a causal role of psychiatric factors in VCD.[62,63] Virtually all prior reports of psychiatric problems are limited by their methodologic reliance on retrospective chart reviews, and their use of self-report or clinical interview assessments of psychopathology rather than research-grade measures.

One exception is the report of Gavin and colleagues,[97] who examined panic anxiety symptoms in adolescent patients admitted to an inpatient tertiary care pulmonary program with a diagnosis of severe, chronic asthma. Children whose primary discharge diagnosis was changed to VCD were matched to a group of adolescents whose discharge diagnosis remained severe, chronic asthma and who showed no clinical evidence of VCD. Medical records for these children were reviewed by a pediatric pulmonologist to ensure that an appropriate work-up had been performed to rule in and rule out VCD in these two groups. Research-grade assessments of anxiety were obtained before the diagnoses of VCD were established. Patients subsequently diagnosed with VCD were found to have higher levels of self-reported and parent-reported panic anxiety and received a higher number of panic anxiety diagnoses during a structured psychiatric interview than the patients with asthma. Two thirds of patients with VCD (i.e., 8 of 12) received such diagnoses, versus 2 of the 12 asthma patients. Furthermore, the vast majority of the VCD patients had onset of their anxiety symptoms prior to onset of their respiratory problems, whereas this was true for none of the asthma controls. Given the evidence presented above that panic disorder may share similar etiologic roots in protective brainstem respiratory reflexes gone awry, the findings of this study deserve replication and extension.

Conversion Disorder and Factitious Disorder

Because virtually all early and many recent reports claim that the patients with VCD have either conversion disorder or factitious disorder (aka Munchausen's syndrome), these disorders are discussed in more detail. Both diagnoses are highly overused, and typically inaccurate. Factitious disorder is diagnosed when a patient intentionally produces or feigns symptoms in order to assume the sick role. The judgment that a symptom is intentionally produced is made by direct evidence and by excluding other causes of the symptom. The presentation may include fabrication of subjective complaints, self-inflicted conditions, or exaggeration or exacerbation of a preexisting medical condition.[13] The motivation is to assume the sick role. If there is an obvious external incentive (e.g., to be out of jail, economic gain, avoiding legal responsibility), the condition is labeled "malingering." Key features of conversion disorder are "the presence of symptoms or deficits affecting voluntary motor or sensory function that suggest a neurological or other general medical condition . . . The initiation or exacerbation of the symptom or deficit is preceded by conflicts or other stressors . . . and the symptoms are not intentionally produced or feigned."[13] Symptoms of conversion disorders do not generally conform to known anatomic pathways or physiologic mechanisms and the diagnosis of conversion disorder should not be given if the symptoms can be fully explained by a neurologic or other general medical condition.[13]

In contrast, in VCD there is a documented physical abnormality, the paradoxical adduction of the vocal cords, which conforms to known neurologic reflex pathways (the enervation of the musculature involved with upper airway muscles includes cranial nerves 5, 7, 9, and 10 and cervical nerves 1, 2, and 3).[98] Concerning factitious disorder, it is doubtful that VCD episodes can be voluntarily feigned or purposely induced. Christopher and colleagues[67] reported that when patients were asked to duplicate their symptoms while the vocal cords were being visualized, they were not able to do so. Conversion disorder is an involuntary (indeed usually considered an unconscious psychodynamic process) but should not be used when a known reflex mechanism exists as a competing explanation. Hence, in most cases where the vocal cords are seen to have the characteristic posterior chink while the patient is symptomatic, conversion or factitious disorders are probably not accurate diagnoses. Some patients may feign wheezing or stridor at times when the cords are not truly adducted, meeting the criteria of purposeful exaggeration of an existing medical condition. These patients could then be appropriately diagnosed as having factitious disorder or malingering depending on the circumstances. Finally, both conversion disorder and factitious disorder are notoriously difficult to treat or interrupt, and most patients with the disorder are severely psychologically disturbed. This is not the case in most patients with VCD, where the available, albeit sparse, evidence suggests that a majority of patients respond to brief and focused treatment.[90,91,96]

Treatment

Martin and associates[84] emphasize the role of a multidisciplinary team (pulmonologist, otolaryngologist, psychiatrist, and speech therapist) in the evaluation and treatment of patients with VCD. The interventions described in the literature for VCD range from simple and quick educational approaches to invasive surgical procedures, and include explanation and reassurance; behavioral medicine, speech therapy, and psychiatric interventions (i.e., breathing exercises, biofeedback, hypnosis, individual or family psychotherapy, psychotropic medication); breathing helium-oxygen mixtures; CPAP; botulinum toxin; bilateral nerve blocks; posterior fossa cystectomy; and tracheotomy.

For most patients, receiving the diagnosis of VCD requires them to change the beliefs they have developed about their illness from prior medical diagnosis and therapeutics, including a sizable number of patients who have suffered iatrogenic harm from misdiagnosis. In general, patients who are pleased and adapt well to being told the nature of their condition usually are more accepting of appropriate therapy and have a better outcome. Therefore, much care should be taken in explaining the diagnosis of VCD to the patient. For example, for those patients who have been previously diagnosed with asthma, they should be told that they do not have asthma, or asthma alone, but another medical condition called VCD. Viewing the videotape of their own or another patient's vocal cords closing on inspiration is often a powerful aid in explaining the medical aspects of this disorder. We find it helpful to suggest to patients that the main pathophysiologic mechanism is a reflex designed to protect their breathing that now has become hyperactive and dysfunctional, although we acknowledge that this is just a reigning hypothesis, not an established fact.

The cornerstone of outpatient VCD therapy is various speech exercises, designed to accomplish two key goals.[64,91] First, a set of rescue techniques that open the cords during episodes and allow patients to regain control over their symptoms which are based on substituting a voluntary and competing behavior, such as panting or sibilant breathing, whenever the vocal cords adduct. Practiced whenever symptoms are triggered, and coached by supportive persons in the environment, these techniques are very specific and effective. Second, patients are coached in techniques (e.g., slow, relaxed, abdominal breathing) to change their breathing outside of episodes (i.e., throughout the day) in such a way so as to refocus their breathing efforts away from the larynx and airway, thereby reducing laryngeal tension and potentially decreasing feedback to the CNS that drives and maintains the hyperactive reflexes.

Evidence exists that biofeedback, relaxation, and hypnosis can be effective, but since they are not as specific and efficient as the speech therapy exercises, they probably are best reserved for patients requiring additional assistance in their recovery. For patients who have associated psychiatric problems, or whose VCD symptoms have become incorporated into their self-image or entangled in interpersonal conflicts, the addition of formal psychotherapy is sometimes required to manage the illness. Antidepressant/antipanic medications are useful in cases when depression and/or panic anxiety are present, and may be helpful more generally. One group has found that pretreatment with an anticholinergic inhaler (ipratroprium) helped all six pediatric patients with exercise-induced VCD control their episodes and continue their sports activities.[90]

Most of the literature suggests that the vast majority (>70%) of patients with VCD have a good outcome with some combination of education/reassurance, speech or breathing exercises, and psychotherapy, including two recent reports of longer term outcomes,[90,91] although in one 10-year follow-up of three patients, all continued to have recurrent symptoms despite speech therapies and psychotherapies, indicating that some minority of the group may be refractory to treatment.[99]

HABIT COUGH

The syndrome of habit cough is characterized by a barking or honking cough that is persistent and disruptive to normal activity. By definition, there are no laboratory, radiographic, bronchoscopic, or pulmonary function abnormalities. The patient does not show bronchoconstriction on methacholine challenge test or other provocative tests for asthma. The cough does not respond to usual antitussive therapies, bronchodilators, or anti-inflammatory medications. Nonetheless, the cough can become chronic and debilitating, preventing the child from attending school or social activities or impairing the adult's sociovocational functioning. The major morbidity from habit cough is iatrogenic, resulting from misdiagnosis and excessive medical treatment. It is not unusual for children to have been hospitalized for this disorder or to receive extensive evaluations. Two features that distinguish this cough from most of the pulmonary causes of cough is that it usually disappears once the patient is soundly asleep, and it seldom is exacerbated by exertion, as are coughs of most respiratory etiologies.

The prevalence of habit cough seems to be low, but it is not rare. There have been well over 100 cases of habit cough reported in the pediatric literature, at times labeled "psychogenic cough," "barking cough of puberty," "honking or psychogenic cough tic," "operant cough," or "respiratory tic"[100-103]; a handful of cases have been reported in adults.[104,105]

Diagnostic Considerations

Because the diagnosis of habit cough is essentially a diagnosis of exclusion, care should be taken to exclude all other causes of cough.[106] The differential diagnosis should include cough variant asthma,[107,108] bronchitis, pneumonia, allergic tracheitis, tuberculosis, cystic fibrosis, congenital pulmonary abnormalities, foreign bodies, and other intrinsic and extrinsic pulmonary disorders.[109,110] These pulmonary disorders would usually cause some abnormalities on laboratory, radiographic, or pulmonary function testing. Occasionally, the only abnormality may be noted on bronchoscopic examination, as in localized tracheomalacia.[111]

In understanding the pathophysiology of habit cough, it may be useful to understand its different eponyms because each of these three key terms implies a different mechanism: *habit*, *tic*, and *psychogenic cough*. Although the initial explanation to the patient and his or her family, as well as the first clinical intervention, in any of these instances may be similar, in general, the major reason to make these distinctions is that the likely treatment plan and overall prognosis will differ for each type of habit cough.

HABITS

Habits are generally semivoluntary activities, often reinforced either because they are self-soothing or because of the response they elicit from people in the environment. Although some habits (e.g., habit cough) disappear during sleep, not all habits do (e.g., bruxism or teeth grinding). In most cases of habit cough, children first develop a cough of infectious etiology, which lingers long after the infection usually should be resolved. Repeated cough continues to irritate the airways and stimulate the cough receptors, lowering the threshold for continued coughing.[109] Another frequently reported source of continued irritation is tobacco smoke exposure. Although never considered in the existing literature on habit cough, due to this common association with URIs and respiratory irritants, it behooves subsequent work in this area to examine whether such cases represent a true "habit" as opposed to cases of central sensitization of protective CNS reflexes, as discussed above, for somatic anxiety disorders and VCD. According to the cases reported in the literature, when a simple suggestive intervention is given and patients are shown how to suppress the urge to cough habit, the cough threshold returns to normal and the condition is "cured."

TICS

Tics are sudden, rapid, recurrent, nonrhythmic, stereotyped motor movements or vocalizations. Like habit cough, tics most often disappear during sleep and are exacerbated by stress, yet are defined as involuntary or semivoluntary. Tics are classified as *simple* or *complex* and as *motor* (movement) or *phonic* (sound producing). Tics may appear to be exaggerated fragments of ordinary motor or phonic behaviors that occur out of context. Simple tics usually involve a single muscle or functionally related group of muscles and are generally brief, lasting less than half a second each. However, they often occur in bouts of rapid succession, each bout lasting seconds up to minutes. Complex tics involve more muscle groups, often have a sustained duration or orchestrated pattern, and may appear purposeful. Complex phonic tics involve linguistically meaningful speech and language at times, whereas simple phonic tics are most often brief sounds, including coughing. Table 74-1 lists common motor and phonic tics. Occasionally, the first presentation of a tic disorder may be the single motor tic of coughing.[112]

Tic disorders involve a spectrum that includes transient tic disorder of childhood on the mild end, chronic motor or vocal tics in the moderate range, and Tourette's syndrome (TS) in the severe range. Transient tic disorder is common, occurring in 5% to 24% of schoolchildren.[112] By definition, tics in this disorder last more than 2 weeks but less than 12 consecutive months. Chronic multiple motor or vocal tics (there may be more than one tic, but all tics are in the same category) appear to represent a mild form of TS because both are transmitted as inherited traits within the same family. The severe end of the spectrum is Tourette's syndrome, in which more than one motor tic and at least one vocal tic occur in the same person, which are not due to the effects of a substance (e.g., stimulants) or a general medical condition (e.g., Huntington's disease or postviral encephalitis).[13] Onset must occur before age 21 (the median age of onset is 7 years), and the tics must be present for at least 1 year. Symptoms that may, but need not necessarily occur, include coprolalia, echo-

Table 74-1
Examples of Simple and Complex Tics

	Simple	Complex
Phonic tics	Coughing	Single words or phrases
	Sniffing	Speech blocking (e.g., stuttering or other interruptions)
	Barking	Palilalia (repeating one's own words)
	Throat clearing	Echolalia (repeating last heard word or sounds)
	Screaming	Coprolalia (inappropriate expression of socially unacceptable words or phrases)
	Sucking	
	Clicking	
	Snorting	
	Chirping	
	Blowing	
	Snorting	
Motor tics	Eye blinking	Jumping
	Jaw thrusting	Touching
	Nose wrinkling	Stomping
	Shoulder shrugging	Squatting
	Eyebrow twitching	Retracing steps
	Wrist snapping	Twirling
	Limb jerking	Hand gestures
	Facial grimacing	Copropraxia (a sudden, tic-like, vulgar gesture)
	Abdominal tensing	Echopraxia (repeating someone else's movements)

lalia, and complex motor tics, such as touching or picking. Approximately one third of individuals diagnosed with TS have resolution of tics by late adolescence; in another third, the tics diminish markedly; and in the remaining third the tics persist into adulthood.

In a child with habit cough, a tic disorder should be considered when more than one tic is noted, or if there is a family history of tics or other disorders genetically associated with tic disorders. These disorders include obsessive-compulsive disorder, attention deficit/hyperactivity disorder, and learning disorders. The vulnerability to Tourette's disorder is transmitted in an autosomal dominant pattern, with approximately 70% penetrance for female gene carriers and 99% penetrance for male gene carriers. Family members often have transient motor and vocal tics without full-blown Tourette's disorder.[113] Interestingly, in the pediatric reports of habit cough, there is note of some obsessive-compulsive symptoms in two of the patients, which is part of the genetic spectrum of tic disorders.[114]

The course of the cough symptom over time, comorbid psychiatric conditions, and family history will be most helpful in distinguishing a tic from a habit cough. Of note, antihistamines and sympathomimetic substances have been associated with exacerbation of motor tics in persons with preexisting tic disorders. These widely used agents could potentially bring on a motor tic in a genetically susceptible child and should be discontinued during evaluation of habit cough for that reason.[115]

Psychiatric Aspects

As discussed earlier in the section of VCD, the term *psychogenic* implies psychological causation. In the case of cough, psychoanalysts in the past have argued that a cough (as also was purported for asthma) can arise to express unconscious conflict: "The automatic cough reflex is expropriated by the voluntary muscle system in an effort to protect the ego. Just as weeping serves the dual function of washing irritants out of the eyes and expressing unhappiness, so does the cough share overlapping roles in discharging emotions and clearing the lungs."[105] Some early psychoanalytic reports suggested that the child's cough may be expressing a single, relatively circumscribed conflict (e.g., a way to protest to an overbearing mother),[100] whereas others indicated more complex motives (e.g., to avoid anxiety-provoking experiences at school).[116] It is important to underscore that outside of the rhetoric of psychoanalysis, there is no scientific evidence base to support psychological causation of cough.

A more evidence-based approach is to recognize that once started through other mechanisms, a cough can become entangled in psychological processes, and/or become entrenched and confounded by preexistent psychopathology. In one description of nine cases of habit cough, eight of the nine children had school phobia, possibly indicating an underlying anxiety disorder.[116] Several other authors described comorbid family conflicts or school phobia, and successful treatment of the patient included psychotherapy[101,117,118] or antidepressant medication.[119] These reports indicate that at least some children with habit cough have significant comorbid psychological problems and benefit from psychosocial intervention.

On the other hand, the existing literature also contains numerous examples that, in many children, reassurance and simple suggestive therapy are very effective in extinguishing the habit cough, usually within minutes to days and without emergence of other emotional or somatic symptoms.[102,103,114,120] Similar to pediatric VCD, many of these children are described as being conscientious, good students, and high achievers. These outcomes suggest that often habit cough is not associated with either underlying or concurrent psychopathology and can be easily treated with simple education and suggestion therapy.

As with VCD, there is a paucity of objective information with which to judge the actual prevalence of comorbid psychiatric problems in children with habit cough. None of the reports used blinded, objective raters to evaluate the presence of psychologic problems. There are no published reports of standardized ratings of emotional or behavioral problems among children with habit cough. None of the studies used control groups to compare rates of psychological or family problems, or overt psychopathology. Until this is done, one should not view habit cough as being caused by psychologic problems. Rather, it is likely that cough starts for a physiologic reason (e.g., post-URI), then gets sustained due to habit (or central sensitization?), and may be complicated and confounded by either preexisting psychological problems or via sickness reinforcing secondary gain, such as being able to stay home from school or receive extra attention from health care personnel. Even more important, if left untreated, it is possible that the habit cough itself may lead to psychosocial complications that become severe and take on a life of their own (e.g., secondary depression or markedly deficient social skills).[104,116]

Treatment

What is the natural course of habit cough? In the largest sample of habit cough syndrome reported, Rojas et al[121] followed up 60 patients (34 males and 26 females) an average of 7.9 years after diagnosis. The mean age at diagnosis was 10.5 years, with a range of 4.6 to 15.6 years. Mean duration of cough before diagnosis was 7.6 months, and mean duration until complete resolution was 6.1 months. In their sample, 73% had complete resolution of cough. However, 16 patients were still coughing a mean of 5.9 years after diagnosis. Because none of these patients was given specific treatments for the cough, this may reflect the natural course over time. The authors argue that more direct intervention would most likely shorten the course and limit the morbidity. It is important to clearly inform the patient and family of the diagnosis and intervene in some behavioral way to expedite recovery of these children, so that they do not form secondary problems from an unresolved habit.

Several types of interventions for habit cough and tic cough have been described in the literature. Treatment for simple motor tics is similar to that reported for habit cough. Current behavioral interventions use a combination of education and suggestion, for example, "This cough started with a cold. It has now become a habit in part because each time you cough, it irritates your throat and you are more likely to cough again. We will teach you how to stop doing that." The child is then taught a voluntary behavior that is incompatible with maintenance of the cough, such as diaphragmatic breathing, panting, or swallowing.[96,114,120] We often recommend that children carry a water bottle and have them swallow water each time they feel the urge to cough, which both inhibits the cough and may enhance mucus drainage at the same time. Finally, the parents are asked to monitor the child's progress (i.e., keep track of how many times an hour the child coughs) and reward the child for decreased coughing. Behavioral therapy has been demonstrated to be effective for most children with habit cough; overall, habit reversal has been found to reduce habit cough and simple phonic tics by 80% to 90%.[122] Pharmacologic interventions are not often used today for transient motor or vocal tics.

Some children and adults require more intensive psychosocial intervention, including hypnosis.[104,105,123,124] The few reported adult cases appeared to have more consistent psychopathology and were more difficult to treat than the pediatric and adolescent cases.[96] Nonetheless, with persistent therapy over 6 to 12 months, the overall morbidity of the disorder was greatly decreased, even if the symptom was not entirely extinguished.[104]

Prognosis and treatment for Tourette's disorder is very different than that for habit cough or simple transient tic disorder, and the patient suspected of having TS should be referred to a neurologist or psychiatrist. Treatment for TS usually includes psychopharmacologic interventions in addition to psychotherapy focused on behavioral strategies to decrease tics and how to cope with the illness in general. At least 20 agents have been tested for the more severe tics of TS. The most effective are pimozide, haloperidol, and clonidine. These are occasionally used for chronic tics. For example, in one description of nine cases of psychogenic cough tic six of nine children were treated with tranquilizers to alleviate symptoms.[116]

Habit cough should be in the differential of every cough persisting more than 2 weeks without any laboratory, pulmonary function, or radiographic abnormalities. Children and parents should be informed that the cough does not reflect any dangerous pathology and is indeed a habit at this point. Children should then be given a behavioral intervention that teaches them to suppress the cough and that allows a face-saving way out of the now dysfunctional habit/pattern. For most children, this approach is successful. If, however, evidence of more than one tic or strong family history for tic disorder exists, referral to a neurologist or pediatric psychiatrist should be considered. Likewise, if a straightforward behavioral approach is unsuccessful or if comorbid secondary psychiatric problems seem now to contribute to maintenance of the cough, referral to a pediatric psychiatrist or psychologist for further evaluation and treatment would be recommended.

CONCLUSION

This chapter has reviewed several common clinical syndromes in which CNS processes lead to respiratory symptoms. In each, a collaborative, potentially multidisciplinary, biopsychosocial orientation toward diagnosis and treatment is indicated because the existing research suggests that these disorders are based in hyperresponsive CNS reflexes, which although intended to protect respiration, can in certain circumstances misfire and produce episodes of cough, dyspnea, and breathing difficulty. As opposed to the notion that these problems are psychogenic and "all in the head," this chapter has argued that an informed clinical approach acknowledges both the central pathophysiologic importance of brain reflexes gone awry as well as the frequent confounding role of psychological stress and psychiatric disorders in the course and prognosis of these conditions. Given the relatively high prevalence rates, frequency of misdiagnosis and iatrogenic harm, significant degree of preventable morbidity, and availability of effective treatments for these

disorders, a clear understanding of the pathophysiology and treatment of the disorders discussed in this chapter will foster the clinical success of pulmonologists with what otherwise can be a difficult and frustrating group of patients to understand and treat.

CHAPTER 75

Pulmonary Manifestations of Systemic Disorders

Laura S. Inselman

TEACHING POINTS

- Obesity and malnutrition can cause pneumonia, atelectasis, respiratory muscle weakness, alterations in control of breathing, and respiratory failure.
- Diabetes mellitus is associated with hypoplastic, polyalveolar lungs; increased amounts of collagen and elastin that are also structurally abnormal; and altered lung architecture, mechanics, and function.
- A recurrent left lower lobe pneumonia with chronic pancreatitis may indicate a pancreaticobronchial fistula.
- Liver disorders can cause pulmonary arterial hypertension and hypotension.
- Renal failure associated with collagen vascular disease is often accompanied by pulmonary vasculitis and alveolar hemorrhage.
- Metastatic pulmonary calcification occurs when an alkaline environment in the lung promotes calcium deposition.
- Sickle cell chronic lung disease often results from multiple episodes of the acute chest syndrome but may occur without a prior acute injury to the lung.
- A hemothorax may be present in thalassemia when extramedullary hematopoiesis develops in the chest wall.
- Familial dysautonomia is associated with aspiration pneumonia, bronchiectasis, airway reactivity, pneumothoraces, and apnea.

Pulmonary physiology and function reflect not only the physiology and function of the lung itself but also that of other tissues and organs in the body. Although the lung's primary roles are the exchange of oxygen (O_2) and carbon dioxide (CO_2) between the environment and the body and the maintenance of acid-base balance within the body, the lung also has metabolic, endocrinologic, and growth-mediating actions that interact in different ways with other organs. Modifications, dysfunction, and malfunction in other tissues and organs may be reflected in alterations in lung growth, structure, function, and physiology. In particular, the lung can be affected by disorders of nutrition; dysfunction of the pancreas, liver, and kidneys; the presence of hemoglobinopathies; and familial dysautonomia.

NUTRITIONAL DISORDERS

Obesity

DEFINITION, RISK FACTORS

Obesity is defined by a body mass index (BMI) ≥ 30 kg/m^2 and is characterized by excessive adipose tissue.[1-5] It may be exogenous, that is, diet-induced, or endogenous, that is, secondary to an underlying disorder. It is associated with a protein, leptin, that helps regulate fat metabolism and satiety. Adipocytes synthesize and secrete leptin under the control of the *OB*, or *LEP*, gene on chromosome 7q31.[5-8] Leptin receptors occur in large airways and alveolar epithelial type II cells in the lung and are identified prenatally and postnatally, during childhood, and in the adult.[9,10] Leptin, its receptors, and its interactions with other proteins, such as neuropeptide Y, insulin, glucocorticoids, and estrogen, regulate appetite, fat deposition, and weight gain.[5,6,8,11-13] Congenital leptin deficiency, genetic mutations, and target organ, that is, adipocyte, resistance are associated with excess caloric intake, diminished fat metabolism, and severe obesity.[2,12,14]

PATHOGENESIS

Developmental, biochemical, structural, and functional changes occur in the lung with obesity.[15-30] The lungs of young obese rats fed a high-fat diet are large when measured by the lung volume/body weight ratio (Table 75-1). They have cellular hyperplasia, indicated by elevations in lung deoxyribonucleic acid (DNA) content; enlarged alveoli, measured by alveolar size and alveolar volume; reduced alveolar surface area relative to alveolar volume; and increased content of lipids and surfactant proteins A (SP-A) and B (SP-B).[15-17] Lipid deposition also occurs in the diaphragm and intercostal muscles in obese individuals, and the fiber type in diaphragmatic muscle is altered, indicating the direct involvement of these muscles in obesity.[7,11,31]

Biochemical and structural changes in the lung, lipid deposits in respiratory muscles, and adipose tissue accumulation in the chest wall cause alterations in lung function and physiology. The most consistent and characteristic change in lung function is a diminution in the expiratory reserve volume (ERV) (Table 75-2).[18,19,32,33] Other lung volumes, maximal voluntary ventilation (MVV), compliance of the lung (C_L) and chest wall (C_{CW}), expiratory flow rates in small airways, and inspiratory flow rates are also reduced. The respiratory

rate (RR), minute ventilation ($\dot{V}_E$), work of breathing, O_2 consumption ($\dot{V}O_2$), CO_2 production ($\dot{V}CO_2$), and the residual volume (RV)/total lung capacity (TLC) ratio, which reflects the presence of air-trapping, are elevated, and diffusing capacity (D_{LCO}) measurements are variably altered.[17-28,32-35] Ventilation-perfusion ($\dot{V}/\dot{Q}$) imbalance and hypoxemia are also present.

Airway reactivity and severe cardiorespiratory deconditioning identified clinically and with pulmonary function testing correlate with the elevation in BMI.[26,29,30,36] Although the occurrence and severity of both obesity and asthma are affected by the environment, genetic loci for these disorders are present in similar regions on the same chromosomes and suggest that obesity and asthma may be genetically linked.[36]

CLINICAL FEATURES

Pneumonia and atelectasis occur with increased frequency with obesity and result from alterations in the chest wall, airways, and lung parenchyma. Reduction in thoracic and diaphragmatic motion secondary to adipose tissue in the chest and abdominal walls promotes basilar atelectasis, $\dot{V}/\dot{Q}$ imbalance, hypoventilation, and retention of airway secretions with a predilection for airway and parenchymal infection. Gastroesophageal reflux (GER) can result from gastric overdistention with large meals and relaxation of the gastroesophageal sphincter. Acute or chronic aspiration of gastric contents resulting from GER predisposes to pneumonia and atelectasis, particularly during sleep in the recumbent position.[33,37,38] Airway reactivity can occur with GER from aspiration of gastric contents and/or bronchoconstriction induced by chemical mediators released when acid is in the lower esophagus.[38] Recurrent airway and parenchymal infections also cause airway reactivity.[37,39] In addition, severe obesity, that is, with a BMI ≥ 40 kg/m^2, can be accompanied by pulmonary embolism, pulmonary arterial hypertension, pulmonary edema, acute respiratory distress syndrome (ARDS), respiratory failure, impaired cardiac function, and cor pulmonale.[18,33,40,41]

Obesity itself is associated with eucapnia or hypocapnia.[20] However, severe obesity attenuates the ventilatory response of the brain stem to CO_2 and can cause the obesity-hypoventilation syndrome, which is characterized by central sleep apnea, daytime somnolence, hypercapnia, hypoxemia, polycythemia, pulmonary hypertension, and cor pulmonale.[20,33] Obstructive sleep apnea can result from relaxation of upper airway muscles and infiltration of soft tissues by adipose tissue.[20,33,42,43]

TREATMENT

Therapy includes dietary, pharmacologic, surgical, and mechanical intervention. Weight loss improves pulmonary function with restoration of lung volumes toward normal, diminution of $\dot{V}/\dot{Q}$ imbalance, and reversal of hypercapnia, hypoxemia, and the obesity-hypoventilation syndrome.[20,23,28,43-46] However, the effect of weight loss on the biochemical and structural changes in the lung in obesity is unknown.

Respiratory stimulants, such as progesterone, theophylline, protriptyline, and buspirone, can enhance the central drive to breathe and normalize the arterial tension of CO_2 ($PaCO_2$) in the obesity-hypoventilation syndrome.[20,33,47-49] Theophylline can also increase diaphragmatic contractility and improve pulmonary mechanics and ventilation.[48] However, the side effects and limited efficacy of these medications in these settings curtail their use.[33,49,50]

If not improved with weight loss, upper airway obstruction causing obstructive sleep apnea may be relieved with surgery, such as a tracheostomy, uvulopalatopharyngoplasty, or dental orthoses.[33,49,51] Nocturnal distending airway pressure, including continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) ventilation, may also be used.[33,49,52] Gastric bypass, or bariatric, surgery can improve lung function and sleep apnea in selected individuals.[28,33,45,46]

Malnutrition

DEFINITION, RISK FACTORS

Malnutrition is characterized by a caloric intake that is inadequate to meet the metabolic requirements of the body.[53] Unlike starvation, which is acute, malnutrition is chronic and can cause either marasmus, which occurs from a deficiency of total calories (including protein), or kwashiorkor, in which the protein deficit is in excess of the caloric insufficiency.[53,54] An inadequate quantity of food and/or inability to absorb and digest food can cause malnutrition.[53]

PATHOGENESIS

As with obesity, malnutrition alters lung growth, physiology, structure, and function; the respiratory muscles; and control of breathing.[55-60] In addition, humoral and cellular defense mechanisms of the body and the lung itself and the lung's response to injury, barotrauma, and hyperoxia are altered.[54,59,61,62] Malnutrition contributes to the pathogenesis of bronchopulmonary dysplasia, cystic fibrosis, and chronic obstructive pulmonary disease and the respiratory manifestations of certain neuromuscular diseases, such as spinal muscular atrophy and Duchenne muscular dystrophy, chronic infections, malignancies, and eating disorders, including anorexia nervosa and obesity.[54,60,62-65]

Although the severity, timing, and duration of the malnutrition determine its effect on lung growth and structure,[55,56,66-76] some general principles may be applied. Whether antenatal, early postnatal (from birth to weaning), or late postnatal (after weaning), malnutrition in the animal model results in reductions in body weight, lung weight, and lung volume[55-57,66-71,74-76] (see Table 75-1). The lung weight/body weight ratio is diminished during the antenatal and early postnatal periods, indicating that reduced caloric intake during this time has a greater effect on the lung than on the body.[66,67,71,74,75] The lung volume/body weight ratio is increased with late postnatal malnutrition, reflecting alveolar enlargement and reduction in body weight present at this time.[69,70]

Normal tissue growth is initially characterized by cell proliferation without cell hypertrophy. This stage is followed by a slowing of cell division while protein accumulates, resulting in new cells that are larger than during the first stage. Finally, cell hypertrophy without cell hyperplasia occurs.[66,67,71] When compared with controls, animal lungs exposed to antenatal or early postnatal malnutrition have fewer cells as measured by lung DNA content but normal cell size as measured by the protein/DNA and ribonucleic acid (RNA)/DNA ratios and thus have interference only with cell division[55,67] (see Table 75-1). Lungs exposed to late postweaning malnutrition have normal numbers of cells that are small in size, which reflect alterations during the later stages of lung tissue growth.[67,70] As a result, the lungs in malnutrition are hypoplastic at all stages, whether defined by cell number or cell size.[66,67]

The newborn animal lung exposed to antenatal malnutrition has reduced contents of lecithin, phospholipid, disaturated phosphatidylcholine (DSPC), and SP-A mRNA; increased glycogen content; delayed cellular differentiation and alveolarization; and architectural immaturity.[55-57,59,71,74-76] Although alveolar number is reduced in early postnatal malnutrition[71,76] and may be decreased or normal in late postnatal malnutrition,[71,72] diminished alveolar surface area (both absolute and relative to alveolar volume), enlarged alveoli, disruptions in alveolar septa, loss of elastic recoil, and reduced C_L occur during both of these periods and reflect biochemical abnormalities in these lungs[59,68-74,76] (see Tables 75-1 and 75-2). Emphysematous changes identified by computed tomography (CT) scans of the lung in anorexia nervosa indicate alterations in pulmonary architecture later in life.[77]

During early and late postnatal malnutrition, pulmonary levels of collagen and elastin as measured by hydroxyproline and desmosine are diminished.[68,72,78] As a result, lung connective tissue content and structure, which provide the framework for alveolar development and stability, are altered.[72,78]

The respiratory muscles are also affected by malnutrition. Diaphragmatic muscle mass is diminished in malnourished individuals, and diaphragmatic weight, DNA, protein, thickness, mitochondrial activity, and contractile force are reduced in the animal model.[59,79-82] Respiratory muscles in malnourished patients have decreased strength and endurance proportional to the loss in body weight and result in part from atrophy of types I and II muscle fibers.[58,59,82-84] In contrast, acute caloric restriction has little effect on diaphragmatic function and morphology in animals.[84]

CLINICAL FEATURES

Alterations in pulmonary function result from the biochemical and structural changes in the lung and respiratory muscles. Reductions occur in vital capacity (VC), functional residual capacity (FRC), MVV, and forced expiratory volume in 1 second (FEV_1)[58,65,85] (see Tables 75-1 and 75-2).

RV and the RV/TLC ratio are elevated, indicating the presence of air-trapping and perhaps the alveolar enlargement

observed morphologically.[58,65,69,86] Maximal respiratory muscle strength measured by inspiratory (PImax) and expiratory (PEmax) pressures is also reduced.[58,59,85,86] In addition, diminutions in exercise endurance despite normal ventilatory and cardiac responses with exercise occur in individuals with anorexia nervosa and likely result from the reduced mass and contractile force of the skeletal and respiratory muscles.[65] The normal hypoxic and, to a lesser degree, hypercapnic ventilatory drives controlled by the central nervous system are attenuated with malnutrition and, as with respiratory muscle weakness, can cause alterations in ventilation and respiratory failure.[59,85,86]

Pulmonary defense mechanisms, such as the cough reflex, secretory immunoglobulin A (sIgA) levels, pulmonary alveolar macrophage (PAM) number and activity, T-cell–mediated immunity, alveolar fluid mobilization, and lung clearance of certain bacteria and viruses, are diminished with malnutrition.[54,59,61,62,85,87-89] Systemic deficiencies in cellular, humoral, neutrophil, complement, and opsonin activity also occur.[54,59,61,62,85,87,90] These changes predispose the lung to acute and chronic infections.

TREATMENT

Therapy includes caloric and protein supplementation, which may reverse some alterations. For example, decreases in lung weight and contents of DNA and protein normalize with refeeding after late postnatal malnutrition but persist with refeeding after early postnatal malnutrition, suggesting that the earlier in life the caloric restriction, the more severe and permanent are the alterations in the lung.[67] In addition, adult rats who are refed for 7 to 10 days after a period of caloric restriction have increases toward control values of body and lung weights; pulmonary contents of elastin, hydroxyproline, lecithin, DSPC, DNA, RNA, protein, and, in some studies, the protein/DNA and RNA/DNA ratios; alveolar surface area but not the alveolar surface area/alveolar volume ratio; and C_L.[67,78,91,92] Pulmonary elastic recoil pressure remains unchanged, and alveolar enlargement persists although less prominently.[78,91] Thus, some biochemical changes reverse, but the morphologic and functional alterations do not, at least in the refed malnourished adult rat.

In malnourished adults with chronic obstructive pulmonary disease, short-term (16 to 21 days) and longer-term (3 months) caloric supplementation increases $\dot{V}O_2$, $\dot{V}CO_2$, respiratory quotient (RQ), and $\dot{V}E$ and improves gas exchange.[59] Respiratory muscle strength, the hypercapnic ventilatory drive, the ability to wean from assisted ventilation, exercise tolerance, T-lymphocyte number, and delayed cutaneous hypersensitivity responses are augmented.[59,64,93,94] However, improvements do not occur in VC, TLC, FEV_1, MVV, arterial blood gas measurements, humoral immunity, and complement levels.[64,93,94] Similarly, malnourished children with cystic fibrosis have reduced numbers of pulmonary infections and increased MVV and respiratory muscle strength with either short-term (1 month) or longer-term (6 to 34 months) caloric supplementation.[60,63,95,96] Lung volumes and airflow rates either improve or decline less rapidly with up to 3 years of nutritional rehabilitation.[95,96]

These observations in both the animal model and the clinical setting are particularly important in intensive care areas, where nutritional needs may be delayed while more acute problems are addressed. Nutritional supplementation in poorly nourished patients can improve lung and respiratory muscle function, ventilation, and local and systemic immunity.

DISORDERS OF THE PANCREAS

Diabetes Mellitus

PATHOGENESIS

As a metabolic disorder resulting from dysfunction of the endocrine portion of the pancreas, diabetes mellitus affects many organs in the body with varying degrees of complexity.[97-99] Pulmonary involvement results from abnormalities in collagen, elastin, and the microvasculature in the lung and includes alterations in lung growth, structure, function, and physiology, which are manifested clinically in disease.

The immature diabetic animal has reduced body weight and length when compared with controls[100,101] (Table 75-3). The lungs are small in weight and volume but have a high lung weight/body weight ratio and lung volume/body weight ratio.[100] This reflects a greater effect of diabetes on the body than on the lung and is unrelated to the presence of undernutrition, which often accompanies diabetes in the animal model.[99,100] The lungs are polyalveolar; have an increased number of alveoli, which are small in size, volume, and total surface area; and intact alveolar septa.[100-102] However, the alveolar surface area/alveolar volume ratio is elevated and indicates enhanced alveolar complexity with an increased gas-exchange area, which results from the augmented number of alveoli.[100,102] Despite the increase in alveolar number, the lung content of DNA is reduced, indicating a reduction in cell replication.[100] Thus, the diabetic lung is hypoplastic in terms of lung weight, volume, and DNA content but is polyalveolar. These somewhat contradictory observations are explained by the occurrence of alveolar multiplication at the tips, or secondary crests, of newly formed alveoli where DNA and elastin synthesis is high.[100] Thus, despite a total decrease in cell multiplication, there appear to be selective areas, that is, alveolar crests, in the diabetic lung where cell hyperplasia is occurring, resulting in new alveoli.[100] Additional morpho-

logic changes in the lung in both experimental and human diabetes mellitus include collagen and elastin deposits in airways, interstitium, and walls of large vessels; interstitial fibrotic nodules; thickening of the basal lamina of the alveolar epithelial and capillary basement membrane; dilation of the endoplasmic reticulum in alveolar epithelial type II cells; and alterations in secretory granules in Clara cells.[102-110]

Pulmonary levels of collagen and elastin are elevated in immature and adult diabetic rats, reflecting both increased synthesis and diminished degradation of these proteins.[99,100,111] The activity of lysyl oxidase, an enzyme associated with normal cross-linking of connective tissue proteins, is augmented in the lungs of diabetic rats and results in tighter cross-linking of collagen and elastin, rendering them resistant to digestion by proteolytic enzymes and increasing their levels in the lung.[99,102,103,111] In addition, hyperglycemia-induced nonenzymatic glycosylation of collagen and elastin causes structurally abnormal cross-linking of these proteins.[97,103,104,112] As a result of both the tighter and structurally abnormal cross-linking, alterations occur in the mechanical properties of the lung. Stiff lungs in the adult diabetic rat and a reduction in pulmonary elastic recoil in humans with diabetes reflect these biochemical and morphologic changes.[103,104,111]

Although lung growth is somewhat enhanced (at least after birth) in diabetes in terms of alveolar number and relative surface area, prenatal lung growth is delayed in the infant of the diabetic mother. The maternal hyperglycemia associated with diabetes crosses the placenta and stimulates the fetal pancreas to secrete insulin.[113] Pulmonary alterations result from the inhibitory effects of the sustained fetal hyperinsulinemia and are observed biochemically with reduced synthesis, availability, and utilization of surfactant precursors and SP-A and increased presence of epidermal growth factor (EGF); morphologically with a decreased number of alveolar epithelial type II cells, increased glycogen content in alveolar epithelial type II cells, and reduced air space relative to the quantity of tissue present; and functionally with diminished lung distensibility.[100,101,113] Immaturity of the lung in the infant predisposes to the development of neonatal respiratory distress syndrome (Box 75-1). Both insulin and insulin-like growth factor (IGF) receptors normally occur in the lung before and after birth, have elevated binding activity in the presence of hyperinsulinemia, and may play a role in the actions of insulin on the lung in the infant of the diabetic mother.[113-115]

Fetal insulin deficiency secondary to a reduced number of pancreatic islet cells occurs with maternal malnutrition and is accompanied by later development of diabetes mellitus and obstructive lung disease even if postnatal nutrition is adequate.[116,117] These observations indicate that maternal nutrition modifies pancreatic development prenatally and postnatally and throughout later life and that fetal alterations in glucose and insulin control have effects on the lung and body decades later.[116,117]

Box 75-1 Respiratory Disorders Associated with Diabetes Mellitus

Neonatal Disorder

Respiratory distress syndrome in infant of diabetic mother

Infectious Disorders

Bacteria: *Staphylococcus aureus, Streptococcus pneumoniae, Escherichia coli, Klebsiella pneumoniae*
Fungi: Zygomycetes (*Mucor, Rhizopus, Absidia* species), *Candida* species, *Aspergillus* species
Mycobacteria: *Mycobacterium tuberculosis*
Viruses

Parenchymal Disorders

ARDS
Pulmonary edema
Aspiration pneumonia
Pneumothorax, pneumomediastinum
Pleural effusion
Cor pulmonale

Airway Disorder

Autonomic neuropathy: reduced bronchial reactivity, mucous plugging

Chest Wall Disorder

Hypokalemic respiratory muscle paralysis

Disorders of Control of Breathing

Diminished responses to hypoxia and hypercapnia
Central hypoventilation
Central apnea
Sleep apnea

CLINICAL FEATURES

Disorders of the lung, chest wall, and control of breathing can complicate diabetes mellitus (see Box 75-1). Individuals with diabetes have an increased incidence of severe acute and chronic infections. Defective cell-mediated immunity, with quantitative and qualitative dysfunction of lymphocytes and monocytes and alterations in the activity of polymorphonuclear leukocytes (PMNs), PAMs, antioxidants, phagocytosis, and chemotaxis in diabetes contribute to the increased frequency and severity of infections.[98,118-120] Diseases caused by gram-positive bacteria (which grow well in a glucose environment), gram-negative rods, Zygomycetes, *Candida* species, influenza virus, and *Mycobacterium tuberculosis* have an increased morbidity and mortality in diabetes.[98,120,121]

Zygomycosis (mucormycosis) is an infection caused by the ubiquitous fungi, *Mucor*, *Rhizopus*, and *Absidia* species, and can result in acute and chronic pulmonary disease in diabetes[98,122] (see Box 75-1). Hyperglycemia and acidemia favor growth of these fungi by inhibiting the phagocytosis of PMNs and PAMs. Although rhinocerebral mucormycosis occurs more frequently in diabetes, pulmonary involvement has also been observed.[98,122,123] Inhalation of spores is the portal of entry to the lung. The fungi invade large airways and blood vessels and cause airway stenosis, thrombosis, ischemic necrosis, and infarction.[98,122] Pulmonary infection occurs as an acute pneumonia. Initially, fever, dyspnea, and cough, which may be dry- or wet-sounding, occur and are followed by pleuritic chest pain and hemoptysis, which can be life-

threatening.[122] Chest radiographs indicate a localized infiltrate or cavity, which then spreads to nearby areas.

The severity of tuberculosis parallels the severity of diabetes.[98] *M. tuberculosis* is more likely to cause cavitary disease, particularly in the lower lobes, in individuals with diabetes than in nondiabetic patients.[98,121]

The direct effect of acidosis in diabetic ketoacidosis can cause increased pulmonary vascular permeability, pulmonary edema, and ARDS[98,124] (see Box 75-1). In addition, crystalloids and fluids used in the therapy of ketoacidosis can contribute to the development of pulmonary edema and ARDS.[98,125] The gastric stasis and impaired gastric emptying occurring with ketoacidosis can cause gastroparesis, emesis, and aspiration pneumonia.[98] Severe vomiting and deep breathing secondary to acidosis can result in a pneumothorax and/or pneumomediastinum.[98] Diabetic autonomic neuropathy resulting in diminished vagal nerve activity can cause sleep-disordered breathing with diminutions in heart rate and ventilatory responses to hypoxia and possibly hypercapnia and may explain the increased incidence of central hypoventilation and apnea in diabetes.[107,126,127] Autonomic neuropathy also causes airway abnormalities, including airway hyporeactivity to inhaled bronchodilators and carbachol and cold air challenge testing.[98,128] Electrolyte imbalance can result in respiratory muscle weakness.[98,107] The lungs can also be affected in diabetic-related diseases of other organs, including heart failure, pulmonary edema, and a transudative pleural effusion with cardiac or renal involvement.[98]

Pulmonary function studies in individuals with diabetes have been performed primarily in adults with type 1 (insulin deficiency, insulin dependency) or type 2 (end-organ insulin resistance, non–insulin dependency) diabetes mellitus and have produced conflicting results. Investigations have included individuals with a history of cigarette smoking, reactive airway disease, and/or obesity and varying degrees of control, duration, and severity of diabetes. Although reductions in VC, forced vital capacity (FVC), TLC, FRC, RV, FEV_1, forced expiratory flow along 25% to 75% of the VC ($FEF_{25-75\%}$), mean maximum expiratory flow rate (MMEF), and MVV are inconsistently observed, diminutions in DLCO corrected for alveolar volume (DLCO/VA), alveolar capillary blood volume, and pulmonary elastic recoil pressure have been frequently noted.[102-104,107,112,127,129-135] Recent studies in children with an early onset of diabetes reveal reductions in FVC, FEV_1, DLCO, and the DLCO/VA ratio; elevations in RV and the RV/TLC ratio; increased airway resistance (Raw); and normal values for ERV, TLC, and the FEV_1/FVC ratio.[108,136] This indicates the presence of narrowed airways, air-trapping, and impaired diffusion of O_2 and CO_2 in the lung.

Reduced pulmonary capillary blood volume, most likely resulting from microangiopathy with thickening of the alveolar epithelial and capillary basal lamina, accounts for the diminished DLCO because the membrane component of DLCO is normal.[103,104,133] Platelet hyperaggregation, which results from reduced synthesis of prostacyclin (an inhibitor of platelet adhesion) and increased synthesis of thromboxane (a stimulant of platelet adhesion), occurs in diabetes and may also contribute to the microangiopathy.[137]

Diminished lung elastic recoil reflects alterations in pulmonary connective tissue.[103,104,107,111] Because immobile joints can result from abnormal connective tissue and are associated with the early development of microangiopathy in diabetes, limited joint mobility may be a clinical marker for abnormal lung connective tissue and altered pulmonary function.[98,128,138] Costosternal and costovertebral joint immobility resulting from connective tissue changes may contribute to the reduced lung volumes.[129] In addition, diaphragmatic and inspiratory muscle strength and respiratory muscle endurance are decreased.[130,131]

Pulmonary function changes correlate directly with the duration of diabetes mellitus in some studies.[103,130,134] Diabetes at its onset may be associated with a faster rate of reduction in lung volumes compared with diabetes of lung duration, that is, the rate of change in lung volumes appears greatest early.[112,135] Investigations of control of hyperglycemia in types 1 and 2 diabetes mellitus suggest the presence of normal pulmonary function, including DLCO/VA measurements, with long-standing near-normal serum glucose levels.[97] However, this may be related to the effects of insulin on the DLCO and not necessarily to normoglycemia.[139] The FVC and FEV_1 are diminished to a lesser extent in type 2 than in type 1 diabetes mellitus, suggesting that the milder the disease, the less severe the reductions in lung volumes and that after good biochemical control of diabetes, the rate of decline in lung volumes may decrease.[112,134,135]

In children who have well-controlled insulin-dependent diabetes and normal lung volumes and airflow rates at rest, exercise testing reveals normal measurements of ventilatory response, anerobic threshold, and maximal heart rate but reduced work capacity, $\dot{V}O_2$, and O_2 pulse measurements.[140] This suggests the presence of inadequate peripheral O_2 use and subclinical microvascular abnormalities with thickening of the capillary basement membrane in skeletal muscles.[140]

DIAGNOSIS

Pulmonary complications of diabetes mellitus are diagnosed by the history, physical examination, radiography, and laboratory studies. The presence of ketoacidosis and/or uncontrolled hyperglycemia in an individual with diabetes and pneumonia should suggest the possibility of a fungal or mycobacterial infection. Pulmonary mucormycosis should be considered in the presence of rhinocerebral disease with a characteristic black eschar.[122] ARDS can develop rapidly in diabetics in the presence of only mild hypoxemia without crackles or radiographic changes initially.[141] Stains and cultures of respiratory secretions and blood for bacteria, fungi, mycobacteria, and viruses; immunologic studies for specific viral antigens and antibodies; anteroposterior and lateral chest radiographs; and when indicated, CT scans are important in the diagnosis of these disorders.

TREATMENT

Therapy includes appropriate antibiotics and antiviral, antifungal, and antimycobacterial agents for the specific etiologic microorganism; thoracentesis for a pleural effusion associated with respiratory distress; supplemental O_2, assisted ventilation, and vasopressors for ARDS; cardiotonic drugs and diuretics for heart failure and pulmonary edema; correction of electrolyte imbalance; and improved serum glucose control. Immunizations with the pneumococcal and influenza vaccines are important in preventing these infections.[98] Studies of the efficacy and safety of inhaled insulin preparations for treat-

ment of diabetes mellitus in children are in progress.[107,136,142,143] However, adequate deposition of the aerosol will be hindered if significant alterations in lung function are already present.[107,136,142,143]

Pancreatitis

RISK FACTORS

The etiologies of pancreatitis in children are listed in Box 75-2, and pulmonary disorders associated with acute and chronic pancreatitis are listed in Box 75-3. Although pleural effusions are recognized in children with pancreatitis, most pleuropulmonary complications of pancreatitis are described in adults, in whom the majority of cases results from alcoholism, trauma, and cholelithiasis.[144-149] Alterations in gene structure and function likely play a role in the development of acute and chronic pancreatitis.[150,151]

PATHOGENESIS, CLINICAL FEATURES

Pleural effusions are usually left-sided but may be right-sided or bilateral.[152-157] They occur shortly after the onset of acute pancreatitis and are characterized by a serous, serosanguinous, or hemorrhagic exudate with a pH of 7.30 to 7.35, a glucose content similar to the level in blood, a predominance of PMNs, and elevations in the pleural/serum ratios of amylase, protein, and lactate dehydrogenase (LDH).[153-155,157-159] Fluid resorption correlates with resolution of acute pancreatitis. However, an effusion persisting greater than 14 days usually indicates chronic pancreatic disease, such as a pseudocyst, abscess, or pancreaticopleural fistula, and represents a chronic effusion.[153] When a pancreaticopleural fistula occurs, a sinus tract develops from the apical aspect of the pseudocyst through the diaphragm to the pleural space.[154-156,159] The resultant pleural effusion may occur after the acute pancreatic symptoms have subsided and characteristically persists despite serial thoracenteses.[154,155,160] A thickened pleura can develop and encase a chronic effusion but usually resolves within 6 months after the onset of disease.[153]

The etiology and pathogenesis of the fluid have not been defined (Box 75-4). Although transdiaphragmatic channels can exist between the pleural cavity and acutely inflamed pancreas, whose tail normally lies just below the diaphragm, they are only infrequently recognized.[152,153,155,158] However, the normally occurring diaphragmatic hiatal openings for the esophagus, aorta, and inferior vena cava can allow passage of pancreatic fluid into the mediastinum and pleural space and cause a right-sided pleural effusion.[154-156,159] Lymph flow across transdiaphragmatic lymphatic vessels between the pancreas and pleural space may also help spread the pancreatic inflammatory exudate.[155,156,158,159] In addition, lymphatic drainage from the pleural space through collecting lymphatics

Box 75-4 Possible Etiologies of Pleural Effusions Associated with Pancreatitis

- Passage of inflammatory exudate through the transdiaphragmatic channels between the pancreas and the pleural space
- Passage of inflammatory exudate through the esophageal, aortic, and inferior vena caval openings in the diaphragm
- Passage of inflammatory exudate in lymph flow through the transdiaphragmatic lymphatic vessels, particularly with impaired diaphragmatic mobility
- Passage of inflammatory exudate via retrograde lymph flow into the pleural space, which results from incompetent valves in the lymphatic vessels
- Increased pleural vascular permeability resulting from the release of pancreatic chemical mediators

to hilar lymph nodes is normally aided by diaphragmatic movement.[152,153] Pain and inflammation occurring with pancreatitis can impair diaphragmatic mobility, hinder normal lymph flow, and cause pleural fluid to accumulate.[152,157] Lymphatic valves help promote lymph flow in the collecting lymphatic vessels from both pleural and peritoneal spaces and can become incompetent with inflammatory pancreatic disease.[152] Lymph flow is bidirectional in these vessels, and lymph can then flow back into the pleural space from the peritoneal area.[152,159] Finally, the pancreatic inflammation itself and chemical mediators, such as proteolytic enzymes, prostaglandins, phospholipase A_2, kinins, histamine, and activated complement, released by the inflammatory process can increase permeability of pleural capillaries, disrupt lymphatic vessels, and promote formation of pleural fluid.[152,153,158,161-163]

Empyema occurs if a bacterial infection results in a pleural effusion (see Box 75-3). *Escherichia coli* and *Staphylococcus aureus* have been isolated in this setting.[155,164] The subdiaphragmatic inflammatory process in the pancreas with its associated pain and limited diaphragmatic mobility can cause elevation of the left hemidiaphragm, lower lobe atelectasis, and pneumonia[153,155,164] (Fig. 75-1). If it is severe, $\dot{V}/\dot{Q}$ imbalance, intrapulmonary shunting of blood, and hypoxemia can result. Recurrent pneumonia of the left lower lobe suggests the presence of a pancreaticobronchial fistula, and sputum containing amylase associated with an amylase-rich pleural effusion indicates a pancreaticobronchopleural fistula, both of which occur with chronic pancreatitis.[160,165]

Atelectasis occurs as the inflamed pancreas releases phospholipase A_2 (lecithinase), an enzyme that hydrolyzes dipalmitoyl phosphatidylcholine (DPPC, lecithin), the main component of the phospholipids in surfactant.[166-168] Pulmonary phospholipid synthesis is also reduced.[167] The resultant diminution in surfactant activity increases alveolar surface tension and promotes lung collapse.[166-168]

Pulmonary embolism and infarction result from release of clotting factors, kinin, and activated complement from the inflamed pancreas.[153,164] Fat emboli emanating from bone marrow, increased serum levels of triglycerides secondary to hypertriglyceridemia, and elevated serum levels of free fatty acids resulting from hydrolysis of triglycerides by lung lipoprotein lipase and cleavage of phospholipid by phospholipase A_2 also predispose to pulmonary embolism.[161,169,170]

If the pancreatic inflammatory process is severe, ARDS can occur (see Box 75-3 and Fig. 75-1). The release of multiple chemical mediators, including (in addition to those already mentioned) leukotrienes, pancreatic proteases (trypsin, chymotrypsin, elastase), substance P, chemokines, and cytokines (platelet activating factor, tumor necrosis factor α [TNF-α], interleukins, macrophage migration inhibitory factor [MIF], intercellular adhesion molecule-1 [ICAM-1]), increases vascular permeability and promotes the development of ARDS.[153,157,171-177] The elevated levels of tri-

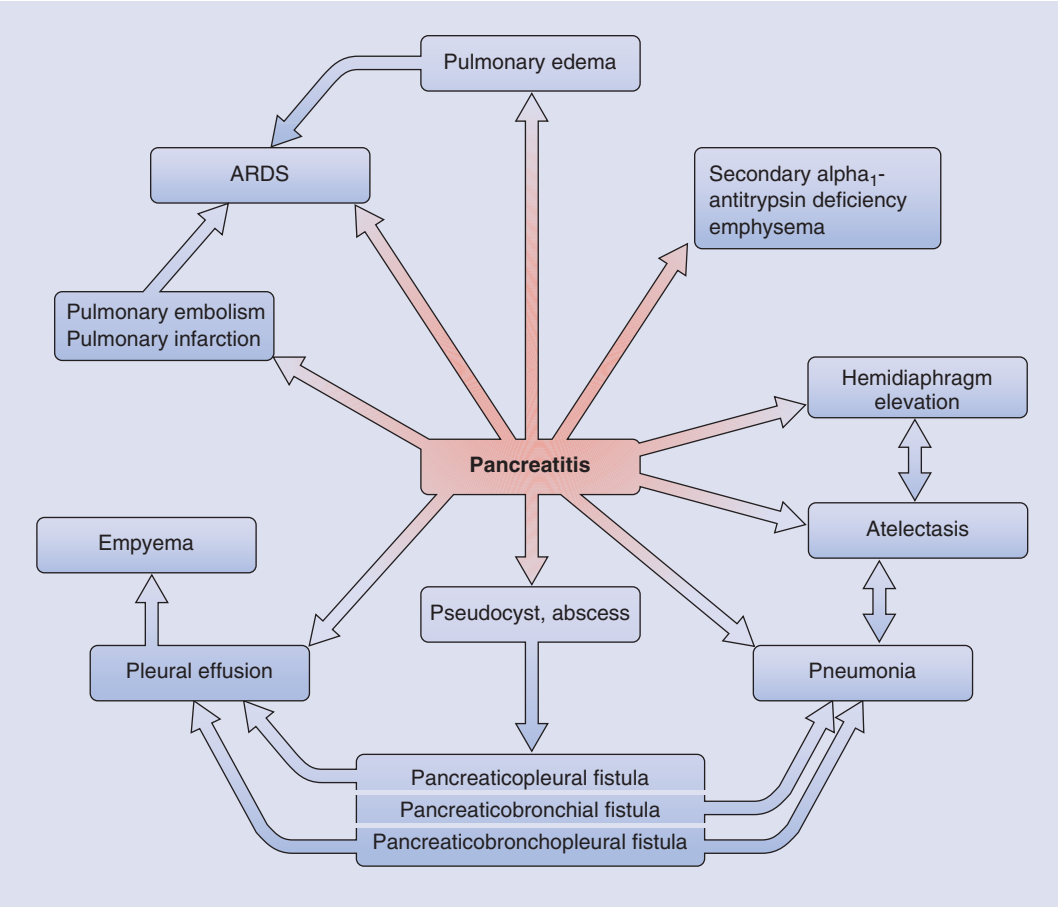

Figure 75-1 Pancreaticopulmonary disorders.

glycerides and free fatty acids also contribute to lung injury by damaging capillary endothelial cell membranes and thereby increasing vascular permeability.[167,170] O_2-free radicals released from activated PMNs and the liver's ability to synthesize, release, and metabolize chemical mediators also aid the inflammatory process in the lung.[163,178,179]

ARDS secondary to acute pancreatitis is accompanied by injury to alveolar epithelial type II cells with destruction of surfactant-containing lamellar bodies, capillary endothelial cell damage, interstitial and alveolar edema, intravascular and interstitial aggregates of PMNs and platelets, intra-alveolar hemorrhage, fibrin deposits, thickening of the alveolar epithelial cell membrane, and distortion of alveolar architecture.[161,163,171-173,180-182] Bronchoalveolar lavage (BAL) fluid contains increased levels of protein and PMNs, and these lungs weigh more and are stiffer than lungs without ARDS.[161,180]

The inflamed pancreas releases trypsin, and as a result, α_1-antitrypsin levels may be decreased and cause an emphysema-like picture in chronic pancreatitis[183] (see Box 75-3 and Fig. 75-1). Elastase released from the pancreas also contributes to the development of emphysema.[183]

Hypoxemia without clinical or radiographic manifestations of lung disease can occur during the early stages of acute pancreatitis and may result from intrapulmonary right-to-left shunting of blood.[146,153,156,157,183-185] Lung function testing reveals reductions in VC, FEV_1, and TLC in acute pancreatitis, but these measurements are normal in chronic disease.[157,183,184] However, the DLCO, both absolute and corrected for lung volume (DLCO/VA), is diminished in acute and chronic pancreatitis.[157,165,183,184] This may reflect a diminution in the effective gas-exchanging surface, thickening of the alveolar epithelial cell membrane, and reduction in capillary blood volume occurring in the lung even without ARDS as a result of the pancreatitis.[183]

DIAGNOSIS

The diagnosis of these pancreaticopulmonary disorders is aided by the history, physical examination, and radiographic and laboratory studies. Pancreatitis is associated with sharp, localized midepigastric abdominal pain that is more severe with eating, vomiting, fever, anorexia, abdominal distention and tenderness, lethargy, and malaise.[144,145,148,149] The signs and symptoms of pleural effusion, atelectasis, and pneumonia are similar with and without pancreatitis.

Pleural effusions are characterized by localized limited chest wall expansion, dullness to percussion, diminished breath sounds, a friction rub, pleuritic pain with splinting, dyspnea, tachypnea, and shallow breathing. Atelectasis is associated with dullness to percussion, localized diminished breath sounds, pectoriloquy, and if large, unilateral tracheal deviation and mediastinal shift. Fever, a wet-sounding cough, crackles, pectoriloquy, and bronchophony indicate pneumonia.

Anteroposterior and lateral chest radiographs reveal the pleural effusion, which if large, may result in contralateral mediastinal shift. Lateral decubitus films are helpful in evaluating the presence of free-moving pleural fluid. Atelectasis on the chest radiograph may be accompanied by unilateral mediastinal shift. Ultrasonography, CT scans, and endoscopic retrograde cholangiopancreatographic (ERCP) studies of the pancreas can help in the diagnosis of an abscess, pseudocyst, or fistula.[148,153,160,165]

Measurements of serum phospholipase A_2 concentrations parallel the severity and course of pancreatitis and atelectasis.[168] Pleural fluid amylase levels are elevated in pancreatitis and remain increased after hyperamylasemia has resolved.[153,157,159] However, unlike chronic pancreatitis, in which pleural fluid amylase levels are characteristically increased, acute pancreatitis may be associated with initially normal levels of pleural fluid amylase that rise later as the disease progresses.[146,154,159] Pleural fluid amylase levels may also be increased in other disorders, including esophageal rupture, pneumonia, pleural fluid metastases, and tuberculosis.[154,159,186] However, in contrast to the pancreatic origin of the amylase in the pleural fluid associated with pancreatitis, the pleural fluid amylase is of salivary origin in these other disorders.[159,186]

TREATMENT

Therapy is directed at the specific pulmonary disorder—antibiotics for pneumonia; thoracentesis for an effusion that causes respiratory distress; chest tube drainage, fibrinolytic agents, and video-assisted thoracoscopic surgery (VATS) for empyema; chest physical therapy for atelectasis; anticoagulants for pulmonary emboli; and assisted ventilation, supplemental O_2, diuretics, vasopressor agents, and extracorporeal membrane oxygenation (ECMO) for ARDS.[187] Nitric oxide (NO) therapy may decrease or even prevent lung damage by prohibiting adherence of PMNs to vascular endothelium and synthesis of O_2-free radicals.[188]

The pleural effusion usually resorbs as the acute pancreatic inflammation resolves.[154] Repeated therapeutic thoracenteses for a pleural effusion may not be helpful if a fistula is present and allows the effusion to recur. Surgery to close the fistulous tract is necessary if the effusion does not resolve with 2 weeks of medical therapy, including parenteral nutrition; therapeutic pharmacologic suppression of pancreatic secretions using somostatin, atropine, acetazolamide, and/or cimetidine; and serial thoracenteses or chest tube drainage.[146,154,159,160] Pseudocysts can be drained percutaneously but are usually removed surgically.[146,148,153,159,160]

DISORDERS OF THE LIVER

Risk Factors, Pathogenesis

Pulmonary disorders can occur with hepatic disease (Table 75-4). Acute hepatic disease associated with lung complications results from infections, medications, and toxins (Box 75-5).[189,190] For example, a pleural effusion can occur with an intrahepatic abscess caused by *Entamoeba histolytica* or a hydatid cyst caused by *Echinococcus granulosus*.[154,159] The pleural effusion associated with *E. histolytica* is composed of blood and liver tissue, has the consistency of chocolate sauce or anchovy paste, and results from direct diaphragmatic irritation by the hepatic lesion causing increased permeability of diaphragmatic pleural capillaries and transudation of fluid into the pleural space.[154] If the hepatic lesion ruptures through the diaphragm, empyema forms, and the communication may remain patent as a hepatopleural fistula.[154,159] Rupture of the lesion into airways can result in hepatobron-

Table 75-4
Pulmonary Disorders Associated with Hepatic Disease

Hepatic Disease	Pulmonary Disorder(s)
Infections	Hilar adenopathy, tracheobronchitis, pneumonia, atelectasis, reactive airway disease, interstitial pneumonitis, interstitial fibrosis, nodules, cysts, pleural effusion, fistulas (hepatopleural, hepatobronchial, biliobronchial)
Primary sclerosing cholangitis	Bronchitis, bronchiectasis
Malignancy	Hilar adenopathy, pneumonitis, nodules, pleural effusion, thromboemboli, lymphangitic carcinomatosis, osteolytic lesions in vertebrae and ribs
α_1-Antitrypsin deficiency	Tracheobronchitis, pneumonia, reactive airway disease, panacinar emphysema, bronchiectasis, bullae, pulmonary angiodysplasia
Chronic granulomatous disease of childhood	Hilar adenopathy, pneumonia, atelectasis, pleural effusion, abscess, honeycomb lung, pulmonary hypertension
Cystic fibrosis	Tracheobronchitis, pneumonia, atelectasis, bronchiectasis, reactive airway disease, cysts, bullae, pneumothorax, pulmonary hemorrhage, pulmonary hypertension
Hereditary hemorrhagic telangiectasia (Osler-Weber-Rendu disease)	Pulmonary angiodysplasia
Langerhans cell histiocytosis	Hilar adenopathy, pneumonitis (lobar, reticulonodular, interstitial), bronchiolitis, noncaseating granulomata, interstitial fibrosis, pleural effusion, pneumothorax, nodules, cysts, bullae, cavitary lesions, honeycomb lung, pulmonary hypertension
Sarcoidosis	Hilar and mediastinal adenopathy, reticulonodular infiltrates, atelectasis, reactive airway disease, bronchial stenosis, noncaseating granulomata, interstitial pneumonitis, interstitial fibrosis, pleural effusion, pneumothorax, nodules, cysts, bullae, honeycomb lung, pulmonary hemorrhage, pulmonary hypertension
Chronic active hepatitis	Pneumonia, atelectasis, interstitial pneumonitis, interstitial fibrosis, fibrosing alveolitis, pleural effusion, pulmonary hypertension, pulmonary hemorrhage, pulmonary angiodysplasia
Cirrhosis (alcoholic, postnecrotic, cryptogenic)	Pneumonia, pleural effusion, pulmonary hypertension, pulmonary angiodysplasia
Primary biliary cirrhosis	Reactive airway disease, interstitial pneumonitis (lymphocytic, usual), interstitial fibrosis, fibrosing alveolitis, noncaseating granulomata, nodules, pleural effusion, bronchiolitis obliterans organizing pneumonia (BOOP), pulmonary hemorrhage, pulmonary hypertension, pulmonary angiodysplasia, rib and vertebral fractures.

chial and biliobronchial fistulae, with sputum that is dark in color with *E. histolytica* or has cystlike structures with *E. granulosus*.[154,159] Viral hepatitis causes an exudative pleural effusion with a predominance of monocytes and without parenchymal disease and may transiently result in the hepatopulmonary syndrome (see later).[154,191] If hepatitis B virus is the etiology, the fluid may have the hepatitis B surface and *e* antigens.[154,159] Hepatitis C virus is associated with lymphocytic alveolitis, interstitial fibrosis, decline in lung function if asthma or chronic obstructive pulmonary disease is present, the hepatopulmonary syndrome, and portopulmonary hypertension.[192-194]

A hepatic hydrothorax forms when ascitic fluid secondary to liver disease passes through normal diaphragmatic openings and/or lymphatics into the pleural space.[154,159,189,195-197] The fluid is usually right-sided but may be bilateral, a transudate with normal protein and glucose levels, and serous or, if a coagulopathy is present, hemorrhagic.[154,159,197] Acute liver failure can cause pulmonary edema, ARDS, and acute respiratory failure.[189,197]

Chronic hepatic disease also causes pulmonary disease (see Table 75-4). Primary sclerosing cholangitis results from cholestasis of intrahepatic and extrahepatic bile ducts, causes cirrhosis and liver failure, frequently accompanies inflammatory bowel disease, and is associated with chronic pulmonary infection.[189,195] Hepatic malignancies metastasize to the diaphragm and lung either directly or hematogenously from the hepatic vein into the inferior vena cava, right heart, and pulmonary artery and cause parenchymal, pleural, vascular, and lymphatic lesions of the lung and bone lesions in the chest wall.[189] Systemic disorders, such as α_1-antitrypsin deficiency, chronic granulomatous disease of childhood, cystic fibrosis, hereditary hemorrhagic telangiectasia, Langerhans cell histiocytosis, and sarcoidosis, can also result in hepatopulmonary disease. For detailed descriptions of these disorders, the reader is referred to other chapters in this book and literature elsewhere.[189,195,198-202]

Clinical Features

The hepatopulmonary syndrome consists of chronic liver disease, pulmonary angiodysplasia with increased pulmonary blood flow, and hypoxemia defined by a partial pressure of arterial oxygen (PaO_2) < 70 mm Hg while breathing room air.[189,194,197,203-212] Portal hypertension may also occur.[205,207,213] Etiologies include chronic active hepatitis, acute viral hepatitis, alcoholic or postnecrotic cirrhosis, primary biliary cirrhosis, congenital liver disease (hepatic fibrosis, biliary atresia, Abernethy malformation), and the Budd-Chiari syndrome (see Table 75-4).[194,205-207,210,213-219] Vasodilating substances that are normally metabolized or detoxified by the liver may bypass the malfunctioning liver, alter the pulmonary vascular endothelium, and cause abnormal vascular dilatations.[189,205,206,220] Possible etiologic agents include NO, glucagon, substance P, vasoactive intestinal peptide, prostacyclin, interleukin (IL)-1, and IL-6, which may have enhanced synthesis in the lung and/or reduced hepatic degradation.[205-207,212,217,221] In addition, levels of endothelin-1, a vasoconstrictor that mediates pulmonary NO activity, may be abnormally reduced.[205,206] Thus, either an excess of vasodilators or deficiency of vasoconstrictors may contribute to the angiodysplasia.[206,212,219]

Pulmonary angiodysplasia results from dilatation of intrapulmonary precapillary and capillary vessels supplying alveoli and anatomic pulmonary arteriovenous communications[189,190,203,206,211,212,220] (Fig. 75-2). An increase in the

Box 75-5 Infections Associated with Hepatopulmonary Disease

Bacteria

Actinomyces israelii
Brucella species
Chlamydia psittacei
Coxiella burnetii
Francisella tularensis
Legionella pneumophila
Leptospira interrogans
Listeria monocytogenes
Mycobacterium tuberculosis, Mycobacterium bovis
Mycoplasma pneumoniae
Rickettsia prowazekii, Rickettsia rickettsii
Treponema pallidum

Viruses

Adenoviruses
Coxsackievirus B
Cytomegalovirus
Hepatitis A, B, and C viruses
Human immunodeficiency virus
Varicella-zoster virus

Fungi

Aspergillus species
Blastomyces dermatitidis
Histoplasma capsulatum
Paracoccidioides brasiliensis

Parasites

Ascaris lumbricoides
Cryptosporidium species

Entamoeba histolytica
Leishmania donovani
Plasmodium species
Schistosoma mansoni
Toxocara canis, Toxocara cati
Toxoplasma gondii

Box 75-6 Cardiorespiratory Manifestations of Hepatopulmonary Disorders

Pulmonary Manifestations

Adventitious breath sounds
Clubbing
Cough
Cyanosis
Diaphragmatic impairment
Dyspnea
Exercise intolerance
Hemoptysis
Hyperventilation
Hypoxemia
Orthodeoxia
Orthopnea
Paroxysmal nocturnal dyspnea
Platypnea
Precordial chest pain
Respiratory alkalosis
Tachypnea

Cardiac Manifestations

Accentuation of pulmonic second sound
Systolic ejection murmur in second or third left intercostal space or over left sternal border
Pulmonary bruit increased by inspiration and Müller's maneuver and decreased by Valsalva maneuver

Electrocardiographic Manifestations

Right ventricular hypertrophy
Right axis deviation
Right bundle branch block

Radiographic Manifestations

Prominence of main pulmonary arteries
Paucity of peripheral pulmonary vessels
Cardiomegaly

number of arterioles supplying an alveolus also occurs.[222] The arteriovenous communications, or spiders, occur not only in the lung parenchyma but also in the pleura, are similar to the cutaneous spiders present in liver disease, and contribute to hypoxemia.[189,190,195,203,220,222] In addition, the precapillary vessels, which are normally 8 to 15 μm in diameter, may dilate to 500 μm and diminish the pulmonary vascular resistance and pulmonary artery pressure and cause pulmonary hypotension.[189,197,212] An elevated cardiac output and rapid transit time for blood flow, which results from diminished systemic vascular resistance and increased peripheral blood flow, do not allow adequate oxygenation of venous blood passing through these dilated vessels, and arterial hypoxemia ensues[189,195-197,206] (see Fig. 75-2). As much as 70% of the cardiac output passes through these vessels.[189,195,197,223]

A "diffusion/perfusion" imbalance is present, with inability of O_2 to adequately reach red blood cells (RBCs) because of marked vascular dilatation.[206,212,216,224] This improves following inhalation of 100% O_2 and is in contrast to shunting through arteriovenous communications in which hypoxemia does not significantly diminish after inhalation of 100% O_2.[206,220] With severe liver dysfunction, hypoxemia may not elicit the normal hypoxic pulmonary vasoconstrictive response, which then augments pulmonary hypotension and hypoxemia.[189,195,206,220,225,226]

The dilated vessels and arteriovenous anastomoses are more numerous at the lung bases than at the apices.[189,195,197,206,220,227] As a result of the effect of gravity on augmenting blood flow through these vessels in the upright position, hypoxemia becomes more pronounced after a change from the supine to standing position.[189,191,195,206,210,212,227] Orthodeoxia, defined by a decrease in the Pa_{O_2} by more than 3 mm Hg between these two positions, is characteristic and often associated with an increase in dyspnea, or platypnea[189,191,195,206,217,227] (Box 75-6).

Paradoxically, pulmonary arterial hypertension can result from portopulmonary venous anastomoses, which develop in

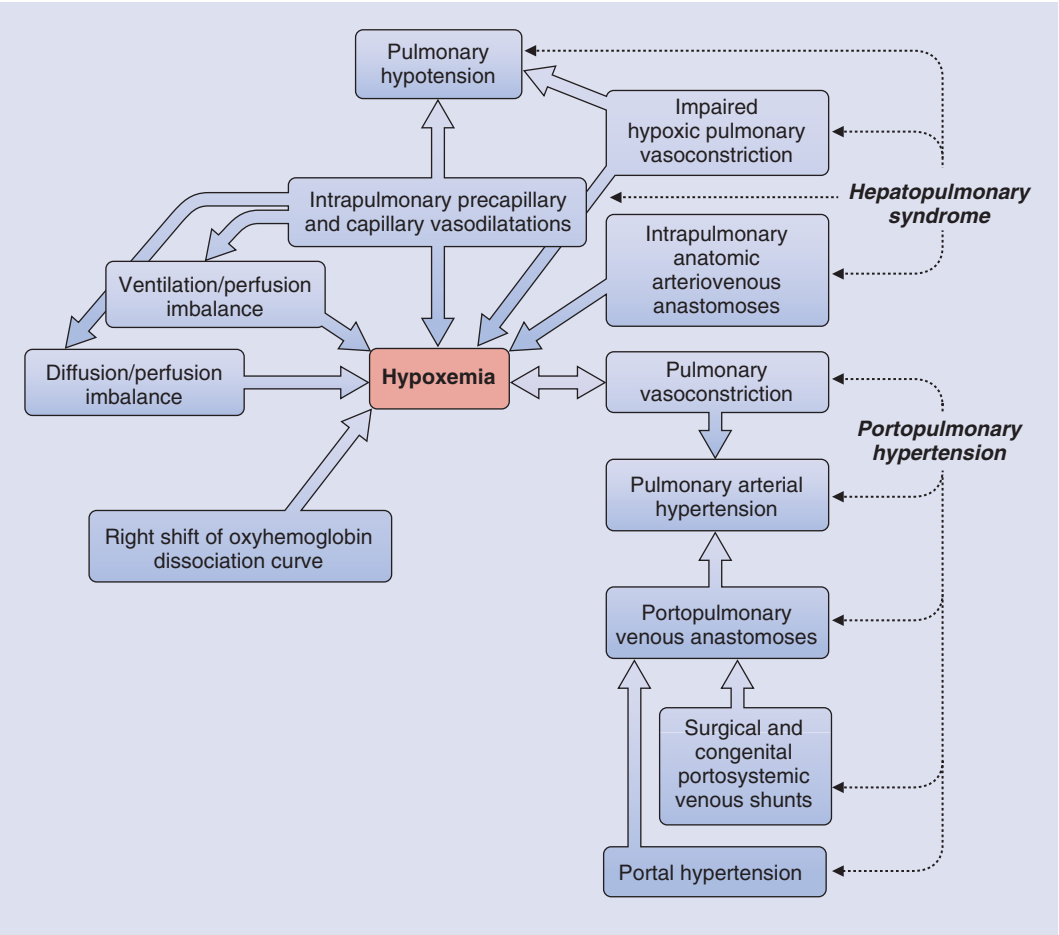

Figure 75-2 Etiology of hypoxemia in hepatopulmonary disorders.

the presence of portal hypertension and surgical or congenital portosystemic venous shunts[207,211,212,220,228-231] (see Fig. 75-2). Portopulmonary hypertension occurs with increases in pulmonary arterial pressure and pulmonary vascular resistance and a normal pulmonary capillary wedge pressure.[194,206,212,230,231] Instead of blood flowing along its normal pathway from the portal vein to the portal triad, where it combines with oxygenated blood from the hepatic artery, and then flowing through the venous system into the inferior vena cava, it is redirected from the portal vein through the periesophageal, mediastinal, and azygous veins, some of which communicate directly with large extrapulmonary and bronchial veins.[195] The contribution of these communications to hypoxemia is negligible because of a relatively high oxyhemoglobin saturation of 70% in portal venous blood and only a small amount of blood flow through these anastomoses.[189,195,196,222] Pulmonary hypertension usually develops after portal hypertension is present but has been identified without it.[189,205,217,220,229,230]

Pulmonary arterial hypertension results from hypoxemia in the presence of moderately severe liver dysfunction; is associated with intravascular platelet aggregation causing endothelial cell injury and vasoconstriction; and has characteristic plexiform lesions of nonfunctional, thin-walled, nonmuscular, saclike dilations of muscular arteries filled with blood, cells, collagen, and elastin.[206,212,217,220,228-231] It may be caused by enhanced activity of a vasoconstrictor, such as hepatocyte growth factor, vascular endothelial growth factor, endothelin-1, and serotonin, or a non-metabolized agent with effects on the pulmonary circulation.[206,212,217,228-230] Right heart failure eventually results from the severe pulmonary vasoconstriction and hypertension.[197,208]

Thus, pulmonary hypotension, which is caused by precapillary and capillary vasodilation and impaired hypoxic pulmonary vasoconstriction in the hepatopulmonary syndrome, and pulmonary hypertension, which is associated with hypoxemia and portal hypertension in portopulmonary hypertension, can occur and may be present simultaneously[206-208,211,212,228,232] (see Fig. 75-2). Although the oxyhemoglobin dissociation curve is shifted to the right with liver disease because of increased RBC 2,3-diphosphoglycerate (2,3-DPG) levels, this does not appear to be an important factor in the development of hypoxemia in hepatopulmonary disorders.[195,216,225,226]

Diagnosis

The history, physical examination, and laboratory and radiographic studies aid in the diagnosis of these disorders. A family history of early onset lung disease may be present with cystic fibrosis and α_1-antitrypsin deficiency. The presence of the signs and symptoms listed in Box 75-6 should signal a possible hepatopulmonary disorder. The occurrence of orthodeoxia and platypnea should alert the examiner to the pres-

ence of pulmonary angiodysplasia and the hepatopulmonary syndrome.[227]

The underlying hepatic disease is diagnosed with appropriate serologic tests for viral hepatitis, serum liver enzyme levels, and stains, cultures, and histologic studies of liver biopsy tissue. Abdominal ultrasonography and CT scans for liver abscesses or cysts; tests for serum α_1-antitrypsin levels and phenotype studies for α_1-antitrypsin deficiency; and cultures of respiratory secretions, a sweat test, and genotype studies for cystic fibrosis are important. Stains and cultures of respiratory secretions, BAL, pleural fluid, and blood are necessary to diagnose pulmonary bacterial infections. Langerhans cell histiocytosis and chronic granulomatous disease are associated with opportunistic infections, including *Pneumocystis jiroveci (P. carinii)*, *S. aureus*, *Enterobacter* species, *Burkholderia cepacia*, and *Proteus*, *Salmonella*, *Aspergillus*, *Serratia*, *Nocardia*, and *Candida* organisms. BAL fluid may be needed for stains and cultures of these organisms. Open lung biopsy aids in the diagnosis of pulmonary angiodysplasia, interstitial lung disease, and pulmonary hypertension.

Anteroposterior and lateral radiographs, ultrasonography, and CT scans of the chest help in the diagnosis of pneumonia, atelectasis, pleural effusion, abscesses, cysts, bullae, nodules, pulmonary hypertension, interstitial fibrosis, and honeycomb lung. Pulmonary angiodysplasia is identified by pulmonary arteriography, which reveals the dilated precapillaries and the arteriovenous anastomoses at the lung bases in a characteristic spongy pattern that correlates radiographically with basilar nodular infiltrates.[189,195,203,206,212,222] Transthoracic contrast-enhanced, two-dimensional echocardiography detects the presence of a shunt by scanning the passage of microbubbles in a contrast material. These particles are normally removed in transit through pulmonary capillaries, but, in the presence of a right-to-left intrapulmonary shunt, bypass the capillaries and appear after several cardiac cycles in the left side of the h eart.[189,191,195,197,203,205,206,210,212,220] Transesophageal contrast echocardiography can identify the contrast in specific veins and if dilatations or arteriovenous communications predominate even when hypoxemia is absent.[205,212,220] Lung perfusion scans using macroaggregated albumin labeled with technetium-99m have particles measuring 20 to 50 μm that wedge into normal capillaries that are 8 to 15 μm wide and do not pass through these vessels. However, these particles travel through arteriovenous fistulas and appear in the systemic circulation of extrapulmonary organs.[189,195,197,203-206,210,212,220,233]

Pulmonary function testing reveals reductions in DLCO, variable decreases in lung volumes and airflow rates, increases in $\dot{V}E$, hypoxemia, and hypocapnia.[196,206,215,216,223,232,233] Diminutions in the transfer factor cause the diminished DLCO, which occurs as a result of an increase in the pathway for gas diffusion from the alveolus through the vasodilated vessel to the RBC and is observed in alveolitis, emphysema, interstitial pneumonitis, and interstitial fibrosis.[206,233] $\dot{V}/\dot{Q}$ imbalance and diffusion/perfusion imbalance result from pulmonary angiodysplasia, pneumonia, atelectasis, bronchiectasis, and emphysema. Adults with the hepatopulmonary syndrome have progressive hypoxemia; reductions in the breathing reserve, $\dot{V}O_2$, and O_2 pulse; and elevations in RR, $\dot{V}E$, and physiologic dead space with exercise.[234]

Measurements of lung volumes and CL may be altered with ascites. Peritoneal fluid can raise intra-abdominal pressure; elevate and fix the diaphragm; reduce lung volumes, CCW, and MVV; and increase the RR.[195,196,232] In addition, oxyhemoglobin saturation, as measured by pulse oximetry, may be underestimated if the serum total bilirubin level is greater than 2.5 mg/dL because of interference of bilirubin pigments in the skin with oximetric readings of light transmission.[189,195]

Treatment

Therapy is directed at the underlying hepatic disorder. However, medications used to treat liver disease can be toxic to the lung. Penicillamine, a drug used in the treatment of Wilson's disease and primary biliary cirrhosis, can cause bronchospasm, bronchiolitis obliterans, bronchitis, hemorrhagic pleural effusion, interstitial pneumonitis, alveolitis, pulmonary fibrosis, hypersensitivity pneumonitis, pulmonary hemorrhage, and a pulmonary-renal syndrome similar to that of Goodpasture's syndrome (Box 75-7).[195,235,236] Methotrexate, an immunosuppressive drug used to treat primary biliary cirrhosis, can result in interstitial pneumonitis and pleural effusions.[154,218,236] Azathioprine, an immunosuppressive agent, can cause pulmonary edema and interstitial pneumonitis and fibrosis, while cyclosporine, another immunosuppressive drug, can cause pulmonary edema and ARDS.[189,195,196] Interferon-α (INF-α) is used in the treatment of chronic hepatitis C viral infection and can result in bronchiolitis obliterans organizing pneumonia (BOOP), interstitial pneumonitis, pleural effusion, pulmonary arterial hypertension, and asthma.[194]

Additional therapy includes treatment of pulmonary infections with appropriate antimicrobial agents and relief of dyspnea caused by pleural effusions or ascites with thoracentesis and paracentesis, respectively. Hypoxemia is treated with supplemental O_2 and positioning to reduce the extent of orthodeoxia and platypnea and can improve with percutaneous embolization of pulmonary angiodysplasia.[237]

Supplemental O_2 and bronchodilators, which improve airflow and minimize Raw and work of breathing, are used to treat pulmonary hypertension. Calcium channel blockers and prostaglandins may also be utilized and include continuous infusion of prostaglandin-I2 (epoprostenol) and inhalation of NO.[206,209,217,228,230,231,238-240] Experimental therapies consist of inhalation of a prostaglandin-I2 (iloprost), subcutaneous infusion of a prostacyclin (treprostinil), an oral prostacyclin (beraprost), oral endothelin receptor antagonists (bosentan, sitaxsentan), and an oral phosphodiesterase inhibitor (sildenafil).[228,238-241] Hypoxemia, clubbing, diffusion/perfusion imbalance, shunts, elevated cardiac output, reduced systemic and pulmonary vascular resistances, abnormal pulmonary function testing, and exercise intolerance may reverse with liver transplantation in selected individuals.[189,205-207,210,216,224,228,231]

DISORDERS OF THE KIDNEY

Renal Failure

DEFINITION

Acute and chronic renal failure can cause disease involving the lung parenchyma, airways, pleural space, blood vessels, chest wall, and control of breathing centers (see Box 75-7).

Box 75-7 Respiratory Disorders Associated with Renal Failure

Parenchymal Disorders

Alveolar hemorrhage
- Goodpasture's syndrome
- Systemic necrotizing vasculitides: Wegener's granulomatosis, Churg-Strauss syndrome, polyarteritis nodosa
- Connective tissue diseases: systemic lupus erythematosus, scleroderma, Behçet's disease
- Henoch-Schönlein purpura, IgA nephropathy
- Medications: penicillamine toxicity, azathioprine toxicity

Bronchiolitis obliterans organizing pneumonia
- Systemic lupus erythematosus, scleroderma, IgA nephropathy, Behçet's disease

Fibrosing alveolitis
- Renal tubular acidosis

Amyloidosis
- Chronic renal failure, end-stage renal disease

Lymphomatoid granulomatosis
- Chronic renal failure, end-stage renal disease

Metastatic pulmonary calcification
- Renal osteodystrophy, chronic hemodialysis, chronic renal failure, end-stage renal disease

Pulmonary edema ("uremic lung")
- Chronic renal failure, end-stage renal disease

Pneumonia: infectious, uremic pneumonitis
- Acute and chronic renal failure, peritoneal dialysis, end-stage renal disease

Rounded atelectasis
- Chronic renal failure, end-stage renal disease

Airway Disorders

Reactive airway disease
- Nephrotic syndrome, peritoneal dialysis, hemodialysis, chronic renal failure, end-stage renal disease

Pleural Disorders

Pleural effusion
- Nephrotic syndrome, peritoneal dialysis, hemodialysis, chronic renal failure, end-stage renal disease
- Wegener's granulomatosis, Churg-Strauss syndrome, systemic lupus erythematosus, scleroderma, Henoch-Schönlein purpura, Behçet's disease

Chylothorax
- Nephrotic syndrome, Behçet's disease

Vascular Disorders

Pulmonary arterial hypertension
- Hemodialysis, chronic renal failure, end-stage renal disease

Chest Wall Disorders

Respiratory muscle myopathy ("uremic myopathy")
- Chronic renal failure, peritoneal dialysis, chronic hemodialysis, end-stage renal disease

Fractures: ribs, vertebrae
- Renal osteodystrophy, chronic renal failure, end-stage renal disease

Disorders of Control of Breathing

Sleep apnea (central, obstructive)
- Chronic renal failure, end-stage renal disease

Pulmonary disease is more likely to be present when the plasma urea concentration is >20 mmol/L, or approximately 60 mg/dL, a level associated with metabolic alterations.[242]

PATHOGENESIS, CLINICAL FEATURES

Alveolar hemorrhage occurs in uremia as a result of vasculitis, alterations in platelet adhesion and aggregation, abnormal coagulation, and hypervolemia.[243] The coexistence of alveolar hemorrhage and glomerulonephritis produces a spectrum of diseases that affect the pulmonary interstitium and vessels, are frequently identified with immune dysfunction, and compose the pulmonary-renal syndrome[244-250] (see Box 75-7 and Table 75-5). For example, antibasement membrane antibody disease, or Goodpasture's syndrome, is associated with linear deposits of IgG, IgA, IgM, and the third component of complement (C_3) in the basement membranes of renal glomerular capillaries and IgG, IgA, and C_3 in the pulmonary alveolar septa; alveolar hemorrhage, inflammation, and fibrosis; PAMs filled with hemosiderin; focal and diffuse interstitial infiltrates; and acute respiratory failure.[244-247,251-253] IgG antibodies combine with basement membrane proteins of type IV collagen in renal tubules and glomeruli and in pulmonary alveoli when factors that increase pulmonary capillary permeability, such as hyperoxia and cigarette smoke, are present.[244,245]

Wegener's granulomatosis is characterized by glomerulonephritis, circulating antineutrophil cytoplasmic IgG antibodies (ANCA), deposits of IgG and complement in alveolar interstitium and small blood vessels, parenchymal cavitary lesions, localized alveolar hemorrhage, alveolitis, and necrotizing granulomatous vasculitis with infiltration by PMNs, T-lymphocytes, monocytes, histiocytes, plasma cells, and giant cells[244,246,252-257] (see Table 75-5). Possible etiologies include genetic susceptibility, chronic exposure to silica, and an association with α_1-antitrypsin deficiency.[258-260]

The pulmonary manifestations of allergic angiitis and granulomatosis, or Churg-Strauss syndrome, include a history of asthma and/or allergies; vasculitis of pulmonary arteries, veins, and capillaries of varying sizes; and eosinophilic infiltrates, granulomata, and necrotizing vasculitis in the lung.[244,248,254,261,262] Although polyarteritis nodosa is infrequently accompanied by respiratory complications, chronic asthma, alveolar hemorrhage, and necrotizing vasculitis of medium and small pulmonary arteries can occur and may represent a variant of Churg-Strauss syndrome.[244,245,254]

Systemic lupus erythematosus is associated with IgG, IgA, IgM, and complement deposition in pulmonary alveolar epithelial and endothelial cells and renal glomerular basement membranes; chronic interstitial pneumonia; pleural effusion; BOOP; hyaline membranes; diffuse alveolar hemorrhage; and

Table 75-5
Pulmonary-Renal Syndrome

Disorder	Signs and Symptoms: Pulmonary	Signs and Symptoms: Systemic	Laboratory Findings	Chest Radiographs
Goodpasture's syndrome	Hemoptysis, cough, dyspnea, hypoxemia	Glomerulonephritis	Anemia, proteinuria, hematuria, RBC casts, ↑ BUN and creatinine, slightly ↑ ESR, serum antiglomerular basement membrane antibodies, antibodies to α3 chain of type IV collagen, association with HLA-DR2 and HLA-B7 antigens	Focal or diffuse, bilateral or unilateral interstitial infiltrates; reticulonodular infiltrates; edema; hemorrhage
Wegener's granulomatosis	Hemoptysis, cough, dyspnea, hypoxemia, pleuritic chest pain, pleural friction rub	Fever, malaise, weight loss, otitis media, hearing loss, uveitis, proptosis, conjunctivitis, arthritis, sinusitis, dermatitis, epistaxis, CNS disease, glomerulonephritis	Anemia; thrombocytosis; ↑ ESR, BUN, and creatinine; RBC casts; hematuria; pyuria; proteinuria; positive RF; circulating immune complexes; ↑ C_3, IgE, and IgA; chemotaxis and cellular dysfunction; hypergammaglobulinemia; association with ANCA IgG antibodies and HLA-DR2 antigen	Bilateral nodular infiltrates with central cavitation; diffuse alveolar, interstitial, or reticulonodular infiltrates; single nodule; platelike atelectasis; pleural effusion; pneumothorax; pyopneumothorax; bronchopleural fistula; hemorrhage
Churg-Strauss syndrome	Wheezing, hemoptysis, dyspnea, hypoxemia, pleuritic chest pain	Allergies, petechiae, purpura, nodular and subcutaneous lesions, seizures, coma, peripheral neuropathy, diarrhea, melena pancreatitis, abdominal pain, myocardial and endocardial lesions, glomerulonephritis	Peripheral eosinophilia; slightly ↑ IgE; ↑ ESR, BUN, and creatinine; circulating immune complexes; hematuria; proteinuria; RBC casts; anemia; ↑ WBC count	Transient diffuse, nodular, or interstitial infiltrates; pleural and pericardial effusions; hemorrhage
Systemic lupus erythematosus	Hemoptysis, cough, dyspnea, hypoxemia, pleuritic chest pain	Fever, malaise, weight loss, CNS disease, alopecia, arthritis, serositis, nephritis, photosensitivity	↓ C_3; positive ANA and anti-DNA titers; circulating immune complexes; positive Coombs test; ↑ ESR, BUN, and creatinine; anemia; ↑ or ↓ WBC count; hypergammaglobulinema; hematuria; proteinuria; RBC and granular casts	Diffuse unilateral or bilateral infiltrates, interstitial infiltrates, atelectasis, pleural effusion, edema, hemorrhage, BOOP, diaphragmatic paresis
Scleroderma	Hemoptysis, cough, dyspnea, hypoxemia, pleuritic chest pain, pleural friction rub, bibasilar crackles	Sclerosis of skin, telangiectasia, myositis, arthritis, cutaneous calcifications, cor pulmonale, Raynaud's phenomenon, hypertension, esophageal hypomotility, gastroesophageal reflux, glomerulonephritis, renal vascular disease and failure	↑ ESR, BUN, and creatinine; positive RF, ANA, and anti-DNA titers; circulating immune complexes; T-cell hyperactivity; hypergammaglobulinemia; proteinuria; hematuria; anemia	Diffuse bilateral interstitial basilar infiltrates, interstitial fibrosis, cystic lesions, honeycomb lung, pleural and pericardial effusions, calcification, hemorrhage, subpleural cysts, pneumothorax, BOOP, prominent pulmonary arteries, cardiomegaly
Henoch-Schönlein purpura	Hemoptysis, cough, dyspnea, hypoxemia	Arthritis, arthralgia, purpura, abdominal pain, melena, glomerulonephritis	↑ ESR, BUN, creatinine, and IgA; hematuria; proteinuria; RBC casts; anemia; ↑ WBC count; normal platelet count	Interstitial pneumonitis, hemorrhage, pleural effusion
IgA nephropathy	Hemoptysis, cough, dyspnea, hypoxemia	Glomerulonephritis	↑ ESR, BUN, creatinine, and LDH; peripheral eosinophilia; ↓ C_3; hematuria; proteinuria; anemia	Interstitial pneumonitis, hemorrhage, BOOP
Behçet's disease	Hemoptysis, cough, dyspnea, hypoxemia, pleuritic chest pain	Uveitis, ulcers (oral, laryngeal, and genital), fever, subcutaneous nodules, thrombophlebitis, glomerulonephritis	↑ ESR, BUN, and creatinine; hematuria; proteinuria; RBC casts; anemia; association with HLA-B51 antigen, herpes simplex virus, hepatitis C virus, and parvovirus B19	Diffuse reticulonodular infiltrates, pleural effusion, chylothorax, infarction, hemorrhage, BOOP, prominent pulmonary arteries, diffuse bilateral perfusion defects on scan

↑, increased; ↓, decreased.; RBC, red blood cell; BUN, blood urea nitrogen; ESR, erythrocyte sedimentation rate; HLA, human leukocyte antigen; RF, rheumatoid factor; C_3, third component of complement; CNS, central nervous system; ANCA, antineutrophil cytoplasmic antibody; WBC, white blood cell; ANA, antinuclear antibodies; BOOP, bronchiolitis obliterans organizing pneumonia; LDH, lactate dehydrogenase.

pulmonary capillary vasculitis.[245-247,252,254,263-265] Progressive systemic sclerosis, or scleroderma, is characterized by fibrous connective tissue deposition in the lung, which may be inflammatory and immunologic in etiology; pulmonary interstitial pneumonitis and fibrosis; alveolitis; BOOP; hemorrhage; and pulmonary hypertension.[250,254,266]

Henoch-Schönlein purpura is associated with alveolar IgA deposition, inflammation, hemorrhage, and widespread pulmonary vasculitis, whereas IgA nephropathy is identified with deposits of IgA-containing immune complexes and C_3 in renal mesangial cells and may be accompanied by IgA deposition in alveolar interstitium and capillaries, pulmonary

hemorrhage, and BOOP.[245,246,248,254,267-269] Behçet's disease is characterized by deposits of IgG, C_3, and C_4 in pulmonary capillaries and venules; vasculitis of different-sized pulmonary vessels; pulmonary thrombosis and infarction; pulmonary arterial aneurysms invading contiguous airways; recurrent pneumonia; hemorrhage; and BOOP.[244-246,254,262,270,271] In most of these disorders, particularly Goodpasture's syndrome and Wegener's granulomatosis, alveolar hemorrhage occurs early in the course of the glomerulonephritis and may be the initial manifestation.[245,247]

The presence and pattern of immunofluorescent staining of ANCA help to identify the type of vasculitis and lung disease present.[244,247,272,273] Two main antigen-staining patterns comprise ANCA—the cytoplasmic pattern (c-ANCA), which has antiproteinase 3 (PR3) antibodies, and the perinuclear pattern (p-ANCA), which has antimyeloperoxidase (MPO) antibodies.[246,247,257,261,272] The c-ANCA, PR3 pattern is specific for Wegener's granulomatosis and is frequently accompanied by acute respiratory failure and bilateral pulmonary nodules radiographically.[246,252,257,272,273] The p-ANCA, MPO pattern is identified with Churg-Strauss syndrome, microscopic polyangiitis, and other types of glomerulonephritis without extrarenal manifestations and is often associated with a ground-glass appearance radiographically.[246,261,272,273] However, exceptions occur, as p-ANCA is recognized in Wegener's granulomatosis, Goodpasture's syndrome, scleroderma, and diabetes mellitus type 2 with glomerulonephritis and pulmonary hemorrhage.[249,250,253,257,274,275] In addition, the activity of PR3 antibody is normally inhibited by α_1-antitrypsin.[260] If α_1-antitrypsin is deficient or absent, the relative increased PR3 antibody activity may enhance synthesis of autoantibodies, including c-ANCA, and promote the development of Wegener's granulomatosis.[260]

Other pulmonary disorders occurring with renal failure include fibrosing alveolitis, which can accompany renal tubular acidosis[276] (see Box 75-7). The presence of both disorders suggests an underlying systemic disease involving the immune system, particularly because autoantibodies and hypergammaglobulinemia may be present with fibrosing alveolitis.[276] Pulmonary airways, alveolar septa, blood vessels, and kidneys are affected by deposits of amyloid, a glycoprotein, with resultant wheezing, dyspnea, pulmonary hemorrhage, pleural effusion, respiratory failure, and diffuse reticulonodular infiltrates and nodular lesions on radiographs.[244,277] Lymphomatoid granulomatosis, a lymphoproliferative vasculitis of medium and small blood vessels injured by atypical lymphocytes and plasma cells, causes lung and renal disease, is associated with T-cell lymphoma formation with a predominance of $CD4^+$ T-lymphocytes, and usually occurs in an already immunocompromised individual.[244,254,278] Bilateral pulmonary nodules, particularly at the bases and occasionally with cavitation, are present on chest radiographs, and pulmonary hemorrhage and pneumonia are frequent causes of death.[244,278] Infections with *Streptococcus pneumoniae*, *Mycoplasma pneumoniae*, *Leptospira*, and Puumala virus and toxic environmental agents can also cause glomerulonephritis, pulmonary hemorrhage, interstitial infiltrates, and acute respiratory failure.[248,259,279]

Metastatic pulmonary calcification occurs in chronic renal failure in the presence of hypercalcemia (see Box 75-7). It can result from primary, secondary, or tertiary hyperparathyroidism; hypervitaminosis D; excessive calcium ingestion (milk-alkali syndrome); and other mechanisms of increased calcium associated with renal insufficiency, including bone infections, bone malignancies, and tumors secreting parathyroid-like hormone.[280-285] Calcium deposits in tissues when the calcium-phosphorus product is larger than the solubility constant of calcium-phosphorus in blood (Table 75-6).[281,283,284] The lung acts as a reservoir for calcium deposition because of its relative alkaline environment resulting from loss of hydrogen ions during ventilation and diminished solubility of calcium salts in areas with a high pH.[281-286] These salts are primarily calcium phosphates.[286] The occurrence and severity of these calcifications are unrelated to the duration of renal failure or dialysis, degree of parathyroid abnormalities, or extent of elevation of the calcium-phosphorus product.[286] Metastatic pulmonary calcification appears as diffuse calcium deposits in walls of alveoli, large and small bronchi, terminal bronchioles, and interstitial blood vessels; may be associated with interstitial thickening, collagen deposition, and fibrosis; can interfere with diffusion across the alveolar-capillary membrane; and can precipitate respiratory failure.[280,284,286,287] Chronic renal failure is the most frequently occurring entity that causes pulmonary calcification in children.[280]

Pulmonary edema results from fluid retention and hypoproteinemia, which occur as the glomerular filtration rate diminishes, and increased pulmonary capillary permeability[242,288,289] (see Box 75-7). This contributes to the increased weight of lungs of individuals dying from uremia.[290] The lung

Table 75-6
Serum Calcium and Phosphorus in Untreated Chronic Renal Failure and Hyperparathyroidism

Disorder	Serum Calcium (mg/dL)	Serum Phosphorus (mg/dL)	Calcium-Phosphorus Product
Chronic renal failure alone	↓	↑	Normal, ↑, or ↓
Chronic renal failure with secondary hyperparathyroidism	Normal or slightly ↓	↑	Normal, ↑↑, or ↓
Primary hyperparathyroidism alone	↑	↓	Normal, ↑, or ↓
Primary hyperparathyroidism with secondary chronic renal failure*	Normal or ↑	↑	↑↑
Tertiary hyperparathyroidism	↑	↓	↑

↑, increased; ↓, decreased.

fluid is abundant with protein, including fibrin, and when present radiographically, causes a "uremic lung."[242,290] Uremic pneumonitis is associated with lungs that are heavy and indurated and have protein-rich edema fluid, hyaline membranes, alveolar hemorrhage, and fibrin in inflamed pleura.[159,244,291]

Renal failure alters cellular immunity and predisposes to pulmonary infection with opportunistic organisms[292] (see Box 75-7). Total lymphopenia, reductions in $CD4^+$ and $CD8^+$ T-lymphocytes, reversal of the $CD4^+/CD8^+$ T-lymphocyte ratio, diminished delayed hypersensitivity reactions, enhanced suppression of T-lymphocytes by PAMs, and impaired phagocytosis by PAMs secondary to metabolic acidosis occur, but humoral immunity is intact.[242,285,293-296] Infections caused by *M. tuberculosis*, *Legionella pneumophila*, *S. aureus*, *S. pneumoniae*, *Enterobacter* species, *Klebsiella* organisms, *Serratia* species, *M. pneumoniae*, Epstein-Barr virus, influenza virus type A, echovirus type 9, varicella-zoster virus, herpes simplex virus, cytomegalovirus, human immunodeficiency virus, *P. jiroveci*, *Candida* species, *Mucor* species, *Aspergillus* species, *Coccidioides immitis*, and *Histoplasma capsulatum* are present with increased frequency and can affect both the lungs and kidneys.[244,289,294,297]

Passage of ascitic fluid across diaphragmatic openings and pleural capillaries causes a unilateral or bilateral serous, serosanguinous, or hemorrhagic exudative pleural effusion, which has a predominance of lymphocytes, a normal glucose concentration, high protein and creatinine levels, and a pleural fluid/serum creatinine ratio less than 1.0[154,159,244] (see Box 75-7 and Table 75-7). This "uremic" pleural effusion usually occurs with long-standing renal failure, that is, lasting at least 1 year.[154] It differs from the transudative pleural fluid of nephrotic syndrome and congestive heart failure, which can also occur in uremia, is bilateral and serous, and has predominantly monocytes or lymphocytes with minimal protein and no creatinine.[154,159] In addition, a chylothorax can be present in the nephrotic syndrome when chylous ascitic fluid passes through diaphragmatic openings or across diaphragmatic lymphatic vessels and in Behçet's syndrome secondary to thrombosis of the jugular veins and superior vena cava.[262,271,298] The pleural and ascitic fluid levels of protein, cholesterol, triglyceride, and LDH are elevated with a chylothorax, most likely secondary to selective absorption of water from the pleural space.[298] Approximately 3% of patients with uremia develop a pleural effusion, although half of these individuals are asymptomatic.[159] Complications of a uremic pleural effusion include a fibrothorax and rounded atelectasis, which occurs when a collapsed lung adjacent to the resolving effusion develops parietal pleural adhesions and tries to expand.[154,159,299]

Respiratory muscle weakness occurs in uremia (see Box 75-7), is part of a more generalized myopathy, and is attributed to the presence of large quantities of ascitic fluid, malnutrition, anemia, uremic toxins, elevated parathyroid hormone levels, vitamin D and carnitine deficiencies, aluminum toxicity, and alterations in cellular metabolism affecting protein, fatty acids, and cations.[292,300,301] Although most studies of respiratory muscle strength in uremia have been performed in individuals receiving dialysis, which contributes to altered muscle function, rats with renal failure secondary to surgical removal of 83% of their kidneys have diaphragmatic dysfunction.[301] In addition, chest wall mechanics are altered by rib and vertebral fractures caused by destructive bone lesions in uremia.

Both central and obstructive sleep apnea can be present in renal failure (see Box 75-7). Metabolic acidosis with secondary hyperventilation and hypocapnia, uremic toxins acting on the central nervous system, chemical mediators, diminished airway muscle tone resulting from uremic myopathy, and metabolic cellular alterations may be etiologies.[49,302]

Dialysis

PATHOGENESIS, CLINICAL FEATURES

Complications of peritoneal dialysis include left lower lobe atelectasis and hypoventilation secondary to diaphragmatic immobility and eventration resulting from the large quantities of dialyzing fluid[242,303] (Box 75-8). A weak cough with sputum retention can also occur with diaphragmatic immobilization.[242] Other complications include pneumonia and pleural effusion caused by peritonitis and bacteremia; massive hydrothorax resulting from leakage of dialysate through diaphragmatic openings, which may be present normally, as defects resulting from the pressure of repeated instillation of large amounts of fluid into the abdomen, or from a pleuroperitoneal fistula; and hypoxemia secondary to $\dot{V}/\dot{Q}$ imbalance.[242,285,303-306]

Hemodialysis is associated with intrapulmonary sequestration of PMNs with concomitant peripheral leukopenia; com-

Metastatic pulmonary calcification

plement activation, particularly C_3 and C_5; anaphylaxis with wheezing secondary to chemical mediator release; silicone emboli in pulmonary capillaries and PAMs originating from blood pump tubing; hypoxemia resulting from $\dot{V}/\dot{Q}$ mismatch and pulmonary embolism caused by blood microemboli; air embolism; pleural hemorrhage induced by anticoagulation; pulmonary hypertension secondary to acidosis and chemical mediator release; and metastatic pulmonary calcification[242,244,284,285,307,308] (see Box 75-8). Hypotension, dyspnea, chest pain, and bronchospasm compose the "first-use syndrome" and result from complement activation and release of inflammatory mediators during an initial hemodialysis with a cuprophane membrane.[242,285,309] Abdominal muscle strength, which is important during expiration, can be reduced after hemodialysis because of diminutions in serum levels of potassium and phosphorus.[310]

DIAGNOSIS

The diagnosis of pulmonary diseases associated with renal failure and dialysis is aided by the history, physical examination, and laboratory and radiographic studies. The presence of pulmonary hemorrhage, particularly bilateral alveolar infiltrates, with renal disease, hematuria, RBC casts, an increased serum creatinine level, anemia, hypocomplementemia, elevated antinuclear and anti-DNA antibody titers, arthritis, and purpura should suggest the parenchymal diseases composing the pulmonary-renal syndrome (see Box 75-7 and Table 75-5). Although most of these diseases have been diagnosed in adults, some have also been identified in children.[248,249,264,267,269,270,278,280,311] With the exceptions of Goodpasture's syndrome and IgA nephropathy, the disorders in this category are accompanied by systemic manifestations.[244,245,251] The identification of hemosiderin-laden PAMs in BAL fluid may aid in the diagnosis of pulmonary hemorrhage, although these cells are also present in other disorders, including congestive heart failure.[245] Serial measurements of serum antiglomerular basement membrane antibodies in Goodpasture's syndrome are useful in evaluating the therapeutic response, but the titers do not parallel the severity or recurrence of pulmonary hemorrhage.[244,245] In addition, the extent of alveolar hemorrhage does not correlate with the quantity of expectorated blood because alveolar hemorrhage is bleeding within the acinus. However, it can be evaluated by chest radiography, oxyhemoglobin saturation, and hemoglobin levels.[245] If serum antiglomerular basement membrane antibody titers are absent in Goodpasture's syndrome, renal and lung biopsy should be considered to identify IgG antibodies on the basement membranes.[247,252] Lung biopsy either with a thoracotomy or VATS helps in the diagnosis of these pulmonary diseases.[244-247,252]

Appropriate stains and cultures of respiratory secretions, pleural fluid, and BAL fluid and serum titers and rapid antigen and antibody studies for viral infections are important in the diagnosis of the etiology of infectious pneumonias. A uremic pleural effusion is frequently associated with cough, chest pain, dyspnea, fever, and a pleural friction rub.[154,159] Evaluation of a pleural effusion by thoracentesis helps determine whether the fluid is a uremic exudate, chylous, or a transudate. A chylothorax occurring in the nephrotic syndrome suggests a peritoneal etiology of the fluid and, if present in Behçet's syndrome, thrombosis of major veins.[262,271,298] An effusion with an elevated glucose level and reduced protein and LDH concentrations reflects the presence of dialysate in the pleural space[304,305] (see Table 75-7). Pleuroperitoneal communications associated with this may be identified by the detection of dialysate stained with methylene blue or by radionuclide scanning of macroaggregated albumin labeled with technetium-99m that passes from peritoneal to pleural spaces.[304-306]

Metastatic pulmonary calcification may not be accompanied by symptoms or visualization on anteroposterior and lateral chest radiographs and may require a CT scan of the chest, lung scan, or lung biopsy for detection.[247,280,284-287,312,313] This diagnosis should be considered in an individual with chronic renal failure; persistent pulmonary infiltrates, which may be diffuse, interstitial, or nodular or appear as pneumonia or edema; hypoxemia; and reduced DLCO measurements.[281,282] Fibrosing alveolitis is associated with a reticulonodular pattern on chest radiographs and decreased DLCO measurements and is more definitively diagnosed by lung biopsy.[276] Alveolar hemorrhage is depicted radiographically as diffuse alveolar and interstitial densities and if chronic, a reticulonodular pattern.[244]

Pulmonary function testing in both acute and chronic uremia reveals reductions in slow vital capacity (SVC), FVC, FEV_1, ERV, TLC, peak expiratory flow rate, DLCO even when corrected for anemia, specific airway conductance, PImax, PEmax, and PaO_2; elevations in RV; and a normal FRC and FEV_1/FVC ratio.[242,290,300,292,309,310] The restrictive ventilatory and gas transfer abnormalities most likely result from interstitial and alveolar edema and fibrin deposits.[290,303] Metastatic pulmonary calcification causes reductions in VC, DLCO,

and PaO_2, which are directly related to the magnitude and extent of the calcium deposits.[287] Wegener's granulomatosis is associated with airflow obstruction and reduced lung volumes and DLCO measurements.[244,254] Decreases in DLCO with normal or reduced lung volumes occur in scleroderma and Henoch-Schönlein purpura.[250,267] An elevated DLCO occurs in pulmonary hemorrhage as a result of carbon monoxide binding to intra-alveolar blood, which may help differentiate hemorrhage from pneumonia and pulmonary edema.[244-246,251,252] The DLCO may be as high as 30% above baseline measurements and return to normal within 48 hours after the acute hemorrhage.[244,245]

Exercise testing in children with renal failure indicates reductions in work capacity, anerobic threshold, $\dot{V}O_2$, and oxygen pulse.[314] These measurements improve after treatment with recombinant human erythropoietin, suggesting that anemia may contribute to the exercise intolerance.[314] In addition, parathyroidectomy improves PImax, FVC, and FEV_1, whereas renal transplantation does not reverse diminished DLCO measurements.[242,300,315]

Peritoneal dialysis results in transient reductions in SVC, FVC, FRC, RV, TLC, and CL, most likely caused by filling the peritoneal cavity with the dialysate and concomitant diaphragmatic elevation.[242,244,303] These measurements return to baseline values with completion of the dialysis.[242,303] Ventilation and perfusion at the lung bases improve after hemodialysis, but elevations in RV, a diminution in the peak expiratory flow rate, respiratory muscle weakness, and hypoxemia become more pronounced, and ERV, $\dot{V}E$, and RQ decrease with this procedure.[242,290,310,316] The DLCO is diminished with chronic hemodialysis, that is, at least 5 years, and may reflect chronic inflammation associated with the membrane used for hemodialysis.[307,309,317]

TREATMENT

Therapy is directed at the underlying renal disease and associated pulmonary disorders. Corticosteroids, immunosuppressive agents, plasmapheresis to remove antibodies, and renal transplantation are used in the treatment of pulmonary-renal disorders.[244,246,253,254,261,271] Azathioprine, an immunosuppressive drug used to treat Goodpasture's syndrome, can cause pulmonary hemorrhage and diffuse alveolar damage.[318] Supplemental O_2, assisted ventilation with positive end-expiratory pressure, and corticosteroids are used in the therapy of pulmonary hemorrhage and concomitant hypoxemia, and factors precipitating the hemorrhage, that is, bleeding disorders, volume overload, and bacterial infection, should be diagnosed and treated.[244,245,253,254] Metastatic pulmonary calcification can be reduced by dialysis to control serum phosphorus levels, parathyroidectomy to reverse hyperparathyroidism, and renal transplantation.[282] VATS with talc pleurodesis may be used to treat persistent pleural effusions secondary to peritoneal dialysis.[306] Although central and obstructive sleep apneas are usually addressed with more conventional modalities of therapy,[49] they have resolved in selected individuals who had kidney transplants for treatment of renal failure.[302]

HEMOGLOBINOPATHIES

Sickle Cell Disease

GENETICS

The sickle cell syndromes comprise three types of anemia—sickle cell disease (hemoglobin SS), sickle cell β-thalassemia (hemoglobin S-thal), and sickle cell hemoglobin C disease (hemoglobin SC)—that cause varying degrees of pulmonary illness.[319-323] Both genes for hemoglobin are altered in these diseases, whereas in sickle cell trait (hemoglobin SA), one gene is abnormal and the other gene encodes the normal hemoglobin A. Homozygosity for hemoglobin S (SS) causes polymerization and sickling of RBCs at a PaO_2 of 50 mm Hg, whereas compound heterozygosity (S-thal, SC, SA) causes variable degrees of sickling at lower reductions in PaO_2 levels.[319,320,322-324]

Human hemoglobin A is composed of two α chains and two β chains, α2β2 or $\alpha^A\alpha^A\beta^A\beta^A$, each of which has amino acids and a heme group that binds with O_2 (Table 75-8).[319-321] The α2 genes are located on chromosome 16, whereas the β2 genes are on chromosome 11.[319,320,325] The genetic mutation causing the synthesis of hemoglobin S occurs at the sixth amino acid position in the β chain, where valine is substituted for glutamic acid.[319-321,323,326,327] Replacement of glutamic acid by lysine at the same position produces hemoglobin C.[319] β-Thalassemia hemoglobin results thalassemia from decreases (β^+-thalassemia) in or absence (β^o-thalassemia) of β chain synthesis and is caused by impaired messenger RNA function or gene transcription or the production of unstable β

Table 75-8
Characteristics of the Sickle Cell Hemoglobinopathies

Disease	Hemoglobin Composition	Genotype	Amino Acid Change	Hemoglobin Level (g/dL)	OxyHb Curve Shift
Sickle cell anemia	SS	$\alpha^A\alpha^A\beta^S\beta^S/\alpha^A\alpha^A\beta^S\beta^S$	S: Glu→Val	6-9 (75-94% S, 2% A_2, 2-23% F)	Yes
Sickle cell β-thalassemia	S-thal	$\alpha^A\alpha^A\beta^S\beta^S/\alpha^A\alpha^A\beta^{thal}\beta^{thal}$	S: Glu→Val	9-11 (75-90% S, <18% A, 5% A_2, 3-7% F)	Yes
Sickle cell hemoglobin C disease	SC	$\alpha^A\alpha^A\beta^S\beta^S/\alpha^A\alpha^A\beta^C\beta^C$	S: Glu→Val C: Glu→Lys	8-10 (49% S, 49% C, 2% F)	Yes
Sickle cell trait	SA	$\alpha^A\alpha^A\beta^S\beta^S/\alpha^A\alpha^A\beta^A\beta^A$	S: Glu→Val	14 (36% S, 60% A, 3% A_2, 1% F)	No
Normal	AA	$\alpha^A\alpha^A\beta^A\beta^A/\alpha^A\alpha^A\beta^A\beta^A$	—	>12 (97% A, 2% A_2, 1% F)	No

chains.[319,325] Both β^+- and β^o-thalassemia hemoglobins can combine with hemoglobin S to form S-thal.[319,322]

PATHOGENESIS

RBC sickling, hemolysis, and anemia occur when hemoglobin S is deoxygenated and its molecules are packed closely together.[319,321-323,328-330] Hemoglobin S has diminished O_2 affinity, and RBCs with hemoglobin S have increased levels of 2,3-DPG.[323,331-333] As a result, the oxyhemoglobin dissociation curve is shifted to the right, causing arterial O_2 desaturation, promoting RBC sickling, and generating the pathophysiologic, clinical, and radiographic manifestations of the sickle cell syndromes (Boxes 75-9 and 75-10).[319,323,332-335] These occur, in decreasing order of severity, in SS, S-thal, SC, and SA hemoglobinopathies.[319,320,332,336,337] Individuals with SA do not have alterations in the oxyhemoglobin dissociation curve[334] (see Table 75-8).

Hypercoagulability, as evidenced by increased production of thrombin and fibrin and increased activation and utilization of platelets, also occurs with hemoglobin SS and contributes to the pathophysiology of events occurring during sickling[323,338] (see Box 75-9). In addition, RBCs with hemoglobin S, as well as with hemoglobin C, are more rigid and less deformable than those with hemoglobin A even when they have a normal shape and oxygenation.[319,323] This results in increased viscosity of blood, which contributes to plugging of blood vessels.[319,320,322,323] RBCs with hemoglobin S also interact with and adhere to the capillary endothelium, a process that is enhanced by hypoxemia and causes the release of vasoactive mediators that promote the sequence of events leading to vaso-occlusive crises.[319,320,323,329,335,339]

CLINICAL FEATURES

The pulmonary disorders occurring most frequently in sickle cell disease are pneumonia, pulmonary vascular injury, pulmonary infarction, acute chest syndrome (ACS), and sickle cell chronic lung disease (SCLD) (see Box 75-10 and Table 75-9). Most hospitalizations of children with sickle cell disease result from bacterial pneumonia.[332] Functional and anatomic asplenia causes deficient phagocytosis associated with opsonin, PMNs, and PAMs; altered chemotaxis; and impaired alternate pathway of complement.[321,323,340-346] Individuals with sickle cell disease are predisposed to lung infections with encapsulated bacteria (*Haemophilus influenzae*, *S. pneumoniae*), *Salmonella typhimurium*, *S. aureus*, *E. coli*, *M. pneumoniae*, *P. jiroveci*, and *Klebsiella*, *Acinetobacter*, and *Plasmodium* species.[321,332,336,340,342,343,345,347-351] Pneumonia caused by *L. pneumophila*, *Cryptococcus neoformans*, respiratory syncytial virus (RSV), adenovirus, influenza virus, parainfluenza virus, and cytomegalovirus has also been identified.[344,345,352,353]

Pulmonary vascular injury results from RBC sickling, pulmonary thrombosis, and pulmonary embolism and can cause sudden death if a large vessel is occluded[321,332] (see Table 75-9). RBC sickling, increased blood viscosity, vascular stasis, and thrombus formation predispose to pulmonary thromboembolism and infarction.[332,347,354] In addition, fat from necrotic bone marrow can enter and occlude the pulmonary circulation and cause pulmonary infarction, particularly during an aplastic crisis.[323,332,347,355,356]

The ACS is characterized by a new pulmonary infiltrate affecting at least one segment of lung, chest pain, fever greater than 38.5°C, wheezing, tachypnea, and cough[321,323,326,328,338,339,355,357-359] (see Box 75-10 and Table 75-9). Hypoxemia ($PaO_2 < 70$ mm Hg) and leukocytosis also occur.[360] It is an acute injury to the lung that can cause pulmonary edema, acute respiratory failure, ARDS, and 25% of deaths in sickle cell disease.[326,339,355,360-363] It can result from pneumonia, particularly with *S. pneumoniae*, *M. pneumoniae*, *Mycoplasma hominis*, *Chlamydia pneumoniae*, *L. pneumophila*, and parvovirus B19.[321,349,353,355,358,362-366] Other etiologies include atelectasis associated with hypoventilation and regional hypoxemia accompanying pain resulting from chest wall infarction or a vaso-occlusive crisis; fat embolism with augmented activity of secretory phospholipase A_2; and pulmonary vascular injury with thrombosis, infarction, and necrosis.[321,323,326,335,349,353,355,357,358,360,367,368]

Plastic bronchitis can occur in the ACS and is identified by the presence of branching mucoid bronchial casts that obstruct airways.[357,369] Possible etiologies include increased

Box 75-9 Characteristics of Sickle Cell Disease That Predispose to Pulmonary Disorders

- Abnormal hemoglobin levels: right shift of the oxyhemoglobin dissociation curve
- Hypoxemia
- Sickling crises: sequestration, vaso-occlusive, aplastic, hyperhemolytic
- Hypercoagulability of blood
- Hyperviscosity of blood
- Arteriolar vasculopathy: adherence of RBCs to endothelium, production of vasoactive mediators
- Lung parenchymal injury: synthesis of free oxygen radicals
- Chest wall: small and narrow thorax
- Immune dysfunction: phagocytosis, chemotaxis, opsonin, alternate complement pathway

Box 75-10 Pulmonary Disorders Occurring in the Sickle Cell Syndromes

Acute Disorders	Chronic Disorders
Pneumonia	Chronic lung disease
Pulmonary thromboembolism	Pulmonary arterial hypertension
Pulmonary infarction	Recurrent acute chest syndrome
Bone marrow and fat embolism	Restrictive lung disease
Acute chest syndrome	Cardiac: cardiomegaly, right ventricular strain, cor pulmonale
ARDS	
Pulmonary edema	
Asthma	
Plastic bronchitis	

Table 75-9
Characteristics of Pneumonia, Pulmonary Vascular Injury, Pulmonary Infarction, Acute Chest Syndrome, and Sickle Cell Chronic Lung Disease (SCLD) in Sickle Cell Disease

Pneumonia	Pulmonary Vascular Injury	Pulmonary Infarction	Acute Chest Syndrome	SCLD
Age				
<4 yr	All ages	>12 yr	All ages	Teenage years, adults
Predisposing Factors				
Defective phagocytic complement, opsonin, PMN leukocytic, and chemotactic function; preceding upper respiratory tract infection	Bone marrow necrosis with bone marrow and fat embolism, RBC sickling, ↑ blood viscosity, hypoxemia, ? pregnancy	Bone marrow necrosis with bone marrow and fat embolism, RBC sickling, pulmonary thrombosis, hypoxemia, pregnancy, preceding upper respiratory tract infection	Presence of hemoglobin S levels >20%, ? lung infection with *Chlamydia pneumoniae* and human parvovirus B19, bone marrow necrosis with bone marrow and fat embolism, lung vascular injury, atelectasis, hypoventilation, infarction of ribs and sternum	Recurrent episodes of acute chest syndrome
Signs and Symptoms				
Fever, chills, cough, malaise, tachypnea, chest wall retractions, flaring of nasal alae, crackles, purulent sputum, pleuritic chest pain, dyspnea	Fever, dyspnea, tachypnea, chest and bone pain, petechiae, funduscopic changes (including refractile bodies), mental status changes	Fever, tachypnea, crackles, jaundice, pleuritic chest pain, dyspnea	Fever; cough; tachypnea; dyspnea; rib and sternal tenderness; local soft tissue swelling; pleuritic or chest wall pain; chest wall retractions; flaring of nasal alae; ↓ breath sounds; crackles; wheezes; hemoptysis; pain in back, abdomen, and extremities	Progressive dyspnea, exercise intolerance, pleuritic chest pain, hypoxemia, syncope, proliferative retinopathy, fatigue
Laboratory Findings				
↑ WBC count, pathogens in cultures of blood and respiratory secretions	Fat globules in sputum, urine, and blood; lipid-laden PAMs in BAL; ↑ fibrin-degradation products	↑ WBC count; fat globules in sputum, urine, and blood; lipid-laden PAMs in BAL; bilirubin level >5 mg/dL; negative cultures; atypical RBCs ("blister" cells) peripherally	↑ WBC count; fat globules in sputum, urine and blood; lipid-laden PAMs in BAL; positive bone scan; negative cultures; ↓ Pa_{O_2}; ↓ O_2 saturation; ↑ fibrin-degradation products; thrombocytopenia; serosanguinous pleural fluid	ECG abnormalities
Chest Radiographs				
Multilobar, frequently in upper or middle lobes, pleural effusion	Infiltrate, edema, ARDS, occluded small blood vessels in CT scan	May be normal initially, unilateral density, may be wedge-shaped, frequently in lower lobes, pleural effusion, filling defects in lung perfusion scan, occluded small blood vessels in CT scan	May be normal initially, unilateral or multilobar infiltrates, frequently in middle and lower lobes, atelectasis, pleural effusion, edema, ARDS, occluded small blood vessels in CT scan	Diffuse interstitial markings, interstitial edema, prominent pulmonary arteries, defects in lung perfusion scan, cardiomegaly
Pulmonary Function Testing				
↓ Lung volumes, hypoxemia	Hypoxemia	↓ Lung volumes, hypoxemia	↓ Lung volumes, ↓ D_{LCO}, hypoxemia	↓ Lung volumes, ↓ D_{LCO}, hypoxemia

PMN, polymorphonuclear; RBC, red blood cell; ↑, increased; ↓, decreased; WBC, white blood cell; ECG, electrocardiogram; PAM, pulmonary alveolar macrophage; BAL, bronchoalveolar lavage; Pa_{O_2}, arterial O_2 tension; ARDS, acute respiratory distress syndrome; CT, computed tomography, D_{LCO}, diffusing capacity.

quantity and viscosity of airway secretions associated with asthma and inflammation, hypoxemia of airways secondary to vaso-occlusion and altered mucociliary clearance, and/or increased amount of lymph in airways resulting from pulmonary hypertension or fat embolism.[357] The impacted airway mucus can potentiate hypoxemia, $\dot{V}/\dot{Q}$ imbalance, and RBC sickling.[357] In addition, airway reactivity and asthma occur with increased frequency with recurrent ACS and may reflect injury to the lung.[370-372]

The ACS is associated with increased activity of secretory endothelial vascular cell adhesion molecule-1 (VCAM-1), which promotes adhesion of RBCs to the pulmonary vascular endothelium; enhanced activity of endothelin-1, a pulmonary vasoconstrictor; and reduced activity of NO, a pulmonary vasodilator, inhibitor of VCAM-1, and modulator of platelet aggregation, thrombus formation, and adhesion to vascular endothelium.[326,329,330,339,366,373,374] Hypoxemia and RBC sickling inhibit NO synthesis.[339] In addition, phospholipase A_2 releases free fatty acids, leukotrienes, thromboxanes, and prostaglandins, which cause bronchospasm and increased airway secretions, vascular permeability, and PMN chemotaxis.[323,326,355,358,367]

Multiple episodes of the ACS may promote the development of SCLD, although SCLD can occur without a previous episode of ACS.[321,323,355,359,361,375,376] Abnormal lung function with restrictive and obstructive lung disease, diminished DLCO, and hypoxemia occurs, and pulmonary arterial hypertension, myocardial ischemia, cardiomegaly, cor pulmonale, respiratory failure, and sudden death can ensue[323,338,347,360,370,375,377,378] (see Box 75-10 and Table 75-9). Pulmonary hypertension may result from chronic hemolysis, persistent hypoxemia, thrombosis, infection, fat emboli, and vascular injury, while hypoxemia occurs with defects in pulmonary perfusion, reductions in diffusion, pulmonary fibrosis, and restrictive lung disease.[338,358,375,378] $\dot{V}/\dot{Q}$ imbalance and intrapulmonary shunts may be present, particularly since the resting PaO_2 and oxyhemoglobin saturation are often 70 to 90 mm Hg and 80% to 90%, respectively.[332,341] $\dot{V}/\dot{Q}$ imbalance results from RBC sickling, potentiates hypoxemia, and promotes further sickling.[347] Chronic lung parenchymal injury occurs with the presence of free O_2 radicals, and elevated pulmonary vascular resistance results from endothelial hyperplasia of small arterioles caused by sickled RBCs.[375] The increased blood flow associated with chronic anemia and myocardial microinfarcts and anoxia occurring with RBC sickling in myocardial blood vessels cause cardiomegaly.[347]

S-thal disease, SC disease, and SA trait are also associated with these pulmonary disorders but to different degrees, depending on the amount of hemoglobin S present and the magnitude of increased blood viscosity[320,321,336,337,346,354-356] (see Tables 75-8 and 75-10). The likelihood of RBC sickling rises as the level of hemoglobin S increases.[319] The course of the anemia and splenic dysfunction in S-thal disease, SC disease, and SA trait is milder and has a later onset than with sickle cell disease, and the risk of pulmonary disorders and their severity are, in general, less than with sickle cell disease.[321,342] Pneumonia occurs in S-thal disease, SC disease, and SA trait with similar organisms as in sickle cell disease and may be unusually severe.[342,343,345,346,379-381]

The early onset of splenomegaly in SC disease is accompanied by an increased incidence of infection.[380] SC disease is frequently associated with bone marrow and fat embolism, pulmonary vascular injury, pulmonary arterial hypertension, and cor pulmonale, particularly during the third trimester of pregnancy.[332,365,377,382,383] This may be a result of a relatively increased hematocrit level with reduced circulatory transit time and elevated blood viscosity in SC disease compared with sickle cell disease.[332,365] SA trait has been identified with pulmonary infarction, ACS, and ARDS caused by hypoxic-induced sickling.[354,384] Unlike S-thal disease and SC disease, SA trait is not associated with immune dysfunction.[321,325,342,343]

S-thal, sickle cell β-thalassemia; SC, sickle cell hemoglobin C disease; SA, sickle cell trait; ARDS, acute respiratory distress syndrome.

DIAGNOSIS

These pulmonary disorders are diagnosed by a history, physical examination, and laboratory and radiographic studies. Pneumonia and pulmonary infarction are often difficult to differentiate, but age, the presence of pathogens in cultures of respiratory secretions and blood, and chest radiographic findings may help[323,332,347] (see Table 75-9). Parvovirus B19 can be identified with the polymerase chain reaction.[356,365] Although a preceding upper respiratory tract infection suggests pneumonia, it can also precipitate a sickle cell crisis with a nonpneumonic pulmonary process.[385] Fever and chills also suggest pneumonia rather than pulmonary infarction, but children with hemoglobin SS can have high fever and appear quite ill despite lack of objective or laboratory findings of pneumonia.[385] Pneumonia in sickle cell disease is usually severe, is associated with fever lasting up to 12 days, and may resolve slowly despite appropriate antibiotic therapy.[319,332,354]

Pulmonary infarction in the sickle cell syndromes is typically not accompanied by hemoptysis, may have a prolonged course, and is suggested by the presence of acute pulmonary symptoms and an initially normal chest radiograph followed by a radiographic density[332,347] (see Table 75-9). The occurrence of extensive jaundice and atypical "blister" RBCs in the peripheral blood also suggests infarction, whereas the white blood cell (WBC) count is of little diagnostic value because it is elevated in pneumonia and pulmonary infarction and during crises.[332] Pneumonia and pulmonary infarction can occur simultaneously since necrotic tissue secondary to infarction can promote a milieu for bacterial growth.[347] Conversely, hypoxemia resulting from a slowly resolving pneumonia can promote RBC sickling, vascular occlusion, and pulmonary infarction.[354] In addition, pulmonary arterial hypertension may be present if unexplained syncope or dyspnea occurs.[377]

The distinguishing extrapulmonary features of the ACS include tenderness along the ribs and sternum with localized soft tissue swelling and pain in the abdomen, extremities, and back[361,362] (see Table 75-9). The presence of fat globules in sputum, urine, and blood and lipid-laden PAMs in BAL during a sickle cell crisis is diagnostic of fat embolism.[321,323,324,355,383] It occurs in ACS, pulmonary vascular injury, and pulmonary infarction and is associated with hypoxemia and disseminated intravascular coagulation.[324]

Bone marrow infarction can be detected by technetium-99m bone scanning, which reveals initially diminished radioactivity in areas of infarction associated with reduced vascularity and later increased tracer uptake secondary to augmented bone activity.[324,361,362] Reversible occlusion in small blood vessels can be identified with thin-section CT scans of the chest, and perfusion defects secondary to throm-

boemboli are revealed with $\dot{V}/\dot{Q}$ lung scans even when chest radiographs are normal.[360,386] Thin-section CT scans can indicate the presence of interstitial lung disease associated with lung injury, and these findings may be present despite normal pulmonary function testing.[376]

Pulmonary function testing in asymptomatic individuals with sickle cell disease reveals reductions in SVC, FVC, FEV_1, FRC, ERV, TLC, $FEF_{25-75\%}$, peak expiratory flow rate, dynamic and specific CL, work capacity, and anerobic threshold; elevations in $\dot{V}E$ and RQ; and a variable FEV_1/FVC ratio.[332,375,387-392] Airway reactivity, particularly of the small airways, also occurs.[391] In addition, infants with sickle cell disease have narrowing in small airways even prior to the occurrence of vaso-occlusive crises and the ACS.[393] As SCLD develops, decreases in the FEV_1/FVC ratio occur.[375] The DLCO is usually normal before the teenage years and subsequently increases when corrected for anemia and lung volume (DLCO/VA), perhaps secondary to an augmented pulmonary capillary blood volume.[388,394] However, the DLCO/VA ratio is diminished when compared with control values as a result of a low membrane diffusing capacity.[387,394]

The reductions in lung volumes, which are unlikely to occur during the first decade of life, reflect the presence of a short and narrow chest wall in relation to standing height and recurrent episodes of pulmonary disease with subsequent pulmonary fibrosis[387,388] (see Box 75-9). When these changes occur during the teenage years before the symptoms of SCLD, they can predict later development of SCLD.[375] S-thal disease and SC disease are also associated with decreased lung volumes, whereas lung volumes, DLCO, and exercise tolerance in settings of ambient O_2 as low as 18% are normal in SA trait.[389,395,396]

O_2 desaturation during sleep without evidence of central or obstructive apnea can occur in sickle cell disease and SA trait and may precipitate RBC sickling and crises.[333] In addition, obstructive sleep apnea secondary to enlarged tonsils can contribute to nocturnal O_2 desaturation.[397]

TREATMENT

Therapy includes appropriate antimicrobial agents for pulmonary infections and should provide coverage for penicillin-resistant *S. pneumoniae*, methicillin-resistant *S. aureus*, ampicillin-resistant *H. influenzae*, *C. pneumoniae*, *M. pneumoniae*, and *L. pneumophila*.[321,398,399]

Antibiotics should be instituted prior to identification of the specific etiologic agent because infections, particularly pneumococcal pneumonia, can be fulminant and life-threatening with hemoglobin SS.[321] Adequate hydration, analgesics, supplemental O_2 administration, correction of acidosis, bronchodilators, and folic acid supplementation are important therapeutic adjuncts.[319,323,326,349,353,355,377] However, vigorous administration of hypotonic saline for hydration, which may alter hydrostatic and oncotic pressures, and narcotics, which may augment vascular permeability, can precipitate pulmonary edema.[321,341,355,400] Corticosteroids can inhibit release of inflammatory mediators associated with hypoxemia and diminish the manifestations of the ACS.[323,355,358,359]

RBC transfusions to maintain a hemoglobin level of 11 to 12 g/dL, a hemoglobin A level of at least 30%, and/or a hemoglobin S level of less than 20% prevent RBC sickling, improve the O_2-carrying capacity of hemoglobin, and reduce the incidence and severity of ACS, myocardial ischemia, and endothelial hyperplasia leading to SCLD.[326,355,359,373,375,377] In addition, exchange transfusion with hemoglobin A improves the O_2-carrying capacity of hemoglobin and thus exercise performance.[389] Chronic transfusion therapy enhances growth and can prevent crises and ACS.[321,323,359,373,401] However, it can cause alloimmunization and iron overload, which can be prevented with chelation with deferoxamine.[321,323,359,371]

Bronchoscopy to relieve airway mucoid impaction associated with plastic bronchitis aids in reducing hypoxemia.[357,369] Use of CPAP or BiPAP can help reduce splinting, hypoventilation, atelectasis, regional hypoxemia, and RBC sickling.[326] Frequent use of incentive spirometry may diminish chest pain and prevent atelectasis and hypoxemia.[326,355,402]

Additional therapeutic modalities for sickle cell disease include splenectomy after 2 years of age to prevent sequestration crises; oral penicillin administered prophylactically starting in infancy to reduce the morbidity and mortality of pneumococcal infections; administration of pneumococcal, influenza, *H. influenzae* type b, and meningococcal vaccines with subsequent boosters when appropriate to confer immunologic protection against *S. pneumoniae*, influenza virus, *H. influenzae* type b, and *Neisseria meningitidis;* and administration of hepatitis B vaccine because of the necessity for multiple blood transfusions.[319,321,323,341,346,350,353,371,399] Pneumococcal infections may occur despite the use of penicillin prophylaxis and pneumococcal vaccine if penicillinase-producing organisms are present or if antibody production is insufficient.[350,398] Administration of palivizumab to prevent RSV infection should be considered for young children with sickle cell disease meeting selective criteria for increased severity of RSV bronchiolitis and pneumonia.[403]

Oral hydroxyurea increases synthesis of fetal hemoglobin (hemoglobin F) in RBCs, reduces the level of hemoglobin S, decreases the activity of VCAM-1, and is oxidized by heme to form NO.[323,326,328,359,404-407] It decreases the incidence of RBC sickling and vaso-occlusive crises, reduces RBC adhesion to vascular endothelium, and can prevent the ACS.

Because serum magnesium levels are reduced in sickle cell disease and diminish further with hydroxyurea, administration of supplemental magnesium may be necessary with hydroxyurea therapy.[405]

Experimental therapy includes inhalation of NO for as long as four hours, which can depress VCAM-1 activity, increase oxyhemoglobin levels, enhance NO transport on hemoglobin S, improve $\dot{V}/\dot{Q}$ imbalance, and reduce RBC sickling, vaso-occlusive crises, and pulmonary hypertension.[326,329,335,371,408] Other modalities consist of the use of chemotherapeutic agents, such as 5-azacytidine and decitabine, which elevate hemoglobin F levels and reduce the incidence and severity of vaso-occlusive crises and RBC sickling; butyrate compounds, which increase hemoglobin F levels by stimulating fetal globin genes; oral L-arginine, which is a substrate for NO synthesis, is reduced in sickle cell disease, and can reduce pulmonary hypertension; and the combination of oral hydroxyurea and L-arginine.[330,371,407,409-411] Transplantation with allogeneic bone marrow and hematopoietic stem cells using cord blood is curative for sickle cell disease.[407,412-417] The incidence of ACS diminishes, lung function plateaus, and functional asplenia improves.[321,414] Gene

replacement therapy with lentiviral and retroviral vectors has also been investigated.[323,327,407,412,418]

Thalassemia

GENETICS, PATHOGENESIS

The more frequently occurring types of thalassemia are caused by an absence of or reduction in the synthesis of α or β chains.[325,419-422] Mutations on chromosomes 16 (for α chains) and 11 (for β chains) are responsible for these alterations.[325,419,421,422] The resultant RBCs have clumps of the unaffected, normally produced chains, which occur in excess, form inclusions, and injure cell membrane integrity.[419] Reduced RBC survival time and intramedullary RBC destruction contribute to the resulting hemolytic anemia, and ineffective erythropoiesis is present.[325,419,423] Hypercoagulability, tissue anoxia, increased blood volume, high-output cardiac failure, and infections are characteristic.[325,419,423] In addition, excessive iron deposits from chronic hemolysis and repeated blood transfusions cause cardiac and liver failure and pancreatic dysfunction with insulin-dependent diabetes mellitus, which can also contribute to lung disease.[325,419,422,423] Iron accumulation in PAMs and airway epithelium enhances free O_2 and hydroxy radical formation, with resultant airway and interstitial injury in the lung.[424-431]

The homozygous β-thalassemias (thalassemia major, thalassemia intermedia) are associated with severe microcytic, hypochromic anemia; extramedullary hematopoiesis; hypersplenism; hepatosplenomegaly; lymphadenopathy; growth retardation; bony changes, including frontal and parietal bossing and mandibular and malar prominence; and shortened survival span.[325,419,421-423]

The heterozygous β-thalassemias (thalassemia minor, thalassemia minima) produce mild, if any, anemia and clinical manifestations.[325,419,421,422]

The α-thalassemias include a homozygous form associated with absence of all four α chains, hydrops fetalis, and perinatal death.[419] The heterozygous forms of α-thalassemia consist of hemoglobin H disease with absence of three α chains and moderately severe anemia; α-thalassemia trait with two missing α chains and mild chronic anemia; and a silent carrier type with only one α chain and no anemia or symptoms.[419,420] However, genetic heterogeneity, that is, different combinations of these genes, can cause variable phenotypic expression.[432]

CLINICAL FEATURES

Pulmonary disorders occurring in thalassemia are primarily described in β-thalassemia (Box 75-11). Severe pulmonary infections occur in β-thalassemia, particularly because the presence of excess iron enhances microbial growth and impairs cytotoxicity, cellular immunity, and activity of PAMs.[325,420,426,433] Hemolytic, sequestration, and aplastic crises often secondary to parvovirus B19 infection occur.[325,434] A hemothorax can result from extramedullary hematopoiesis in the chest wall.[435] Recurrent chest pains and pulmonary thromboembolism are associated with thrombocytosis postsplenectomy.[420] Pulmonary arterial hypertension, cor pulmonale, cardiomyopathy, congestive heart failure, and dysrhythmias resulting from iron deposits are the usual causes of death.[325,422,436,437]

Box 75-11 Pulmonary Disorders Associated with Thalassemia Major

Pneumonia
Chronic pneumonitis
Hemothorax
Pulmonary edema
Pulmonary thromboembolism
Pulmonary arterial hypertension
Cardiac: cor pulmonale, right and left ventricular hypertrophy, dysrhythmias, cardiomyopathy, congestive heart failure

Other pulmonary disorders relate to therapy for β-thalassemia, with serial blood transfusions to maintain a hemoglobin level of at least 9 to 10 g/dL and use of the iron-chelating agent, deferoxamine.[423,424,430,431,438-444] Although children with thalassemia intermedia who never receive blood transfusions have elevations in FRC, RV, and the RV/TLC ratio, which indicate the presence of abnormal lung function secondary to the disease,[438] multiple blood transfusions in thalassemia major are associated with restrictive lung disease, small airway obstruction, air-trapping, alterations in DLCO, and hypoxemia. These are observed as reductions in FVC, FEV_1, FRC, ERV, TLC, MMEF, maximal expiratory flow rates at 60% TLC, $FEF_{25-75\%}$, static and dynamic CL, and PaO_2; elevations in RV, the RV/TLC ratio, lung elastic recoil pressure, Raw, and $\dot{V}E$; and variable measurements of DLCO corrected for hemoglobin concentration[424-429,438-442,445,446] (Table 75-11). These findings are unchanged with diuresis; improve somewhat after splenectomy, that is, VC and ERV increase and RV decreases; and, when measured before and after a blood transfusion, indicate further reductions in FVC and PaO_2 after the transfusion.[441,442] The presence of massive hepatosplenomegaly can impair chest wall mobility and contribute to these reductions in lung volumes.[439]

Exercise testing of individuals with thalassemia major reveals reduced exercise tolerance and hypoventilation, with reductions in anerobic threshold, $\dot{V}E$, $\dot{V}O_2$, O_2 pulse, and ventilatory equivalents for O_2 ($\dot{V}E/\dot{V}O_2$) and CO_2 ($\dot{V}E/\dot{V}CO_2$) and elevations in end-tidal CO_2, cardiac output, and heart rate.[447-449] Only the anerobic threshold, $\dot{V}O_2$, O_2 pulse, and $\dot{V}E/\dot{V}CO_2$ increase somewhat after a blood transfusion, most likely resulting from improved arterial oxygenation and enhanced availability of O_2 to exercising muscles.[447-449]

Histologic observations of the lungs in thalassemia major indicate interstitial fibrosis; subpleural emphysema; vascular congestion and fibrosis; pulmonary angiodysplasia; emboli from bone marrow and thrombi; and hemosiderin, iron, and lipofuscin deposits in PAMs, epithelial cells, smooth muscle, blood vessels, and interstitial connective tissue[439,450] (see Table 75-11). This helps explain the occurrence of restrictive lung disease, reduced DLCO, and hypoxemia.[439,450] CT scans of the chest reveal air-trapping and interstitial fibrosis.[425,427] Elevated numbers of lymphocytes and iron-containing PAMs are identified in BAL, indicating a lymphocytic alveolitis.[427]

Intravenous infusions of deferoxamine to prevent iron accumulation and hemosiderosis are associated with an acute pulmonary disorder characterized by fever, tachypnea, a dry

Table 75-11
Correlation of Histologic Features and Functional Abnormalities of the Lung in Thalassemia Major

Histologic Features	Pulmonary Function Testing
Parenchymal	
Interstitial fibrosis	↓ Lung volumes, ↓ D_{LCO}, ↓ C_L, hypoxemia, ↑ $\dot{V}_E$
Subpleural emphysema	air-trapping (↑ RV, ↑ RV/TLC), ↑ elastic recoil, hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Hemosiderin, iron, and lipofuscin deposits	↓ D_{LCO}, ↓ C_L
Ferrugination of interstitial and airway connective tissue	↓ D_{LCO}, ↓ C_L, ↓ airflow rates in small airways, ↑ Raw
Chronic interstitial pneumonitis	↓ Lung volumes, ↓ D_{LCO}, hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Pulmonary edema	↓ Lung volumes, ↓ D_{LCO}, ↓ C_L, ↓ airflow rates in small airways, ↑ Raw, hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Vascular	
Pulmonary angiodysplasia	Hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Vascular fibrosis	↓ D_{LCO}, hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Ferrugination of vascular connective tissue	↓ D_{LCO}, ↓ C_L
Thromboemboli	Hypoxemia, $\dot{V}/\dot{Q}$ imbalance
Bone marrow emboli	Hypoxemia, $\dot{V}/\dot{Q}$ imbalance

↑, increased; ↓, decreased; D_{LCO}, diffusing capacity; C_L, lung compliance; $\dot{V}_E$, minute ventilation; RV, residual volume; TLC, total lung capacity; $\dot{V}/\dot{Q}$, ventilation/perfusion; Raw, airway resistance.

cough, hypoxemia, and bilateral interstitial pneumonitis radiographically.[430,434,441,442] Diffuse alveolar damage, interstitial inflammation and fibrosis, and mast cell proliferation with fixation of IgE antibody observed with immunofluorescence are also present.[443] Pulmonary function testing reveals restrictive lung disease with reductions in FVC, FEV_1, and TLC and air-trapping with elevations in the RV/TLC ratio.[429,430,443] Resolution may be slow even with discontinuation of the drug and corticosteroid therapy.[443]

TREATMENT

In addition to serial blood transfusions and deferoxamine administration, therapy of thalassemia includes splenectomy to relieve abdominal pressure resulting from massive splenic enlargement and to control hypersplenism, which is evidenced by an increasing requirement for blood transfusions; oral penicillin prophylaxis postsplenectomy; immunizations with the pneumococcal, *H. influenzae* type b, influenza, meningococcal, and hepatitis B vaccines; and daily folic acid supplementation.[325,419,421,423,424] Experimental procedures include gene therapy and administration of hydroxyurea, butyrate, and 5-azacytidine, which enhance fetal hemoglobin synthesis and decrease the percentage of abnormal hemoglobin and the frequency and severity of hemolysis.[325,327,419,421-423,451] Transplantation with hematopoietic stem cells from peripheral blood, bone marrow, or umbilical cord is curative.[412,419,421,423,444]

Familial Dysautonomia

GENETICS, RISK FACTORS

Familial dysautonomia (Riley-Day syndrome, hereditary sensory neuropathy type III) is an autosomal recessive neurologic disease characterized by abnormalities of the autonomic, sensory, and central nervous systems and specific clinical features[452-456] (Box 75-12). It occurs in 1 of 3600 live births of Ashkenazi Jewish ancestry, is associated with mutations of the *IKAP* (1κB kinase complex-associated protein) gene on chromosome 9 at the q31-33 locus, and can be diagnosed prenatally.[456-459] An enzyme involved with dopamine catabolism appears to be deficient, as reflected by reduced urinary vanillylmandelic acid levels.[453,460] Histopathology reveals loss of neurons and atrophied nerve fibers in the reticular formation of the pons and medulla; cerebellum; nucleus of the vagus nerve; sympathetic, parasympathetic, and dorsal root ganglia; and along the spinal cord in the spinothalamic tract and posterior columns.[453,454,461]

Box 75-12 Characteristic Features of Familial Dysautonomia

- Dysautonomic crises
  - Episodic vomiting
  - Diaphoresis
  - Hypertension
  - Tachycardia
  - Skin blotching
- Typical facies
- Feeding disturbances
  - Swallowing difficulties with excessive salivation and drooling
  - Absent gag reflex
  - Esophageal dysmotility
  - Alterations in taste perception, particularly to bitter or sweet substances
- Growth retardation
- Hyporesponsiveness to temperature
- Recurrent fevers
- Absent lacrimation
- Corneal ulcers
- Insensitivity to pain
- Postural hypotension
- Ataxia
- Seizures
- Psychomotor retardation
- Nasal speech

PATHOGENESIS, CLINICAL FEATURES

Individuals with familial dysautonomia have recurrent wheezing and pneumonia secondary to aspiration from GER and oropharyngeal secretions and bronchiectasis resulting from repeated pulmonary infections[452,453,456,462-464] (Box 75-13). GER may be overshadowed clinically by autonomic dysfunction and can cause autonomic symptoms, that is, syncope, hypotension, and bradycardia, without emesis.[462] Insensitivity to pain and inadequate cough and gag reflexes contribute to an inability to mobilize aspirated material.[452,454,457,464] Atelectasis, air-trapping, and pneumothoraces can occur.[452] Kyphoscoliosis contributes to reactive airway disease and alterations in pulmonary function.[452,453,464,465] Neonatal respiratory difficulties include delayed initiation of breathing, difficulty in coordination of sucking with swallowing resulting

Box 75-13 Respiratory Disorders Associated with Familial Dysautonomia

Pulmonary Disorders

Reactive airway disease
Pneumonia: infectious, aspiration
Tracheobronchitis
Bronchiectasis
Atelectasis
Pneumothorax

Chest Wall Disorders

Kyphosis
Scoliosis

Disorders of Control of Breathing

Delayed initiation of breathing in neonate
Diminished responses to hypoxia and hypercapnia
Breath-holding with syncope
Sleep apnea

in aspiration of feedings, and meconium aspiration pneumonitis.[452,466]

Diminished responses to hypoxia and hypercapnia cause abnormalities in control of breathing, including breath-holding with syncope and nonresponsiveness to hypoxia while swimming underwater, resulting in drowning[452-454,465] (see Box 75-13). Irregular breathing patterns and apnea can occur during sleep.[452,464,465]

DIAGNOSIS

The history, physical examination, and laboratory and radiographic studies help in the diagnosis. The presence of repeated pneumonias, episodes of cyclic vomiting, temperature instability with recurrent fevers, and mottling of the skin in a child whose family is of Ashkenazi Jewish descent suggests the diagnosis.[452,453,460,466] Familial dysautonomia can be diagnosed in the neonate who is likely to be born full-term in a breech presentation, small for gestational age, meconium-stained, and hypotonic and has respiratory distress, incoordination of suck and swallow, feeding difficulties, lack of weight gain, temperature instability, and mottling of the skin.[452,459,466] Three clinical tests that can be used as early as 3 days of life are helpful in confirming the diagnosis[452,453] (Table 75-12). Pulmonary function studies reveal reduced lung volumes, airflow rates, and DLCO measurements and hypoxemia at rest and with exercise, which correlate with the repeated episodes of lung infections.[465] Pneumonia, atelectasis, air-trapping, and pneumothoraces occurring during acute episodes of respiratory distress are observed on chest radiographs. Residual markings from repeated episodes of pneumonia may be present radiographically. Fluoroscopic examination of ingested barium may reveal GER and oropharyngeal aspiration of the barium. A salivogram with a radioactively labeled contrast material can diagnose aspiration of oropharyngeal secretions.

TREATMENT

Therapy includes the use of appropriate antibiotics for lung infections; bronchodilators, anti-inflammatory agents, and leukotriene inhibitors for wheezing; chest physical therapy and airway clearance devices for mobilization of respiratory secretions; and supplemental O_2 for hyoxemia. Daily use of high-frequency chest wall oscillation can prevent pneumonia, increase O_2 saturation, and improve lung function.[464] β-Adrenergic bronchodilators are used with caution because familial dysautonomia is associated with reduced sympathetic neuronal innervation and augmented sensitivity to sympathomimetic agents.[452,463,464] Feeding difficulties are addressed with enteral nutrition, such as a gastrostomy or jejunostomy tube, and a fundoplication if GER is present.[462] Maintenance of a patent airway, often with a tracheostomy and laryngotracheal separation, is helpful for preventing aspiration of saliva and for suctioning and removing secretions. Adequate hydration, appropriate temperature control, and aggressive airway care, including endotracheal intubation, assisted ventilation, BiPAP or CPAP, antibiotics, and chest physical therapy, during

Table 75-12
Clinical Tests Used in the Diagnosis of Familial Dysautonomia

	Histamine Test	Methacholine or Pilocarpine Test	Observation of Tongue
Procedure	Intradermal injection of 1 : 1000 dilution of histamine phosphate, use 1 : 10,000 dilution in infant	Instillation of 2.5% methacholine or 0.0625% pilocarpine into conjunctival sac of one eye, comparison of both eyes every 5 minutes for 20 minutes	Examination of tip and sides of tongue for red, vascularized papillae
Normal response	Pain and erythema, development of central wheal with surrounding axon, flare of erythema measuring 1-3 cm in radius, wheal and axon flare occur within 10 minutes	No effect	Red, vascularized papillae at tip and sides of tongue
Response in familial dysautonomia	↓↓ Pain, absence of axon flare	Meiosis in eye with methacholine or pilocarpine	Absent fungiform papillae with smooth and pale sides and tip of tongue, lack of vascularization
False-negative results	None	None	None
False-positive results	Congenital sensory neuropathy, atopic dermatitis	Disorders with parasympathetic denervation	Present

↓, decreased.

the perioperative period help reduce the incidence and severity of post-operative lung infections and atelectasis.[463] Because responses to hypoxia and hypercapnia are diminished, administration of drugs less likely to cause respiratory depression, that is, non-narcotic agents, can help prevent post-operative respiratory difficulties.[463] Gastric decompression and sedation aid in the treatment of dysautonomic crises after surgery.[463] Although individuals with familial dysautonomia are surviving into adulthood, pulmonary infections, sepsis, cor pulmonale, and respiratory arrest while asleep or precipitated by hypotension remain frequent causes of death.[452,465,467]
